Part D Regression

Part D Regression Methods and Data Mining

Part D focuses on regression methods and data mining. The first chapter in this part, Chapt. 28, describes various diagnostic procedures for detecting single and multiple outliers and influential observations in linear regression. It also discusses procedures for detecting high-leverage outliers in large, high-dimensional data sets. Chapter 29 gives an overview of various logistic regression methods for fitting models to a binary-valued response variable and introduces the idea of a logistic regression tree based on a recursive partitioning algorithm to fit a linear logistic regression model for solving large, complex data sets. Chapter 30 introduces the basic structure of tree-based methods for constructing trees for both classification and regression problems by recursively partitioning a learning sample over its input variable space. It also compares classification and regression trees to multivariate adaptive regression splines, neural networks and support-vector machines. Chapter 31 presents the concept of a generalization of least-squares estimation (LSE), called M estimators, to solve the statistical problems involving unknown coordinate systems and image registration problems. This chapter also discusses in detail the differences between the LSE and M estimators and presents the statistical properties of M estimates for spherical regression.

The following three chapters focus on the statistical analysis of genomic and proteomics data. Chapter 32 provides an overview of the emerging statistical concepts of statistical genetics, which are commonly used to analyze microarray gene-expression data, and further introduces recent statistical testing methods, such as significance analysis of microarray and local pooled-error tests, as well as supervised-learning discovery tools. Chapter 33 describe several statistical methods, such as the empirical Bayesian approach, significance analysis of microarray, support-vector machines, and tree- and forest-based classification, for analyzing genomic data and their applications in biochemical and genetic research. Chapter 34 discusses two proteomics statistical techniques, disease biomarker discovery and protein/peptide identification, and their applications in both the biological and medical research for analyzing mass-spectrometry data. The next two chapters focus on data mining and its applications. Chapter 35 describes the radical basis-function model architecture and its applications in bio-informatics and biomedical engineering and also describes the four algorithms commonly used for its design: clustering, orthogonal least squares, regularization, and gradient descent, while Chapt. 36 presents the basic principles of data-mining methodologies in databases, including knowledge discovery, supervised learning, software, the classification problem, neural networks, and association rules, and discusses several popular data-mining methods with applications in industry and business practice.

28. Measures of Influence and Sensitivity in Linear Regression

This chapter reviews diagnostic procedures for detecting outliers and influential observations in linear regression. First, the statistics for detecting single outliers and influential observations are presented, and their limitations for multiple outliers in high-leverage situations are discussed; second, diagnostic procedures designed to avoid masking are shown. We comment on the procedures by *Hadi* and *Smirnoff* [28.1,2], *Atkinson* [28.3] and *Swallow* and *Kianifard* [28.4] based on finding a clean subset for estimating the parameters and then increasing its size by incorporating new homogeneous observations one by one, until a heterogeneous observation is found. We also discuss procedures for detecting high-leverage outliers in large data sets based on eigenvalue analysis of the influence and sensitivity matrix, as proposed by *Peña* and *Yohai* [28.5, 6]. Finally we show that the joint use of simple univariate statistics, as predictive residuals, and Cook's distances, jointly with the sensitivity statistic proposed by *Peña* [28.7] can be a useful diagnostic tool for large high-dimensional data sets.

Data often contain outliers or atypical observations. Outliers are observations which are heterogeneous with the rest of the data, due to large measurement errors, different experimental conditions or unexpected effects. Detecting these observations is important because they can lead to new discoveries. For instance, penicillin was found because Pasteur, instead of ignoring an outlier, tried to understand the reason for this atypical effect. As *Box* [28.8] has emphasized "every operating system supplies information on how it can be improved and if we use this information it can be a source of continuous improvement". A way in which this information appears is by outlying observations, but in many engineering processes these observations are not easy to detect. For instance, in a production process a large value in one of the variables we monitor may be due, among other causes, to: (1) a large value of one of the input control variables; (2) an unexpected interaction among the input variables; (3) a large measurement error due to some defect in the measurement instrument. In the first case, the outlying observations may provide no new information about the performance of the process but in the second case may lead to a potentially useful discovery and in the third, to an improvement of the process control. A related problem is to avoid the situation where these outliers affect the estimation of the statistical model and this is the aim of robust estimation methods.

This chapter discusses outliers, influential and sensitive observations in regression models and presents methods to detect them. Influential observations are those which have a strong influence on the global properties of the model. They are obtained by modifying the weights attached to each case, and looking at the standardized change of the parameter vector or the vector of forecasts. Influence is a global analysis. Sensitive observations can be declared outliers or not by small modifications in the sample. Sensitivity is more a local concept. We delete each sample point in turn and look at the change that these modifications produce in the forecast of a single point. We will see that influence

and sensitivity are important concepts for understanding the effect of data in building a regression model and in finding groups of outliers.

Many procedures are available to identify a single outlier or an isolated influential point in linear regression. The books of *Belsley* et al. [28.9], *Hawkins* [28.10], *Cook* and *Weisberg* [28.11], *Atkinson* [28.12], *Chatterjee* and *Hadi* [28.13] *Barnett* and *Lewis* [28.14] and *Atkinson* and *Riani* [28.15] present good analyses of this problem. To identify outliers and to measure influence the point can be deleted, as proposed by *Cook* [28.16] and *Belsley* et al. [28.9], or its weight decreased, as in the local influence analysis introduced by *Cook* [28.17]. See *Brown* and *Lawrence* [28.18] and *Suárez Rancel* and *González Sierra* [28.19] for a review of local influence in regression and many references, and *Hartless* et al. [28.20] for recent results on this approach. A related way to analyze influence has been proposed by *Critchley* et al. [28.21] by an extension of the influence-curve methodology. The detection of influential subsets or multiple outliers is more difficult, due to the masking and swamping problems. Masking occurs when one outlier is not detected because of the presence of others; swamping happens when a non-outlier is wrongly identified due to the effect of some hidden outliers, see *Lawrance* [28.22]. Several procedures have been proposed for dealing with multiple outliers, see *Hawkins*, *Bradu* and *Kass* [28.23], *Gray* and *Ling* [28.24], *Marasinghe* [28.25], *Kianifard* and *Swallow* [28.26, 27], *Hadi* and *Simonoff* [28.1, 2], *Atkinson* [28.3, 28] and *Swallow* and *Kianifard* [28.4]. A different analysis for detecting groups of outliers by looking at the eigenvectors of an influence matrix was presented by *Peña* and *Yohai* [28.5]. These authors later proposed [28.6] the sensitivity matrix as a better way to find interesting groups of data, and from this approach *Peña* [28.7] has proposed a powerful diagnostic statistic for detecting groups of outliers.

We do not discuss in this chapter, due to lack of space, robust regression methods and only refer to them when they are used as a first step in a diagnosis procedure. See *Huber* [28.29] for a good discussion of the complementary role of diagnosis and robustness. For robust estimation in regression see *Rousseeuw* and *Leroy* [28.30] and *Maronna*, *Martin* and *Yohai* [28.31]. Robust estimation of regression models has also received attention in the Bayesian literature since the seminal article of *Box* and *Tiao* [28.32]. See *Justel* and *Peña* [28.33] for a Bayesian approach to this problem and references.

The paper is organized as follows. In Sect. 28.1 we present the model and the notation, and define the main measures which will be used for outlier and influence analysis. In Sect. 28.2 we review procedures for detecting single outliers and influential observations in regression. In Sect. 28.3 we discuss the multiple-outlier problem and two types of diagnostic procedures, those based on an initial clean subset and those based on eigenvalue analysis of some diagnostic matrices. In Sect. 28.4 we introduce a simple statistic which can be used for diagnostic analysis of a large data set, avoiding the masking problem. Section 28.5 includes an example of the use of diagnostic methods for detecting groups of outliers and Sect. 28.6 contains some concluding remarks.

28.1 The Leverage and Residuals in the Regression Model

We assume that we have observed a sample of size n of a random variable $\boldsymbol{y} = (y_1, \ldots, y_n)'$ and a set of $p-1$ explanatory variables which are linearly related by

$$y_i = \boldsymbol{x}_i'\boldsymbol{\beta} + u_i, \tag{28.1}$$

where the u_i are the measurement errors, which will be independent normal zero-mean random variables with variance σ^2, and $\boldsymbol{u} = (u_1, \ldots, u_n)'$. The $\boldsymbol{x}_i = (1, x_{2i}, \ldots, x_{pi})$ are numerical vectors in R^p and we will denote by $\mathbf{X}$ the $n \times p$ matrix of rank p whose i-th row is $\boldsymbol{x}_i'$. Then, the least-squares estimate of $\boldsymbol{\beta}$ is obtained by projecting the vector $\boldsymbol{y}$ onto the space generated by the columns of $\mathbf{X}$, which leads to

$$\hat{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\boldsymbol{y}$$

and the vector of fitted values, $\hat{\boldsymbol{y}} = (\hat{y}_1, \ldots, \hat{y}_n)'$, is given by

$$\hat{\boldsymbol{y}} = \mathbf{X}\hat{\boldsymbol{\beta}} = \mathbf{H}\boldsymbol{y}, \tag{28.2}$$

where

$$\mathbf{H} = \mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'$$

is the idempotent projection matrix. The vector orthogonal to the space generated by the $\mathbf{X}$ variables is the residual vector, $\boldsymbol{e} = (e_1, \ldots, e_n)'$, which is defined

by

$$\boldsymbol{e} = \boldsymbol{y} - \hat{\boldsymbol{y}} = (\mathbf{I} - \mathbf{H})\boldsymbol{y} \tag{28.3}$$

and we will let $\widehat{s}^2_{\mathrm{R}} = \boldsymbol{e}'\boldsymbol{e}/(n-p)$ be the estimated residual variance.

From (28.3), inserting $\mathbf{X}\boldsymbol{\beta} + \boldsymbol{u}$ instead of $\boldsymbol{y}$ and using $\mathbf{HX} = \mathbf{X}$, we obtain the relationship between the residuals and the measurement errors, $\boldsymbol{e} = (\mathbf{I} - \mathbf{H})\boldsymbol{u}$. Thus, each residual is a linear combination of the measurement errors. Letting $h_{ij} = \boldsymbol{x}_i' \left(\mathbf{X}'\mathbf{X}\right)^{-1} \boldsymbol{x}_j$ be the elements of the matrix, $\mathbf{H}$, we have

$$e_i = u_i - \sum_{j=1}^{n} h_{ij} u_j \tag{28.4}$$

and, if the second term is small, the residual e_i will be close to the measurement error, u_i. The variance of this second term is

$$Var(\sum_{j=1}^{n} h_{ij} u_j) = \sigma^2 \sum_{j=1}^{n} h_{ij}^2 = \sigma^2 h_{ii}$$

and if h_{ii}, the diagonal term of $\mathbf{H}$, is large, the difference between the residual and the measurement error can be large. The values h_{ii} are called the leverage of the observation and measure the discrepancy of each observation $\boldsymbol{x}_i$ with respect to the mean of the explanatory variables. It can be shown (see for instance [28.11] p. 12) that

$$h_{ii} = \boldsymbol{x}_i'(\mathbf{X}'\mathbf{X})^{-1}\boldsymbol{x}_i = \frac{1}{n}\left[1 + \left(\widetilde{\boldsymbol{x}}_i - \bar{\boldsymbol{x}}\right)' \mathbf{S}_{xx}^{-1} (\widetilde{\boldsymbol{x}}_i - \bar{\boldsymbol{x}})\right],$$

where $\widetilde{x}_h = (x_{2h}, \ldots, x_{ph})$ does not include the constant term, $\bar{\boldsymbol{x}}$ is the vector of means of the $p-1$ explanatory variables and $\mathbf{S}_{xx}$ is their covariance matrix. Note that, if the variables were uncorrelated, h_{ii} would be the sum of the standardized distances $[(x_{ij} - x_j)/s_j]^2$. As $\sum_{i=1}^{n} h_{ii} = \mathrm{tr}(\mathbf{H}) = p$, the average value of the leverage is $\bar{h} = \sum h_{ii}/n = p/n$, and it can be shown that $1/n \le h_{ii} \le 1$. From (28.4) we conclude that the residual will be close to the measurement error for those observations close to the center of the explanatory data, where $h_{ii} \simeq 1/n$, but will be very different for the extreme points where $h_{ii} \simeq 1$. Note that the residual covariance matrix is

$$\begin{aligned} Var(\boldsymbol{e}) = E[\boldsymbol{e}\boldsymbol{e}'] &= E[(\mathbf{I} - \mathbf{H})\boldsymbol{u}\boldsymbol{u}'(\mathbf{I} - \mathbf{H})] \\ &= \sigma^2(\mathbf{I} - \mathbf{H}) \end{aligned} \tag{28.5}$$

and $Var(e_i) = \sigma^2(1 - h_{ii})$, which will be large when $h_{ii} \simeq 1/n$, and close to zero if $h_{ii} \simeq 1$. As the mean of the residuals is zero if the variance of e_i is very small this implies that its value will be close to zero, whatever the value of u_i.

The problem that each residual has a different variance leads to the definition of the standardized residuals, given by

$$r_i = \frac{e_i}{\widehat{s}_{\mathrm{R}}\sqrt{1 - h_{ii}}} \tag{28.6}$$

which will have variance equal to one. A third type of useful residuals are the predictive, deleted, or out-of-sample residuals, defined by $e_{(i)} = y_i - \widehat{y}_{i(i)}$, where $\widehat{y}_{i(i)}$ is computed in a sample with the i-th observation deleted. It can be shown that

$$e_{(i)} = \frac{e_i}{(1 - h_{ii})} \tag{28.7}$$

and the variance of these predictive residuals is $\sigma^2/(1 - h_{ii})$. If we estimate σ^2 by $\widehat{s}^2_{\mathrm{R}(i)}$, the residual variance in a regression which does not include the i-th observation, the standardization of the predictive residual leads to the Studentized residual, defined by

$$\widehat{t}_i = \frac{e_i}{\widehat{s}_{\mathrm{R}(i)}\sqrt{1 - h_{ii}}} \tag{28.8}$$

which has a Student t distribution with $n - p - 1$ degrees of freedom. An alternative useful expression of these residuals is based on $h_{ii(i)} = \boldsymbol{x}_i'(\mathbf{X}_{(i)}\mathbf{X}_{(i)})^{-1}\boldsymbol{x}_i = h_{ii}/(1 - h_{ii})$, where $\mathbf{X}_{(i)}$ is the $(n-1) \times p$ matrix without the row $\boldsymbol{x}_i'$, and therefore, we have the alternative expression:

$$\widehat{t}_i = \frac{e_{(i)}}{\widehat{s}_{\mathrm{R}(i)}\sqrt{1 + h_{ii(i)}}}. \tag{28.9}$$

28.2 Diagnosis for a Single Outlier

28.2.1 Outliers

If one observation, y_h, does not follow the regression model, either because its expected value is not $\boldsymbol{x}_h'\boldsymbol{\beta}$, or its conditional variance is not σ^2, we will say that it is an outlier. These discrepancies are usually translated to the residuals. For instance, if the observation has been generated by a different model, $g(\boldsymbol{x}_h') + u_h$, then

$$e_h = g(\boldsymbol{x}_h') - \boldsymbol{x}_h'\hat{\boldsymbol{\beta}} + u_h$$

and the deviation $\left|g(\boldsymbol{x}_h')-\boldsymbol{x}_h'\hat{\boldsymbol{\beta}}\right|$ will be larger than $\left|\boldsymbol{x}_h'(\boldsymbol{\beta}-\hat{\boldsymbol{\beta}})\right|$. However, we may not detect this observation because of the key role of the variable $\boldsymbol{x}_h'$. Suppose, in order to simplify, that we write $g(\boldsymbol{x}_h')=\boldsymbol{x}_h'\boldsymbol{\alpha}$, that is, the data is also generated by a linear model but with different parameter values. Then, even if $\boldsymbol{\alpha}$ is very different from $\boldsymbol{\beta}$, the size of $\left|\boldsymbol{x}_h'(\boldsymbol{\alpha}-\hat{\boldsymbol{\beta}})\right|$ depends on $\boldsymbol{x}_h'$ and the discrepancy between the parameter values would be easier to detect when $\left|\boldsymbol{x}_h'\right|$ is large than when it is small.

When the observation is an outlier because it has a measurement error which comes from a distribution with variance $k\sigma^2$, where $k>1$, we expect that $|u_h|$ will be larger than the rest of the measurement errors. It is intuitive, and it has been formally shown [28.34], that we cannot differentiate between a change in the mean and a change in the variance by using just one observation; also models which assume a change in the variance are equivalent to those which assume shifts in the mean of the observations. Thus, we consider a simple mean-shift model for a single outlier

$$y_h=\boldsymbol{x}_h'\boldsymbol{\beta}+w+u_h,$$

where w is the size of the outlier and u_h is $N(0,\sigma^2)$. A test for outliers can be made by estimating the parameter w in the model

$$y_i=\boldsymbol{x}_i'\boldsymbol{\alpha}+wI_i^{(h)}+u_i,\quad i=1,..,n,$$

where $I_i^{(h)}$ is a dummy variable given by $I_i^{(h)}=1$, when $i=h$ and $I_i^{(h)}=0$, otherwise. We can test for outliers by fitting this model for $h=1,\ldots,n$, and checking if the estimated coefficient $\widehat{w}$ is significant. It is easy to show that:

1. $\widehat{\boldsymbol{\alpha}}=(\mathbf{X}_{(i)}'\mathbf{X}_{(i)})^{-1}\mathbf{X}_{(i)}'\boldsymbol{y}_{(i)}=\widehat{\boldsymbol{\beta}}_{(i)}$, the regression parameters are estimated in the usual way, but deleting case $(y_j,\boldsymbol{x}_j)$;
2. $\widehat{w}=y_h-\boldsymbol{x}_h'\widehat{\boldsymbol{\alpha}}$, and therefore the estimated residual at this point, $e_h=y_h-\boldsymbol{x}_h'\widehat{\boldsymbol{\alpha}}-\widehat{w}=0$.
3. The t statistic to check if the parameter $\widehat{w}$ is significant is equal to the Studentized residual, t_h, as defined in (28.8).

Assuming that only one observation is an outlier the test is made by comparing the standardized residual to the maximum of a t distribution with $n-p-2$ degrees of freedom. Often, for moderate n, cases are considered as outliers if their Studentized residuals are larger than 3.5.

28.2.2 Influential Observations

An intuitive way to measure the effect of an observation on the estimated parameters, or on the forecasts, is to delete this observation from the sample and see how this deletion affects the vector of parameters or the vector of forecasts. A measure of the influence of the $i-$th observation on the parameter estimate is given by:

$$D(i)=\frac{(\widehat{\boldsymbol{\beta}}-\widehat{\boldsymbol{\beta}}_{(i)}')\mathbf{X}'\mathbf{X}(\widehat{\boldsymbol{\beta}}-\widehat{\boldsymbol{\beta}}_{(i)})}{p\widehat{s}_{\mathrm{R}}^2},\tag{28.10}$$

which, as the covariance of $\widehat{\boldsymbol{\beta}}$ is $\widehat{s}_{\mathrm{R}}^2(\mathbf{X}'\mathbf{X})^{-1}$, measures the change between $\widehat{\boldsymbol{\beta}}$ and $\widehat{\boldsymbol{\beta}}_{(i)}$ with relation to the covariance matrix of $\widehat{\boldsymbol{\beta}}$, standardized by the dimension of the vector p. This measure was introduced by *Cook* [28.16]. Of course other standardizations are possible. *Belsley* et al. [28.9] propose using $\widehat{s}_{\mathrm{R}(i)}^2$, the variance of the regression model when the ith observation is deleted, instead of $\widehat{s}_{\mathrm{R}}^2$, and *Diaz-García* and *Gonzalez-Farias* [28.35] have suggested standardizing the vector $(\widehat{\boldsymbol{\beta}}-\widehat{\boldsymbol{\beta}}_{(i)})$ by its variance, instead of using the variance of $\widehat{\boldsymbol{\beta}}$. See *Cook*, *Peña* and *Weisberg* [28.36] for a comparison of some of these possible standarizations.

Equation (28.10) can also be written as the standardized change in the vector of forecasts:

$$D_i=\frac{\left(\widehat{\boldsymbol{y}}-\widehat{\boldsymbol{y}}_{(i)}\right)'\left(\widehat{\boldsymbol{y}}-\widehat{\boldsymbol{y}}_{(i)}\right)}{p\widehat{s}_{\mathrm{R}}^2},\tag{28.11}$$

where $\widehat{\boldsymbol{y}}_{(i)}=\mathbf{X}\widehat{\beta}_{(i)}=(\hat{y}_{1(i)},\ldots,\hat{y}_{n(i)})'$. Note that from (28.2) we have that $Var(\widehat{y}_i)=\sigma^2h_{ii}$ and as the average value of h_{ii} is p/n, (28.11) is standardized by this average value and by the dimension n of the vector. A third way to measure the influence of the ith point is to compare $\widehat{y}_i$ with $\widehat{y}_{(i)}$, where $\widehat{y}_{(i)}=\boldsymbol{x}_i'\widehat{\boldsymbol{\beta}}_{(i)}$. With the usual standardization by the variance we have:

$$D_i=\frac{\left(\widehat{y}_i-\widehat{y}_{(i)}\right)^2}{p\widehat{s}_R^2h_{ii}}\tag{28.12}$$

and, using the relation between the inverse of $\mathbf{X}'\mathbf{X}$ and $\mathbf{X}_{(i)}'\mathbf{X}_{(i)}$, we obtain

$$\boldsymbol{\beta}-\widehat{\boldsymbol{\beta}}_{(i)}=(\mathbf{X}'\mathbf{X})^{-1}\boldsymbol{x}_i\frac{e_i}{1-h_{ii}}.\tag{28.13}$$

Inserting this into (28.10) it is easy to see that (28.12) is equivalent to (28.10) and (28.11). Also, as from (28.13) we have that

$$\widehat{\boldsymbol{y}}-\widehat{\boldsymbol{y}}_{(i)}=\boldsymbol{h}_i\frac{e_i}{1-h_{ii}},\tag{28.14}$$

where $\boldsymbol{h}_i$ is the $i-$th column of the $\mathbf{H}$ matrix, inserting this expression into (28.11) we obtain a convenient expression for the computation of Cook's statistics:

$$D_i = \frac{r_i^2 h_{ii}}{p(1-h_{ii})}, \tag{28.15}$$

where r_i is the standardized residual given by (28.6). For large n, the expected value of D_i can be approximated by

$$E(D_i) \simeq \frac{h_{ii}}{p(1-h_{ii})}, \tag{28.16}$$

and it will be very different for observations with different leverage.

Cook proposed judging the values of D_i by an $F(p; n-p; 1-\alpha)$, where F is the distribution used in building a confidence region for the $\boldsymbol{\beta}$ parameters. Thus, we may identify points as influential when they are able to move the estimate out of the confidence region for a fixed value of α and declare as influential those observations which verify $D_i \geq F(p; n-p; 1-\alpha)$. This solution is not satisfactory for large sample sizes because it is difficult for any observation to be deemed influential. *Muller* and *Mok* [28.37] have obtained the distribution of the D_i for normal explanatory variables, but this distribution is complicated.

Cook [28.17] proposed a procedure for the assessment of the influence on a vector of parameters θ of minor perturbation of a statistical model. This approach is very flexible and can be used to see the effect of small perturbations which would not normally be detected by deletion of one observation. He suggested introducing a $n \times p$ vector $\boldsymbol{w}$ of case weights and use the likelihood displacement $[L(\hat{\theta}) - L(\hat{\theta}_w)]$, where $\hat{\theta}$ is the maximum likelihood (ML) estimator of $\hat{\theta}$, and $\hat{\theta}_w$ is the ML when the case weight $\boldsymbol{w}$ is introduced. Then, he showed that the directions of greatest local change in the likelihood displacement for the linear regression model are given by the eigenvectors linked to the largest eigenvalues of the curvature matrix, $\mathbf{L} = \mathbf{EHE}$, where $\mathbf{E}$ is the vector of residuals. Later, we will see how this approach is related to some procedures for multiple-outlier detection.

28.2.3 The Relationship Between Outliers and Influential Observations

An outlier may or may not be an influential observation and an influential observation may or may not be an outlier. To illustrate this point consider the data in Table 28.1. We will use these data to build four data sets. The first includes cases 1–9 repeated three times, and has sample size $n = 27$. The other three are formed by adding a new observation to this data set. The set (a) is built by adding case 28(a), the set (b) by adding case 28(b) and the set (c) by adding case 28(c). Table 28.2 shows some statistics of these four data sets where (0) refers to the set of 27 observations and (a), (b) and (c) to the sets of 28 observations as defined before. The table gives the values of the estimated parameters, their t statistics in parentheses, the residual standard deviation, the leverage of the added point, the standardized residual for the added point and the value of Cook's statistics.

In set (a) observation 28 is clearly an outlier with a value of the standardized residual of 4.68, but it is not influential, as $D_{28}(a) = 0.92$, which is a small value. In case (b) the 28-th point is not an outlier, as $r_{28}(b) = 1.77$ is not significant, but it is very influential, as indicated by the large D_{28} value. Finally, in set (c) the observation is both an outlier, $r_{28} = 4.63$, and very influential, $D_{28} = 13.5$.

Table 28.1 Three sets of data which differ in one observation

Case	1	2	3	4	5	6	7	8	9	(a)	(b)	(c)
x_1	−2	0	2	−4	3	1	−3	−1	4	0	−3	−3
x_2	6.5	7.3	8.3	6.0	8.8	8.0	5.9	6.9	9.5	7.2	9	7.3
y	−1.5	0.5	1.6	−3.9	3.5	0.8	−2.7	−1.3	4.1	5	−1.5	4

Table 28.2 Some statistics for the three regressions fitted to the data in Table 28.1

	$\widehat{\beta}_0$	$t(\widehat{\beta}_0)$	$\widehat{\beta}_2$	$t(\widehat{\beta}_2)$	$\widehat{\beta}_1$	$t(\widehat{\beta}_1)$	$\widehat{s}_R$	h_{28}	r_{28}	D_{28}
(0)	2.38	(0.82)	−0.30	(0.78)	1.12	(6.24)	0.348	–	–	–
(*a*)	13.1	(1.7)	−1.72	(−1.66)	1.77	(3.69)	0.96	0.11	4.68	0.92
(*b*)	−2.74	(−2.9)	0.38	(3.08)	0.80	(13.87)	0.36	0.91	1.77	11.1
(*c*)	−25.4	(−5.41)	3.43	(5.49)	−0.624	(2.22)	0.91	0.65	4.63	13.5

Note that if the leverage is small $h_{ii} \simeq 1/n$, $h_{ii}/(1-h_{ii}) \simeq (n-1)^{-1}$, and by (28.15):

$$D_i = \frac{r_i^2}{p}\left(\frac{1}{n-1}\right),$$

then, if n is large, the observation cannot be influential, whatever the value of r_i^2. On the other hand, high-leverage observations with h_{ii} close to one will have a ratio $h_{ii}/(1-h_{ii})$ that is arbitrarily large and, even if r_i^2 is small, will be influential.

28.3 Diagnosis for Groups of Outliers

The procedures that we have presented in the previous section are designed for a single outlier. We can extend these ideas to multiple outliers as follows. Let I be an index set corresponding to a subset of r data points. The checking of this subset can be done by introducing dummy variables as in the univariate case. Assuming normality, the F test for the hypothesis that the coefficients of the dummy variables are zero is given by

$$F_{r,(n-p-r)} = \frac{\boldsymbol{e}_I'(\mathbf{I}-\mathbf{H}_I)^{-1}\boldsymbol{e}_I}{r\widehat{s}^2_{\mathrm{R}(I)}}$$

where $\boldsymbol{e}_I$ is the vector of least-squares residuals, $\mathbf{H}_I$ the $r\times r$ submatrix of $\mathbf{H}$, corresponding to the set of observations included in I, and $\widehat{s}^2_{\mathrm{R}(I)}$ the residual variance of the regression with the set I deleted. *Cook* and *Weisberg* [28.11] proposed to measure the joint influence of the data points with index in I by deleting the set I and computing, as in the single outlier case,

$$D_I = \frac{(\widehat{\boldsymbol{\beta}}-\widehat{\boldsymbol{\beta}}_{(I)}')\mathbf{X}'\mathbf{X}(\widehat{\boldsymbol{\beta}}-\widehat{\boldsymbol{\beta}}_{(I)})}{p\widehat{s}^2_{\mathrm{R}}},$$

which can also be written as a generalization of (28.15) by $D_I = [\boldsymbol{e}_I'(\mathbf{I}-\mathbf{H}_I)^{-1}\mathbf{H}_I(\mathbf{I}-\mathbf{H}_I)^{-1}\boldsymbol{e}_I]/p\widehat{s}^2_{\mathrm{R}}$. Note that a large value of D_I may be due to a single influential observation included in the set I or a sum of small individual effects of a set of observations that are masking each other. However, in the first case this single observation will be easily identified. Also, a subset of individually highly influential points, whose effect is to cancel each other out, will lead to a small value of D_I; again in this case, the individual effects will be easy to identify. However, to build this measure we should compute all sets of I in the n data, which would be impossible for large I and n.

The procedures for finding multiple outliers in regression can be divided into three main groups. The first is based on robust estimation. If we can compute an estimate that is not affected by the outliers, we can then find the outliers as those cases with large residuals with respect to the robust fit. We present briefly here the least median of squares (LMS) estimate proposed by *Rousseeuw* [28.38], which is used as an initial estimate in some diagnostic procedures based on a clean set, which we will review below. *Rousseeuw* [28.38] proposed generating many possible values of the parameters, $\boldsymbol{\beta}_1, \ldots, \boldsymbol{\beta}_N$, finding the residuals associated with each parameter value, $\boldsymbol{e}_i = \boldsymbol{y} - \mathbf{X}\,\boldsymbol{\beta}_i$ $(i = 1, .., N)$, and using the median of these residuals as a robust scale

$$s(\boldsymbol{\beta}_i) = median(e_{1i}^2, \ldots, e_{ni}^2). \qquad (28.17)$$

The value $\boldsymbol{\beta}_i$ that minimizes this robust scale is the LMS estimate. *Rousseeuw* [28.38] generates the parameter values $\boldsymbol{\beta}_1, \ldots, \boldsymbol{\beta}_N$ by resampling, that is, by taking many random samples of size p, $(\mathbf{X}_i, \boldsymbol{y}_i)$, where the matrix $\mathbf{X}_i$ is $p\times p$ and $\boldsymbol{y}_i$ is $p\times 1$, and computing the least-squares estimate (LSE) for each sample, $\boldsymbol{\beta}_i = \mathbf{X}_i^{-1}\boldsymbol{y}_i$. The LMS, although very robust, is not very efficient, and many other robust methods have been proposed to keep high robustness and achieve better efficiency in regression [28.31].

A second class of procedures uses robust ideas to build an initial clean subset and then combine least-squares estimates in clean subsets and diagnosis ideas for outlier detection. Three procedures in this spirit will be presented next; they can be very effective when p and n are not large.

For large data sets with many predictors and high-leverage observations, robust estimates can be very difficult to compute and procedures based on the clean-set idea may not work well, because of the difficulty in selecting the initial subset. The third type of procedures are based on eigenstructure analysis of some diagnostic matrices and are especially useful for large data sets.

28.3.1 Methods Based on an Initial Clean Set

Kianifard and *Swallow* [28.26, 27] proposed to build a *clean* set of observations and check the rest of the data with respect to this set. If the observation closest to the clean set is not an outlier, then the clean set is increased by one observation, and continue to do so until no new

observations can be incorporated into the basic set. The key step in this procedure is to find the initial subset, because if it contains outliers the whole procedure breaks down. These authors proposed using either the predictive or standardized residuals, or a measure of influence such as D_i.

A similar procedure was proposed by *Hadi* and *Simonoff* [28.1, 2]. In [28.2] they recommend building the initial subset using the LMS. The clean set is built by computing this robust estimate and then uses the $h = \left(\frac{n+p+1}{2}\right)$ observations with the smallest residuals with respect to this robust fit to form the initial clean set, which we call M. The procedure continues by fitting a regression model by least squares to this clean set M. Calling $\widehat{\boldsymbol{\beta}}_M$ the estimated LSE parameters and $\widehat{\sigma}_M$ the residual standard deviation, a set of in-sample and out-of-sample residuals is obtained as follows

$$d_i = \frac{\left|y_i - \boldsymbol{x}_i'\boldsymbol{\beta}_M\right|}{\widehat{\sigma}_M\sqrt{1-\boldsymbol{x}_i'(\mathbf{X}_M'\mathbf{X}_M)^{-1}\boldsymbol{x}_i}}, \quad \text{if } i \in M,$$

$$d_i = \frac{\left|y_i - \boldsymbol{x}_i'\boldsymbol{\beta}_M\right|}{\widehat{\sigma}_M\sqrt{1+\boldsymbol{x}_i'(\mathbf{X}_M'\mathbf{X}_M)^{-1}\boldsymbol{x}_i}}, \quad \text{if } i \notin M.$$

That is, d_i represents the standardized residual (28.6) for the data in set M and the predictive residual (28.9) for observations outside this set. Then, all of the observations are arranged in increasing order according to d_i. Let s be the size of the set M (which is h in the first iteration, but will change as explained below). If $d_{(s+1)}$ is smaller than some critical value, a new set of size $s+1$ is built with the $s+1$ observations with smallest d values. If $d_{(s+1)}$ is larger than some critical value, all observations out of the set M are declared as outliers and the procedure stops. If $n = s+1$ we stop and declare that there are no outliers in the data. These authors proposed using as critical values those of the t distribution adjusted by Bonferroni, that is $t\left(\frac{\alpha}{2(s+1)}, s-p\right)$.

Atkinson [28.3] proposed a similar approach called the forward search. His idea is again to combine a robust estimate with diagnostic analysis. He computes the LMS estimate but, instead of generating a large set of candidates by random sample, he generates a set of candidate values for $\widehat{\boldsymbol{\beta}}$ by fitting least-squares subsamples of size p, $p+1, \ldots, n$. The procedure is as follows. We start by generating a random sample of size p; let I_p be the indices of the observations selected. Then, we compute the parameters $\widehat{\boldsymbol{\beta}}(p)$ by LSE, and the residual for all cases, $\boldsymbol{e} = \boldsymbol{y} - \mathbf{X}\widehat{\boldsymbol{\beta}}(p)$. The residuals are corrected by

$$u_i^2 = e_i^2, \qquad i \in I \tag{28.18}$$

$$u_i^2 = e_i^2/(1+h_{ii}), \qquad i \notin I$$

and these residuals u_i^2 are ordered and the smallest $p+1$ are selected. With this new sample of size $m = p+1$ the process is repeated, that is, the parameters are computed by LSE and the residuals to this fit for the n points are obtained. The corrected residuals (28.18) are computed and the process is continued. In this way we obtain a set of estimates, $\widehat{\boldsymbol{\beta}}(m), m = p, .., n$, the corresponding residuals, $\boldsymbol{e}(m) = \boldsymbol{y} - \mathbf{X}\widehat{\boldsymbol{\beta}}(m)$, and the robust scales (28.17), $s[\widehat{\boldsymbol{\beta}}(m)]$. The value selected is the $\widehat{\boldsymbol{\beta}}(m)$ which minimizes the robust scale. This process is a complete forward search and several forward searches are done starting with different random samples. The residuals are then identified by using this LMS estimate computed from several forward searches. An improvement of this procedure was proposed by *Atkinson* and *Riani* [28.15], which clearly separates the estimation of the clean subset and the forward search. The initial estimate is computed, as proposed by *Rousseeuw* [28.38], by taking many random samples of size p. The forward search is then applied, but stressing the use of diagnostic statistics to monitor the performance of the procedure.

Finally, *Swallow* and *Kianifard* [28.4] also suggested a similar procedure, which uses a robust estimate of the scale and determines the cutoff values for testing from simulations.

These procedures work when both p and n are not large and the proportion of outliers is moderate, as shown in the simulated comparison by *Wisnowski* et al. [28.39]. However, they do not work as well in large data sets with high contamination. The LMS estimates rely on having at least a sample of size p without outliers, and we need an unfeasible number of samples to have a large probability of this event when p and n are large [28.6]. This good initial estimate is the key for procedures based on clean sets. In the next section we will present procedures that can be applied to large data sets.

28.3.2 Analysis of the Influence Matrix

Let us define the matrix of forecast changes, as the matrix of changes in the forecast of one observation when another observation is deleted. This matrix is given by

$$\mathbf{T} = \begin{pmatrix} \widehat{y}_1 - \widehat{y}_{1(1)} & \widehat{y}_1 - \widehat{y}_{1(2)} & \ldots & \widehat{y}_1 - \widehat{y}_{1(n-1)} & \widehat{y}_1 - \widehat{y}_{1(n)} \\ \widehat{y}_2 - \widehat{y}_{2(1)} & \widehat{y}_2 - \widehat{y}_{2(2)} & \ldots & \widehat{y}_2 - \widehat{y}_{2(n-1)} & \widehat{y}_2 - \widehat{y}_{2(n)} \\ \ldots & \ldots & \ldots & \ldots & \ldots \\ \widehat{y}_{n-1} - \widehat{y}_{n-1(1)} & \widehat{y}_n - \widehat{y}_{n(2)} & \ldots & \widehat{y}_n - \widehat{y}_{n(n-1)} & \widehat{y}_n - \widehat{y}_{n(n)} \\ \widehat{y}_n - \widehat{y}_{n(1)} & \widehat{y}_n - \widehat{y}_{n(2)} & \ldots & \widehat{y}_n - \widehat{y}_{n(n-1)} & \widehat{y}_n - \widehat{y}_{n(n)} \end{pmatrix}.$$

The columns of this matrix are the vectors $\boldsymbol{t}_i = \hat{\boldsymbol{y}} - \hat{\boldsymbol{y}}_{(i)}$, and Cook's statistic is their standardized norm. These

vectors can also be written as $\boldsymbol{t}_i = \boldsymbol{e}_{(i)} - \boldsymbol{e}$, where $\boldsymbol{e}_{(i)}$ is the vector of residuals when the i-th observation is deleted. Therefore, $\mathbf{T}$ can also be considered the matrix of residual changes. *Peña* and *Yohai* [28.5] define the $n \times n$ influence matrix $\mathbf{M}$ as

$$\mathbf{M} = \frac{1}{ps_{\mathrm{R}}^2}\mathbf{T}'\mathbf{T}.$$

As $\mathbf{H}$ is idempotent it can be shown immediately that $\mathbf{M}$ is given by

$$\mathbf{M} = \frac{1}{ps_{\mathrm{R}}^2}\mathbf{EDHDE}, \tag{28.19}$$

where $\mathbf{E}$ is a diagonal matrix with the residuals on the main diagonal, and $\mathbf{D}$ is a diagonal matrix with elements $(1-h_{ii})^{-1}$. By (28.7) $\mathbf{ED}$ is the diagonal matrix of predictive residuals. Therefore, the ij-th element of $\mathbf{M}$, is

$$m_{ij} = \frac{e_i e_j h_{ij}}{(1-h_{ii})(1-h_{jj})ps_{\mathrm{R}}^2} = \frac{e_{i(i)}e_{j(j)}h_{ij}}{ps_{\mathrm{R}}^2}\,.$$

Assuming that all the residuals are different from zero, from (28.4) the rank of $\mathbf{M}$ is equal to p, the rank of $\mathbf{H}$. Observe that the diagonal elements of $\mathbf{M}$ are the Cook's statistics.

Let $r_{ij} = m_{ij}/m_{ii}^{1/2}m_{jj}^{1/2}$ be the uncentered correlation coefficient between $\boldsymbol{t}_i$ and $\boldsymbol{t}_j$. Let us show that the eigenvectors of the matrix $\mathbf{M}$ will be able to indicate groups of influential observations. Suppose that there are k groups of influential observations $I_1, \ldots, I_k$, such that

1. If $i, j \in I_h$, then $|r_{ij}| = 1$. This means that the effects on the least-squares fit produced by the deletion of two points in the same set I_h have correlation 1 or -1.
2. If $i \in I_j$ and $l \in I_h$ with $j \neq h$, then $r_{il} = 0$. This means that the effects produced on the least-squares fit by observations i and j belonging to different sets are uncorrelated.
3. If i does not belong to any I_h, then $m_{ij} = 0$ for all j. This means that data points outside these groups have no influence on the fit.

Now, according to (1) we can split each set I_h into I_h^1 and I_h^2 such that: (1) if $i, j \in I_h^q$, then $r_{ij} = 1$; (2) if $i \in I_h^1$ and $j \in I_h^2$, then $r_{ij} = -1$. Let $\boldsymbol{v}_1 = (v_{11}, \ldots, v_{1n})', \ldots, \boldsymbol{v}_k = (v_{k1}, \ldots, v_{kn})'$ be defined by $v_{hj} = m_{jj}^{1/2}$ if $j \in I_h^1$; $v_{hj} = m_{jj}^{1/2}$ if $j \in I_h^1$; $v_{hj} = -m_{jj}^{1/2}$ if $j \in I_h^2$ and $v_{hj} = 0$ if $j \notin I_h$. Then, if (1)–(3) hold, by (28.6) the matrix $\mathbf{M}$ is

$$\mathbf{M} = \sum_{i=1}^{k} \boldsymbol{v}_i \boldsymbol{v}_i',$$

and since the $\boldsymbol{v}_i$ are orthogonal, the eigenvectors of $\mathbf{M}$ are $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k$, and the corresponding eigenvalues $\lambda_1, \ldots, \lambda_k$ are given by

$$\lambda_h = \sum_{i \in I_h} m_{ii}.$$

It is clear that, when the matrix $\mathbf{M}$ satisfies (1)–(3), the only sets I with large C_I are I_h^q, $1 \leq h \leq k$, $q = 1, 2$, and these sets may be found by looking at the eigenvectors associated with non-null eigenvalues of $\mathbf{M}$. Note that (28.6) can also be written as

$$r_{ij} = \mathrm{sign}(e_i)\mathrm{sign}(e_j)h_{ij}/(h_{ii}h_{jj})^{1/2},$$

which means that, in the extreme case that we have presented, the $\mathbf{H}$ matrix and the signs of the residuals are able, by themselves, to identify the set of points that are associated with masking. For real data sets, (1)–(3) do not hold exactly. However, the masking effect is typically due to the presence of blocks of influential observations in the sample having similar or opposite effects. These blocks are likely to produce a matrix $\mathbf{M}$ with a structure close to that described by (1)–(3). In fact, two influential observations i, j producing similar effects should have r_{ij} close to 1, and close to -1 when they have opposed effects. Influential observations with non-correlated effects have $|r_{ij}|$ close to 0. The same will happen with non-influential observations. Therefore, the eigenvectors will have approximately the structure described above, and the null components will be replaced by small values.

This suggests that we should find the eigenvectors corresponding to the p non-null eigenvalues of the influence matrix $\mathbf{M}$, consider the eigenvectors corresponding to large eigenvalues, and define the sets I_j^1 and I_j^2 by those components with large positive and negative weights, respectively. *Peña* and *Yohai* [28.5] proposed the following procedure.

Step 1: *Identifying sets of outlier candidates*. A set of candidate outlier is obtained by analyzing the eigenvectors corresponding to the non-null eigenvalues of the influence matrix $\mathbf{M}$, and by searching in each eigenvector for a set of coordinates with relatively large weight and the same sign.

Step 2: *Checking for outliers*. (a) Remove all candidate outliers. (b) Use the standard F and t statistics to

test for groups or individual outliers. Reject sets or individual points with F or t statistics larger than some constant c. For the F statistic the c value corresponds to the distribution of the maximum F over all sets of the same size, and this distribution is unknown. Therefore, it is better to use the t statistic and choose the c value by the Bonferroni inequality or, better still, by simulating the procedure with normal errors. (c) If the number of candidate outliers is larger than $n/2$, the previous procedure can be applied separately to the points identified in each eigenvector.

As an illustration we will use the simulated data from Table 28.3, which are plotted in Fig. 28.1.

The three sets of data have in common cases 1–8 and differ in cases 9 and 10. In the first set of data the largest values of the Cook's statistics are $D_{10} = 0.795$, $D_1 = 0, 29$ and $D_9 = 0.228$. The most influential observation is the 10-th, which has a standardized residual $r_{10} = 1.88$, thus there is no evidence that the point is an outlier. However, the first eigenvector of the influence matrix leads to the results shown in Table 28.4. We see that both cases 9 and 10 appear separated from the rest. When they are deleted from the sample and checked against the first eight observations we obtain the values indicated in Table 28.5, where they are clearly declared as outliers. Thus, in this example the eigenvalues of the influence matrix are able to avoid the masking effect which was clearly present in the univariate statistics.

In case (b), as both outliers have a different sign, they do not produce masking, and both of them are detected by the univariate analysis: $D_9 = 1.889$, and $D_{10} = 1.893$, and the outlier tests are $t_{10} = 5.20$ and $t_9 = -5.24$. The two points are also shown in the extremes of the eigenvalue. Finally in case (c) there is only one outlier which is detected by both the univariate and multivariate analysis.

The influence matrix $\mathbf{M}$ may be considered a generalization of Cook's local influence matrix $\mathbf{L} = \mathbf{EHE}$ [28.17]. It replaces the matrix of residuals $\mathbf{E}$ by the matrix of standardized residuals $\mathbf{ED}$. If there are no high-leverage observations and the h_{ii} are similar for all points, both matrices will also be similar, and will have similar eigenvectors. However, when the observations have very different leverages, the directions corresponding to the eigenvectors of the matrix $\mathbf{M}$ give more weight to the influence of the high-leverage observations, which are

Table 28.5 Values of the t statistics for testing each point as an outlier

precisely those that are more likely to produce masking effects.

Note that the rank of the influence matrix **M** is p, the same as the rank of **H**, and therefore we do not need to compute n eigenvectors as we only have p eigenvalues linked to nonzero eigenvalues. Thus, the procedure can be applied for very large data sets, see *Peña* and *Yohai* [28.5] for the details of the implementation.

28.3.3 The Sensitivity Matrix

If instead of looking at the columns of the matrix of forecast changes **T** we look at its rows, a different perspective appears. The rows indicate the sensitivity of each point, that is, how the forecast for a given point changes when we use as the sample the n sets of $n-1$ data built by deleting each point of the sample. In this way we analyze the sensitivity of a given point under a set of small perturbations of the sample. Let

$$\boldsymbol{s}_i = (\widehat{y}_i - \widehat{y}_{i(1)}, \ldots, \widehat{y}_i - \widehat{y}_{i(n)})'$$

be the i-th row of the matrix **T**. From (28.14) we can write

$$\boldsymbol{s}_i = (h_{i1}e_1/(1-h_{11}), \ldots, h_{in}e_n/(1-h_{nn})) = \mathbf{ED}\boldsymbol{h}_i,$$

where **E** and **D** are diagonal matrices of residuals and inverse leverage, respectively, defined in the previous section, and $\boldsymbol{h}_i$ is the i-th column of **H**. We define the sensitivity matrix by

$$\mathbf{P} = \frac{1}{p\widehat{s}_{\mathrm{R}}^2}\begin{pmatrix} \boldsymbol{s}_1'\boldsymbol{s}_1 & \ldots & \boldsymbol{s}_1'\boldsymbol{s}_n \\ \ldots & \ldots & \ldots \\ \boldsymbol{s}_1'\boldsymbol{s}_n & \ldots & \boldsymbol{s}_n'\boldsymbol{s}_n \end{pmatrix},$$

which can be computed by

$$\mathbf{P} = \frac{1}{p\widehat{s}_{\mathrm{R}}^2}\mathbf{HED}^2\mathbf{EH}, \tag{28.20}$$

and has elements

$$p_{ij} = \frac{1}{p\widehat{s}_{\mathrm{R}}^2}\sum_{k=1}^{n}\frac{e_k^2}{(1-h_{kk})^2}h_{ik}h_{jk}.$$

It can be shown that the sensitivity and the influence matrix have the same eigenvalues and we can obtain the eigenvectors of one matrix from the eigenvectors of the other. *Peña* and *Yohai* [28.6] have shown that eigenvectors of the sensitivity matrix are more powerful for the identification of groups of outliers than those of the influence matrix, although they often lead to the same results. These authors also show that these methods work very well for large sets with many predictors and high levels of contamination.

In the following example we show the use of this matrix for detecting groups of outliers. If we compute the eigenvectors of the sensitivity matrix for the data in Table 28.3 we obtain the results presented in Table 28.6. The first eigenvector clearly separates the observations 9 and 10 from the rest. In fact, if we order the coordinates of this vector we find the largest ratio at $170/20 = 8.5$ which separates cases 9 and 10 from the others.

28.4 A Statistic for Sensitivity for Large Data Sets

The analysis of the eigenvalues of the sensitivity matrix is a very powerful method for finding outliers. However, for large data sets it would be very convenient to have a simple statistic, fast to compute, which can be incorporated into the standard output of regression fitting and which could indicate groups of high-leverage outliers, which are the most difficult to identify. This statistic can be obtained through a proper standardization of the diagonal elements of the sensitivity matrix. *Peña* [28.7] defines the sensitivity statistic at the i-th observation S_i as the squared norm of the standardized vector $\boldsymbol{s}_i$, that is,

$$S_i = \frac{\boldsymbol{s}_i'\boldsymbol{s}_i}{p\widehat{Var}(\hat{y}_i)}, \tag{28.21}$$

and using (28.14) and $\widehat{Var}(\hat{y}_i) = \hat{s}^2_{\mathrm{R}} h_{ii}$, this statistic can be written as

$$S_i = \frac{1}{p\hat{s}^2_{\mathrm{R}} h_{ii}} \sum_{j=1}^{n} \frac{h^2_{ji} e^2_j}{(1-h_{jj})^2}. \tag{28.22}$$

An alternative way to write S_i, is as a linear combination of the sample Cook's distance. From (28.12) and (28.22), we have

$$S_i = \sum_{j=1}^{n} \rho^2_{ji} D_j, \tag{28.23}$$

where $\rho_{ij} = (h^2_{ij}/h_{ii}h_{jj})^{1/2} \leq 1$ is the correlation between forecasts $\hat{y}_i$ and $\hat{y}_j$. Also, using the predictive residuals, $e_{j(j)} = e_j/(1-h_{jj})$, we have that

$$S_i = \frac{1}{p\hat{s}^2_{\mathrm{R}}} \sum_{j=1}^{n} w_{ji} e^2_{j(j)} \tag{28.24}$$

and S_i is a weighted combination of the predictive residuals.

The sensitivity statistics has three interesting properties. The first is that, in a sample without outliers or high-leverage observations, all the cases have the same expected sensitivity, approximately equal to $1/p$. This is an important advantage over Cook's statistic, which has an expected value that depends heavily on the leverage of the case. The second property is that, for large sample sizes with many predictors, the distribution of the S_i statistic will be approximately normal. This again is an important difference from Cook's distance, which has a complicated asymptotic distribution [28.37]. This normal distribution allows the computation of cutoff values for finding outliers. The third property is that, when the sample is contaminated by a group of similar outliers with high leverage, the sensitivity statistic will discriminate between the outliers and the good points, and the sensitivity statistic S_i is expected to be smaller for the outliers than for the good data points.

These properties are proved in *Peña* [28.7]. The normality of the distribution of the S_i statistic implies that we can search for outliers by finding observations with large values of $[S_i - E(S_i)]/std(S_i)$. As the possible presence of outliers and high leverage points will affect the distribution of S_i, it is better to use robust estimates such as as the median or the median of the absolute deviations (MAD) from the sample median, and consider as heterogeneous observations those which satisfy:

$$|S_i - med(S)| \geq 4.5\mathrm{MAD}(S_i) \tag{28.25}$$

where $med(S)$ is the median of the S_i values and $\mathrm{MAD}(S_i) = med\,|S_i - med(S)|$. For normal data $\mathrm{MAD}(S_i)/.645$ is a robust estimate for the standard deviation and the previous rule is roughly equivalent to taking three standard deviations in the normal case. In *Peña* [28.7] it is shown that this statistic can be very useful for the diagnostic analysis of large data sets.

28.5 An Example: The Boston Housing Data

As an example of the usefulness of the sensitivity statistics and to compare it with the procedures based on eigenvalues, we will use the Boston housing data set which consists of 506 observations on 14 variables, available at Carnegie Mellon University, Department of Statistics, Pittsburgh (http://lib.stat.cmu.edu). This data set was given by *Belsley* et al. [28.9] and we have used the same variables they considered: the dependent variable is the logarithm of the median value of owner-occupied homes.

Figure 28.2 shows the diagnostic analysis of this data set. The first row corresponds to the residuals of the regression model. The residuals have been divided by their standard error and the first plot shows a few points which can be considered as outliers. The plot of the Studentized residual is similar and identifies the same points as outliers. The second row gives information about Cook's D statistics. There are clearly some points in the middle of the sample which are more influential than the rest, but all the values of the statistic are small and, as we expect a skewed distribution, the conclusion is not clear. However, the sensitivity statistics clearly identifies a group of extreme observations which are not homogeneous with the rest. The median of the sensitivity statistic is 0.0762, which is very close to the expected value $1/p = 1/14 = 0.0714$. The MAD is 0.0195 and the plot indicates that 45 observations are heterogeneous with respect to the rest. These observations are most of the cases 366–425 and some other isolated points. From *Belsley* et al. [28.9] we obtain that cases 357–488 correspond to Boston, whereas the rest correspond to the suburbs. Also, the 45 points indicated by the statistic S_i as outliers all correspond to some central districts of Boston, including the downtown area, which suggests that the relation among the variables could be different in these dis-

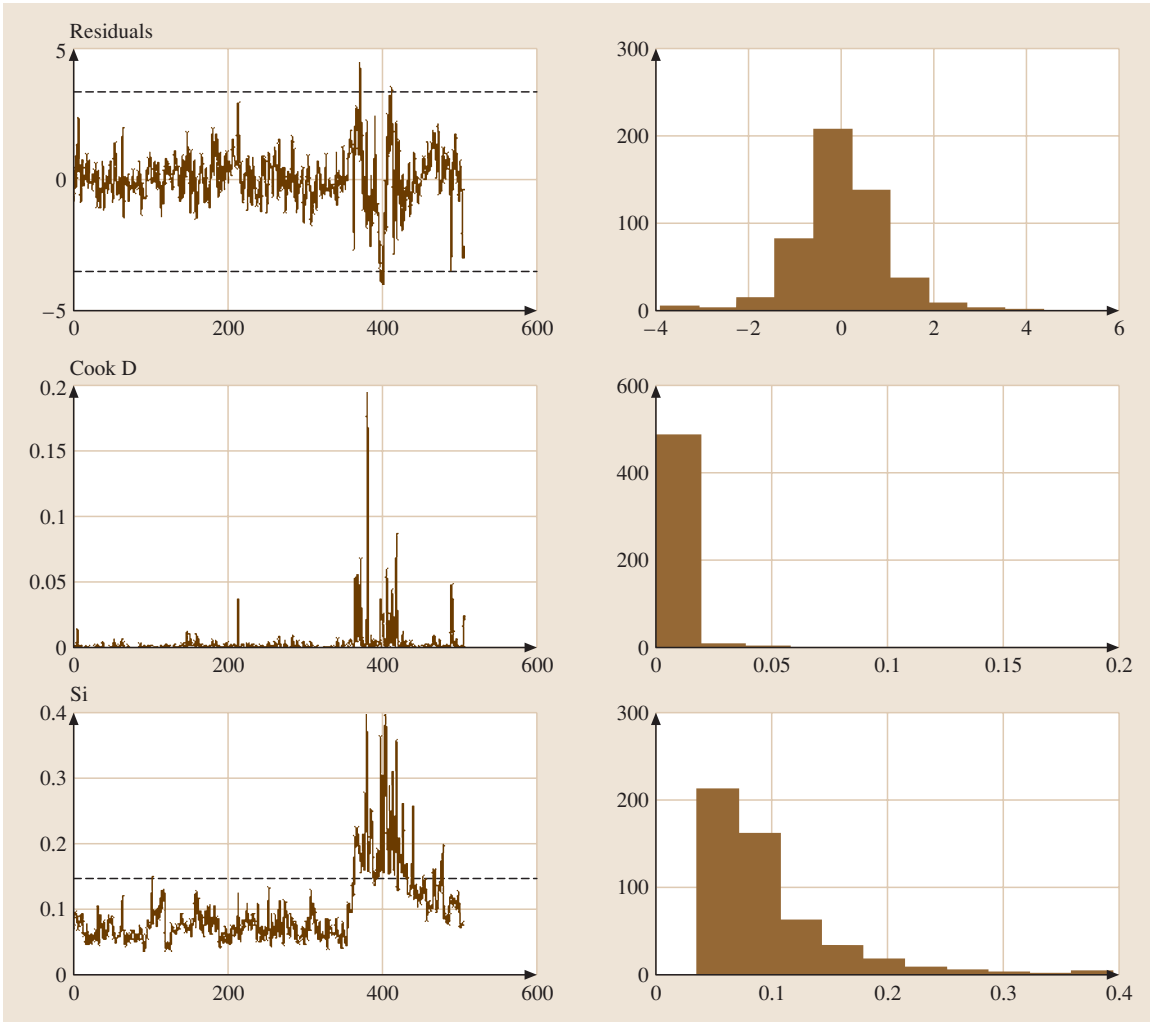

Fig. 28.2 Residuals, Cook's statistics and sensitivity statistics for the Boston housing data. *Right*, histogram; *left* case plot of the value of the statistic

tricts than in the rest of the sample. In fact, if we fit regression equations to these two groups we find very different coefficients for the regression coefficients in both groups of data, and in the second group only five variables are significant. Also, we obtain a large reduction in the residual sum of squares (RSE) when fitting different regression equations in the two groups.

Figure 28.3 shows the first eigenvalues of the matrix of influence and sensitivity. Although both eigenvectors indicate heterogeneity, the one from the matrix of sensitivity is more clear.

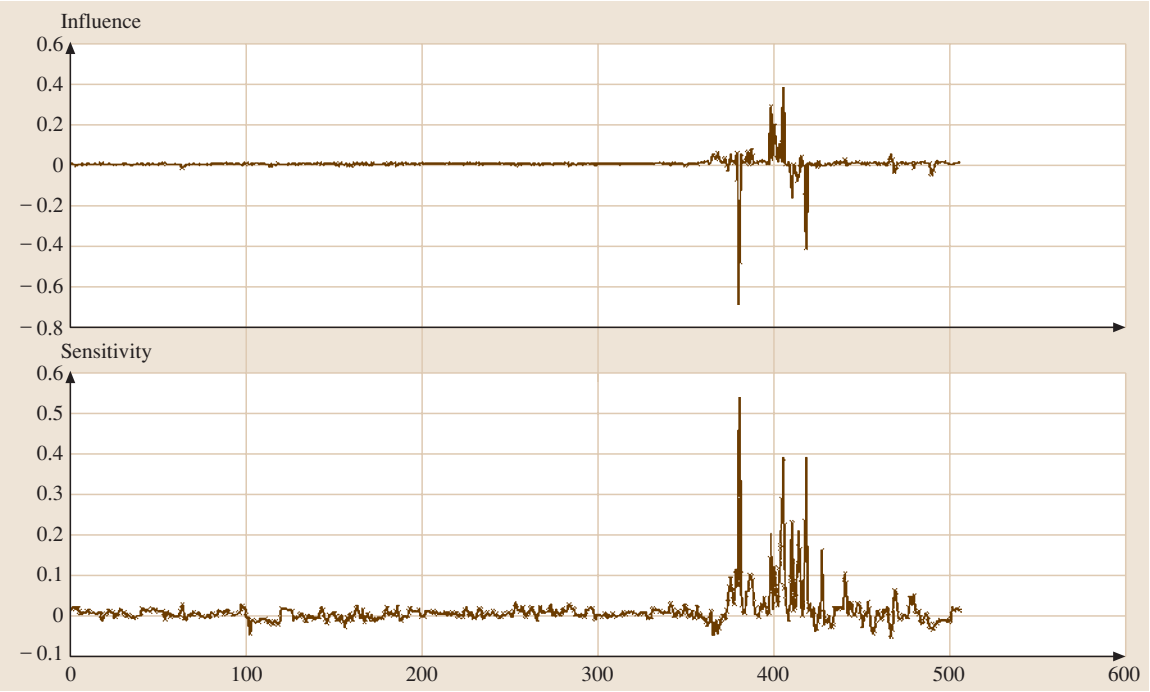

Fig. 28.3 First eigenvalue of the influence and sensitivity matrices

28.6 Final Remarks

We have shown different procedures for diagnosis in regression models and have stressed that the detection of groups of outliers in regression in large data sets can be made by eigen-analysis of the influence and sensitivity matrices. We have also shown that a single statistic of sensitivity is able to reveal masked outliers in many difficult situations. The most challenging problem today is to identify heterogeneity when we do not have a central model which explains more than 50% of the data and groups of outliers, as has been assumed in this article, but different regression models in different regions of the parameter space. In this case robust methods are no longer useful and we need other methods to solve this problem. A promising approach is the split and recombine (SAR) procedure, which has been applied to find heterogeneity in regression models by *Peña* et al. [28.40]. These situations are very close to cluster analysis and finding clusters around different regression lines is today a promising line of research.

29. Logistic Regression Tree Analysis

This chapter describes a tree-structured extension and generalization of the logistic regression method for fitting models to a binary-valued response variable. The technique overcomes a significant disadvantage of logistic regression viz. the interpretability of the model in the face of multi-collinearity and Simpson's paradox. Section 29.1 summarizes the statistical theory underlying the logistic regression model and the estimation of its parameters. Section 29.2 reviews two standard approaches to model selection for logistic regression, namely, model deviance relative to its degrees of freedom and the Akaike information criterion (AIC) criterion. A dataset on tree damage during a severe thunderstorm is used to compare the approaches and to highlight their weaknesses. A recently published partial one-dimensional model that addresses some of the weaknesses is also reviewed.

Section 29.3 introduces the idea of a logistic regression tree model. The latter consists of a binary tree in which a simple linear logistic regression (i.e., a linear logistic regression using a single predictor variable) is fitted to each leaf node. A split at an intermediate node is characterized by a subset of values taken by a (possibly different) predictor variable. The objective is to partition the dataset into rectangular pieces according to the values of the predictor variables such that a simple linear logistic regression model adequately fits the data in each piece. Because the tree structure and the piecewise models can be presented graphically, the whole model can be easily understood. This is illustrated with the thunderstorm dataset using the LOTUS algorithm.

Section 29.4 describes the basic elements of the LOTUS algorithm, which is based on recursive partitioning and cost-complexity pruning. A key feature of the algorithm is a correction for bias in variable selection at the splits of the tree. Without bias correction, the splits can yield incorrect inferences. Section 29.5 shows an application of LOTUS to a dataset on automobile crash tests involving dummies. This dataset is challenging because of its large size, its mix of ordered and unordered variables, and its large number of missing values. It also provides a demonstration of Simpson's paradox. The chapter concludes with some remarks in Sect. 29.5.

Logistic regression is a technique for modeling the probability of an event in terms of suitable explanatory or predictor variables. For example, [29.1] use it to model the probability that a tree in a forest is blown down during an unusually severe thunderstorm that occurred on July 4, 1999, and caused great damage over 477 000 acres of the Boundary Waters Canoe Area Wilderness in northeastern Minnesota. Data from a sample of 3666 trees were collected, including for each tree, whether it was blown down ($Y = 1$) or not ($Y = 0$), its trunk diameter D in centimeters, its species S, and the local intensity L of the storm, as measured by the fraction of damaged trees in its vicinity. The dataset may be obtained from www.stat.umn.edu/~sandy/pod.

Let $p = \Pr(Y = 1)$ denote the probability that a tree is blown down. In *linear logistic regression*, we model $\log[p/(1-p)]$ as a function of the predictor variables, with the requirement that it be linear in any unknown parameters. The function $\log[p/(1-p)]$ is also often written as $\text{logit}(p)$. If we use a single predictor such

as L, we have the *simple linear* logistic regression model

$$\text{logit}(p) = \log[p/(1-p)] = \beta_0 + \beta_1 L \qquad (29.1)$$

which can be re-expressed in terms of p as $p = \exp(\beta_0 + \beta_1 L)/[1 + \exp(\beta_0 + \beta_1 L)]$.

In general, given k predictor variables $X_1, \ldots, X_k$, a linear logistic regression model in these variables is $\text{logit}(p) = \beta_0 + \sum_{j=1}^{k} \beta_j X_j$. The parameters $\beta_0, \beta_1, \ldots, \beta_k$ are typically estimated using maximum likelihood theory. Let n denote the sample size and let $(x_{i1}, \ldots, x_{ik}, y_i)$ denote the values of $(X_1, \ldots, X_k, Y)$ for the ith observation $(i = 1, \ldots, n)$. Treating each y_i as the outcome of an independent Bernoulli random variable with success probability p_i, we have the likelihood function

$$\prod_{i=1}^{n} p_i^{y_i}(1-p_i)^{1-y_i} = \frac{\exp\left[\sum_i y_i \left(\beta_0 + \sum_j \beta_j x_{ij}\right)\right]}{\prod_i \left[1 + \exp\left(\beta_0 + \sum_j \beta_j x_{ij}\right)\right]} .$$

The *maximum likelihood estimates* (MLEs) $(\hat{\beta}_0, \hat{\beta}_1, \ldots, \hat{\beta}_k)$ are the values of $(\beta_0, \beta_1, \ldots, \beta_k)$ that maximize this function. Newton–Raphson iteration is usually needed to compute the MLEs.

29.1 Approaches to Model Fitting

The result of fitting model (29.1) is

$$\text{logit}(p) = -1.999 + 4.407L. \qquad (29.2)$$

Figure 29.1 shows a plot of the estimated p function. Clearly, the stronger the local storm intensity, the higher the chance for a tree to be blown down.

Figure 29.2 shows boxplots of D by species. Because of the skewness of the distributions, we follow [29.1] and use $\log(D)$, the natural logarithm of D, in our analysis. With $\log(D)$ in place of L, the fitted model becomes

$$\text{logit}(p) = -4.792 + 1.749\log(D) \qquad (29.3)$$

suggesting that tall trees are less likely to survive a storm than short ones. If we use both $\log(D)$ and L, we obtain the model

$$\text{logit}(p) = -6.677 + 1.763\log(D) + 4.420L . \qquad (29.4)$$

Finally, if we include the product $L\log(D)$ to account for interactions between D and L, we obtain

$$\text{logit}(p) = -4.341 + 0.891\log(D) - 1.482L + 2.235L\log(D) . \qquad (29.5)$$

So far, we have ignored the species S of each tree in our sample. We might get a model with higher prediction accuracy if we include S. As with least-squares regression, we can include a categorical variable that takes m distinct values by first defining $m-1$ indicator variables, $U_1, \ldots, U_{m-1}$, each taking the value 0 or 1. The definitions of the indicator variables corresponding

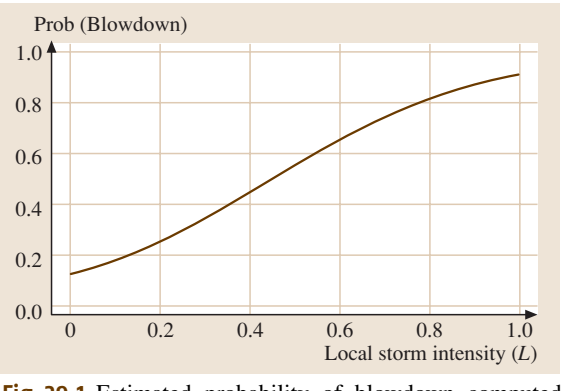

Fig. 29.1 Estimated probability of blowdown computed from a simple linear logistic regression model using L as predictor

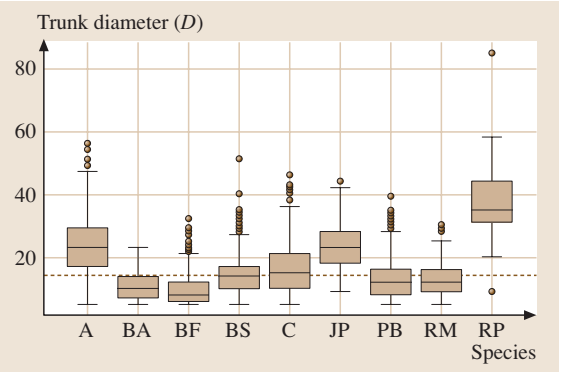

Fig. 29.2 Boxplots of trunk diameter D. The median value of 14 for D, or 2.64 for $\log(D)$, is marked with a *dotted line*

to our nine-species variable S are shown in Table 29.1. Note that we use the *set-to-zero constraint*, which sets all the indicator variables to 0 for the first category (aspen). A model that assumes the same slope coefficients for all species but that gives each a different intercept term is

$$\begin{aligned}\text{logit}(p) = &-5.997 + 1.581\log(D) + 4.629L \\ &- 2.243U_1 + 0.0002U_2 + 0.167U_3 \\ &- 2.077U_4 + 1.040U_5 - 1.724U_6 \\ &- 1.796U_7 - 0.003U_8\,. \end{aligned} \tag{29.6}$$

How well do the models (29.2–29.6) fit the data? One popular method of assessing fit is by means of significance tests based on the model deviance and its *degrees of freedom* (DF)—see, e.g., [29.2] for the definitions. The deviance is analogous to the residual sum of squares in least-squares regression. For the model (29.6), the deviance is 3259 with 3655 DF. We can evaluate the fit of this model by comparing its deviance against that of a larger one, such as the 27-parameter model

$$\begin{aligned}\text{logit}(p) = &\beta_0 + \beta_1\log(D) + \beta_2 L + \sum_{j=1}^{8}\gamma_j U_j \\ &+ \sum_{j=1}^{8}\beta_{1j}U_j\log(D) + \sum_{j=1}^{8}\beta_{2j}U_j L \end{aligned} \tag{29.7}$$

which allows the slope coefficients for $\log(D)$ and L to vary across species. Model (29.7) has a deviance of 3163 with 3639 DF. If the model (29.6) provides a suitable fit to the data, statistical theory says that the difference in deviance should be approximately distributed as a chi-square random variable with DF equal to the difference in the DF of the two models. For our example, the difference in deviance of $3259 - 3163 = 96$ is much too large to be explained by a chi-square distribution with $3655 - 3639 = 16$ DF.

Rejection of model (29.6) does not necessarily imply, however, that the model (29.7) is satisfactory. To find out, we need to compare it with a larger model, such as the 28-parameter model

$$\begin{aligned}\text{logit}(p) = &\beta_0 + \beta_1\log(D) + \beta_2 L + \beta_3 L\log(D) \\ &+ \sum_{j=1}^{8}\gamma_j U_j + \sum_{j=1}^{8}\beta_{1j}U_j\log(D) \\ &+ \sum_{j=1}^{8}\beta_{2j}U_j L \end{aligned} \tag{29.8}$$

which includes an interaction between $\log(D)$ and L. This has a deviance of 3121 with 3638 DF. Model (29.7) is therefore rejected because its deviance differs from that of (29.8) by 42 but their DFs differ only by 1. It turns out that, using this procedure, each of models (29.2–29.7) is rejected when compared against the next larger model in the set.

A second approach chooses a model from a given set by minimizing some criterion that balances model fit with model complexity. One such is the AIC criterion, defined as the deviance plus twice the number of estimated parameters [29.3]. It is well known, however, that the AIC criterion tends to overfit the data. That is, it often chooses a large model. For example, if we apply it to the set of all models up to third order for the current data, it chooses the largest, i. e., the 36-parameter model

$$\begin{aligned}\text{logit}(p) = &\beta_0 + \beta_1\log(D) + \beta_2 L + \sum_{j=1}^{8}\gamma_j U_j \\ &+ \beta_3 L\log(D) + \sum_{j=1}^{8}\beta_{1j}U_j\log(D) \\ &+ \sum_{j=1}^{8}\beta_{2j}U_j L + \sum_{j=1}^{8}\delta_j U_j L\log(D)\,. \end{aligned} \tag{29.9}$$

Table 29.1 Indicator variable coding for the species variable S

Species	U_1	U_2	U_3	U_4	U_5	U_6	U_7	U_8
A (aspen)	0	0	0	0	0	0	0	0
BA (black ash)	1	0	0	0	0	0	0	0

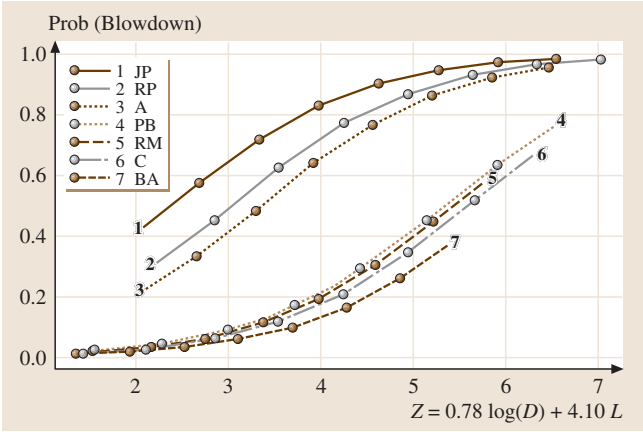

Fig. 29.3 Estimated probability of blowdown for seven speciesTable 29.1, excluding balsam fir (BF) and black spruce (BS), according to model (29.10)

Graphical interpretation of models (29.8) and (29.9) is impossible. The simple and intuitive solution of viewing the estimated p-function by a graph such as Fig. 29.1 is unavailable when a model involves more than one predictor variable. This problem is exacerbated by the fact that model complexity typically increases with increasing sample size or number of predictors. Interpretation of the estimated coefficients is frequently futile, because the estimates typically do not remain the same from one model to another. For example, the coefficient for L is 4.407, 4.424, 1.870, and 4.632 in models (29.2), (29.4), (29.5), and (29.6), respectively. This is due to multi-collinearity among the predictor variables.

Cook and *Weisberg* [29.1] try to solve the problem of interpretation by using a *partial one-dimensional* (POD) model, which employs a single linear combination of the noncategorical variables, $Z = \delta_1 \log(D) + \delta_2 L$, as predictor. For the tree data, they find that if balsam fir (BF) and black spruce (BS) are excluded, the model $\text{logit}(p) = \beta_0 + Z + \sum_j \gamma_j U_j$, with $Z = 0.78 \log(D) + 4.1L$, fits the other species quite well. One advantage of this model is that the estimated p-functions may be displayed graphically, as shown in Fig. 29.3. The graph is not as natural as Fig. 29.1, however, because Z is a linear combination of two variables. In order to include the species BF and BS, [29.1] choose the larger model

$$\begin{aligned}\text{logit}(p) = \beta_0 + Z + \sum_{j=1}^{9} \gamma_j U_j \\ + (\theta_1 I_{\text{BF}} + \theta_2 I_{\text{BS}}) \log(D) \\ + (\phi_1 I_{\text{BF}} + \phi_2 I_{\text{BS}}) L \end{aligned} \quad (29.10)$$

which contains separate coefficients, θ_j and ϕ_j, for BF and BS. Here $I_{(\cdot)}$ denotes the indicator function, i. e., $I_A = 1$ if the species is A, and $I_A = 0$ otherwise. Of course, this model does not allow a graphical representation for BF and BS.

29.2 Logistic Regression Trees

The type of models and the method of selection described in the previous section are clearly not totally satisfactory. As the sample size or the number of predictor variables increases, so typically does model complexity. But a more complex model is always harder to interpret than a simple one. On the other hand, an overly simple model may have little predictive power.

A logistic regression tree model offers one way to retain simultaneously the graphical interpretability of simple models and the predictive accuracy of richer ones. Its underlying motivation is that of divide and conquer. That is, a complex set of data is divided into sufficiently many subsets such that a simple linear logistic regression model adequately fits the data in each subset. Data subsetting is performed recursively, with the sample split on one variable at a time. This results in the partitions being representable as a binary decision tree. The method is implemented by [29.4] in a computer program called LOTUS.

Figure 29.4 shows a LOTUS model fitted to the tree data. The data are divided into ten subsets, labeled 0–9. Balsam fir (BF), one of the two species excluded from the [29.1] model, is isolated in subsets 0 and 9, where $\log(D)$ is the best linear predictor. The estimated p-functions for these two subsets are shown in Fig. 29.5. The estimated p-functions for the trees that are not balsam firs can be displayed together in one graph, as shown in Fig. 29.6, because they all employ L as the best simple linear predictor.

From the graphs, we can draw the following conclusions:

1. The probability of blowdown consistently increases with D and L, although the value and rate of increase are species-dependent.

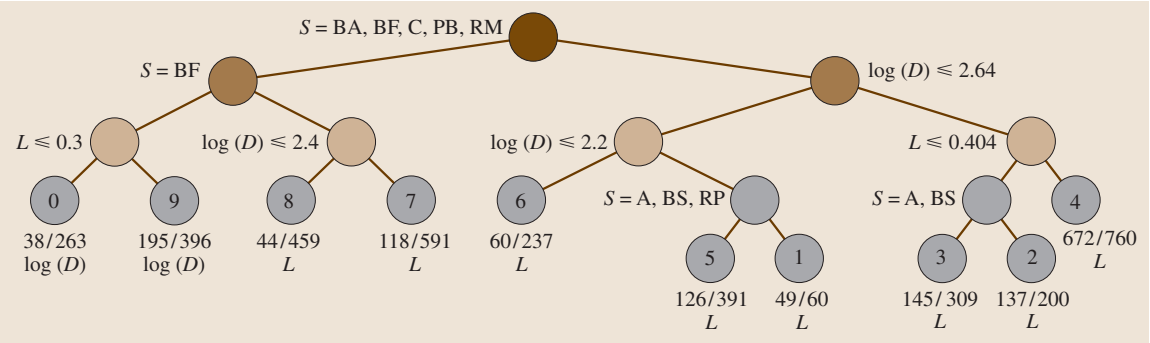

Fig. 29.4 A piecewise simple linear LOTUS model for estimating the probability that a tree is blown down. A splitting rule is given beside each intermediate node. If a case satisfies the rule, it goes to the left child node; otherwise the right child node. The second level split at $\log(D) = 2.64$ corresponds to the median value of D. Beneath each leaf node are the ratio of cases with $Y = 1$ to the node sample size and the name of the selected predictor variable

2. Balsam fir (BF) has the highest chance of blowdown, given any values of D and L.
3. The eight species excluding the balsam fir can be divided into two groups. Group I consists of black ash (BA), cedar (C), paper birch (PB), and red maple (RM). They belong to subsets 7 and 8, and are most likely to survive. This is consistent with the POD model of [29.1]. Group II contains aspen (A), black spruce (BS), jack pine (JP), and red pine (RP).
4. The closeness of the estimated p-functions for subsets 6 and 7 show that the smaller group II trees and the larger group I trees have similar blowdown probabilities for any given value of L.
5. Although aspen (A) and black spruce (BS) are always grouped together, namely, in subsets 3–6, less than 15% of the aspen trees are in subsets 5 and 6. Similarly, only 2% of the red pines (RP) are in these two subsets. Hence the p-function of aspen (A) is mainly described by the curves for subsets 3 and 4, and that for red pine (RP) by the curves for

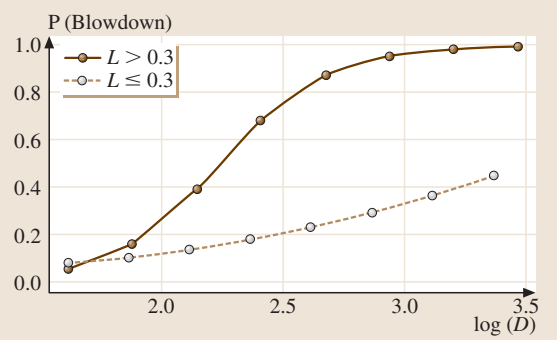

Fig. 29.5 Estimated probability of blowdown for balsam fir (BF), according to the LOTUS model in Fig. 29.4

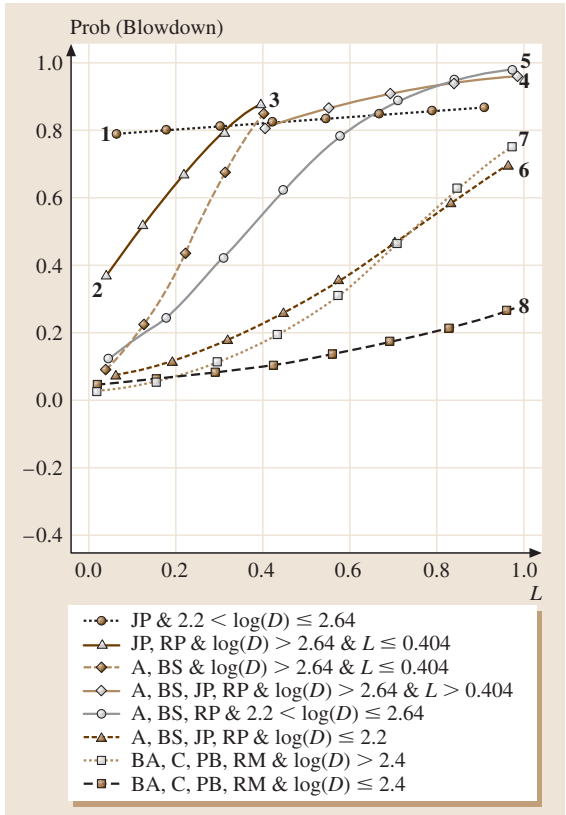

Fig. 29.6 Estimated probability of blowdown for all species except balsam firs, according to the LOTUS model in Fig. 29.4

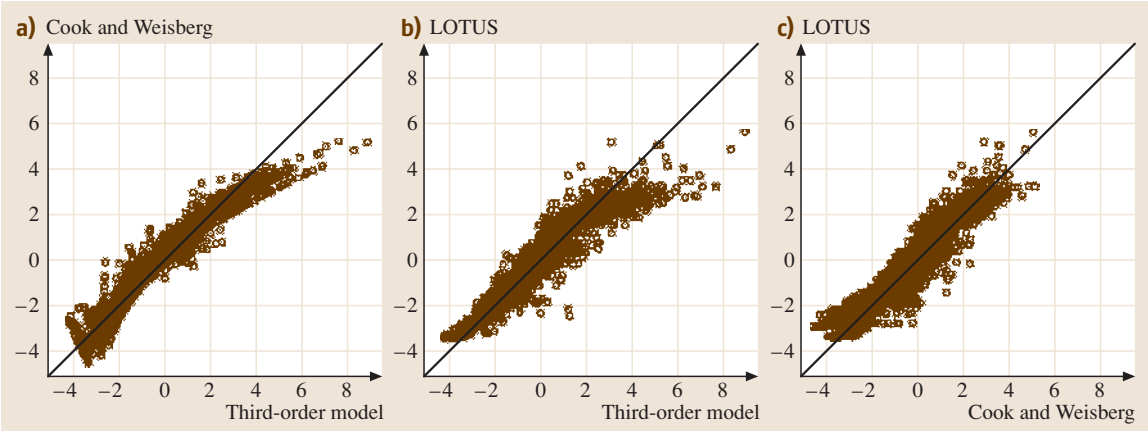

Fig. 29.7a–c Comparison of fitted logit values among three models. **(a)** Cook & Weisenberg versus third-order model **(b)** LOTUS versus third-order model **(c)** Cook & Weisenberg versus LOTUS

subsets 2 and 4. We conclude that, after balsam fir (BF), the three species most at risk of blowdown are the jack pine (JP), red pine (RP), and aspen (A), in that order. This ordering of JP, RP, and A is the same as the POD model of [29.1], as can be seen in Fig. 29.3.

6. Recall that the black spruce (BS) was the other species that [29.1] could not include in their POD model. The reason for this is quite clear from Fig. 29.6, where we use solid lines to draw the estimated p-function for black spruce. Four curves are required, corresponding to subsets 3, 4, 5, and 6. The spread of these curves suggests that the p-function of black spruce is highly sensitive to changes in D. This explains why the species cannot be included in the POD model.

How does the LOTUS model compare with the others? The former is clearly superior in terms of interpretability. But does it predict future observations as well as the other models? Unfortunately, this question cannot be answered completely, because we do not have an independent set of data to test the models. The best we can do is to compare the fitted values from the different models. This is done in Fig. 29.7, which plots the fitted logit values of the LOTUS model against those of the POD and the linear logistic regression model with all interactions up to third order. The plots show that there is not much to choose among them.

29.3 LOTUS Algorithm

As already mentioned, the idea behind LOTUS is to partition the sample space into one or more pieces such that a simple model can be fitted to each piece. This raises two issues: (i) how to carry out the partitioning, and (ii) how to decide when a partition is good enough. We discuss each question in turn.

29.3.1 Recursive Partitioning

Like all other regression tree algorithms, LOTUS splits the dataset recursively, each time choosing a single variable X for the split. If X is an ordered variable, the split has the form $s = \{X \le c\}$, where c is a constant. On the other hand, if X is a categorical variable, the split has the form $s = \{X \in \omega\}$, where ω is a subset of the values taken by X. The way s is chosen is critically important if the tree structure is to be used for inference about the variables.

For least-squares regression trees, many algorithms, such as automatic interaction detector (AID) [29.5], CART [29.6] and M5 [29.7], choose the split s that minimizes the total sum of squared residuals of the regression models fitted to the two data subsets created by s. Although this approach can be directly extended to logistic regression by replacing the sum of squared residuals with the deviance, it is fundamentally flawed, because it is biased toward choosing X

variables that allow more splits. To see this, suppose that X is an ordered variable taking n unique values. Then there are $n-1$ ways to split the data along the X axis, with each split $s = \{X \le c\}$ being such that c is the midpoint between two consecutively ordered values. This creates a selection bias toward X variables for which n is large. For example, in our tree dataset, variable L has 709 unique values but variable $\log(D)$ has only 87. Hence if all other things are equal, L is eight times more likely to be selected than $\log(D)$.

The situation can be worse if there are one or more categorical X variables with many values. If X takes n categorical values, there are $2^{n-1}-1$ splits of the form $s = \{X \in \omega\}$. Thus the number of splits grows exponentially with the number of categorical values. In our example, the species variable S generates $2^{9-1}-1 = 255$ splits, almost three times as many splits as $\log(D)$.

Doyle [29.8] was the first to warn that this bias can yield incorrect inferences about the effects of the variables. The GUIDE [29.9] least-squares regression tree algorithm avoids the bias by employing a two-step approach to split selection. First, it uses statistical significance tests to select X. Then it searches for c or ω. The default behavior of GUIDE is to use categorical variables for split selection only; they are not converted into indicator variables for regression modeling in the nodes. LOTUS extends this approach to logistic regression. The details are given in [29.4], but the essential steps in the recursive partitioning algorithm can be described as follows.

1. Fit a logistic regression model to the data using only the noncategorical variables.
2. For each ordered X variable, discretize its values into five groups at the sample quintiles. Form a 2×5 contingency table with the Y values as rows and the five X groups as columns. Compute the significance probability of a trend-adjusted chi-square test for nonlinearity in the data.
3. For each categorical X variable, since they are not used as predictors in the logistic regression models, compute the significance probability of the chi-square test of association between Y and X.
4. Select the variable with the smallest significance probability to partition the data.

By using tests of statistical significance, the selection-bias problem due to some X variables taking more values than others disappears. Simulation results to support the claim are given in [29.4].

After the X variable is selected, the split value c or split subset ω can be found in many ways. At the time of this writing, LOTUS examines only five candidates. If X is an ordered variable, LOTUS evaluates the splits at c equal to the 0.3, 0.4, 0.5, 0.6, and 0.7 quantiles of X. If X is categorical, it evaluates the five splits around the subset ω that minimizes a weighted sum of the binomial variance in Y in the two partitions induced by the split. The full details are given in [29.4]. For each candidate split, LOTUS computes the sum of the deviances in the logistic regression models fitted to the data subsets. The split with the smallest sum of deviances is selected.

29.3.2 Tree Selection

Instead of trying to decide when to stop the partitioning, GUIDE and LOTUS follow the CART method of first growing a very big tree and then progressively pruning it back to the root node. This yields a nested sequence of trees from which one is chosen. If an independent test dataset is available, the choice is easy: just apply each tree in the sequence to the test set and choose the tree with the lowest prediction deviance.

If a test set is not available, as is the case in our example, the choice is made by ten-fold crossvalidation. The original dataset is divided randomly into ten subsets. Leaving out one subset at a time, the entire tree-growing process is applied to the data in the remaining nine subsets to obtain another nested sequence of trees. The subset that is left out is then used as a test set to evaluate this sequence. After the process is repeated ten times, by leaving out one subset in turn each time, the combined results are used to choose a tree from the original tree sequence grown from all the data. The reader is referred to [29.6, Chapt. 3] for details on pruning and tree selection. The only difference between CART and LOTUS here is that LOTUS uses deviance instead of the sum of squared residuals.

29.4 Example with Missing Values

We now show how LOTUS works when the dataset has missing values. We use a large dataset from the National Highway Transportation Safety Administration (ftp://www.nhtsa.dot.gov/ges) on crash tests of vehicles

Table 29.2 Predictor variables in the crash-test dataset. Angular variables `crbang`, `pdof`, and `impang` are measured in degrees clockwise (from -179 to 180) with 0 being straight ahead

Name	Description	Variable type
make	Vehicle manufacturer	63 categories
model	Vehicle model	466 categories
year	Vehicle model year	continuous
body	Vehicle body type	18 categories
engine	Engine type	15 categories
engdsp	Engine displacement	continuous
transm	Transmission type	7 categories
vehtwt	Vehicle test weight	continuous
vehwid	Vehicle width	continuous
colmec	Steering column collapse mechanism	10 categories
modind	Vehicle modification indicator	4 categories
vehspd	Resultant speed of vehicle before impact	continuous
crbang	Crabbed angle	continuous
pdof	Principal direction of force	continuous
tksurf	Test track surface	5 categories
tkcond	Test track condition	6 categories
impang	Impact angle	continuous
occloc	Occupant location	6 categories
occtyp	Occupant type	12 categories
dumsiz	Dummy size percentile	8 categories
seposn	Seat position	6 categories
rsttyp	Restraint type	26 categories
barrig	Rigid or deformable barrier	2 categories
barshp	Barrier shape	15 categories

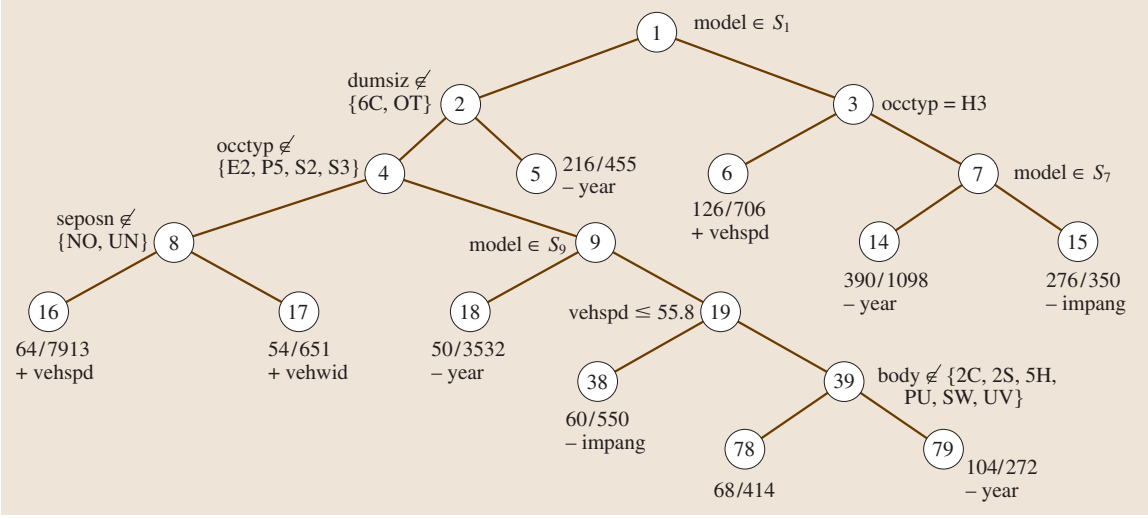

Fig. 29.8 LOTUS model for the crash-test data. Next to each leaf node is a fraction showing the number of cases with $Y = 1$ divided by the sample size, and the name of the best predictor variable, provided it is statistically significant. If the latter has a positive regression coefficient, a plus sign is attached to its name; otherwise a minus sign is shown. The constituents of the sets S_1, S_7, and S_9 may be found from Tables 29.3 and 29.4

involving test dummies. The dataset gives the results of 15 941 crash tests conducted between 1972 and 2004. Each record consists of measurements from the crash of a vehicle into a fixed barrier. The head injury criterion (`hic`), which is the amount of head injury sustained by a test dummy seated in the vehicle, is the main variable of interest. Also reported are eight continuous variables and 16 categorical variables; their names and descriptions are given in Table 29.2. For our purposes, we define $Y = 1$ if `hic` exceeds 1000, and $Y = 0$ otherwise. Thus Y indicates when severe head injury occurs.

One thousand two hundred and eleven of the records are missing one or more data values. Therefore a linear logistic regression using all the variables can be fitted only to the subset of 14 730 records that have complete values. After transforming each categorical variable into a set of indicator variables, the model has 561 regression coefficients, including the constant term. All but six variables (`engine`, `vehwid`, `tkcond`, `impang`, `rsttyp`, and `barrig`) are statistically significant. As mentioned in Sect. 29.1, however, the regression coefficients in the model cannot be relied upon to explain how each variable affects $p = P(Y = 1)$. For example, although `vehspd` is highly significant in this model, it is not significant in a simple linear logistic model that employs it as the only predictor. This phenomenon is known as Simpson's paradox. It occurs when a variable has an effect in the same direction within subsets of the data, but when the subsets are combined, the effect vanishes or reverses in direction.

Being composed of piecewise simple linear logistic models, LOTUS is quite resistant to Simpson's paradox. Further, by partitioning the dataset one variable at a time, LOTUS can use all the information in the dataset, instead of only the complete data records. Specifically, when LOTUS fits a simple linear logistic model to a data subset, it uses all the records that have complete information in Y and the X variable used in the model. Similarly, when X is being evaluated for split selection, the chi-square test is applied to all the records in the subset that have complete information in X and Y.

Figure 29.8 gives the LOTUS tree fitted to the crash-test data. The splits together with the p-functions fitted to the leaf nodes in Fig. 29.9 yield the following conclusions:

1. The tree splits first on `model`, showing that there are significant differences, with respect to p, among vehicle models. The variable is also selected for splitting in nodes 7 and 9. Tables 29.3 and 29.4 give the precise nature of the splits.
2. Immediately below the root node, the tree splits on `dumsiz` and `occtyp`, two characteristics of the test dummy. This shows that some types of dummies are more susceptible to severe injury than others. In

particular, the cases in node 5 contain mainly dummies that correspond to a six-year-old child. The fitted p-function for this node can be seen in the upper left panel of Fig. 29.9. Compared with the fitted p-functions of the other nodes, this node appears to have among the highest values of p. This suggests that six-year-old children are most at risk of injury. They may be too big for child car seats and too small for adult seat belts.

3. The split on `seposn` at node 8 shows that passengers in vehicles with adjustable seats are ten times (average p of 0.008 versus 0.08) less likely to suffer severe head injury than those with nonadjustable seats. This could be due to the former type of vehicle being more expensive and hence able to withstand collisions better.
4. Similarly, the split on `body` at node 39 shows that passengers in two-door cars, pick-ups, station wagons, and sports utility vehicles (SUVs) are twice as likely (average p of 0.38 versus 0.16) to suffer severe head injury than other vehicles.
5. The linear predictor variables selected in each leaf node tell us the behavior of the p-function within each partition of the dataset. Four nodes have `year` as their best linear predictor. Their fitted p-functions are shown in the upper left panel of Fig. 29.9. The

decreasing trends show that crash safety is improving over time.

6. Three nodes have `vehspd` as their best linear predictor, although the variable is not statistically significant in one (node 78). The fitted p-functions are shown in the upper right panel of Fig. 29.9. As expected, p is nondecreasing in `vehspd`.
7. Two nodes employ `impang` as their best linear predictor. The fitted p-functions shown in the bottom left panel of Fig. 29.9 suggest that side impacts are more serious than frontal impacts.

8. One node has `vehwid` as its best linear predictor. The decreasing fitted p-function shown in the lower right panel of Fig. 29.9 shows that vehicles that are smaller are less safe.

29.5 Conclusion

Logistic regression is a statistical technique for modeling the probability p of an event in terms of the values of one or more predictor variables. The traditional approach expresses the logit of p as a linear function of these variables. Although the model can be effective for predicting p, it is notoriously hard to interpret. In particular, multi-collinearity can cause the regression coefficients to be misinterpreted.

A logistic regression tree model offers a practical alternative. The model has two components, namely, a binary tree structure showing the data partitions and a set of simple linear logistic models, fitted one to each partition. It is this division of model complexity that makes the model intuitive to interpret. By dividing the dataset into several pieces, the sample space is effectively split into different strata such that the p-function is adequately explained by a single predictor variable in each stratum. This property is powerful because: (i) the partitions can be understood through the binary tree, and (ii) each p-function can be visualized through its own graph. Further, stratification renders each of the individual p-functions resistant to the ravages of multi-collinearity among the predictor variables and to Simpson's paradox. Despite these advantages, it is crucial for the partitioning algorithm to be free of selection bias. Otherwise, it is very easy to draw misleading inferences from the tree structure. At the time of writing, LOTUS is the only logistic regression tree algorithm designed to control such bias.

Finally, as a disclaimer, it is important to remember that, in real applications, there is no *best* model for a given dataset. This situation is not unique to logistic regression problems; it is prevalent in least-squares and other forms of regression as well. Often there are two or more models that give predictions of comparable average accuracy. Thus a LOTUS model should be regarded as merely one of several possibly different ways of explaining the data. Its main virtue is that, unlike many other methods, it provides an *interpretable* explanation.

30. Tree-Based Methods and Their Applications

The first part of this chapter introduces the basic structure of tree-based methods using two examples. First, a classification tree is presented that uses e-mail text characteristics to identify spam. The second example uses a regression tree to estimate structural costs for seismic rehabilitation of various types of buildings. Our main focus in this section is the interpretive value of the resulting models.

This brief introduction is followed by a more detailed look at how these tree models are constructed. In the second section, we describe the algorithm employed by classification and regression tree (CART), a popular commercial software program for constructing trees for both classification and regression problems. In each case, we outline the processes of growing and pruning trees and discuss available options. The section concludes with a discussion of practical issues, including estimating a tree's predictive ability, handling missing data, assessing variable importance, and considering the effects of changes to the learning sample.

The third section presents several alternatives to the algorithms used by CART. We begin with a look at one class of algorithms – including QUEST, CRUISE, and GUIDE– which is designed to reduce potential bias toward variables with large numbers of available splitting values. Next, we explore C4.5, another program popular in the artificial-intelligence and machine-learning communities. C4.5 offers the added functionality of converting any tree to a series of *decision rules*, providing an alternative means of viewing and interpreting its results. Finally, we discuss chi-square automatic interaction detection (CHAID), an early classification-tree construction algorithm used with categorical predictors. The section concludes with a brief comparison of the characteristics of CART and each of these alternative algorithms.

In the fourth section, we discuss the use of ensemble methods for improving predictive ability. Ensemble methods generate collections of trees using different subsets of the training data. Final predictions are obtained by aggregating over the predictions of individual members of these collections. The first ensemble method we consider is boosting, a recursive method of generating small trees that each specialize in predicting cases for which its predecessors perform poorly. Next, we explore the use of random forests, which generate collections of trees based on bootstrap sampling procedures. We also comment on the tradeoff between the predictive power of ensemble methods and the interpretive value of their single-tree counterparts.

The chapter concludes with a discussion of tree-based methods in the broader context of supervised learning techniques. In particular, we compare classification and regression trees to multivariate adaptive regression splines, neural networks, and support vector machines.

30.1 Overview

Given a data set for a particular application, a researcher will typically build a statistical model with one (or both) of the following objectives in mind: (1) to use information from this data to make useful predictions about future observations, and (2) to gain some insights into the underlying structure of the data. Tree-based models are attractive because of their potential to blend both of these characteristics quite effectively.

Tree-based models comprise one set of tools useful for supervised learning tasks. In supervised learning problems, a researcher is trying to use a set of *inputs*, or *independent variables*, to predict an *output*, or *dependent variable*. If the output is a categorical variable, we call this a problem of classification. On the other hand, if the output is a continuous variable, we call this a problem of regression.

Tree-based models approach these problems by recursively partitioning a learning sample over its input variable space and fitting a simple function to each resulting subgroup of cases. In classification, this function is assignment to a single category; in regression, the function could be a constant. We shall discuss several tree-fitting procedures in detail throughout this chapter.

To see the tree-based models at work, we present two applications in this section.

30.1.1 Classification Example: Spam Filtering

First, we consider the task of designing an automatic spam (junk e-mail) filter. The data for this task are publicly available from the University of California, Irvine (UCI) machine learning repository [30.1], and were donated by George Forman from Hewlett–Packard laboratories in Palo Alto, California.

The data consist of 58 variables describing 4601 messages. The dependent variable indicates whether or not each message is spam. The 57 predictor variables are all continuous, and describe the relative frequencies of various keywords, characters, and strings of consecutive uppercase letters. A resulting tree model is shown in Fig. 30.1, and the variables present in the tree are summarized in Table 30.1.

In Fig. 30.1, we see that the messages are first partitioned based on the frequency of the "$" character. Messages with few dollar signs are sent down the left branch, and messages with many dollar signs are sent down the right branch. Following the right branch, we find that those messages with many dollar signs are further partitioned based on the frequency of the word "hp". If "hp" appears only infrequently, the message is classified as spam, otherwise, it is classified as a legitimate message. This splitting makes sense in the context of this data set, because messages containing "hp" most likely address company business.

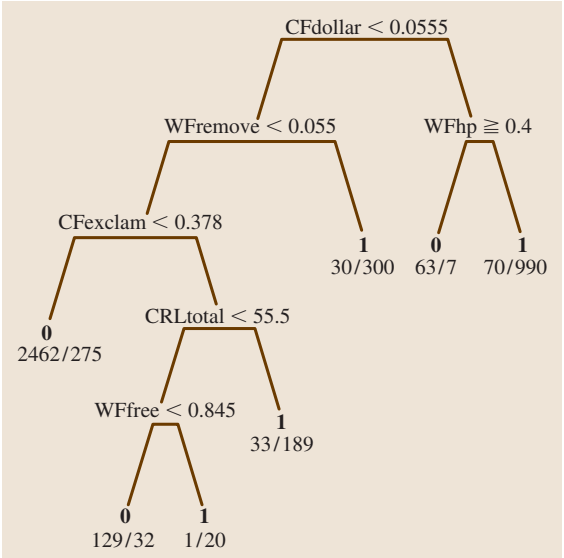

Fig. 30.1 A classification tree for the spam filtering data. Terminal nodes labeled "1" are classified as spam, and those labeled "0" are classified as non-spam

Following the left branch from the root (top) node, we find that a message will be classified as spam if it has a high frequency of the word "remove", or a combination of exclamation points and either the word "free" or many strings of uppercase letters. The structure of the tree is consistent with our intuition about the message characteristics that separate spam from legitimate e-mail.

Table 30.1 Electronic mail characteristics

Variable	Definition
spam	1 if spam, 0 if not
CFdollar	percent of "$" characters in message
CFexclam	percent of "!" characters in message
CRLtotal	sum of lengths of uppercase letter strings
WFfree	percent of "free" words in message
WFhp	percent of "hp" words in message
WFremove	percent of "remove" words in message

Table 30.2 Seismic rehabilitation cost-estimator variables

Variable	Definition
AGE	Year of construction
AREA	Building area in square feet
MODELC1	Building has concrete moment frame (yes = 1, no = 0)
MODELC3	Building has concrete frame w/ infill walls (yes = 1, no = 0)
MODELS5	Building has steel frame w/ infill walls (yes = 1, no = 0)
MODELURM	Building has unreinforced masonry (yes = 1, no = 0)
MODELW1	Building has light wood frame (yes = 1, no = 0)
POBJ_DC	Performance objective is damage control (yes = 1, no = 0)
POBJ_IO	Performance objective is immediate occupancy (yes = 1, no = 0)
POBJ_RR	Performance objective is risk reduction (yes = 1, no = 0)
SEISMIC	Location seismicity on a scale from 1 (low) to 7 (very high)

We have chosen a small tree for the sake of illustration. For this particular application, one may consider competing methods such as logistic regression or logistic regression trees described in Chapt. 29 by Loh; also see *Chan* and *Loh* [30.2]. Having seen a successful classification example, we now examine a regression tree application.

30.1.2 Regression Example: Seismic Rehabilitation Cost Estimator

The seismic rehabilitation cost estimator is an online program developed by the Federal Emergency Management Agency (FEMA) [30.3,4] that enables calculation of structural cost estimates for seismic rehabilitation of buildings. A group of structural engineers collaborated with us to develop two tree models based on data from over 1900 seismic rehabilitation projects.

The first model is designed for use early in developing budget estimates when specific building details are not yet available. This model requires information about a building's original year of construction, its size, its structural system, the seismic zone in which it resides, and the rehabilitation performance objective. We summarize the 11 relevant predictor variables in Table 30.2.

The regression tree is presented in Fig. 30.2. We see that the first split is based on the building's original date of construction. As one might expect, rehabilitation tends to be more costly for older buildings. Regardless of the age of the building, the cost estimate is refined based on the purpose of the rehabilitation effort. Far more expense is required to prepare a building for immediate occupancy than for other purposes. Further down the tree, these cost estimates may be adjusted based on the building's structural characteristics, size, and location.

The second model is used to refine these estimates as more comprehensive data become available. In addition to the basic information included in the smaller model, this larger model uses information about occupancy, number of floors, diaphragm type, the rehabilitation project scope, and other details. More detailed information about the data set used to build these models can be found in FEMA [30.3,4].

30.1.3 Outline

In the rest of this chapter, we will review various tree-based methods for classification and prediction. Section 30.2 details the classification and regression trees (CART) method [30.5] and discusses issues common to all tree-building algorithms. Section 30.3 outlines competing methods, including QUEST [30.6], CRUISE [30.7], GUIDE [30.8], C4.5 [30.9], and chi-square automatic interaction detection (CHAID) [30.10]. Section 30.4 introduces ensemble methods. Finally, Sect. 30.5 discusses briefly how tree methods compare to a broader spectrum of classification and prediction methods.

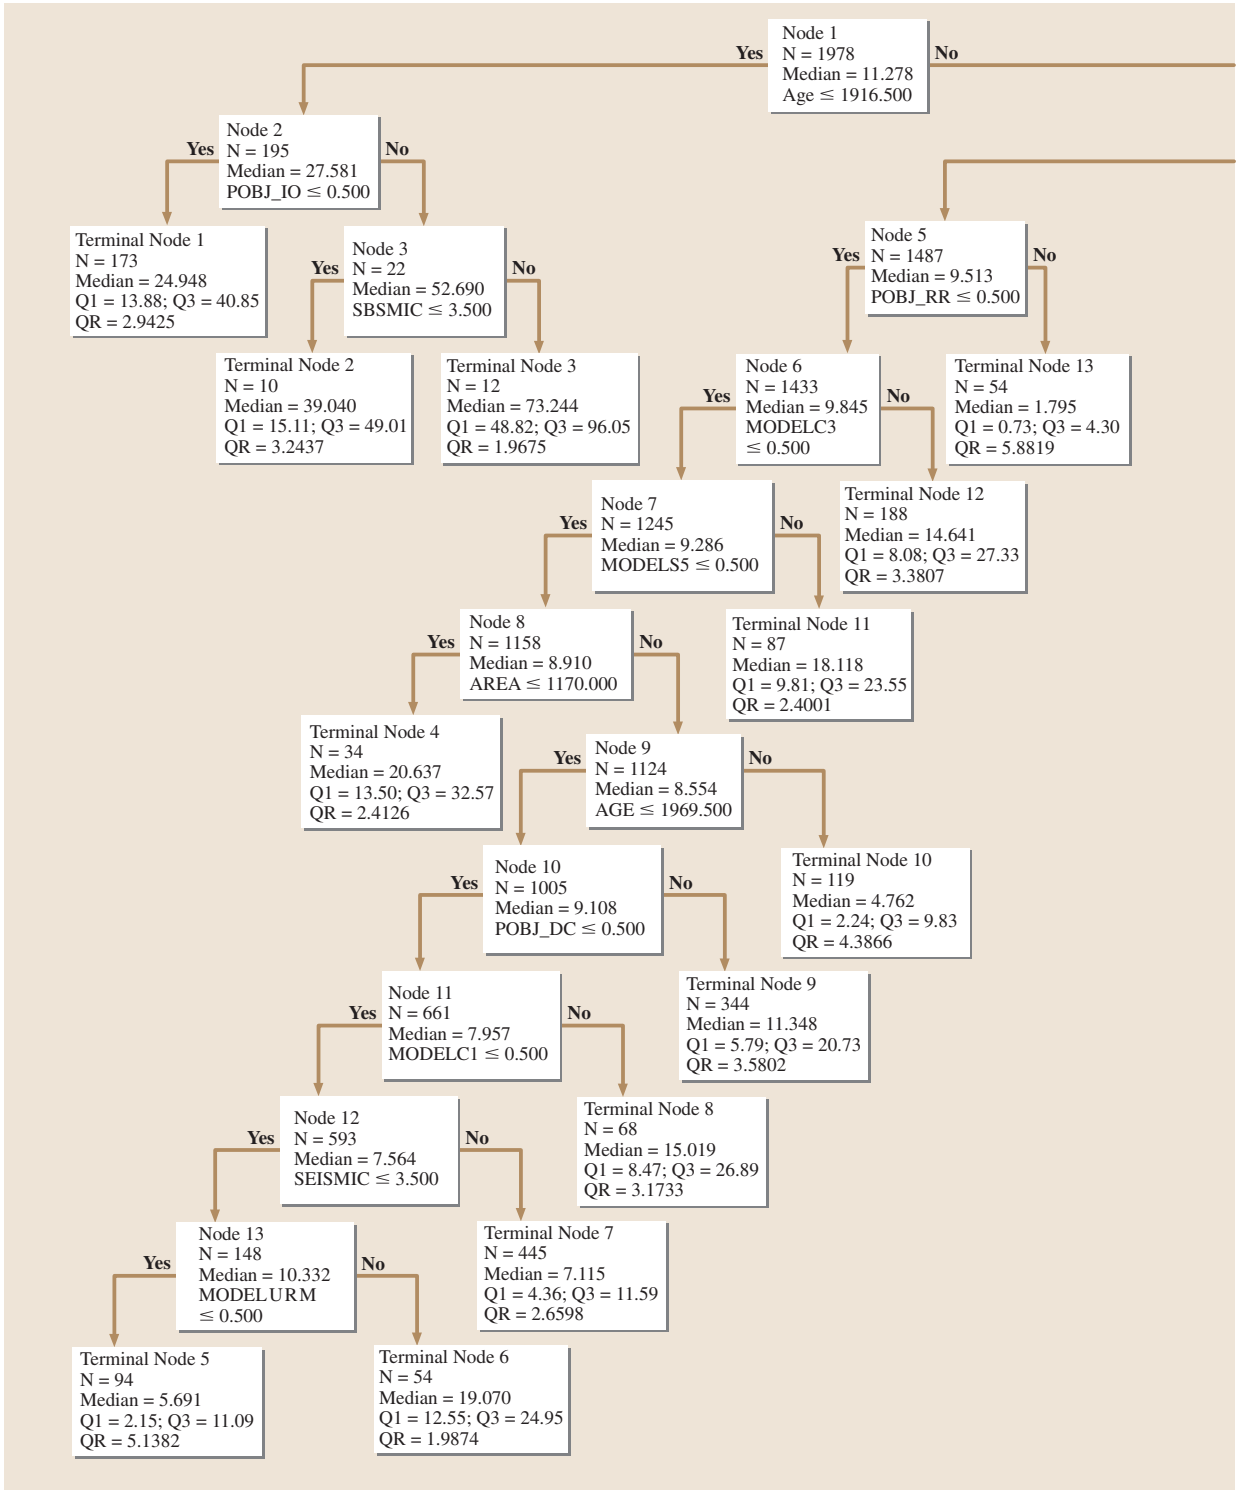

Fig. 30.2 FEMA seismic rehabilitation cost estimator

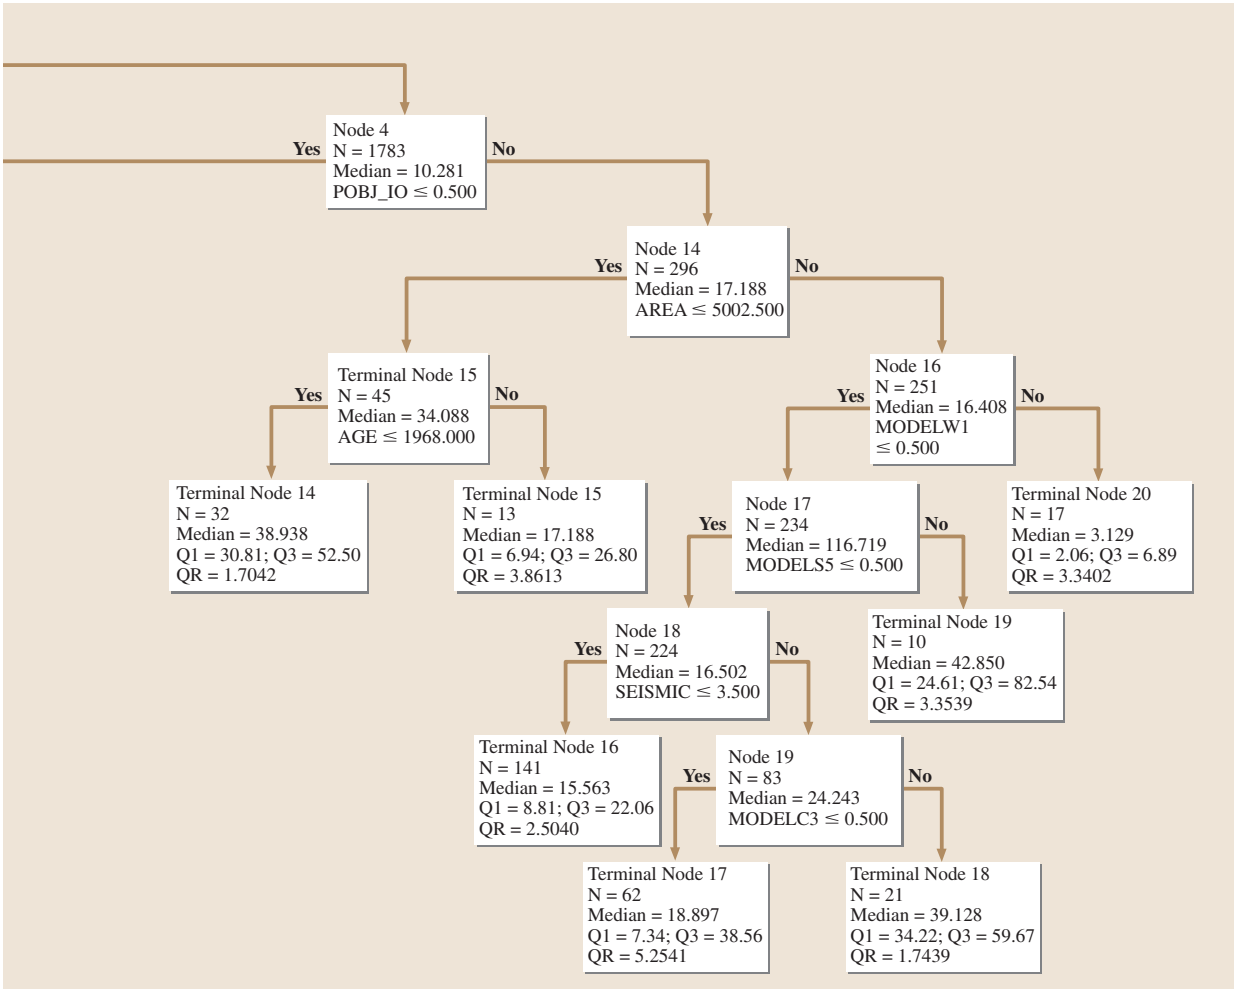

30.2 Classification and Regression Tree (CART)

30.2.1 Introduction

A widely used tree-based method and software is called CART, which stands for classification and regression tree [30.5]. CART is based on statistical methodology developed for classification with categorial outcomes or regression with continuous outcomes. We shall start with classification trees in Sect. 30.2.2 and 30.2.3 and then discuss the regression tree in Sect. 30.2.4.

Take the iris data classification problem [30.11] as an example. The iris data set contains the lengths and widths of sepals and petals of three types of irises: Setosa, Versicolor, and Virginica. The purpose of the analysis is to learn how one can discriminate among the three types of flowers, Y, based on four measures of width and length of petals and sepals, denoted by X_1, X_2, X_3, and X_4, respectively. Figure 30.3 presents the classification tree constructed by CART. The whole sample sits at the top of the tree. The tree first splits the entire sample into two groups at $X_2 = 2.45$. Observations satisfying the condition $X_2 < 2.45$ are assigned to the left branch and classified as Setosa, while the other observations ($X_2 \geq 2.45$) are assigned to the right branch and split further into two groups at $X_1 = 1.75$.

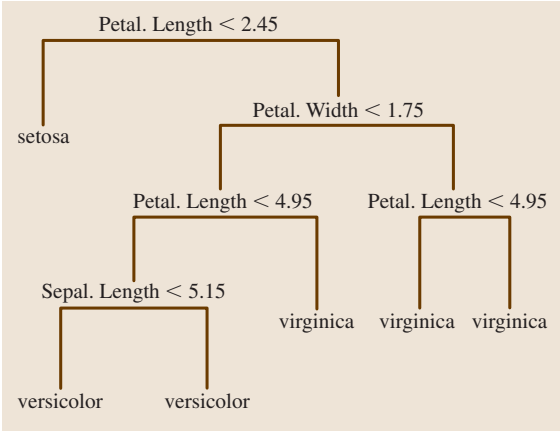

Fig. 30.3 A classification tree for the iris data

At the end, the tree partitions the whole sample into six exclusive subgroups (terminal nodes in the tree). This tree indicates that a good classification rule can be constructed based on the width and length of the petal, and the length of the sepal. The binary tree structure also makes the classification rule easily understood. For example, if the sepal length of an iris with unknown type is 3 cm, its petal length is 4 cm and width is 1.3 cm, then this iris will be classified as a Versicolor iris.

The basic idea of CART is to first grow a very large and complicated tree classifier that explains the sample very accurately but may have poor generalization characteristics, and then prune this tree using cost-complexity pruning to avoid overfitting but still with good accuracy. The CART algorithm grows the classification tree by recursive binary partitioning the sample into subsets. It first splits the entire sample into two subsets, and classifies the observations in each subset using the majority rule. Other class assignment rules can be derived based on preassigned classification costs for different classes. Then one or both of these subsets are split further into more subsets, and this process is continued until no further splits are possible or some stopping rule is triggered. A convenient way to represent this recursive binary partition of the feature space is to use a binary tree like the one in Fig. 30.3, in which subsets are represented by nodes.

30.2.2 Growing the Tree

Let us first look at how CART grows the tree, i. e., how to determine the splitting variable and the split point at each partition. The fundamental idea is to select each split of a node so that the observations in each of the descendant nodes are *purer* than those in the parent node.

Consider a classification problem with a categorical response Y taking values $1, 2, \ldots, K$, and p predictors $X_1, \ldots, X_p$ based on a sample of size N. At node m, which contains a subset of N_m observations, define the node proportion of class k by

$$\hat{p}_m(k) = \frac{1}{N_m} \sum_{i=1}^{N_m} I(y_i = k), \quad k = 1, \ldots, K ,$$

where $I(A) = 1$ when condition A is satisfied and 0 otherwise.

Before discussing how CART splits at a node, we first describe how it classifies a node. In its basic form, CART classifies observations in node m to the majority class $k(m) = \arg\max_k \left[\hat{p}_m(k)\right]$. A more general rule is to assign node m to class $k(m) = \arg\min_k [r_k(m)]$, where $r_k(m)$ is the expected misclassification cost for class k. Letting $\pi_m(k)$ be the prior probability of node m as class k, and $c(i|j)$ be the cost of classifying a class j case as a class i case that satisfies $c(i|j) \geq 0$ if $i \neq j$ and $c(i|j) = 0$ if $i = j$, we have

$$r_k(m) = \sum_j c(k|j)\pi_m(j) .$$

The application of this rule takes into account the severity of misclassifying cases to certain class. If the misclassification cost is constant and the priors $\pi_m(j)$ are estimated by the node proportions, it converts back to the basic form.

CART has two types of splitting criteria: the Gini criterion and the twoing criterion. In general, for a nominal outcome variable, either criterion can be used; for an ordinal outcome variable, the twoing criterion is used.

Gini Criterion

By the Gini criterion, we seek the splitting variable and the split point for node m by maximizing the decrease in the Gini index. The Gini index is an impurity measure defined as a nonnegative function of node proportions $\hat{p}_m(k), k = 1, \ldots, K$,

$$i(m) = \sum_{k=1}^{K} \hat{p}_m(k)\left[1 - \hat{p}_m(k)\right] = 1 - \sum_{k=1}^{K} \left[\hat{p}_m(k)\right]^2 . \tag{30.1}$$

This impurity measure attains its minimum when all cases at a node belong to only one class, so $i(m) = 0$ defines node m as a pure node. Let m_L and m_R be the left and right branches resulting from splitting node m

on predictor x_j, and q_L and q_R be the proportion of cases in node m classified into m_L and m_R, respectively. For each predictor x_j, the algorithm finds the split by maximizing the decrease in the impurity measure

$$\Delta i_j(t,m) = i(m) - [q_L i(m_L) + q_R i(m_R)] \,. \tag{30.2}$$

This is equivalent to minimizing the weighted average of the two child nodes' impurity measures, $q_L i(m_L) + q_R i(m_R)$. When x_j is continuous or ordinal, m_L and m_R are given by $x_j < t$ and $x_j \geq t$ for a splitting point t, and the solution of t can be obtained quickly; if x_j is nominal with a large number of levels, finding the split point t by exhaustive subset search can be computationally prohibitive. The computer program CART only searches over all possible subsets of a categorical predictor for a limited number of levels. The CART algorithm proceeds with a greedy approach that scans through all predictor variables to find the best pair (j, t) with the largest decrease in $\Delta i_j(t, m)$.

Possible choices of $i(m)$ include

- Cross-entropy or deviance:

$$\sum_{k=1}^{K} \hat{p}_m(k) \log \hat{p}_m(k) \,. \tag{30.3}$$

- Misclassification error:

$$\frac{1}{N_m} \sum_{i=1}^{N_m} I\left[y_i \neq k(m)\right] \,. \tag{30.4}$$

The cross-entropy measure (30.3) was used in the early development of CART but the Gini index was adopted in later work. The misclassification error measure (30.4) is typically used during the pruning stage (Sect. 30.2.3). For further discussion of the impurity measures, we refer to *Hastie* et al. [30.12].

Twoing Rule

Under the second splitting criterion, the split at a node m is determined by minimizing the twoing rule

$$q_L q_R \left[\sum_{k=1}^{K} |\hat{p}_{m_L}(k) - \hat{p}_{m_R}(k)|\right]^2 \,.$$

When K is large, twoing is a more desirable splitting criterion.

Comparisons between the Gini and twoing splitting criteria have shown only slight differences, but the Gini criterion is preferred by the inventors of CART and implemented as the default option in the commercial CART software by Salford Systems.

A tree continues to grow until either (1) there is only one observation in each of the terminal nodes, or (2) all observations within each terminal node have an identical distribution of independent variables or dependent variable, making splitting impossible, or (3) it reaches an external limit on the number of observations in each terminal node set by the user.

30.2.3 Pruning the Tree

Growing a very large tree can result in overfitting, that is, the tree classifier has small classification errors on the training sample, but may perform poorly on a new test data set. To avoid overfitting but still capture the important structures of the data, CART reduces the tree to an optimal size by *cost-complexity pruning*. Suppose the tree-growing algorithm stops at a large tree $T_{\max}$. The size of $T_{\max}$ is not critical as long as it is large enough. Define a subtree $T \subset T_{\max}$ to be any tree that can be obtained by pruning $T_{\max}$, that is, collapsing any number of its nodes. The idea is first to find subtrees $T_\alpha \subset T_{\max}$ for a given tuning parameter $\alpha \geq 0$ that minimize the cost-complexity criterion

$$R_\alpha(T) = R(T) + \alpha|T| = \sum_{m=1}^{|T|} N_m i(m) + \alpha|T| \,, \tag{30.5}$$

where m indexes the terminal nodes, $|T|$ is the number of terminal nodes in tree T, and N_m and $i(m)$ are the number of observations and the impurity measure of node m, respectively. Then the optimal tree is selected from this sequence of T_αs. The cost-complexity criterion is a combination of the misclassification cost of the tree, $R(T)$, and its complexity $|T|$. The constant α can be interpreted as the complexity cost per terminal node. If α is small, the penalty for having a larger tree is small and hence T_α is large. As α increases, $|T_\alpha|$ also increases. Typically, the misclassification error impurity measure (30.4) is used in pruning the tree. Equation (30.5) presents a special form of the misclassification cost $R(T)$ when the cost of misclassifying an observation of class j to class i is the same for all $i \neq j$. Other misclassification cost functions $R(T)$ can be applied; see *Breiman* et al. [30.5], but our description of the algorithm will be based on (30.5).

CART uses *weakest-link pruning* to find the T_αs. The algorithm successively collapses the branch that produces the smallest per-node increase in $R(T)$ from the bottom up and continues until it produces the single-node (root) tree. This gives us a sequence of nested subtrees $\{T_0, T_1, T_2, \ldots, T_I\}$ with decreasing

complexity and increasing cost. It is shown in *Breiman* et al. [30.5] that this sequence of subtrees is characterized by distinct and increasing α_is and the α corresponding to the optimal size tree can be found from $\{\alpha_i | i = 0, \ldots, I\}$.

The weakest-link pruning works as follows. Define T_m as a branch of T_{i+1} containing a node m and its descendants. When T_i is pruned at node m, its misclassification cost increases by $R(m) - R(T_m)$, while its complexity decreases by $|T_m| - 1$. Hence the ratio

$$g_i(m) = \frac{R(m) - R(T_m)}{|T_m| - 1}$$

measures the increase in misclassification cost per pruned terminal node, and T_{i+1} is obtained by pruning all nodes in T_i with the lowest value of $g_i(m)$, i. e., the weakest link. The α associated with tree T_i is given by $\alpha_i = \min_m g_i(m)$ and it is easily seen that $\alpha_i < \alpha_{i+1}$. The first tree T_0 is obtained by pruning $T_{\max}$ of those branches whose $g_0(m)$ value is 0. Starting with T_0, the cost-complexity pruning algorithm initially tends to prune off large branches with many terminal nodes. As the trees get smaller, it tends to cut off fewer at a time. The pruning stops when the last subtree T_I is the root tree. These recursive pruning steps are computationally rapid and require only a small fraction of the total tree construction time.

CART then identifies from $\{T_i | i = 0, 1, \ldots, I\}$ the optimal subtree as the one with the minimal classification error (0-SE rule) or the smallest tree within one standard error of the minimum error rate (1-SE rule). The classification error of each subtree T_i can be estimated using test samples when data are sufficient or V-fold cross-validation. The reason for using the 1-SE rule is to favor smaller trees with estimated misclassification errors close to that of the minimum error tree. The 1-SE rule is good for small data sets, whereas the 0-SE rule works better on large data sets. With sufficient data, one can simply divide the sample into learning and test sub-samples. The learning sample is used to grow $T_{\max}$ and to obtain the subsequence $\{T_i | i = 0, 1, \ldots, I\}$. The test sample is then used to estimate the misclassification error rate for the T_is.

When the data are insufficient to allow a good-sized test sample, CART employs cross-validation to estimate the misclassification rate. Cross-validation is a computationally intensive method for validating a procedure for model building, which avoids the requirement for a new or independent validation data set. For V-fold cross-validation, CART proceeds by dividing the learning sample into V parts, stratified by the dependent variable, to assure that a similar outcome distribution is present in each of the V subsets of data. CART takes the first $V - 1$ parts of the data, constructs the auxiliary trees for $\{T_i | i = 0, 1, \ldots, I\}$ characterized by the α_is, and uses the remaining data to obtain initial estimates of the classification error of selected subtrees. The same process is then repeated on other $V - 1$ parts of the data. The process repeats V times until each part of the data has been held in reserve one time as a test sample. The estimates of the classification errors for $\{T_i | i = 0, 1, \ldots, I\}$ are then given by averaging their initial estimates over V artificial test samples.

Many other pruning methods are also available for decision trees, such as reduced error pruning (REP), pessimistic error pruning (PEP), minimum error pruning (MEP), critical value pruning (CVP) and error-based pruning (EBP). *Esposito* et al. [30.13] provides a comprehensive empirical comparison of these methods.

30.2.4 Regression Tree

CART constructs a regression tree when the outcome variable is continuous. The process of constructing a regression tree is similar to that for a classification tree, but differs in the criteria for splitting and pruning. CART constructs the regression tree by detecting the heterogeneity that exists in the data set and then purifying the data set. At each node, the predicted value of the dependent variable is a constant, usually as the average value of the dependent variable within the node. An example of a regression tree is given in Fig. 30.4. The analysis tried to construct a predictive model of cen-

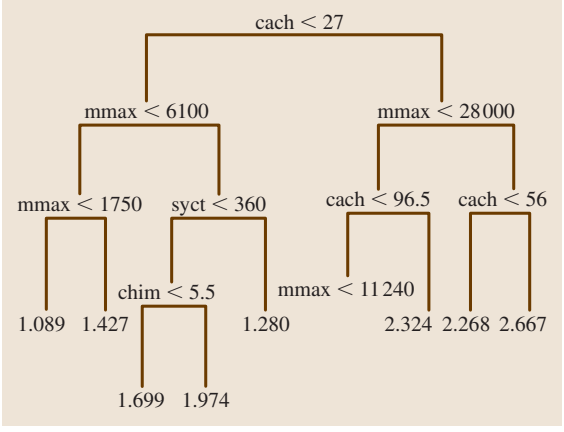

Fig. 30.4 A regression tree for predicting CPU performance

tral processing unit (CPU) performance using nine CPU characteristics (Table 30.3) based on a learning sample of 209 CPUs [30.14].

When CART grows a regression tree, it determines the splitting variable and split point by minimizing the mean square error (MSE) or the mean absolute deviation from the median. Since the mechanisms for the two rules are similar, we only describe the former. Under this circumstance, the node impurity is measured by

$$i(m) = \frac{1}{N_m} \sum_i \left[y_i - \bar{y}(m) \right]^2 , \tag{30.6}$$

where $\bar{y}(m)$ is the average value of the dependent variable at node m. The best split (j, t) is hence determined by solving

$$\min_{j,t} \left\{ \sum_{i \in m_L} \left[y_i - \bar{y}(m_L) \right]^2 + \sum_{i \in m_R} \left[y_i - \bar{y}(m_R) \right]^2 \right\} , \tag{30.7}$$

where m_L is the left descendent node given by $x_j < t$, and m_R is for the right branch. An alternative criterion to (30.7) is the weighted variance

$$p_L i(m_L) + p_R i(m_R) ,$$

where p_L and p_R are the proportions of cases in node m that go left and right, respectively. Correspondingly, the cost-complexity criterion in the pruning process also adopts (30.6).

30.2.5 Some Algorithmic Issues

In this section, we discuss several algorithmic issues of CART that are important in practice.

Estimating Within-Node Classification Error

In practice, the users desire to know not only the class assignment from a CART tree for any future case, but also about a classification error associated with this prediction. This classification error can be represented by the probability of misclassification given that the case falls into a particular terminal node. We denote this value by $r(m)$ if a case falls into terminal node m. A naive estimate of $r(m)$ is the proportion of cases that are misclassified by the tree constructed from the entire sample, as shown in (30.4). This estimate however can be misleading since it is computed from the same data used in constructing the tree. It is also unreliable if the terminal node m is tracked down through many splits from the root and has a relatively small number of observations.

Table 30.3 Characteristics of CPUs

Variable	Definition
name	Manufacturer and model
syct	Cycle time in nanoseconds
mmin	Minimum main memory in kilobytes
mmax	Maximum main memory in kilobytes
cach	Cache size in kilobytes
chmin	Minimum number of channels
chmax	Maximum number of channels
perf	Published performance on a benchmark mix
	relative to an IBM 370/158-3
estperf	Estimated performance by the authors

Breiman et al. [30.5] proposed an ad hoc estimate that is significantly better than the naive one,

$$\hat{r}(m) = \hat{r}_o(m) + \frac{\epsilon}{N_m + \lambda} , \tag{30.8}$$

where $\hat{r}_o(m)$ is defined in (30.4), N_m is the size of node m, and ϵ and λ are constants to be determined below. Define the resubstitution classification error of the tree T by aggregating the classification errors across all terminal nodes as follows,

$$\hat{R}_o(T) = \sum_{m=1}^{|T|} \hat{r}_o(m) N_m .$$

Denote the cross-validated classification error of tree T by $\hat{R}_{CV}(T)$. Then the constants λ and ϵ are obtained from the following equations

$$\lambda \sum_{m=1}^{|T|} \frac{N_m}{N_m + \lambda} = \frac{\hat{R}_{CV}(T) - \hat{R}_o(T)}{2 \min_V \hat{R}_{CV}(T_V)} ,$$

$$\epsilon = 2\lambda \min_V \hat{R}_{CV}(T_V) ,$$

where $\min_V \hat{R}_{CV}(T_V)$ is the minimum obtained during V-fold cross-validation. If $\hat{R}_{CV}(T) \le \hat{R}_o(T)$, the naive estimate (30.4) is used.

Splitting on a Linear Combination of Variables

Sometimes, the data are intrinsically classified by some hyperplanes. This can possibly challenge the tree-based method in its original form using binary partitions, which tends to produce a large tree in trying to approximate the hyperplanes by many hyperrectangular regions. It is also very hard for the analysts to recognize the neat linear structure from the output. The CART algorithm deals with this problem by allowing splits over

linear combination of predictor variables $\sum_j a_j X_j$. The weights a_j and split point t are optimized to minimize the relevant criterion (such as the Gini index). While this can improve the predictive power of the tree, the results are no longer invariant under monotone transformations of individual independent variables. The introduction of linear combinations also causes a loss in interpretability that is viewed as an important advantage of tree-based methods.

Missing Data on Predictors

We often have incomplete data with missing values on some independent variables. We might exclude these incomplete observations from analysis, but this could lead to serious depletion of the learning sample. A common alternative is to impute the missing values [30.15]. CART however uses two different approaches. A simple treatment for categorical predictors is to put the missing values into a new "missing" category. This however puts all observations with missing values into the same branch of the tree, which could be misleading in practice. A more refined approach is to use surrogate splits. This approach makes full use of the data to construct the tree, and results in a tree that can classify cases with missing information. Surrogate variables are constructed as follows. When we consider a split on a predictor x_j with missing values, only the cases containing values of x_j are used, and we find the best split as discussed in Sect. 30.2.2. The first surrogate split is the split on a predictor that most accurately predicts the action of the best split in terms of a predictive measure of association. The second surrogate is the split on another predictor that does second best, and so on; for details see [30.5]. The surrogate splits can cope with missing observations during both the training phase of CART and prediction. If a case has missing values so that the best split is not useable, the next best surrogate split would be used.

Variable Importance

Another nice feature of CART is that it automatically produces a variable ranking. The ranking considers the fact that an important variable might not appear in any split in the final tree when the tree includes another masking variable. If we remove the masking variable, this variable could show up in a prominent split in a new tree that is almost as good as the original. The importance score of a particular variable is the sum of the improvement of impurity measures across all nodes in the tree when it acts as a primary or surrogate splitter.

Instability of Trees

Small changes in the learning sample may cause dramatic changes in the output tree. Thus two similar samples could generate very different classification rules, which is against human intuition and complicates interpretation of the trees. The major reason for this instability is the hierarchical nature of the recursive partitioning. For example, if at some partition, there are surrogate splits that are almost as good as the primary split, the tree could be very sensitive to small changes, because a minor change in the learning sample could cause the surrogate split to become slightly superior to the primary split. This effect in the top nodes can cascade to all their descendant nodes. Aggregating methods, such as bagging [30.16] and boosting [30.17] have been incorporated into the algorithm to mitigate the instability problem, but the improvement comes at the price of sacrificing the simple interpretability of a single tree.

30.2.6 Summary

CART makes no distributional assumptions on any dependent or independent variable, and allows both categorical and continuous variables. The algorithm can effectively deal with large data sets with many independent variables, missing values, outliers and collinearity. Its simple binary tree structure offers excellent interpretability. Besides, CART ranks the independent variables in terms of their importance to prediction power and therefore serves as a powerful exploratory tool for understanding the underlying structure in the data.

However, CART does have limitations. While it takes advantages of the simple binary tree structure, it suffers from instability and has difficulty capturing additive structures. In general, if a parametric statistical model fits the data well and its assumptions appear to be satisfied, it would be preferable to a CART tree.

30.3 Other Single-Tree-Based Methods

30.3.1 Loh's Methods

One drawback of exhaustive-search tree-growth algorithms such as that used in CART is the potential for variable selection bias. In particular, such algorithms tend to choose variables that provide greater numbers of potential splitting points. Hence, continuous variables tend to be favored over categorical variables, and polychotomous variables are selected more frequently than dichotomous ones. These characteristics complicate interpretation of resulting trees, because any insights gained from the tree structure could potentially be clouded by systematic biases toward certain variables. The methods developed by Loh and his coauthors attempt to address this bias issue.

QUEST

Loh and *Shih* [30.6] developed the quick, unbiased and efficient statistical tree (QUEST) algorithm to address this variable selection bias issue. The algorithm is an enhancement of the much earlier fast algorithm for classification trees (FACT) of *Loh* and *Vanichsetaukul* [30.18], which was primarily designed as a computationally efficient alternative to exhaustive-search methods, but still suffered from variable-selection bias in the presence of categorical predictors.

The basic strategy employed by QUEST is to select each splitting variable and its associated split value sequentially rather than simultaneously. To determine the splitting variable at a particular node, a series of statistical tests is performed:

1. Specify an overall level of significance, $\alpha \in (0, 1)$. Let K be the number of variables, and K_1 be the number of continuous and ordinal variables.
2. Identify the variable with the smallest p-value resulting from the appropriate analysis of variance test (for continuous or ordinal variables) or Pearson's χ^2 test (for categorical variables). If this p-value is less than α/K, split on this variable.
3. If the lowest p-value exceeds this threshold, perform Levene's F-test for unequal variances on each continuous/ordinal variable. If the smallest of these p-values from the F-tests is less than $\alpha/(K + K_1)$, split on its associated variable. Otherwise, split on the variable with the smallest p-value in step 2.

The Bonferroni-adjusted thresholds used above is meant to render the potential variable-selection bias negligible.

Once the splitting variable is selected, the split point is needed. If more than two classes are present at the node, they are first combined into two *superclasses* using two-means clustering [30.19]. Then, a modified quadratic discriminant analysis is employed to select the split point. Categorical variables must be transformed into ordered variables before this split can be performed. This is accomplished by recoding the represented categories as 0–1 dummy vectors and projecting them onto their largest discriminate coordinate.

The algorithm described above focuses on univariate splits. However, as with CART, QUEST can also be used to build trees with linear-combination splits. Generally, QUEST trees based on linear-combination splits tend to be shorter and more accurate than those based on univariate splits.

The QUEST package may be obtained from http://www.stat.wisc.edu/~loh/loh.html. The full package includes an exhaustive-search algorithm to mimic basic CART, and offers options for pruning or stopping rules.

CRUISE

Kim and *Loh* [30.7] extended the unbiased variable selection idea beyond the capabilities of QUEST. First, while QUEST forces binary splits at each node, classification rule with unbiased interaction selection and estimation (CRUISE) allows multiway splitting. Moreover, CRUISE includes look-ahead methods for detecting two-variable interactions during variable selection.

Multiway splitting offers two key advantages over binary splitting. First, although any multiway split can be represented by a series of binary splits, trees that allow multiway splits are often shorter and thus more easily interpreted. Second, Kim and Loh demonstrate that, with binary trees, some dependent variable categories can be completely dropped after pruning. For example, a tree intended to classify cases into two categories might ultimately include paths to only two of the classes of interest. Trees employing multiway splits are less apt to *losing* categories in this manner.

Another key benefit of CRUISE is the inclusion of look-ahead methods for detecting two-variable interactions during variable selection. CRUISE contains two methods for splitting-variable selection: 1D and 2D. The

1D method is similar to what is used in the QUEST algorithm. p-values are obtained from F-tests for continuous and ordinal variables and from Pearson's χ^2 tests for categorical variables. If the smallest p-value is significant, its associated variable is selected for the split. Otherwise, Levene's test for unequal variances is carried out for the continuous and ordinal variables to select the splitting variable. A major drawback of the 1D method is that, because analysis of variation (ANOVA) and Levene's tests do not look ahead, strong interactions are often completely overlooked. In addition, because these tests restrict their attention to differences in means and variances, other distributional differences may remain unnoticed.

The 2D method uses contingency tables to remedy these problems. First, consider interaction detection. Given a pair of categorical variables, category pairs are tabulated against classifications. Then, Pearson's χ^2 test for independence is performed. If a strong interaction is present between the two categorical variables, the test is likely to result in a low p-value. Interactions involving continuous variables are detected similarly. Prior to testing, each continuous variable is transformed into a dichotomous variable by partitioning its domain at the median.

The same idea is applied to identify marginal distributional effects. For each categorical variable, Pearson's χ^2 test for independence is performed. Continuous variables are handled similarly, first transforming them into four-category variables by partitioning at their quartiles. The basic idea is that the one- or two-variable table with the smallest p-value should determine the splitting variable. However, this simple procedure would be somewhat biased toward categorical variables, so Kim and Loh employ a bootstrap adjustment prior to variable selection.

Once the splitting variable has been selected, CRUISE uses linear discriminant analysis (LDA) to determine the splitting points. Since LDA is best applied to normally distributed data, Kim and Loh apply a Box–Cox transformation to the selected variable prior to running the discriminant analysis. Categorical variables must be converted to their discriminant coordinate values before this process is carried out. A shift transformation may be needed to produce the positive-valued inputs required for the Box–Cox procedure. Split points are converted back to the original scale when constructing the tree.

Our description thus far assumes the availability of complete data, but an important advantage of CRUISE is the elimination of the variable-selection bias that often results from the treatment of missing data. Kim and Loh note that, because CART uses proportions rather than sample sizes to determine variable selections, the procedure is biased toward variables with more missing data. CRUISE on the other hand, through its use of statistical tests that take account of sample size, does not encounter this type of bias. This bias may not be critical if it does not affect the overall predictive quality of the tree, but it may have a large impact on the interpretation of CART's variable-importance measures.

GUIDE

With generalized, unbiased interaction detection and estimation (GUIDE), *Loh* [30.8] expanded unbiased variable selection to regression tree applications. GUIDE includes procedures for weighted least squares, Poisson regression and quantile regression. In addition, categorical variables may be used for prediction through dummy coding, or they may be restricted to node-splitting.

30.3.2 Quinlan's C4.5

Quinlan [30.9, 20] wrote his first decision tree program in 1978 while visiting Stanford University. His iterative dichotomizer 3rd (ID3) and its replacement, C4.5, programs have served as the primary decision tree programs in the artificial-intelligence and machine-learning communities. He attributes the original ideas to the concept learning systems of *Hunt* et al. [30.21].

Splitting Rules

Suppose a node T contains $|T|$ observations that fall into K classes. Letting $p_k(T)$ represent the proportion of these cases belonging to class k, we define the *information* contained within T (also known as the *entropy* of T) by:

$$\text{Info}(T) = -\sum_{k=1}^{K} p_k(T) \times log_2 \left[p_k(T) \right] .$$

Now suppose that a candidate variable X partitions T into n smaller nodes, $T_1, T_2, \ldots, T_n$. The information of T given the value of X is given by the weighted average of the information contained within each subnode:

$$\text{Info}(X, T) = \sum_{i=1}^{n} \frac{|T_i|}{|T|} \times \text{Info}(T_i) .$$

Therefore, the *information gain* provided by the split is simply

$$\text{Gain}(X, T) = \text{Info}(T) - \text{Info}(X, T) . \qquad (30.9)$$

ID3 selects attributes and splits to maximize the information gain at each node. However, this procedure tends to heavily favor variables with many categories. To compensate for this effect at least partially, C4.5 instead uses the *gain ratio* criterion. The gain ratio of a split is defined as the ratio of the information gain to the information contained in the resulting split:

$$\text{GainRatio}(X, T) = \frac{\text{Gain}(X, T)}{\text{SplitInfo}(X, T)}\,, \qquad (30.10)$$

where

$$\text{SplitInfo}(X, T) = -\sum_{i=1}^{n} \frac{|T_i|}{|T|} \times \log_2\left(\frac{|T_i|}{|T|}\right).$$

The C4.5 algorithm creates binary splits on continuous variables and multiway splits on categorical variables. To determine the best splits on categorical variables, each category is first assigned to a unique branch. Then, pairs of branches are iteratively merged until only two branches exist. The split with the maximum gain ratio among those observed becomes the candidate split for that variable. This search method is, of course, heuristic and might not actually find the categorical split with the largest gain ratio. On the other hand, searches on continuous variables always find the best possible binary split. To determine the ultimate splitting variable, the algorithm first restricts its choices to those variables achieving at least average information gain (30.9). The split is then selected to maximize the gain ratio (30.10) among these choices.

Variable-Selection Bias

Even if the gain ratio is used as an alternative to straight information gain to alleviate the algorithm's bias toward continuous variables, this original remedy is far from perfect. *Dougherty* et al. [30.22] demonstrated that, for many data sets, the predictive performance of C4.5 was improved by first discretizing all continuous variables. This result suggested that the existing selection method was biased toward continuous variables.

In C4.5 release 8, *Quinlan* [30.23] introduces a complexity-cost parameter into the information gain expression for continuous variables. For a continuous variable with n distinct values, the information gain is redefined as

$$\text{Gain}(X, T) = \text{Info}(T) - \text{Info}(X, T) - \log_2(n-1)/|T|\,.$$

Effectively, each continuous variable is penalized for the information required to search among its numerous potential splitting points.

Missing Values

The description of C4.5 has thus far assumed complete data. Cases with missing values for a particular variable are excluded from the split search on that variable, and also from the numerator of the gain ratio. The entropy of the split is computed as if missing values constitute an additional branch.

When a missing value prevents the application of a splitting rule to a new case, the case is replaced by weighted replicates, each being assigned to a different branch. The weights are equal to the proportion of non-missing training cases assigned to that branch. Class probabilities for the original case are based on the weighted sum of the probabilities of the generated observations.

Pruning

Quinlan [30.9] advocates retrospective pruning instead of stopping rules. If enough data were available, the pruning process would use data withheld from training the tree to compare error rates of candidate sub-trees. The software does not assume that data are withheld from training, so it implements *pessimistic* pruning. In each node, an upper confidence limit of the number of misclassified cases is estimated assuming a binomial distribution around the observed number of misclassified cases. The confidence limit serves as an estimate of the error rate on future data. The pruned tree minimizes the sum over leaves of upper confidence limits.

Decision Rules

C4.5 includes the capability to convert its decision trees to an equivalent simplified set of decision rules. Decision rules are often preferred to the tree structure because their interpretation is very straightforward. Given a decision tree, rule-set generation proceeds as follows:

1. Convert every decision tree path to a decision rule. (Each decision encountered along a path becomes a *test* in the resulting decision rule.)
2. Prune each decision rule by removing as many tests as possible without reducing its accuracy.
3. Track the estimated accuracy of each resulting rule, and classify new items based on high-accuracy rules first.

Improvements in C5.0/See5

C5.0 and See5 are the current commercial implementations of Quinlan's methods. These programs offer several enhancements to C4.5, including the ability to specify unequal misclassification costs, the application of fuzzy splits on continuous variables, and boosting trees.

30.3.3 CHAID

Chi-square automatic interaction detection (CHAID) is a parametric recursive partitioning technique that builds non-binary classification trees. It was originally developed by *Kass* [30.10] to handle categorical predictors only. Continuous predictors need to be discretized into a number of categories with approximately equal number of observations. In dealing with missing values on predictors, CHAID simply places them in an additional category. The algorithm employs a sequential merge-and-split procedure based on significance tests on predictor variables to generate node splits and determine the size of a tree. It is worth noting that CHAID differs from CART in that it determines where to stop in tree growth rather than using retrospective pruning after growing an oversized tree.

CHAID produces non-binary trees that are sometimes more succinct representations than equivalent binary trees. For example, it may yield a split on an income variable that divides people into four income groups according to some important consumer-behavior-related variable (e.g., types of cars most likely to be purchased). In this case, a binary tree is not an efficient representation and can be hard to interpret. On the other hand, CHAID is primarily a step-forward model-fitting method. Known problems with forward stepwise regression fitting models are probably applicable for this type of analysis.

30.3.4 Comparisons of Single-Tree-Based Methods

We have discussed six single-tree methods, viz. CART, C4.5, CHAID, CRUISE, GUIDE and QUEST. Table 30.4 lists the features offered by these six methods. Among these methods, GUIDE is a regression tree method, CHAID, CRUISE and QUEST are classification tree methods, and CART and C4.5 deal with both classification and regression problems.

Empirical comparisons on real data sets [30.24] showed that, among all these methods, there is none

that is absolutely superior to the others in terms of accuracy, complexity, interpretability and computation time. There is no significant difference in terms of prediction accuracy among these methods. Therefore, users may choose algorithms based on desired features for their applications, e.g., binary-split, multi-split, split on combination of variables. C4.5 tends to produce trees with many more leaves than other algorithms possibly due to under-pruning. In general, the multi-split tree methods (C4.5, CHAID, CRUISE) take more computation time than the binary-split methods. In problems with mixtures of continuous variables and categorical variables having different numbers of levels, methods such as QUEST, CRUISE, and GUIDE may be preferable because they are likely to protect against variable-selection bias.

CART, CHAID and C4.5 have been implemented in several commercial software platforms; see the list of software providers in Table 30.5. Free software for CRUISE, GUIDE, and QUEST can be obtained from the website http://www.stat.wisc.edu/~loh/. An earlier version of C4.5 is available free of charge http://www.cse.unsw.edu.au/~quinlan/.

30.4 Ensemble Trees

Instability of single trees provides room for improvement by ensemble methods. Ensemble methods create a collection of prediction/classification models by applying the same algorithm on different samples generated from the original training sample, then make final predictions by aggregating (voting) over the ensembles. It has been shown to improve the prediction/classification accuracy of a single model with significant effectiveness; see *Bauer* and *Kohavi* [30.25], *Breiman* [30.16, 26, 27], *Dietterich* [30.28], and *Freund* and *Schapire* [30.29]. The mechanism used by the ensemble methods to reduce prediction errors for unstable prediction models, such as trees, is well understood in terms of variance reduction due to averaging [30.12]. In this section, we will discuss two ensemble tree methods: boosting decision trees [30.17] and random forests [30.26, 27] that are motivated by boosting [30.29] and bagging [30.16], the two most widely used ensemble techniques today. However, it should be realized that better performance of ensemble trees comes at the price of sacrificing the explicit structure of a single tree and hence becoming less interpretable.

30.4.1 Boosting Decision Trees

Boosting was originally developed to improve the performance of binary classifiers. In his original boosting algorithm, *Schapire* [30.30] enhances a *weak learner* (i. e., a binary classifier with slightly better performance than random guessing) by using it to train two additional classifiers on specially filtered versions of the training data. The first new classifier is trained on cases for which the original weak learner performs no better than random guessing. The second new classifier is trained on cases where the first two learners disagree. In this way, each successive learner is trained on cases which are increasingly difficult to classify. The final boosted classifier is obtained by taking the majority vote of the orig-

inal weak learner and its two subsequent derivatives. Schapire's *strength of weak learnability* theorem proves that this simple boosted classifier always improves on the performance of the original weak learner.

In later work, *Freund* [30.31] improved on the performance of Schapire's method by expanding to a much larger ensemble of combined weak learners and again employing the majority vote principle. Subsequent theoretical improvements led to the more flexible AdaBoost algorithm [30.29] and various derivatives.

Our presentation of boosting algorithms and their application to classification and regression trees is based on the example of *Hastie* et al. [30.12].

AdaBoost

We begin by presenting the most popular of the AdaBoost algorithms, AdaBoost.M1 [30.32], which is used for binary classification problems.

Consider a binary classification problem with categories coded as $Y \in \{-1, 1\}$. Given a predictor vector $\boldsymbol{X}$, the classifier $G(\boldsymbol{X})$ takes on values in $\{-1, 1\}$. The error rate on the training sample is given by:

$$\overline{err} = \frac{1}{N} \sum_{i=1}^{N} I\left[y_i \neq G(x_i)\right]$$

and the expected future prediction error is

$$E_{XY} I\left[Y \neq G(X)\right] \ .$$

The AdaBoost.M1 algorithm proceeds as follows:

1. Initialize the observation weights $w_i = 1/N, i = 1, 2, \ldots, N$.
2. For $m = 1$ to M:
   a) Fit a classifier $G_m(x)$ to the training data using the weights w_i.
   b) Compute
   $$err_m = \frac{\sum_{i=1}^{N} w_i I\left[y_i \neq G_m(x_i)\right]}{\sum_{i=1}^{N} w_i} \ ;$$
   c) Compute
   $$\alpha_m = \log\left(\frac{1 - err_m}{err_m}\right) \ ;$$
   d) Set $w_i \leftarrow w_i \exp\left\{\alpha_m I\left[y_i \neq G_m(x_i)\right]\right\}$, $i = 1, 2, \ldots, N$.
3. Define the boosted classifier as $G(x)$
   $= \text{sign}\left[\sum_{m=1}^{M} \alpha_m G_m(x)\right]$.

This boosting process begins with a weak learner, G_1, which is developed using an unweighted training set. The data are then weighted to deemphasize correctly classified observations and focus on incorrectly classified observations. A new weak classifier, G_2, is then trained from this weighted data. Next, these two classifiers are weighted according to their individual error rates (with the more accurate classifier given greater influence). Based on the weighted performance of the two classifiers, the training data is again reweighted for emphasis on difficult-to-classify observations, and the process iterates. Each new learner, G_m, is thus designed to address increasingly difficult aspects of the classification problem. The final boosted classifier, $G(x) = \text{sign}\left[\sum_{m=1}^{M} \alpha_m G_m(x)\right]$, is derived from the weighted votes of the M individual weak classifiers. The error rates of the individual weak classifiers G_m tend to increase with each iteration, but prediction from the overall ensemble, G, tends to improve.

Our discussion of boosting thus far applies to classifiers in general. We now narrow our discussion to the particular application of boosting techniques to tree-based models.

Boosting Trees

Boosting procedures in general fit additive expansions of weak classifiers or regressors. In the case of tree models, such expansions have the form

$$f(x) = \sum_{m=1}^{M} \beta_m T(x; \Theta_m) \ ,$$

where the parameter Θ includes information about the structure of each tree.

Such models are fit by minimizing a loss function, L, averaged over the training data, that is, y solving

$$\min_{\{\beta, \Theta\}} \sum_{i=1}^{N} L\left[y_i, \sum_{m=1}^{M} \beta_m T(x_i; \Theta_m)\right] \ .$$

The solution to this problem is approximated using a forward stagewise additive algorithm. The idea is to build the expansion one term at a time. At a given iteration m, the optimal basis tree and scaling coefficient are sought to append to the old expansion f_{m-1}, producing f_m. The algorithm goes as follows:

1. Initialize $f_0(x) = 0$.
2. For $m = 1$ to M:
   a) Compute
   $$(\beta_m, \Theta_m) = \arg\min_{\beta, \Theta} \sum_{i=1}^{N} L\left[y_i, f_{m-1}(x_i) + \beta T(x_i; \Theta)\right] \ .$$

b) Set $f_m(x) = f_{m-1}(x) + \beta_m T(x; \Theta_m)$.

Friedman et al. [30.33] discovered that, under the exponential loss, $L[y, T(x; \Theta)] = \exp[-yf(x)]$, for binary classification problems, the forward stagewise algorithm is equivalent to the AdaBoost.M1 procedure discussed earlier. The expansion $\sum_{m=1}^{M} \alpha_m G_m(x)$ produced by the AdaBoost procedure estimates half the log-odds of $P(Y = 1|x)$. Therefore, taking the sign of this expression provides a reasonable classification rule.

For K-class classification and regression problems, the multiple additive regression trees (MART) procedure is used. MART is based on the gradient tree-boosting algorithm for regression, and can be implemented using a variety of available loss functions; see *Hastie* et al. [30.12] for details.

Selecting Component Tree Sizes

One consideration when applying boosting to tree models is the appropriate size of each weak learner tree. Early tree boosting applications, of which *Drucker* and *Cortes's* [30.17] optical character-recognition problem was the first, applied standard pruning methods to each weak learner in sequence. However, as *Hastie* et al. [30.12] note, this method implicitly prunes each weak learner as if it were the last in the sequence. This can result in poor predictive performance of the ensemble, as well as some unnecessary computations.

A common strategy to avoid this problem is to restrict each tree in the ensemble to a fixed number, J, of terminal nodes. The choice of this parameter is dependent on the problem at hand. Of course, the degree of variable interaction will be affected by the tree size. For example, boosting tree stumps (i. e., trees with only one split) considers no interaction effects, whereas boosting three-node trees can capture two-variable interactions. If each weak learner consists of J terminal nodes, interactions of up to $J-1$ variables may be estimated.

In practice, J is typically determined through trial and error to maximize performance. *Hastie* et al. [30.12] indicate that $4 \le J \le 8$ terminal nodes per tree typically work well, with little sensitivity to choices within that range. For some applications, boosting stumps ($J = 2$) may be sufficient, and very rarely is $J > 10$ needed.

Interpretation

Although boosting trees provides significant improvements in classification and predictive accuracy, these benefits do come at a cost. Because the final model is comprised of the weighted average of many weaker models, we lose the attractive structural interpretability of a single tree.

However, additional useful information can still be gleaned from the data. As we discussed in Sect. 30.2.5, *Breiman* et al. [30.5] provide a measure of the relative importance of predictor variables in a single tree. This measure is easily generalized to the context of boosting. Single-tree importance measures are calculated for each weak learner and averaged over the group. In K-class classification problems, importance measures are generated in this manner for each class. These values can be averaged across classes to obtain overall importance measures for each variable, or across subsets of variables to determine the relevance of each subset in predicting each class.

Once the most relevant variables are identified, certain visualization tools can aid interpretation. *Hastie* et al. [30.12] suggest the use of partial dependence plots to look for interactions between variables.

30.4.2 Random Forest

Breiman [30.26, 27] developed random forests (RF) based on bagging and random feature selection [30.28, 34]. Bagging is a resampling procedure that produces bootstrap samples by randomly sampling with replacement from the original training sample. A random forest is essentially an ensemble of CART trees in which each tree is grown in accordance with a different bootstrap sample. Suppose M bootstrap samples are generated, viewing them as realizations of independent identically distributed (iid) random vectors $\Theta_1, \ldots, \Theta_M$, we denote the random forest by $h(\boldsymbol{x}; \Theta)$ as an ensemble of individual CART trees $h(\boldsymbol{x}; \Theta_j)$, $j = 1, \ldots, M$. For classification problems, the final prediction of the forest is made by majority vote,

$$h(\boldsymbol{x}; \Theta) = \arg\max_k \sum_{j=1}^{M} I\left[h(\boldsymbol{x}; \Theta_j) = k\right] ;$$

for regression problems, the final prediction is obtained by aggregating over M trees, typically using equal weights,

$$h(\boldsymbol{x}; \Theta) = \frac{1}{M} \sum_{j=1}^{M} h(\boldsymbol{x}; \Theta_j) .$$

In accordance with the basic principle of bagging to reduce prediction errors from averaging over the ensemble, better accuracy of the random forest can be obtained by keeping errors of individual trees low, and

minimization of the correlation between multiple trees. Therefore, individual trees are not pruned but grown to maximum depth. Recently, *Segal* [30.35] suggested that this strategy can overfit the data and it is beneficial to regulate tree size by limiting the number of splits and/or the size of nodes for which splitting is allowed. In addition, the correlation of multiple trees can be reduced by random feature selection. Instead of determining the split at a given node in an individual tree using all the predictors, only $m < p$ randomly selected predictors are considered for the split. This also enables the algorithm to build models for high-dimensional data very quickly. Alternatives to this random feature selection include: (1) picking the best out of several random feature subsets by comparing how well the subsets perform on the samples left out of the bootstrap training sample (out-of-bag samples), and (2) using random linear combinations of features in the selected feature subset, i. e., selected features are added together with coefficients that are uniform random numbers on $[-1, 1]$. Due to the large number of simple trees and the minimized correlations among the individual trees, the prediction error of the forest converges toward the error rates comparable to AdaBoost [30.29].

Usually, about one third of the observations are left out of each bootstrap sample. These out-of-bag (oob) observations are used to internally estimate prediction error for future data, the strength of each tree, and correlation between trees; see details in *Breiman* [30.27]. This avoids the cross-validation needed for construction of a single tree and greatly enhances the computational efficiency of random forests.

With random forests, an intuitive measure of variable importance can be computed as follows. In every tree grown in the forest, put down the oob cases and count the number of votes cast for the correct class. Now randomly permute the values of variable m in the oob cases and put these cases down the tree. Subtract the number of votes for the correct class in the variable-m-permuted oob data from the number of votes for the correct class in the untouched oob data. The average of this number over all trees in the forest is the raw importance score for the variable m.

For each case, consider all the trees for which it is oob. Subtract the percentage of votes for the correct class in the variable-m-permuted oob data from the percentage of votes for the correct class in the untouched oob data. This is the local importance score for variable m for this case, and is used in the graphics program RAFT (Random Forest Tool).

For further details on random forests, please refer to the random forests website http://www.math.usu.edu/~adele/forests/cc_home.htm maintained by Professor Adele Cutler at Utah State University.

In summary, random forests do not overfit and and enjoy prediction accuracy that is as good as AdaBoost and sometimes better. The algorithm runs fast on large high-dimensional data and is somewhat robust to outliers. It also has an effective mechanism for handling missing data. In the forest-building process, it internally estimates the classification error, the strength of each tree and the correlation between trees. It also distinguishes itself from some black-box methods (e.g. neural networks) by providing the importance score for each predictor, and hence makes the output more interpretable to users. Furthermore, random forests can serve as an exploratory tool to find interactions among predictors, locate outliers and provide interesting views of the data. Its application can also be extended to unsupervised clustering.

30.5 Conclusion

In this chapter, we have discussed several tree-based methods for classification and regression. Of course, many more supervised learning methods are available, including multivariant adaptive regression splines (MARS), neural networks, and support vector machines (SVM). In this last section, we discuss the relative merits of tree-based methods among this much larger set of well-known supervised learning tools.

Hastie et al. [30.12] note that typical characteristics found in real-world data sets make direct application of most supervised-learning tools difficult. First, data-mining applications tend to involve very large data sets in terms of both the number of observations and the number of variables (the majority of which are often irrelevant). Moreover, these data sets generally contain both quantitative and qualitative variables. The quantitative variables are typically measured on different scales, and the qualitative variables may have different numbers of categories. Missing data are abundant, and outliers are also very common.

Tree-based methods are particularly well-suited to deal with these difficulties. Trees grow quickly, so the

size of a data set is not a big concern. Tree algorithms readily admit mixed variable types, and feature selection is a part of the building process, so irrelevant variables have little impact on the resulting model. Tree-building methods account for missing data in an effective way, and the results for classification or prediction are often robust against outliers.

Many other supervised learning methods fall short in some of these areas. MARS has difficulty with outliers in predictor variables, and transformations on variables can dramatically impact its results. Neural networks and SVM both require dummy coding of categorical variables, they are not adept at handling missing values, and they are sensitive to outliers and transformations.

Tree-based methods have one other important advantage over black-box techniques such as neural networks; tree models are much more readily interpretable. This characteristic is vital to those applications for which predictive accuracy is secondary to the main goal of obtaining qualitative insight into the structure of the data.

In spite of these advantages, tree-based methods do suffer one key drawback: a relative lack of predictive power. Neural networks and support vector machines commonly outperform classification and regression trees, particularly when the underlying structure of the data depends on linear combinations of variables. As we discussed in Sect. 30.4, ensemble methods such as boosting and random forests can be quite effective at improving their accuracy. However, this predictive improvement comes with some cost. Ensemble methods lose the interpretive value in a single tree, and they are much more computationally expensive. The tree-based methods do not always yield the best possible results for classification and prediction, but they are worth a try in a wide variety of applications. In any scientific application, we certainly encourage you to see the forest – not just a few trees.

31. Image Registration and Unknown Coordinate Systems

This chapter deals with statistical problems involving unknown coordinate systems, either in Euclidean 3-space $\mathbb{R}^3$ or on the unit sphere Ω_3 in $\mathbb{R}^3$. We also consider the simpler cases of Euclidean 2-space $\mathbb{R}^2$ and the unit circle Ω_2. The chapter has five major sections.

Although other problems of unknown coordinate systems have arisen, a very important problem of this class is the problem of *image registration* from landmark data. In this problem we have two images of the same object (such as satellite images taken at different times) or an image of a prototypical object and an actual object. It is desired to find the rotation, translation, and possibly scale change, which will best align the two images. Whereas many problems of this type are two-dimensional, it should be noted that medical imaging is often three-dimensional.

After introducing some mathematical preliminaries we introduce the concept of M-*estimators*, a generalization of least squares estimation. In least squares estimation, the registration that minimizes the sum of squares of the lengths of the deviations is chosen; in M estimation, the sum of squares of the lengths of the deviations is replaced by some other objective function. An important case is L_1 estimation, which minimizes the sum of the lengths of the deviations; L_1 estimation is often used when the possibility of outliers in the data is suspected.

The second section of this chapter deals with the calculation of least squares estimates. Then, in the third section, we introduce an iterative modification of the least squares algorithm to calculate other M-estimates. Note that minimization usually involves some form of differentiation and hence this section starts with a short introduction to the geometry of the group of rotations and differentiation in the rotation group. Many statistical techniques are based upon approximation by derivatives and hence a little understanding of geometry is necessary to understand the later statistical sections.

The fourth section discusses the statistical properties of M-estimates. A great deal of emphasis is placed upon the relationship between the geometric configuration of the landmarks and the statistical errors in the image registration. It is shown that these statistical errors are determined, up to a constant, by the geometry of the landmarks. The constant of proportionality depends upon the objective function and the distribution of the errors in the data.

General statistical theory indicates that, if the data error distribution is (anisotropic) multivariate normal, least squares estimation is optimal. An important result of this section is that, even in this case when least squares estimation is theoretically the most efficient, the use of L_1 estimation can guard against outliers with a very modest cost in efficiency. Here optimality and efficiency refer to the expected size of the statistical errors. In practice, data is often long-tailed and L_1 estimation yields *smaller* statistical errors than least squares estimation. This will be the case with the three-dimensional image registration example given here.

Finally, in the fifth section, we discuss diagnostics that can be used to determine which data points are most influential upon the registration. Thus, if the registration is unsatisfactory, these diagnostics can be used to determine which data points are most responsible and should be reexamined.

31.1 Unknown Coordinate Systems and Their Estimation

31.1.1 Problems of Unknown Coordinate Systems

Wahba [31.1] posed the following question. Suppose we have the directions of certain stars with respect to the unknown coordinate system of a satellite. How can we estimate the orientation of the satellite? Let $\mathbf{A}$ be the unknown 3×3 matrix whose rows represent the axes of the satellite's coordinate system with respect to a fixed and known (Earth) coordinate system. Furthermore let $\boldsymbol{u}_i$ be the directions of the stars with respect to the known coordinate systems, where each $\boldsymbol{u}_i$ is written as a three-dimensional column vector with unit length. Similarly let $\boldsymbol{v}_i$ be the directions of the stars with respect to the satellite's coordinate system. Then

$$\boldsymbol{v}_i = \mathbf{A}\boldsymbol{u}_i + \text{error}\,. \tag{31.1}$$

In essence the question was to estimate $\mathbf{A}$. Wahba gave the least squares solution.

Chapman et al. [31.2] posed the same question in the following form. Suppose we have an object defined by a computer-aided design (CAD) program and a prototype is measured using a coordinate measuring machine (CMM). The orientations of lines on the object can be defined by unit vectors parallel to the lines and the orientations of planes can be defined by unit vectors normal to the planes. So we have unit vectors $\boldsymbol{u}_i$ defined by the CAD program and the corresponding unit vectors $\boldsymbol{v}_i$ as measured by the CMM. If $\mathbf{A}$ is the coordinate system of the CMM relative to the CAD program, then (31.1) holds.

Chapman et al. again used a least squares estimate $\widehat{\mathbf{A}}$ of $\mathbf{A}$. The main question of interest, that is the geometric integrity of the prototype, was then answered by analyzing the residuals of $\boldsymbol{v}_i$ from $\widehat{\mathbf{A}}\boldsymbol{u}_i$.

Since the $\boldsymbol{u}_i$ and $\boldsymbol{v}_i$ are of unit length, these two problems involve spherical data.

31.1.2 Image Registration

If we enlarge the inquiry to Euclidean space data, we arrive at the widely used *image registration* problem. Suppose $\boldsymbol{u}_i \in \mathbb{R}^p$ represent the locations of some landmarks in one image, and $\boldsymbol{v}_i \in \mathbb{R}^p$ the locations of corresponding landmarks in a second image of the same

object. The usual applications occur with $p = 2.3$. Under certain conditions, it might be reasonable to suppose that

$$\boldsymbol{v}_i = \mathbf{B}\boldsymbol{u}_i + \boldsymbol{b} + \text{error} \tag{31.2}$$

for an unknown $p \times p$ matrix $\mathbf{B}$ and an unknown p-dimensional column vector $\boldsymbol{b}$. The matrix $\mathbf{B}$ represents a coordinate change and the vector $\boldsymbol{b}$ represents a translation of coordinates. The image registration problem is to estimate $\mathbf{B}$ and $\boldsymbol{b}$.

The model (31.2) also arises in a slightly different context. Suppose we have landmarks $\boldsymbol{u}_i$ on a prototypical face. For example the $\boldsymbol{u}_i$ might represent the locations of the nose, the two eyes, the base of the chin, etc. For the purpose of automated processing of a large number of facial images of different subjects, we might want to bring each facial image into alignment with the prototypical image using a transformation of the form (31.2) where the $\boldsymbol{v}_i$ represent the same locations (nose, two eyes, base of chin, etc.) on the subject facial image.

In the absence of measurement error, one does not expect the landmarks on two faces to be related using a transformation of the form

$$\boldsymbol{v}_i = \mathbf{B}\boldsymbol{u}_i + \boldsymbol{b} \,. \tag{31.3}$$

The reader might be puzzled why a transformation of this form is under consideration. Statistical error, however, is not limited to measurement error. Statistical error incorporates all effects not included in the systematic portion of the model. In building a model of the form (31.2), we hope to separate out the most important relationship (31.3) between the landmarks $\boldsymbol{u}_i$ on one object and the corresponding landmarks $\boldsymbol{v}_i$ on the other object; the rest is placed in the statistical error.

Unlike the Wahba problem, the unknown $(\mathbf{B}, \boldsymbol{b})$ of the image registration problem, or the unknown $\mathbf{A}$ in the *Chapman* et al. problem, are not of primary interest. Rather, they must be estimated as a preliminary step to more interesting problems. We will discuss herein the properties of various methods of estimating these unknowns. These properties will hopefully help the interested reader to choose a good estimation technique which will hopefully yield better results after this preliminary step is completed.

31.1.3 The Orthogonal and Special Orthogonal Matrices

Consider, for example the data set in Table 31.1 from *Chang* and *Ko* [31.3], which we will analyze repeatedly in what follows. This data consists of the digitized locations of 12 pairs of landmarks on the left and right hands of one of the authors. This is a $p = 3$ three-dimensional image registration problem. We might decide that, apart from the statistical error term, the shape of the two hands is the same; that is the distance between two points on one hand is the same as the distance between the corresponding two points on the other hand.

This condition translates mathematically to the equation $\mathbf{B}^{\mathrm{T}}\mathbf{B} = \mathbf{I}_p$, the $p \times p$-dimensional identity matrix. We outline a derivation of this well-known mathematical fact for the primary purpose of introducing the reader to the mathematical style of the remainder of this chapter. The distance between two p-dimensional column vectors $\boldsymbol{v}_1$ and $\boldsymbol{v}_2$ is

$$||\boldsymbol{v}_2 - \boldsymbol{v}_1|| = \sqrt{(\boldsymbol{v}_2 - \boldsymbol{v}_1)^{\mathrm{T}}(\boldsymbol{v}_2 - \boldsymbol{v}_1)} \,, \tag{31.4}$$

where the operations on the right-hand side of (31.4) are matrix multiplication and transposition. If the $\boldsymbol{v}_i$ and $\boldsymbol{u}_i$ are related by (31.3),

$$\begin{aligned}\left(\boldsymbol{v}_j - \boldsymbol{v}_i\right)^{\mathrm{T}} \left(\boldsymbol{v}_j - \boldsymbol{v}_i\right) &= \left[\mathbf{B}(\boldsymbol{u}_j - \boldsymbol{u}_i)\right]^{\mathrm{T}} \times \left[\mathbf{B}(\boldsymbol{u}_j - \boldsymbol{u}_i)\right] \\ &= \left[(\boldsymbol{u}_j - \boldsymbol{u}_i)\right] \mathbf{B}^{\mathrm{T}}\mathbf{B} \left[(\boldsymbol{u}_j - \boldsymbol{u}_i)\right] \,.\end{aligned}$$

Thus if $||\boldsymbol{v}_j - \boldsymbol{v}_i|| = ||\boldsymbol{u}_j - \boldsymbol{u}_i||$ for all i and j, and if the $\boldsymbol{u}_i$ do not all lie in a $(p-1)$-dimensional hyperplane of $\mathbb{R}^p$,

$$\mathbf{I}_p = \mathbf{B}^{\mathrm{T}}\mathbf{B} = \mathbf{B}\mathbf{B}^{\mathrm{T}} \,. \tag{31.5}$$

Table 31.1 12 digitized locations on the left and right hand

	Left hand $\boldsymbol{u}_i$			Right hand $\boldsymbol{v}_i$		
A	5.17	11.30	16.18	5.91	11.16	16.55
B	7.40	12.36	17.50	8.63	10.62	18.33
C	8.56	12.59	17.87	10.09	10.60	18.64
D	9.75	13.62	17.01	10.89	10.95	17.90
E	11.46	14.55	12.96	12.97	10.13	13.88
F	7.10	13.12	12.56	8.79	11.21	13.17
G	8.85	13.82	12.60	10.70	11.10	13.42
H	6.77	13.07	10.32	8.47	11.09	11.35
I	6.26	11.62	13.34	7.28	12.52	14.04
J	6.83	12.00	13.83	8.05	12.42	14.56
K	7.94	12.29	13.84	9.07	12.39	14.86
L	8.68	12.71	13.67	10.15	12.17	14.44

A: Top of little finger; B: Top of ring finger; C: Top of middle finger; D: Top of forefinger; E: Top of thumb; F: Gap between thumb and forefinger; G: Center of palm; H: Base of palm; I: Little finger knuckle; J: Ring finger knuckle; K: Middle finger knuckle; L: Forefinger knuckle

Note that the first equality of (31.5) implies that $\mathbf{B}^{-1} = \mathbf{B}^{\mathrm{T}}$ and hence the second equality follows. Matrices which satisfy condition (31.5) are said to be *orthogonal*.

On the other hand, we might want to hypothesize that the two hands (again apart from statistical error) have the same shape except that one hand might be larger than the other. In this case we are hypothesizing

$$\mathbf{B} = \gamma \mathbf{A} \tag{31.6}$$

where $\mathbf{A}$ is orthogonal and γ is a positive real number.

In the Wahba and Chapman et al. problems, the rows of $\mathbf{A}$ are known to be an orthonormal basis of $\mathbb{R}^3$. Since the (i, j) entry of $\mathbf{A}\mathbf{A}^{\mathrm{T}}$ is the dot product of the i-th and j-th rows of $\mathbf{A}$, it follows that $\mathbf{A}$ is orthogonal. However, more is known. Since the unknown coordinate system is known to be right-handed,

$$\mathbf{A}^{\mathrm{T}}\mathbf{A} = \mathbf{I}_p, \quad \det(\mathbf{A}) = 1\,, \tag{31.7}$$

where $\det(\mathbf{A})$ is the determinant of the matrix $\mathbf{A}$. Such matrices are said to be *special orthogonal*.

In the hands data of Table 31.1, if we use the model (31.2) with condition (31.6), then $\mathbf{A}$ will not be special orthogonal. This is because the left and right hands have different orientations. However, it is common in image registration problems to assume that condition (31.6) is true with $\mathbf{A}$ assumed to be special orthogonal.

Following standard mathematical notation, we will use $\mathcal{O}(p)$ to denote the $p \times p$ orthogonal matrices [that is the set of all matrices which satisfy (31.5) and $\mathcal{SO}(p)$ to denote the subset of $\mathcal{O}(p)$ of special orthogonal matrices [that is the set of all matrices which satisfy (31.7)].

31.1.4 The Procrustes and Spherical Regression Models

In this chapter, we will be concerned with statistical methods which apply to the model (31.2) for Euclidean space data $\boldsymbol{u}_i, \boldsymbol{v}_i \in \mathbb{R}^p$, for arbitrary p, where $\mathbf{B}$ satisfies the condition (31.6) with $\mathbf{A}$ constrained to be either orthogonal or special orthogonal. Following Goodall [31.4], we will call this model the *Procrustes* model.

We will also consider models of the form (31.1), where the p-vectors $\boldsymbol{u}_i$ and $\boldsymbol{v}_i$ are constrained to be of unit length, that is

$$\boldsymbol{u}_i, \boldsymbol{v}_i \in \Omega_p = S^{p-1} = \left(\boldsymbol{x} \in \mathbb{R}^p \;\middle|\; \boldsymbol{x}^{\mathrm{T}}\boldsymbol{x} = 1\right)$$

and $\mathbf{A}$ is constrained to be either orthogonal or special orthogonal. Following *Chang* [31.5], we will call this model the *spherical regression* model.

The statistical methodology for these two models can easily be described in parallel. In general, we will focus on the Procrustes model, while giving the modifications that apply to the spherical regression model.

31.1.5 Least Squares, L_1, and M Estimation

In Sect. 31.2, we will derive the least squares estimate of $\mathbf{A}$, γ, $\boldsymbol{b}$ for the Procrustes model. This estimate minimizes

$$\rho_2(\mathbf{A}, \gamma, \boldsymbol{b}) = \sum_i ||\boldsymbol{v}_i - \gamma \mathbf{A}\boldsymbol{u}_i - \boldsymbol{b}||^2 \tag{31.8}$$

over all $\mathbf{A}$ in either $\mathcal{O}(p)$ or $\mathcal{SO}(p)$, constants $\gamma > 0$, and p-vectors $\boldsymbol{b} \in \mathbb{R}^p$. For the spherical regression model, the least squares estimate minimizes

$$\rho_2(\mathbf{A}) = \sum_i ||\boldsymbol{v}_i - \mathbf{A}\boldsymbol{u}_i||^2 \tag{31.9}$$

$$= 2n - 2\sum_i \boldsymbol{v}_i^{\mathrm{T}}\mathbf{A}\boldsymbol{u}_i \tag{31.10}$$

over all $\mathbf{A}$ in either $\mathcal{O}(p)$ or $\mathcal{SO}(p)$. For the second equality in (31.9), we have used that if $1 = \boldsymbol{v}^{\mathrm{T}}\boldsymbol{v} = \boldsymbol{u}^{\mathrm{T}}\boldsymbol{u}$, then

$$\begin{aligned} ||\boldsymbol{v} - \mathbf{A}\boldsymbol{u}||^2 &= (\boldsymbol{v} - \mathbf{A}\boldsymbol{u})^{\mathrm{T}}\,(\boldsymbol{v} - \mathbf{A}\boldsymbol{u}) \\ &= \boldsymbol{v}^{\mathrm{T}}\boldsymbol{v} - \boldsymbol{v}^{\mathrm{T}}\mathbf{A}\boldsymbol{u} - (\mathbf{A}\boldsymbol{u})^{\mathrm{T}}\boldsymbol{v} + \boldsymbol{u}^{\mathrm{T}}\mathbf{A}^{\mathrm{T}}\mathbf{A}\boldsymbol{u} \\ &= 2 - 2\boldsymbol{v}^{\mathrm{T}}\mathbf{A}\boldsymbol{u}\,. \end{aligned}$$

Least squares estimates have the advantage that an explicit closed-form solution for them is available. They have the disadvantage that they are very sensitive to *outliers*, that is points $(\boldsymbol{u}_i, \boldsymbol{v}_i)$ for which the error term in (31.2) is unusually large. In the image registration problem, an outlier can arise in several contexts. It can be the result of a measurement error, or it can be the result of a misidentified landmark. Perhaps the image is not very clear, or the landmark (e.g. 'point of the nose') cannot be very precisely determined, or the landmark is obscured (by clouds or shrubs, etc.). Or perhaps there are places in the image where the image is not really rigid, that is the ideal match (31.3) does not apply very well. It is easy to conceive of a myriad of situations which might give rise to outliers.

L_1 estimators are often used to ameliorate the effects of outliers. These estimators minimize

$$\rho_1(\mathbf{A}, \gamma, \boldsymbol{b}) = \sum_i ||\boldsymbol{v}_i - \gamma \mathbf{A}\boldsymbol{u}_i - \boldsymbol{b}||\,, \tag{31.11}$$

for the Procrustes model, or the sum of the distances along the surface of the sphere

$$\rho_1(\mathbf{A}) = \sum_i \arccos(\boldsymbol{v}_i^{\mathrm{T}} \mathbf{A} \boldsymbol{u}_i) \tag{31.12}$$

for the spherical regression model. Unfortunately, an explicit closed-form solution for the L_1 estimate is not available and it must be calculated by numerical minimization. We will offer a few suggestions on approaches for numerical minimization in Sect. 31.3.5.

The least squares and L_1 estimators are special cases of the so-called *M estimators*. These estimators minimize an objective function of the form

$$\rho(\mathbf{A}, \gamma, \boldsymbol{b}) = \sum_i \rho_0(s_i) \,, \tag{31.13}$$

where

$$s_i = ||\boldsymbol{v}_i - \gamma \mathbf{A} \boldsymbol{u}_i - \boldsymbol{b}||$$

and ρ_0 is some increasing function. Intermediate between the least squares and L_1 estimate is the *Huber* estimate for which

$$\rho_0(s) = \begin{cases} (s/b)^2 & s < b \\ s/b & s \geq b \end{cases}$$

for some preset constant b. Or we can *Windsorize* the estimate

$$\rho_0(s) = \begin{cases} (s/b)^2 & s < b \\ 1 & s \geq b \end{cases} .$$

In the linear regression context, these and other objective functions are discussed in *Huber* [31.6].

For the spherical regression model, an M-estimator minimizes an objective function of the form

$$\rho(\mathbf{A}) = \sum_i \rho_0(t_i) \,, \tag{31.14}$$

where

$$t_i = \boldsymbol{v}_i^{\mathrm{T}} \mathbf{A} \boldsymbol{u}_i \,.$$

Notice that, as $\boldsymbol{v}$ moves away from $\mathbf{A}\boldsymbol{u}$ towards the antipodal point $-\mathbf{A}\boldsymbol{u}$, $t = \boldsymbol{v}^{\mathrm{T}} \mathbf{A} \boldsymbol{u}$ *decreases* from 1 to -1. Thus, for the spherical case, $\rho_0(t)$ is chosen to be a decreasing function of t.

In Sect. 31.4 we will discuss the statistical properties of M-estimates. We will see how the geometry of the data translates into the error structure of the estimate. In the image registration problem, this information can be used, for example, to help select landmarks. General statistical theory indicates under certain conditions ("normal distribution") the least squares solution is optimal. However, if we were to use a L_1 estimate to guard against outliers, we would suffer a penalty of 13% for image registrations in two dimensions and only 8% for image registrations in three dimensions, even when least squares is theoretically optimal. We will make more precise in Sect. 31.4 how this *penalty* is defined. The important point to realize is that, especially for three-dimensional image registrations, L_1 estimators offer important protections against outliers in the data at very modest cost in the statistical efficiency of the estimator.

In Sect. 31.5, we will discuss diagnostics for the Procrustes and spherical regression models. If the image registration is not satisfactory, this section will give tools to determine which of the landmarks is causing the unsatisfactory registration. It will follow, for example, that landmarks which greatly influence $\mathbf{A}$ will have negligible influence on γ and vice versa.

31.2 Least Squares Estimation

31.2.1 Group Properties of $\mathcal{O}(p)$ and $\mathcal{SO}(p)$

It is important to note that $\mathcal{O}(p)$ and $\mathcal{SO}(p)$ are groups in the mathematical sense. That is, if $\mathbf{A}, \mathbf{B} \in \mathcal{O}(p)$, then

$$(\mathbf{AB})^{\mathrm{T}}(\mathbf{AB}) = \mathbf{B}^{\mathrm{T}}\mathbf{A}^{\mathrm{T}}\mathbf{AB} = \mathbf{B}^{\mathrm{T}}\mathbf{I}_p\mathbf{B} = \mathbf{I}_p$$

since both $\mathbf{A}$ and $\mathbf{B}$ satisfy (31.5). Thus $\mathbf{AB} \in \mathcal{O}(p)$. Similarly if $\mathbf{A} \in \mathcal{O}(p)$, then (31.5) implies that $\mathbf{A}^{-1} = \mathbf{A}^{\mathrm{T}} \in \mathcal{O}(p)$. This implies that $\mathcal{O}(p)$ is a group. Furthermore, if $\det(\mathbf{A}) = \det(\mathbf{B}) = 1$, then $\det(\mathbf{AB}) = \det(\mathbf{A})\det(\mathbf{B}) = 1$ and $\det(\mathbf{A}^{-1}) = 1/\det(\mathbf{A}) = 1$. In summary we have

$$\begin{aligned} &\text{If } \mathbf{A}, \mathbf{B} \in \mathcal{O}(p), \text{ then } \mathbf{AB} \in \mathcal{O}(p) \\ &\text{and } \mathbf{A}^{-1} = \mathbf{A}^{\mathrm{T}} \in \mathcal{O}(p) \\ &\text{If } \mathbf{A}, \mathbf{B} \in \mathcal{SO}(p), \text{ then } \mathbf{AB} \in \mathcal{SO}(p) \\ &\text{and } \mathbf{A}^{-1} = \mathbf{A}^{\mathrm{T}} \in \mathcal{SO}(p) \,. \end{aligned} \tag{31.15}$$

Notice also that, if $\mathbf{A}$ satisfies (31.5), then

$$1 = \det(\mathbf{A}^{\mathrm{T}}\mathbf{A}) = [\det(\mathbf{A})]^2$$

so that $\det(\mathbf{A}) = 1, -1$.

31.2.2 Singular Value Decomposition

Given a $p \times q$ matrix $\mathbf{X}$ its *singular value decomposition* is

$$\mathbf{X} = \mathbf{O}_1 \Lambda \mathbf{O}_2^{\mathrm{T}} , \tag{31.16}$$

where $\mathbf{O}_1 \in \mathcal{O}(p)$, $\mathbf{O}_2 \in \mathcal{O}(q)$ and $\mathbf{\Lambda}$ is $p \times q$. If $p \le q$, $\mathbf{\Lambda}$ has block form

$$\mathbf{\Lambda} = \left[\operatorname{diag}(\lambda_1, \cdots, \lambda_p) \;\; \mathbf{0}_{(p,q-p)} \right]$$

Here $\operatorname{diag}(\lambda_1, \cdots, \lambda_p)$ is a diagonal matrix with entries $\lambda_1 \ge \cdots \ge \lambda_p$ and $\mathbf{0}_{(p,q-p)}$ is a $p \times (q-p)$ matrix with all zeros. If $q \le p$

$$\mathbf{\Lambda} = \begin{pmatrix} \operatorname{diag}(\lambda_1, \cdots, \lambda_q) \\ \mathbf{0}_{(p-q,q)} \end{pmatrix} .$$

Most mathematical software packages now include the singular value decomposition. However, it can be computed using a package which only computes eigen-decompositions of symmetric matrices. Suppose temporarily $p \le q$. Since $\mathbf{X}\mathbf{X}^{\mathrm{T}}$ is a symmetric nonnegative definite matrix, its eigen-decomposition has the form

$$\mathbf{X}\mathbf{X}^{\mathrm{T}} = \mathbf{O}_1 \mathbf{\Lambda}_1 \mathbf{O}_1^{\mathrm{T}} ,$$

where $\mathbf{O}_1 \in \mathcal{O}(p)$ and $\mathbf{\Lambda}_1 = \operatorname{diag}(\lambda_1^2, \cdots, \lambda_p^2)$ with $\lambda_1 \ge \cdots \ge \lambda_p \ge 0$. The columns of $\mathbf{O}_1$ are the eigenvectors of $\mathbf{X}\mathbf{X}^{\mathrm{T}}$ and $\lambda_1^2, \cdots, \lambda_p^2$ are the corresponding eigenvalues. Suppose $\lambda_p > 0$ and let $\widetilde{\mathbf{O}}_2 = \mathbf{X}^{\mathrm{T}} \mathbf{O}_1 \mathbf{\Lambda}_1^{-1/2}$. $\widetilde{\mathbf{O}}_2$ is $q \times p$, but

$$\begin{aligned} \widetilde{\mathbf{O}}_2^{\mathrm{T}} \widetilde{\mathbf{O}}_2 &= \mathbf{\Lambda}_1^{-1/2} \mathbf{O}_1^{\mathrm{T}} \mathbf{X}\mathbf{X}^{\mathrm{T}} \mathbf{O}_1 \mathbf{\Lambda}_1^{-1/2} \\ &= \mathbf{\Lambda}_1^{-1/2} \mathbf{O}_1^{\mathrm{T}} \mathbf{O}_1 \mathbf{\Lambda}_1 \mathbf{O}_1^{\mathrm{T}} \mathbf{O}_1 \mathbf{\Lambda}_1^{-1/2} \\ &= \mathbf{\Lambda}_1^{-1/2} \mathbf{\Lambda}_1 \mathbf{\Lambda}_1^{-1/2} = \mathbf{I}_p , \end{aligned}$$

so that the columns of $\widetilde{\mathbf{O}}_2$ are orthonormal. Furthermore

$$\mathbf{O}_1 \mathbf{\Lambda}_1^{1/2} \widetilde{\mathbf{O}}_2^{\mathrm{T}} = \mathbf{O}_1 \mathbf{\Lambda}_1^{1/2} \mathbf{\Lambda}_1^{-1/2} \mathbf{O}_1^{\mathrm{T}} \mathbf{X} = \mathbf{X} .$$

Filling $\mathbf{\Lambda}_1^{1/2}$ with $q - p$ columns of zeros, and completing the columns of $\widetilde{\mathbf{O}}_2$ to an orthonormal basis of $\mathbb{R}^q$ yields the decomposition (31.16).

Extensions to the cases when $\lambda_p = 0$ or when $q \le p$ will not be difficult for the careful reader.

31.2.3 Least Squares Estimation in the Procrustes Model

The least squares estimation of the Procrustes model (31.2) has long been known (see, for example, Goodall [31.4]). Let $\overline{\boldsymbol{u}} = n^{-1} \sum_i \boldsymbol{u}_i$, where n is the number of pairs $(\boldsymbol{u}_i, \boldsymbol{v}_i)$ and let $\overline{\boldsymbol{v}}$ be similarly defined. Define the $p \times p$ matrix $\mathbf{X}$ by

$$\mathbf{X} = \sum_i (\boldsymbol{u}_i - \overline{\boldsymbol{u}})(\boldsymbol{v}_i - \overline{\boldsymbol{v}})^{\mathrm{T}} .$$

Then

$$\begin{aligned} \rho_2(\mathbf{A}, \gamma, \boldsymbol{b}) &= \sum_i ||\boldsymbol{v}_i - \gamma \mathbf{A}\boldsymbol{u}_i - \boldsymbol{b}||^2 \\ &= \sum_i ||\boldsymbol{v}_i - \overline{\boldsymbol{v}} - \gamma \mathbf{A}(\boldsymbol{u}_i - \overline{\boldsymbol{u}}) \\ &\quad - [\boldsymbol{b} - (\overline{\boldsymbol{v}} - \gamma \mathbf{A}\overline{\boldsymbol{u}})]\,||^2 \\ &= \sum_i ||\boldsymbol{v}_i - \overline{\boldsymbol{v}}||^2 \\ &\quad - \gamma \sum_i (\boldsymbol{u}_i - \overline{\boldsymbol{u}})^{\mathrm{T}} \mathbf{A}^{\mathrm{T}} (\boldsymbol{v}_i - \overline{\boldsymbol{v}}) \\ &\quad - \gamma \sum_i (\boldsymbol{v}_i - \overline{\boldsymbol{v}})^{\mathrm{T}} \mathbf{A} (\boldsymbol{u}_i - \overline{\boldsymbol{u}}) \\ &\quad + \gamma^2 \sum_i ||\boldsymbol{u}_i - \overline{\boldsymbol{u}}||^2 \\ &\quad + n||\boldsymbol{b} - (\overline{\boldsymbol{v}} - \gamma \mathbf{A}\overline{\boldsymbol{u}})||^2 . \end{aligned}$$

All the other cross-product terms sum to zero. Now

$$\begin{aligned} &\sum_i (\boldsymbol{v}_i - \overline{\boldsymbol{v}})^{\mathrm{T}} \mathbf{A} (\boldsymbol{u}_i - \overline{\boldsymbol{u}}) \\ &= \sum_i \operatorname{Tr}\left[(\boldsymbol{v}_i - \overline{\boldsymbol{v}})^{\mathrm{T}} \mathbf{A} (\boldsymbol{u}_i - \overline{\boldsymbol{u}}) \right] \\ &= \sum_i \operatorname{Tr}\left[\mathbf{A} (\boldsymbol{u}_i - \overline{\boldsymbol{u}})(\boldsymbol{v}_i - \overline{\boldsymbol{v}})^{\mathrm{T}} \right] = \operatorname{Tr}(\mathbf{A}\mathbf{X}) \end{aligned}$$

and

$$\begin{aligned} &\sum_i (\boldsymbol{u}_i - \overline{\boldsymbol{u}})^{\mathrm{T}} \mathbf{A}^{\mathrm{T}} (\boldsymbol{v}_i - \overline{\boldsymbol{v}}) \\ &= \sum_i (\boldsymbol{v}_i - \overline{\boldsymbol{v}})^{\mathrm{T}} \mathbf{A} (\boldsymbol{u}_i - \overline{\boldsymbol{u}}) = \operatorname{Tr}(\mathbf{A}\mathbf{X}) . \end{aligned}$$

Therefore

$$\begin{aligned} \rho_2(\mathbf{A}, \gamma, \boldsymbol{b}) &= \sum_i ||\boldsymbol{v}_i - \overline{\boldsymbol{v}}||^2 - 2\gamma \operatorname{Tr}(\mathbf{A}\mathbf{X}) \\ &\quad + \gamma^2 \sum_i ||\boldsymbol{u}_i - \overline{\boldsymbol{u}}||^2 \\ &\quad + n||\boldsymbol{b} - (\overline{\boldsymbol{v}} - \gamma \mathbf{A}\overline{\boldsymbol{u}})||^2 . \end{aligned} \tag{31.17}$$

Substituting (31.16),

$$\begin{aligned} \operatorname{Tr}(\mathbf{A}\mathbf{X}) &= \operatorname{Tr}\left(\mathbf{A}\mathbf{O}_1 \mathbf{\Lambda} \mathbf{O}_2^{\mathrm{T}} \right) = \operatorname{Tr}\left(\mathbf{O}_2^{\mathrm{T}} \mathbf{A}\mathbf{O}_1 \mathbf{\Lambda} \right) \\ &= \sum_i \lambda_i e_{ii} , \end{aligned}$$

where e_{ii} are the diagonal entries of $\mathbf{O}_2^{\mathrm{T}}\mathbf{A}\mathbf{O}_1 \in \mathcal{O}(p)$. Now $|e_{ii}| \le 1$ and hence $\mathrm{Tr}\,(\mathbf{A}\mathbf{X})$ is maximized when $e_{ii} = 1$ or, equivalently, when $\mathbf{O}_2^{\mathrm{T}}\mathbf{A}\mathbf{O}_1 = \mathbf{I}_p$. This implies $\mathbf{A} = \mathbf{O}_2\mathbf{O}_1^{\mathrm{T}}$.

Thus if $\left(\widehat{\mathbf{A}}, \widehat{\gamma}, \widehat{\boldsymbol{b}}\right)$ minimizes (31.17),

$$\begin{aligned}
\widehat{\mathbf{A}} &= \mathbf{O}_2\mathbf{O}_1^{\mathrm{T}}\,, \\
\widehat{\gamma} &= \left(\sum_i ||\boldsymbol{u}_i - \overline{\boldsymbol{u}}||^2\right)^{-1} \mathrm{Tr}\left(\widehat{\mathbf{A}}\mathbf{X}\right) \\
&= \left(\sum_i ||\boldsymbol{u}_i - \overline{\boldsymbol{u}}||^2\right)^{-1} \sum_i \lambda_i\,, \qquad (31.18) \\
\widehat{\boldsymbol{b}} &= \overline{\boldsymbol{v}} - \widehat{\gamma}\widehat{\mathbf{A}}\overline{\boldsymbol{u}}\,.
\end{aligned}$$

If $\mathbf{A}$ is constrained to lie in $\mathcal{SO}(p)$, we use a modified singular value decomposition. Let $\mathbf{X} = \widetilde{\mathbf{O}}_1\widetilde{\mathbf{\Lambda}}\widetilde{\mathbf{O}}_2^{\mathrm{T}}$ be the (usual) singular value decomposition of $\mathbf{X}$ and let

$$\mathbf{E} = \mathrm{diag}(1, \cdots, 1, -1) \qquad (31.19)$$

be the identity matrix with its last entry changed to -1. Let $\mathbf{O}_1 = \widetilde{\mathbf{O}}_1\mathbf{E}^{\delta_1}$ where $\delta_1 = 0$ if $\widetilde{\mathbf{O}}_1 \in \mathcal{SO}(p)$ and $\delta_1 = 1$ otherwise.

Similarly define δ_2 and $\mathbf{O}_2$. Finally write $\mathbf{\Lambda} = \widetilde{\mathbf{\Lambda}}\mathbf{E}^{\delta_1+\delta_2}$. Then (31.16) is valid with $\mathbf{O}_1, \mathbf{O}_2 \in \mathcal{SO}(p)$ and $\lambda_1 \ge \cdots \ge \lambda_{p-1} \ge |\lambda_p|$.

This is the modified singular value decomposition.

The least squares estimates, subject to the contraint $\widehat{\mathbf{A}} \in \mathcal{SO}(p)$, is still given by (31.18) when a modified singular value decomposition is used for $\mathbf{X}$.

31.2.4 Example: Least Squares Estimates for the Hands Data

Consider, for example, the hands data in Table 31.1. For this data

$$\begin{aligned}
\overline{\boldsymbol{u}} &= \begin{pmatrix} 7.8975 \\ 12.7542 \\ 14.3067 \end{pmatrix}\,, \quad \overline{\boldsymbol{v}} = \begin{pmatrix} 9.2500 \\ 11.3633 \\ 15.0950 \end{pmatrix}\,, \\
\mathbf{X} &= \left[\begin{pmatrix} 5.17 \\ 11.30 \\ 16.18 \end{pmatrix} - \overline{\boldsymbol{u}}\right]\left[\begin{pmatrix} 5.91 \\ 11.16 \\ 16.55 \end{pmatrix} - \overline{\boldsymbol{v}}\right]^{\mathrm{T}} + \\
&\quad \cdots + \left[\begin{pmatrix} 8.68 \\ 12.71 \\ 13.67 \end{pmatrix} - \overline{\boldsymbol{u}}\right]\left[\begin{pmatrix} 10.15 \\ 12.17 \\ 14.44 \end{pmatrix} - \overline{\boldsymbol{v}}\right]^{\mathrm{T}} \\
&= \begin{pmatrix} 34.0963 & -6.9083 & 3.5769 \\ 17.3778 & -4.9028 & -5.6605 \\ -2.3940 & -5.7387 & 57.8598 \end{pmatrix}\,.
\end{aligned}$$

The singular value decomposition $\mathbf{X} = \mathbf{O}_1\mathbf{\Lambda}\mathbf{O}_2^{\mathrm{T}}$ is given by

$$\mathbf{O}_1 = \begin{pmatrix} 0.0465 & -0.8896 & -0.4544 \\ -0.1012 & -0.4567 & 0.8838 \\ 0.9938 & -0.0048 & 0.1112 \end{pmatrix}\,,$$

$$\mathbf{O}_2 = \begin{pmatrix} -0.0436 & -0.9764 & -0.2114 \\ -0.0944 & 0.2147 & -0.9721 \\ 0.9946 & -0.0224 & -0.1015 \end{pmatrix}$$

$$\mathbf{\Lambda} = \mathrm{diag}(58.5564, 39.1810, 1.8855)\,.$$

Hence (31.18) yields

$$\widehat{\mathbf{A}} = \begin{pmatrix} 0.9627 & 0.2635 & -0.0621 \\ 0.2463 & -0.9477 & -0.2030 \\ 0.1123 & -0.1801 & 0.9772 \end{pmatrix}\,,$$

$$\widehat{\gamma} = 0.9925\,, \qquad (31.20)$$

$$\widehat{\boldsymbol{b}} = \begin{pmatrix} -0.7488 & 24.3115 & 2.6196 \end{pmatrix}^{\mathrm{T}}\,.$$

Notice that $\det(\widehat{\mathbf{A}}) = -1$ so $\widehat{\mathbf{A}} \notin \mathcal{SO}(3)$. We expect this result since, as previously remarked, the left and right hands have different orientations. The value of $\widehat{\gamma}$ is somewhat puzzling since the subject is right-handed and one would expect, therefore, $\gamma > 1$. Although, as we will see in Sect. 31.4, the difference between $\widehat{\gamma}$ and 1 is not significant, a better estimate would have been achieved if the L_1 objective function (31.11) were numerically minimized instead. In this case $\widehat{\gamma} = 1.0086$. Our analysis will show that the hands data set has an outlier and we see here an example of the superior resistance of L_1 estimates to outliers.

31.2.5 Least Squares Estimation in the Spherical Regression Model

Least squares estimation for the spherical regression model is similar to least squares estimation in the Procrustes model. Let $\mathbf{X} = \sum_i \boldsymbol{u}_i\boldsymbol{v}_i^{\mathrm{T}}$ and define $\mathbf{O}_1, \mathbf{O}_2 \in \mathcal{O}(p)$ using a singular value decomposition of $\mathbf{X}$. Then $\widehat{\mathbf{A}} = \mathbf{O}_2\mathbf{O}_1^{\mathrm{T}}$. If, on the other hand, it is desired to constrain $\widehat{\mathbf{A}}$ to $\mathcal{SO}(p)$, one defines $\mathbf{O}_1, \mathbf{O}_2 \in \mathcal{SO}(p)$ using a modified singular value decomposition and, again, $\widehat{\mathbf{A}} = \mathbf{O}_2\mathbf{O}_1^{\mathrm{T}}$.

31.3 Geometry of $\mathcal{O}(p)$ and $\mathcal{SO}(p)$

$\mathcal{O}(p)$ and $\mathcal{SO}(p)$ arise because they give distance-preserving transformations of $\mathbb{R}^p$, and to formulate properly the statistical properties of $\widehat{\mathbf{A}}$ defined by (31.18), it is important to understand the geometry of these two groups.

31.3.1 $\mathcal{SO}(p)$ for $p = 2$

For $p = 2$,

$$\mathcal{SO}(2) = \left\{ \Phi_2(h) = \begin{pmatrix} \cos(h) & -\sin(h) \\ \sin(h) & \cos(h) \end{pmatrix} \middle| \, h \in \mathbb{R}^1 \right\} . \tag{31.21}$$

Physically $\Phi_2(h)$ represents a rotation of $\mathbb{R}^2$ by an angle of h radians. Since $\Phi_2(h) = \Phi_2(h + 2\pi)$, $\mathcal{SO}(2)$ is geometrically a circle.

Since each element of $\mathcal{SO}(2)$ has four entries, it is tempting to think of $\mathcal{SO}(2)$ as four-dimensional. However as (31.21) makes clear, $\mathcal{SO}(2)$ can be described by one parameter $h \in \mathbb{R}^1$. Thus $\mathcal{SO}(2)$ is really one-dimensional. Suppose we were constrained to live on a circle Ω_2 (instead of the sphere Ω_3). At each point on Ω_2 we can only travel to our left or to our right, and, if our travels were limited, it would appear as if we only had one-dimensional travel. Mathematicians describe this situation by saying that $\mathcal{SO}(2)$ is a one-dimensional *manifold*.

Notice also $\Phi_2(0) = \mathbf{I}_2$ and that, if h is small, then $\Phi_2(h)$ is close to $\mathbf{I}_2$. Thus, if h is small, $\Phi_2(h)\boldsymbol{x}$ is close to $\boldsymbol{x}$ for all $\boldsymbol{x} \in \mathbb{R}^2$. As we shall see, this simple observation is key to understanding our approach to the statistical properties of $\widehat{\mathbf{A}}$.

31.3.2 $\mathcal{SO}(p)$ for $p = 3$

$\mathcal{SO}(3)$ can be described as the collection of all rotations in $\mathbb{R}^3$. That is

$$\mathcal{SO}(3) = \left\{ \Phi_3(\boldsymbol{h}) \mid \boldsymbol{h} \in \mathbb{R}^3 \right\} , \tag{31.22}$$

where $\Phi_3(\boldsymbol{h})$ is right-hand rule rotation of $||\boldsymbol{h}||$ radians around the axis $||\boldsymbol{h}||^{-1}\boldsymbol{h}$. Writing $\theta = ||\boldsymbol{h}||$ and $\xi = ||\boldsymbol{h}||^{-1}\boldsymbol{h}$, so that ξ is a unit-length three-dimensional vector, it can be shown that

$$\begin{aligned} &\Phi_3(\boldsymbol{h}) \\ &= \Phi_3(\theta\xi) \\ &= \cos(\theta)\mathbf{I}_3 + \sin(\theta)M_3(\xi) + [1 - \cos(\theta)]\,\xi\xi^{\mathrm{T}} , \end{aligned} \tag{31.23}$$

where

$$M_3(\xi) = M_3 \begin{pmatrix} \xi_1 \\ \xi_2 \\ \xi_3 \end{pmatrix} = \begin{pmatrix} 0 & -\xi_3 & \xi_2 \\ \xi_3 & 0 & -\xi_1 \\ -\xi_2 & \xi_1 & 0 \end{pmatrix} .$$

Thus, although each $\mathbf{A} \in \mathcal{SO}(3)$ has nine entries, $\mathcal{SO}(3)$ is actually a three-dimensional manifold.

Again we notice that $\Phi_3(\mathbf{0}) = \mathbf{I}_3$ and that if $||\boldsymbol{h}||$ is small then $\Phi_3(\boldsymbol{h})\boldsymbol{x}$ is close to $\boldsymbol{x}$ for all $\boldsymbol{x} \in \mathbb{R}^3$.

For future use, we note that if $\mathbf{C} \in \mathcal{SO}(3)$, then the axis ξ of the rotation represented by $\mathbf{C}$ satisfies $\mathbf{C}\xi = \xi$. Thus ξ is the eigenvector associated to the eigenvalue 1 of $\mathbf{C}$. By re-representing $\mathbf{C}$ in an orthonormal basis which includes ξ, one can show that the angle of rotation θ of the rotation represented by $\mathbf{C}$ satisfies $1 + 2\cos(\theta) = \mathrm{Tr}(\mathbf{C})$. Thus, if ξ and θ are calculated in this way, $\Phi_3(\theta\xi) = \mathbf{C}$.

31.3.3 $\mathcal{SO}(p)$ and $\mathcal{O}(p)$, for General p, and the Matrix Exponential Map

For general p, let $\mathbf{H}$ be a $p \times p$ *skew-symmetric* matrix; that is

$$\mathbf{H}^{\mathrm{T}} = -\mathbf{H} .$$

We define the matrix exponential map by

$$\exp(\mathbf{H}) = \sum_{k=0}^{k=\infty} \frac{\mathbf{H}^k}{k!} .$$

It can be shown that the skew-symmetry condition implies that $\exp(\mathbf{H})\left[\exp(\mathbf{H})\right]^{\mathrm{T}} = \mathbf{I}_p$ and indeed

$$\mathcal{SO}(p) = \left[\exp(\mathbf{H}) \mid \mathbf{H} \text{ is skew-symmetric}\right] . \tag{31.24}$$

A skew-symmetric matrix must have zeros on its main diagonal and its entries below the main diagonal are determined by its entries above the main diagonal. Thus the skew-symmetric $p \times p$ matrices have $p(p-1)/2$ independent entries and hence $\mathcal{SO}(p)$ is a manifold with dimension $p(p-1)/2$.

Let $\mathbf{0}_{(p,p)}$ be a $p \times p$ matrix of zeros. Then

$$\exp(\mathbf{0}_{(p,p)}) = \mathbf{I}_p . \tag{31.25}$$

Thus, if the entries of $\mathbf{H}$ are small (in absolute value), then $\exp(\mathbf{H})$ will be close to the identity matrix.

For $p = 3$, it can be shown, by using (31.23), that $\Phi_3(\boldsymbol{h}) = \exp\left[M_3(\boldsymbol{h})\right]$ for $\boldsymbol{h} \in \mathbb{R}^3$. Similarly we define for

$h \in \mathbb{R}^1$ the skew-symmetric matrix

$$M_2(h) = \begin{pmatrix} 0 & -h \\ h & 0 \end{pmatrix}$$

and it follows that $\Phi_2(h) = \exp[M_2(h)]$. Thus (31.21) and (31.22) are indeed special cases of (31.24).

$\mathcal{O}(p)$ has two connected components; one is $\mathcal{SO}(p)$ and the other is

$$\mathcal{SO}(p)\boldsymbol{E} = \{\mathbf{A}\boldsymbol{E} \mid \mathbf{A} \in \mathcal{SO}(p)\}\,,$$

where $\boldsymbol{E}$ has been previously defined in (31.19). Notice that $\boldsymbol{E}$ is a reflection of $\mathbb{R}^p$ through the $(p-1)$-dimensional hyperplane perpendicular to the last coordinate vector. Indeed all reflections of $\mathbb{R}^p$ are in $\mathcal{O}(p)$.

31.3.4 Geometry and the Distribution of *M*-Estimates

So, heuristically speaking, suppose we have estimates $\left(\widehat{\mathbf{A}}, \widehat{\gamma}, \widehat{\boldsymbol{b}}\right)$ which minimize an objective function of the form (31.13). What values of the unknown parameters $(\mathbf{A}, \gamma, \boldsymbol{b})$ should we consider as reasonable given the data? The obvious answer, which is fully consistent with the usual practices of statistics, is those $(\mathbf{A}, \gamma, \boldsymbol{b})$ which do not excessively degrade the fit of the best-fit parameters $\left(\widehat{\mathbf{A}}, \widehat{\gamma}, \widehat{\boldsymbol{b}}\right)$; that is those $(\mathbf{A}, \gamma, \boldsymbol{b})$ for which

$$\begin{aligned}\rho(\mathbf{A}, \gamma, \boldsymbol{b}) - \rho\left(\widehat{\mathbf{A}}, \widehat{\gamma}, \widehat{\boldsymbol{b}}\right) \\ = \sum_i \left[\rho_0(||\boldsymbol{v}_i - \gamma\mathbf{A}\boldsymbol{u}_i - \boldsymbol{b}||)\right. \\ \left. - \rho_0(||\boldsymbol{v}_i - \widehat{\gamma}\widehat{\mathbf{A}}\boldsymbol{u}_i - \widehat{\boldsymbol{b}}||)\right]\end{aligned}$$

is not too large.

Recall that, for $p = 3$, if $\boldsymbol{h}$ is small, then $\Phi_3(\boldsymbol{h})\boldsymbol{u}_i$ will be close to $\boldsymbol{u}_i$. This suggests writing

$$\widehat{\mathbf{A}} = \mathbf{A}\Phi_3(\widehat{\boldsymbol{h}})\,, \tag{31.26}$$

where $\widehat{\boldsymbol{h}} \in \mathbb{R}^3$. Then $\mathbf{A}\boldsymbol{u}_i = \widehat{\mathbf{A}}\Phi_3(-\widehat{\boldsymbol{h}})\boldsymbol{u}_i$ will be close to $\widehat{\mathbf{A}}\boldsymbol{u}_i$ when $\widehat{\boldsymbol{h}}$ is small. Rather than focus on the distribution of $\widehat{\mathbf{A}}$, we will focus on the distribution of the *deviation* of $\widehat{\mathbf{A}}$ from $\mathbf{A}$ as measured by the (hopefully) small vector $\widehat{\boldsymbol{h}}$.

Similarly, for $p = 2$, we will write

$$\widehat{\mathbf{A}} = \mathbf{A}\Phi_2(\widehat{h})\,, \tag{31.27}$$

where $\widehat{h} \in \mathbb{R}^1$. For general p, one writes

$$\widehat{\mathbf{A}} = \mathbf{A}\exp(\widehat{\mathbf{H}})\,, \tag{31.28}$$

where $\widehat{\mathbf{H}}$ is $p \times p$ skew-symmetric.

The most elementary procedures in statistics are based upon the fact

> *If $X_1, \cdots, X_n$ are independent and each X_i is distributed $N(\mu, \sigma^2)$, then $\overline{X}$ is distributed $N(\mu, \sigma^2/n)$.*

An equivalent result is

> *If $X_1, \cdots, X_n$ are independent and each X_i is distributed $N(\mu, \sigma^2)$, then $\overline{X} - \mu$ is distributed $N(0, \sigma^2/n)$.*

In the latter form, we have an estimator (in this case $\overline{X}$) and the distribution of the *deviation* $\widehat{h} = \overline{X} - \mu$ of the estimator from the unknown parameter μ. This is sufficient for both confidence intervals and hypothesis testing and is analogous to what we propose to do in Sect. 31.4.

We note that $\Phi_3(\boldsymbol{h}) = \mathbf{I}_3$ whenever $||\boldsymbol{h}|| = 2\pi$. This implies that Φ_3 will have a singularity as $||\boldsymbol{h}|| \to 2\pi$. However, Φ_3 behaves very well for small $\boldsymbol{h}$ and hence (31.26) is a good way to parameterize $\widehat{\mathbf{A}}$ close to $\mathbf{A}$.

All parameterizations of $\mathcal{SO}(3)$ have singularities somewhere. By using parameterizations such as (31.26), (31.27), or (31.28), we put those singularities far away from the region of interest, that is far away from $\mathbf{A}$. As we will see in Sects. 31.4 and 31.5, the result is very clean mathematics. However, some formulations of Euler angles [31.7] have a singularity at $\boldsymbol{h} = \mathbf{0}$. This means that Euler angles are an especially poor parameterization of small rotations in $\mathcal{SO}(3)$ (that is, for $\mathbf{A}$ close to $\mathbf{I}_3$) and that, if we were to repeat the calculations of Sect. 31.4 and 31.5 using Euler angles, the results would be much messier.

31.3.5 Numerical Calculation of *M*-Estimates for the Procrustes Model

We use here the geometric insights into $\mathcal{SO}(p)$ to propose a method of minimizing the objective function (31.13) for the Procrustes model. The simplifications necessary to minimize the objective function (31.14) for the spherical regression model should be reasonably clear.

In what follows, it will be convenient to rewrite the Procrustes model

$$\boldsymbol{v}_i = \gamma\mathbf{A}\boldsymbol{u}_i + \boldsymbol{b} + \text{error}$$

in the equivalent form

$$\boldsymbol{v}_i = \gamma\mathbf{A}(\boldsymbol{u}_i - \overline{\boldsymbol{u}}) + \boldsymbol{\beta} + \text{error}\,, \tag{31.29}$$

where $\boldsymbol{\beta} = \gamma\mathbf{A}\overline{\boldsymbol{u}} + \boldsymbol{b}$.

Let $\psi(s) = \rho_0'(s)$. Differentiating (31.13) with respect to γ and $\boldsymbol{\beta}$ we get that the M-estimates $(\widehat{\mathbf{A}}, \widehat{\gamma}, \widehat{\boldsymbol{\beta}})$ must satisfy.

$$0 = \sum_i \psi(s_i) s_i^{-1} \left[\boldsymbol{v}_i - \widehat{\gamma}\widehat{\mathbf{A}}(\boldsymbol{u}_i - \overline{\boldsymbol{u}}) - \widehat{\boldsymbol{\beta}} \right]^{\mathrm{T}} \times \widehat{\mathbf{A}}(\boldsymbol{u}_i - \overline{\boldsymbol{u}}) \,, \tag{31.30}$$

$$0 = \sum_i \psi(s_i) s_i^{-1} \left[\boldsymbol{v}_i - \widehat{\gamma}\widehat{\mathbf{A}}(\boldsymbol{u}_i - \overline{\boldsymbol{u}}) - \widehat{\boldsymbol{\beta}} \right] \,, \tag{31.31}$$

where $s_i = \left|\left| \boldsymbol{v}_i - \widehat{\gamma}\widehat{\mathbf{A}}(\boldsymbol{u}_i - \overline{\boldsymbol{u}}) - \widehat{\boldsymbol{\beta}} \right|\right|$.

To differentiate (31.13) with respect to $\mathbf{A}$, we note that, if $\mathbf{H}$ is any skew-symmetric matrix, and using (31.25),

$$\begin{aligned} 0 &= \frac{\mathrm{d}}{\mathrm{d}t}\Big|_{t=0} \left\{ \sum_i \rho_0 \left[\left|\left| \boldsymbol{v}_i - \widehat{\gamma}\widehat{\mathbf{A}}\exp(t\mathbf{H}) \right.\right.\right. \\ &\quad \left.\left.\left. \times (\boldsymbol{u}_i - \overline{\boldsymbol{u}}) - \widehat{\boldsymbol{\beta}} \right|\right| \right] \right\} \\ &= -\gamma \sum_i \psi(s_i) s_i^{-1} \left[\boldsymbol{v}_i - \widehat{\gamma}\widehat{\mathbf{A}}\,(\boldsymbol{u}_i - \overline{\boldsymbol{u}}) - \widehat{\boldsymbol{\beta}} \right]^{\mathrm{T}} \\ &\quad \times \widehat{\mathbf{A}}\mathbf{H}(\boldsymbol{u}_i - \overline{\boldsymbol{u}}) \\ &= -\gamma \mathrm{Tr}(\widetilde{\mathbf{X}}\mathbf{H}), \end{aligned}$$

where

$$\widetilde{\mathbf{X}} = \sum_i \psi(s_i) s_i^{-1} \, (\boldsymbol{u}_i - \overline{\boldsymbol{u}}) \left[\boldsymbol{v}_i - \widehat{\gamma}\widehat{\mathbf{A}}(\boldsymbol{u}_i - \overline{\boldsymbol{u}}) - \widehat{\boldsymbol{\beta}} \right]^{\mathrm{T}} \widehat{\mathbf{A}} \,.$$

Since $\mathbf{H}$ is any skew-symmetric matrix, $\widetilde{\mathbf{X}}$ is symmetric. Equivalently

$$\mathbf{X} = \sum_i \psi(s_i) s_i^{-1} (\boldsymbol{u}_i - \overline{\boldsymbol{u}})(\boldsymbol{v}_i - \widehat{\boldsymbol{\beta}})^{\mathrm{T}} \widehat{\mathbf{A}} \text{ is symmetric} \,. \tag{31.32}$$

Equations (31.32), (31.30), and (31.31) lead to the following iterative minimization algorithm. Start with the least squares solution given in Sect. 31.2.3 and use these estimates to calculate s_i. Using these s_i and the current guess for $\widehat{\mathbf{A}}$, solve (31.30) and (31.31) to update the guesses for $\widehat{\gamma}$ and $\widehat{\beta}$. Now writing $\mathbf{X} = \mathbf{O}_1 \mathbf{\Lambda} \mathbf{O}_2^{\mathrm{T}}$ for the singular value decomposition of $\mathbf{X}$, the next guess for $\widehat{\mathbf{A}}$ is $\mathbf{O}_2\mathbf{O}_1^{\mathrm{T}}$. This yields a minimum in $\mathcal{O}(p)$. If minimization in $\mathcal{SO}(p)$ is desired, a modified singular value decomposition is used for $\mathbf{X}$ instead. Having updated the guesses for $\left(\widehat{\mathbf{A}}, \widehat{\gamma}, \widehat{\boldsymbol{\beta}}\right)$, we now iterate.

For example consider the hands data of Table 31.1. We calculate the L_1 estimate for which $\psi(s) = 1$. Starting with the least squares estimates in (31.20), we convert $\widehat{\boldsymbol{b}}$ to

$$\widehat{\beta} = \widehat{\gamma}\widehat{\mathbf{A}}\overline{\boldsymbol{u}} + \widehat{\boldsymbol{b}} = \begin{pmatrix} 9.2500 & 11.3633 & 15.0950 \end{pmatrix}^{\mathrm{T}} . \tag{31.33}$$

We use these least squares estimate as an initial guess; a single iteration of the minimization algorithm yields the updated guess

$$\begin{aligned} \widehat{\mathbf{A}} &= \begin{pmatrix} 0.9569 & 0.2823 & -0.0690 \\ 0.2614 & -0.9399 & -0.2199 \\ 0.1269 & -0.1924 & 0.9731 \end{pmatrix} , \\ \widehat{\gamma} &= 1.0015 \,, \\ \widehat{\beta} &= \begin{pmatrix} 9.2835 & 11.4092 & 15.0851 \end{pmatrix}^{\mathrm{T}} . \end{aligned}$$

Convergence is achieved after around a dozen iterations. We arrive at the L_1 estimates

$$\begin{aligned} \widehat{\mathbf{A}} &= \begin{pmatrix} 0.9418 & 0.3274 & -0.0760 \\ 0.3045 & -0.9268 & -0.2200 \\ 0.1425 & -0.1840 & 0.9725 \end{pmatrix} , \\ \widehat{\gamma} &= 1.0086 \,, \\ \widehat{\beta} &= \begin{pmatrix} 9.2850 & 11.4255 & 15.0883 \end{pmatrix}^{\mathrm{T}} . \end{aligned} \tag{31.34}$$

31.4 Statistical Properties of *M*-Estimates

31.4.1 The Σ Matrix and the Geometry of the u_i

Let $\mathbf{\Sigma}$ be the $p \times p$ matrix

$$\mathbf{\Sigma} = n^{-1} \sum_i (\boldsymbol{u}_i - \overline{\boldsymbol{u}})(\boldsymbol{u}_i - \overline{\boldsymbol{u}})^{\mathrm{T}}$$

$\mathbf{\Sigma}$ is nonnegative definite symmetric and hence its eigenvalues are real and its eigenvectors form an orthonormal basis of $\mathbb{R}^p$. We can use this eigen-decomposition of $\mathbf{\Sigma}$ to summarize the geometry of the point $\boldsymbol{u}_i$. More specifically, let $\lambda_1 \geq \cdots \geq \lambda_p \geq 0$ be the eigenvalues of $\mathbf{\Sigma}$ with corresponding eigenvectors $\boldsymbol{e}_1, \cdots, \boldsymbol{e}_p$. Then $\boldsymbol{e}_1$ points in the direction of the greatest variation in the $\boldsymbol{u}_i$, and $\boldsymbol{e}_p$ in the direction of the least variation.

31.4.2 Example: Σ for the Hands Data

For example, for the data of Table 31.1,

$$\overline{\boldsymbol{u}} = \begin{pmatrix} 7.8975 \\ 12.7542 \\ 14.3067 \end{pmatrix}$$

$$\boldsymbol{\Sigma} = \frac{1}{12}\left\{\left[\begin{pmatrix} 5.17 \\ 11.30 \\ 16.18 \end{pmatrix} - \overline{\boldsymbol{u}}\right]\left[\begin{pmatrix} 5.17 \\ 11.30 \\ 16.18 \end{pmatrix} - \overline{\boldsymbol{u}}\right]^{\mathrm{T}} + \cdots + \left[\begin{pmatrix} 8.68 \\ 12.71 \\ 13.67 \end{pmatrix} - \overline{\boldsymbol{u}}\right]\left[\begin{pmatrix} 8.68 \\ 12.71 \\ 13.67 \end{pmatrix} - \overline{\boldsymbol{u}}\right]^{\mathrm{T}}\right\}$$

$$= \begin{pmatrix} 2.6249 & 1.2525 & 0.1424 \\ 1.2525 & 0.8095 & -0.5552 \\ 0.1424 & -0.5552 & 4.9306 \end{pmatrix},$$

$$\lambda_1 = 5.004\,, \quad \lambda_2 = 3.255\,, \quad \lambda_3 = 0.1054\,,$$

$$\boldsymbol{e}_1 = \begin{pmatrix} -0.0115 \\ -0.1346 \\ 0.9908 \end{pmatrix}, \quad \boldsymbol{e}_2 = \begin{pmatrix} -0.8942 \\ -0.4420 \\ -0.0704 \end{pmatrix},$$

$$\boldsymbol{e}_3 = \begin{pmatrix} -0.4474 \\ 0.8869 \\ 0.1152 \end{pmatrix}.$$

Examining the data of Table 31.1, one sees that $\overline{\boldsymbol{u}}$ is close to point G, the center of the left palm. Examining the displacement of G to C, top of the middle finger, it is evident that left hand was close to vertically oriented. This is the direction $\boldsymbol{e}_1$. Examining the displacement of G to E, the top of the thumb, it appears that the left thumb was pointed in roughly the direction of the x-axis. This is the direction of $-\boldsymbol{e}_2$. Thus the left hand was roughly parallel to the x–z plane. The normal vector to the plane of the left hand is thus approximately parallel to the y-axis. This is the direction of $\boldsymbol{e}_3$. Notice that λ_3 is much smaller than λ_1 or λ_2, indicating that the thickness of the hand is much smaller than its length or breadth.

31.4.3 Statistical Assumptions for the Procrustes Model

Before giving the statistical properties of $\left(\widehat{\mathbf{A}}, \widehat{\gamma}, \widehat{\boldsymbol{b}}\right)$ it is necessary to make explicit the statistical assumptions of the Procrustes model (31.2). These assumptions are:

- $\boldsymbol{u}_1, \cdots, \boldsymbol{u}_n \in \mathbb{R}^p$ are fixed (non-random) vectors.
- $\boldsymbol{v}_1, \cdots, \boldsymbol{v}_n \in \mathbb{R}^p$ are independent random vectors.
- The distribution of $\boldsymbol{v}_i$ is of the form $f_0(s_i)$, where $s_i = ||\boldsymbol{v}_i - \gamma \mathbf{A}\boldsymbol{u}_i - \boldsymbol{b}||$. Here $(\mathbf{A}, \gamma, \boldsymbol{b})$ are unknown, $\mathbf{A} \in \mathcal{SO}(p)$ or $\mathcal{O}(p)$, γ is a positive real constant, and $\boldsymbol{b} \in \mathbb{R}^p$.

The most obvious example of a suitable distribution f_0 is

$$f_0(s) = (2\pi\sigma^2)^{-p/2}\, \mathrm{e}^{-\frac{s^2}{2\sigma^2}} \tag{31.35}$$

for a fixed constant σ^2. In what follows, we will not need to know the value of σ^2. In fact, we will not even need to know the form of f_0, only that the distribution of $\boldsymbol{v}_i$ depends only upon its distance s_i from $\gamma\mathbf{A}\boldsymbol{u}_i + \boldsymbol{b}$.

The distribution (31.35) is a multivariate normal distribution with mean vector $\gamma\mathbf{A}\boldsymbol{u}_i + \boldsymbol{b}$ and covariance matrix $\sigma^2\mathbf{I}_p$. Equivalently, the p components of $\boldsymbol{v}_i$ are independent and each has variance σ^2. If the components of $\boldsymbol{v}_i$ were to have different variances, then the distribution of $\boldsymbol{v}_i$ would not satisfy the Procrustes model assumptions.

In essence we assume that $\boldsymbol{v}_i$ is isotropically (i.e., that all directions are the same) distributed around its mean vector.

31.4.4 Theorem (Distribution of $(\widehat{\mathbf{A}},\widehat{\gamma},\widehat{\boldsymbol{b}})$ for the Procrustes Model)

Suppose $\left(\widehat{\mathbf{A}}, \widehat{\gamma}, \widehat{\boldsymbol{b}}\right)$ minimize an objective function of the form (31.13). Let $\boldsymbol{\beta} = \gamma\mathbf{A}\overline{\boldsymbol{u}} + \boldsymbol{b}$ and $\widehat{\boldsymbol{\beta}} = \widehat{\gamma}\widehat{\mathbf{A}}\overline{\boldsymbol{u}} + \widehat{\boldsymbol{b}}$. Then

- $\widehat{\mathbf{A}}$, $\widehat{\gamma}$, and $\widehat{\boldsymbol{\beta}}$ are independent;
- $\widehat{\boldsymbol{\beta}}$ is distributed multivariate normal with mean $\boldsymbol{\beta}$ and covariance matrix $\frac{k}{n}\mathbf{I}_p$;
- If $p = 2$, write $\widehat{\mathbf{A}} = \mathbf{A}\Psi_2(\widehat{h})$, for $\widehat{h} \in \mathbb{R}^1$. Then $\widehat{h}$ is normally distributed with mean 0 and variance $\frac{k}{n\mathrm{Tr}(\Sigma)}$;
- If $p = 3$, write $\widehat{\mathbf{A}} = \mathbf{A}\Psi_3(\widehat{\boldsymbol{h}})$, for $\widehat{\boldsymbol{h}} \in \mathbb{R}^3$. Let $\Sigma = \lambda_1\boldsymbol{e}_1\boldsymbol{e}_1^{\mathrm{T}} + \lambda_2\boldsymbol{e}_2\boldsymbol{e}_2^{\mathrm{T}} + \lambda_3\boldsymbol{e}_3\boldsymbol{e}_3^{\mathrm{T}}$ be the spectral decomposition of $\boldsymbol{\Sigma}$. Then $\widehat{\boldsymbol{h}}$ is distributed trivariate normal with mean $\mathbf{0}$ and covariance matrix

$$\frac{k}{n}\Big[(\lambda_2+\lambda_3)^{-1}\boldsymbol{e}_1\boldsymbol{e}_1^{\mathrm{T}} + (\lambda_3+\lambda_1)^{-1}\boldsymbol{e}_2\boldsymbol{e}_2^{\mathrm{T}} + (\lambda_1+\lambda_2)^{-1}\boldsymbol{e}_3\boldsymbol{e}_3^{\mathrm{T}}\Big].$$

- For general p, write $\widehat{\mathbf{A}} = \mathbf{A}\exp(\widehat{\mathbf{H}})$, where $\widehat{\mathbf{H}}$ is $p \times p$ skew-symmetric. Then $\widehat{\mathbf{H}}$ has a multivariate normal density proportional to $\exp\left[-\frac{n}{2k}\mathrm{Tr}(\widehat{\mathbf{H}}^{\mathrm{T}}\boldsymbol{\Sigma}\widehat{\mathbf{H}})\right]$;
- $\widehat{\gamma}$ is normally distributed with mean γ and variance $\frac{k}{n\mathrm{Tr}(\boldsymbol{\Sigma})}$.

These results are asymptotic, that is they are large-sample approximate distributions.

The constant k is defined to be

$$k = \frac{pE\left[\psi(s)^2\right]}{E^2\left[\psi'(s)+(p-1)\psi(s)s^{-1}\right]}, \tag{31.36}$$

where $\psi(s) = \rho_0'(s)$. Thus k can be estimated from the sample by

$$\widehat{k} = \frac{np\sum_i \psi(s_i)^2}{\left\{\sum_i\left[\psi'(s_i)+(p-1)\psi(s_i)s_i^{-1}\right]\right\}^2}, \tag{31.37}$$

where $s_i = \left|\left|\boldsymbol{v}_i - \widehat{\gamma}\widehat{\mathbf{A}}\boldsymbol{u}_i - \widehat{\boldsymbol{b}}\right|\right|$.

Theorem 31.4.4 is proven in *Chang* and *Ko* [31.3]. (In [31.3], s is defined to be $s = ||\boldsymbol{v} - \widehat{\gamma}\widehat{\mathbf{A}}\boldsymbol{u} - \widehat{\boldsymbol{b}}||^2$ and this causes the formulas (31.36) and (31.37) to be somewhat different there.)

31.4.5 Example: A Test of $\gamma = 1$

For the hands data, the least squares estimates were given in Example 31.2.4. Table 31.2 gives the calculation of the s_i. Substituting $p = 3$, $\rho_0(s) = s^2$, $\psi(s) = 2s$ into (31.37), $\widehat{k} = (3n)^{-1}\sum_i s_i^2 = 0.0860$.

To test if the two hands are the same size, we test $\gamma = 1$. Using Example 31.4.2, $\mathrm{Tr}(\boldsymbol{\Sigma}) = 8.365$. Hence the variance of $\widehat{\gamma}$ is 0.000 860 and hence its standard error is 0.0293. Since $\widehat{\gamma} = 0.9925$, we see that $\widehat{\gamma}$ is not significantly different from 1.

The L_1 estimate of γ is 1.0086. To calculate the standard error of this estimate, we use $\rho_0(s) = s$ and $\psi(s) = 1$. Hence for the L_1 estimate, (31.37) yields $\widehat{k} = 0.75\left(n^{-1}\sum_i s_i^{-1}\right)^{-2}$. After recomputing the s_i using L_1 estimates of $(\mathbf{A}, \gamma, \boldsymbol{b})$, we obtain $\widehat{k} = 0.023$. Thus the L_1 estimate of γ has a standard error of 0.0150 and this estimate is also not significantly different from 1.

Apparently, the two hands have the same size.

General statistical theory implies that if the $\boldsymbol{v}_i$ were really normally distributed, the least squares estimates would be the most efficient. In other words, least squares estimates should have the smallest standard errors. Evidently this is not true for the hands data and it appears that this data is not, in fact, normally distributed.

31.4.6 Example: A Test on A

As discussed in 31.4.2, the eigenvector $\boldsymbol{e}_3$ of $\boldsymbol{\Sigma}$ is perpendicular to the plane of the left palm. It might be of interest to test if the two hands have the same orientation; that is, after reflecting the left hand in the plane perpendicular to $\boldsymbol{e}_3$, do the fingers and thumb of the two hands point in the same directions. We formulation this hypothesis as $H_0 : \mathbf{A} = \mathbf{R}_{\boldsymbol{e}_3}$ where $\mathbf{R}_{\boldsymbol{e}_3}$ is the matrix of the reflection in plane perpendicular to $\boldsymbol{e}_3$.

$$\begin{aligned}\mathbf{R}_{\boldsymbol{e}_3} &= \mathbf{I}_3 - 2\boldsymbol{e}_3\boldsymbol{e}_3^{\mathrm{T}} \\ &= \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \\ &\quad -2\begin{pmatrix} -0.4474 \\ 0.8869 \\ 0.1152 \end{pmatrix}\begin{pmatrix} -0.4474 \\ 0.8869 \\ 0.1152 \end{pmatrix}^{\mathrm{T}} \\ &= \begin{pmatrix} 0.5996 & 0.7936 & 0.1031 \\ 0.7936 & -0.5731 & -0.2044 \\ 0.1031 & -0.2044 & 0.9734 \end{pmatrix},\end{aligned}$$

$\widehat{\boldsymbol{h}}$ is defined by

$$\begin{aligned}\Phi_3(\widehat{\boldsymbol{h}}) &= \mathbf{R}_{\boldsymbol{e}_3}^{\mathrm{T}}\widehat{\mathbf{A}} \\ &= \begin{pmatrix} 0.7843 & -0.6127 & -0.0976 \\ 0.5999 & 0.7890 & -0.1327 \\ 0.1583 & 0.0455 & 0.9863 \end{pmatrix},\end{aligned} \tag{31.38}$$

where $\widehat{\mathbf{A}}$ was calculated in 31.2.4.

To solve for $\widehat{\boldsymbol{h}}$ we use the results at the end of Sect. 31.3.2. The matrix of (31.38) has an eigenvector of $\xi = (0.1395 \quad -0.2003 \quad 0.9494)^{\mathrm{T}}$ corresponding to the eigenvalue of 1. Its angle of rotation is given by

$$\theta = \arccos\left[0.5\mathrm{Tr}\left(\mathbf{R}_{\boldsymbol{e}_3}^{\mathrm{T}}\widehat{\mathbf{A}}\right) - 0.5\right] = 0.6764\,.$$

Thus $\widehat{\boldsymbol{h}} = \theta\boldsymbol{\xi} = (0.0944 \quad -0.1355 \quad 0.6422)^{\mathrm{T}}$.

By Theorem 31.4.4, if H_0 is true, $\widehat{\boldsymbol{h}}$ is trivariate normally distributed with mean $\mathbf{0}$ and covariance matrix

$$\begin{aligned}&\frac{k}{n}\Big[(\lambda_2+\lambda_3)^{-1}\boldsymbol{e}_1\boldsymbol{e}_1^{\mathrm{T}} + (\lambda_3+\lambda_1)^{-1}\boldsymbol{e}_2\boldsymbol{e}_2^{\mathrm{T}} \\ &+(\lambda_1+\lambda_2)^{-1}\boldsymbol{e}_3\boldsymbol{e}_3^{\mathrm{T}}\Big].\end{aligned}$$

The constant k was estimated in 31.4.5 and the λ_i and $\boldsymbol{e}_i$ were calculated in 31.4.2. Using these calculations, the covariance matrix of $\widehat{\boldsymbol{h}}$ is estimated to be

$$\begin{aligned}&\widehat{\mathrm{Cov}}(\widehat{\boldsymbol{h}}) \\ &= \begin{pmatrix} 0.001\,296 & 0.000\,2134 & 0.000\,019\,23 \\ 0.000\,2134 & 0.000\,9951 & -0.000\,1520 \\ 0.000\,019\,23 & -0.000\,1520 & 0.002\,112 \end{pmatrix}.\end{aligned}$$

Table 31.2 Calculation of residual lengths for data from Table 31.1

	Predicted $\widehat{v}_i$ $\widehat{\gamma}\widehat{A}u_i+\widehat{b}$			Residual $v_i-\widehat{v}_i$			s_i $\|\|v_i-\widehat{v}_i\|\|$
A	6.148	11.687	16.868	−0.238	−0.527	−0.318	0.660

C	9.620	10.962	18.654	0.470	−0.362	−0.014	0.593
D	11.080	10.457	17.769	−0.190	0.493	0.131	0.544
E	13.206	10.816	13.865	−0.236	−0.686	0.015	0.726
F	8.691	11.176	13.247	0.099	0.034	−0.077	0.129
G	10.544	10.938	13.355	0.156	0.162	0.065	0.234
H	8.501	11.594	11.046	−0.031	−0.504	0.304	0.589
I	7.449	12.225	14.178	−0.169	0.295	−0.138	0.367
J	8.062	11.908	14.649	−0.012	0.512	−0.089	0.520
K	9.198	11.904	14.730	−0.128	0.486	0.130	0.519
L	10.026	11.724	14.573	0.125	0.446	−0.133	0.481

Under the null hypothesis

$$\chi^2 = \widehat{\boldsymbol{h}}^{\mathrm{T}}\widehat{\mathrm{Cov}}(\widehat{\boldsymbol{h}})^{-1}\widehat{\boldsymbol{h}} = 213$$

has an approximate χ^2 distribution with three degrees of freedom.

We emphatically conclude that, after reflecting the left hand, the orientations of the two hands are not the same.

31.4.7 Asymptotic Relative Efficiency of Least Squares and L_1 Estimates

Examining Theorem 31.4.4, we see that the covariance of the *M*-estimate $(\widehat{\mathbf{A}}, \widehat{\gamma}, \widehat{\boldsymbol{b}})$ is determined, up to a constant k, by the geometry of the $\boldsymbol{u}_i$, as summarized by the matrix $\boldsymbol{\Sigma}$. Only the constant k, see (31.36), depends upon the probability distribution of the $\boldsymbol{v}_i$ and the objective function (31.13) that $(\widehat{\mathbf{A}}, \widehat{\gamma}, \widehat{\boldsymbol{b}})$ minimize. Furthermore, a sample estimate of k, see (31.37) is available which does not require knowledge of the distribution of the $\boldsymbol{v}_i$.

Let $k(f_0, L_2)$ denote the constant k as defined in (31.36) when the underlying density is of the form f_0 and least squares (L_2) estimation is used, and $k(f_0, L_1)$ the corresponding value when L_1 estimation is used. The ratio $\mathrm{ARE}(L_1, L_2; f_0) = k(f_0, L_2)/k(f_0, L_1)$ is called the *asymptotic relative efficiency* of the L_1 to the least squares estimators at the density f_0.

We see that

$$\mathrm{ARE}(L_1, L_2; f_0) = \frac{\text{variance of least squares estimator}}{\text{variance of } L_1 \text{estimator}}, \tag{31.39}$$

where we recognize that both variances are matrices, but the two variance matrices are multiples of each other.

If f_0 is a p-dimensional normal density (31.35), it can be shown from (31.36) that

$$\mathrm{ARE}(L_1, L_2; N_p) = \frac{2\Gamma^2[(p+1)/2]}{p\Gamma^2(p/2)}. \tag{31.40}$$

We have used N_p in (31.40) to denote the p-dimensional normal density function.

The Γ function in (31.40) has the properties

$$\Gamma(1) = 1 \quad \Gamma(0.5) = \sqrt{\pi}$$
$$\Gamma(q+1) = q\Gamma(q).$$

Thus when $p = 2.3$

$$\mathrm{ARE}(L_1, L_2; N_2) = \frac{\pi}{4} = 0.785,$$
$$\mathrm{ARE}(L_1, L_2; N_3) = \frac{8}{3\pi} = 0.849. \tag{31.41}$$

$\mathrm{ARE}(L_1, L_2; N_p)$ increases to 1 as $p \to \infty$.

When the underlying distribution is normal, statistical theory indicates that least squares procedures are optimal, that is, they have the smallest variance. Using (31.39) and (31.41), we see that, even when the data is normal, the use of L_1 methods results in only an 8% penalty in standard error. And L_1 methods offer superior resistance to outliers.

Indeed, as we saw in Example 31.4.5, the standard error of the L_1 estimator was *smaller* than the standard error of the least squares estimator. Evidently the hands data set is long-tailed, that is it has more outliers than would be expected with normal data.

31.4.8 The Geometry of the Landmarks and the Errors in $\widehat{\mathbf{A}}$

In this section we will constrain our discussion to the case $p = 3$.

Suppose we write the estimate $\widehat{\mathbf{A}}$ in the form

$$\widehat{\mathbf{A}} = \mathbf{A}\Phi_3(\widehat{\boldsymbol{h}}) \,. \tag{31.42}$$

$\Phi_3(\widehat{\boldsymbol{h}})$ is a (hopefully) small rotation which expresses the deviation of the estimate $\widehat{\mathbf{A}}$ from the true value $\mathbf{A}$.

Recall that $\Phi_3(\widehat{\boldsymbol{h}})$ is a rotation of $||\widehat{\boldsymbol{h}}||$ radians around the axis $||\widehat{\boldsymbol{h}}||^{-1}\widehat{\boldsymbol{h}}$.

In particular $\Phi_3(\widehat{\boldsymbol{h}})^{-1} = \Phi_3(-\widehat{\boldsymbol{h}})$ and

$$\mathbf{A} = \widehat{\mathbf{A}}\Phi_3(-\widehat{\boldsymbol{h}}) \,.$$

According to Theorem 31.4.4, the covariance matrix of $\widehat{\boldsymbol{h}}$ has the form

$$\begin{aligned}\mathrm{Cov}(\widehat{\boldsymbol{h}}) = \frac{k}{n}\Big[&(\lambda_2+\lambda_3)^{-1}\boldsymbol{e}_1\boldsymbol{e}_1^{\mathrm{T}} + (\lambda_3+\lambda_1)^{-1}\boldsymbol{e}_2\boldsymbol{e}_2^{\mathrm{T}} \\ &+ (\lambda_1+\lambda_2)^{-1}\boldsymbol{e}_3\boldsymbol{e}_3^{\mathrm{T}}\Big] \,,\end{aligned} \tag{31.43}$$

where $\lambda_1 \geq \lambda_2 \geq \lambda_3$ are the eigenvalues of Σ with corresponding eigenvectors $\boldsymbol{e}_1, \boldsymbol{e}_2, \boldsymbol{e}_3$. Since $\widehat{\boldsymbol{h}}$ is normally distributed

$$\chi^2 = \widehat{\boldsymbol{h}}^{\mathrm{T}}\left[\mathrm{Cov}(\widehat{\boldsymbol{h}})\right]^{-1}\widehat{\boldsymbol{h}}$$

is distributed χ^2 with three degrees of freedom.

Thus a confidence region for $\mathbf{A}$ is of the form

$$\left\{\widehat{\mathbf{A}}\Phi_3(-\widehat{\boldsymbol{h}}) \,\middle|\, \widehat{\boldsymbol{h}}^{\mathrm{T}}\left[\mathrm{Cov}(\widehat{\boldsymbol{h}})\right]^{-1}\widehat{\boldsymbol{h}} < \chi^2_{3,\alpha}\right\} \,, \tag{31.44}$$

where $\chi^2_{3,\alpha}$ is the appropriate critical point of a χ^2_3 distribution.

Let $\theta = ||\widehat{\boldsymbol{h}}||$ and $\xi = -||\widehat{\boldsymbol{h}}||^{-1}\widehat{\boldsymbol{h}}$ so that $\widehat{\boldsymbol{h}} = -\theta\xi$.

Thus $\Phi_3(-\widehat{\boldsymbol{h}})$ is a rotation of θ radians around the axis ξ.

Substituting (31.43) into the confidence region (31.44), we can re-express this confidence region as

$$\begin{aligned}\Big\{\widehat{\mathbf{A}}\Phi_3(\theta\xi) \mid \theta^2\frac{n}{k}\Big[&(\lambda_2+\lambda_3)(\xi^{\mathrm{T}}\boldsymbol{e}_1)^2 + (\lambda_3+\lambda_1) \\ &\times(\xi^{\mathrm{T}}\boldsymbol{e}_2)^2 + (\lambda_1+\lambda_2)(\xi^{\mathrm{T}}\boldsymbol{e}_3)^2\Big] < \chi^2_{3,\alpha}\Big\} \,.\end{aligned} \tag{31.45}$$

Now

$$\lambda_2+\lambda_3 \leq \lambda_3+\lambda_1 \leq \lambda_1+\lambda_2 \,.$$

Thus the confidence region (31.45) constrains θ the most (that is the limits on θ are the smallest) when ξ points in the direction $\boldsymbol{e}_3$. It bounds θ the least when ξ points in the direction $\boldsymbol{e}_1$.

Recall also that $\boldsymbol{e}_1$ is the direction of the greatest variation in the $\boldsymbol{u}_i$ and $\boldsymbol{e}_3$ the direction of the least variation.

For the hands data of Table 31.1, $\boldsymbol{e}_1$ points in the direction of the length of the left hand and $\boldsymbol{e}_3$ in the normal direction to the palm.

Thus the angle θ of the small rotation $\Phi_3(\theta\xi)$ is the most constrained when its axis ξ points in the direction of the least variation in the $\boldsymbol{u}_i$. θ is least constrained when ξ points in the direction of the greatest variation of the $\boldsymbol{u}_i$.

For the hands data, if $\widehat{\boldsymbol{h}}$ is in the direction of $\boldsymbol{e}_1$, the length of the hand, it represents a small rotation at the elbow with the wrist held rigid. The variance of the deviation rotation $\widehat{\boldsymbol{h}}$ in the direction $\boldsymbol{e}_1$ is $(\lambda_2+\lambda_3)^{-1} = 0.298$. If $\widehat{\boldsymbol{h}}$ points in the direction of $\boldsymbol{e}_2$, the width of the hand, it represents a forwards and backwards rotation at the wrist; the variance of $\widehat{\boldsymbol{h}}$ in this direction is $(\lambda_2+\lambda_3)^{-1} = 0.196$. Finally if $\widehat{\boldsymbol{h}}$ points in the direction of $\boldsymbol{e}_3$, the normal vector to the hand, it represents a somewhat awkward sideways rotation at the wrist (this rotation is represented in Fig. 31.1b; the variance of $\widehat{\boldsymbol{h}}$ in this direction is $(\lambda_1+\lambda_2)^{-1} = 0.121$. If the variability of the component of $\widehat{\boldsymbol{h}}$ in the direction of a rotation at the elbow

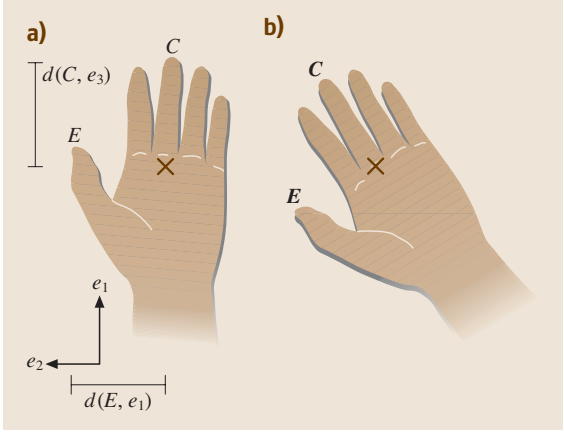

Fig. 31.1 **(a)**A hand with axes $\boldsymbol{e}_1, \boldsymbol{e}_2$; axis $\boldsymbol{e}_3$ points out of paper. X marks the center point $\overline{\boldsymbol{u}}$. The distances $d(C, \boldsymbol{e}_3)$ and $d(E, \boldsymbol{e}_1)$ are the lengths of the indicated line segments. **(b)**The effect of a rotation of angle θ around the axis $\boldsymbol{e}_3$. The point C moves a distance of approximately $d(C, \boldsymbol{e}_3)\theta$. Under a rotation of θ around $\boldsymbol{e}_1$ (not shown), the point E moves a distance of approximately $d(E, \boldsymbol{e}_1)\theta$. Notice that $d(E, \boldsymbol{e}_1) < d(C, \boldsymbol{e}_3)$, and, indeed, the landmarks $\boldsymbol{u}_i$ tend to be closer to $\boldsymbol{e}_1$ than to $\boldsymbol{e}_3$. It follows that a rotation of θ around $\boldsymbol{e}_3$ will move the figure more than a rotation of θ around $\boldsymbol{e}_1$

is unacceptably large, we need to increase λ_3; in effect to create, if possible, landmarks which effectively thicken the palm.

A heuristic derivation of this result is due to *Stock* and *Molnar* [31.8, 9]. It appeared in the geophysical literature and is considered a major development in our understanding of the uncertainties in tectonic plate reconstructions. We will present their argument below, suitably modified for the image registration context.

It is convenient to rewrite the model, as in Theorem 31.4.4, in the form (31.29). If we substitute $\mathbf{A} = \widehat{\mathbf{A}}\Phi_3(\theta\xi)$, we see that $\mathbf{A}$ first perturbs the $\boldsymbol{u}_i - \overline{\boldsymbol{u}}$ by the small rotation $\Phi_3(\theta\xi)$ and then applies the best fitting orthogonal matrix $\widehat{\mathbf{A}}$.

Let $d(\boldsymbol{u}_i, \xi)$ be the distance of the landmark $\boldsymbol{u}_i$ to the line through the center point $\overline{\boldsymbol{u}}$ and in the direction of the axis ξ. Refer to Fig. 31.1. Since the landmarks vary most in the direction $\boldsymbol{e}_1$ and least in the direction $\boldsymbol{e}_3$, the distances $d(\boldsymbol{u}_i, \boldsymbol{e}_3)$ will tend to be biggest and the distances $d(\boldsymbol{u}_i, \boldsymbol{e}_1)$ smallest.

A point $\boldsymbol{x}$ will move a distance of approximately $d(\boldsymbol{x}, \xi)\theta$ under a rotation of angle θ around the axis ξ. It follows that a rotation of angle θ will most move the landmarks $\boldsymbol{u}_i$ if the axis is $\boldsymbol{e}_3$. It will move the landmarks $\boldsymbol{u}_i$ least if the axis is $\boldsymbol{e}_1$. In other words, for a fixed θ, the small rotation $\Phi_3(\theta\xi)$ will most degrade the best fit, provided by $\widehat{\mathbf{A}}$, if $\xi = \boldsymbol{e}_3$; it will least degrade the best fit if $\xi = \boldsymbol{e}_1$.

An orthogonal transformation $\mathbf{A} = \widehat{\mathbf{A}}\Phi_3(\theta\xi)$ is considered a possible transformation if it does not degrade the best fit by too much. It follows that θ is most constrained if $\xi = \boldsymbol{e}_3$, the direction of the least variation in the landmarks $\boldsymbol{u}_i$, and is least constrained if $\xi = \boldsymbol{e}_1$, the direction of greatest variation in the landmarks $\boldsymbol{u}_i$.

Suppose instead we were to write the estimate $\widehat{\mathbf{A}}$ in the form

$$\widehat{\mathbf{A}} = \Phi_3(\widehat{\boldsymbol{h}}_v)\mathbf{A}\,, \qquad (31.46)$$
$$\mathbf{A} = \Phi_3(-\widehat{\boldsymbol{h}}_v)\widehat{\mathbf{A}}\,.$$

Then (31.43) is replaced by

$$\begin{aligned}\mathrm{Cov}(\widehat{\boldsymbol{h}}_v) = \frac{k}{n}\Big[&(\lambda_2+\lambda_3)^{-1}(\mathbf{A}\boldsymbol{e}_1)(\mathbf{A}\boldsymbol{e}_1)^{\mathrm{T}}\\ &+(\lambda_3+\lambda_1)^{-1}(\mathbf{A}\boldsymbol{e}_2)(\mathbf{A}\boldsymbol{e}_2)^{\mathrm{T}}\\ &+(\lambda_1+\lambda_2)^{-1}(\mathbf{A}\boldsymbol{e}_3)(\mathbf{A}\boldsymbol{e}_3)^{\mathrm{T}}\Big]\,.\end{aligned}$$

The same reasoning then expresses the errors of $\widehat{\boldsymbol{h}}_v$, and hence of $\widehat{\mathbf{A}}$, in terms of the geometry of the landmarks $\boldsymbol{v}_i$. In other words, for the hands data, using the definition (31.46) expresses the errors of $\widehat{\mathbf{A}}$ in terms of the orientation of the right hand.

31.4.9 Statistical Properties of *M*-Estimates for Spherical Regressions

The statistical assumptions of the spherical regression model (31.1) are:

- $\boldsymbol{u}_1, \cdots, \boldsymbol{u}_n \in \Omega_p$ are fixed (non-random) vectors.
- $\boldsymbol{v}_1, \cdots, \boldsymbol{v}_n \in \Omega_p$ are independent random vectors.
- The distribution of $\boldsymbol{v}_i$ is of the form $f_0(t_i)$ where $t_i = \boldsymbol{v}_i^{\mathrm{T}}\mathbf{A}\boldsymbol{u}_i$. Here $\mathbf{A} \in \mathcal{SO}(p)$ or $\mathcal{O}(p)$ is unknown.

A commonly used distribution for spherical data $\boldsymbol{x} \in \Omega_p$ is the distribution whose density (with respect to surface measure, or uniform measure, on Ω_p) is

$$f(\boldsymbol{x};\theta) = c(\kappa)\exp(\kappa\boldsymbol{x}^{\mathrm{T}}\theta)\,. \qquad (31.47)$$

This distribution has two parameters: a positive real constant κ which is commonly called the *concentration parameter* and $\theta \in \Omega_p$. It is easily seen that $f(\boldsymbol{x})$ is maximized over $\boldsymbol{x} \in \Omega_p$ at θ and hence θ is usually refered to as the *modal vector*; $c(\kappa)$ is a normalizing constant.

If $\kappa = 0$, (31.47) is a uniform density on Ω_p. On the other hand as $\kappa \to \infty$, the density (31.47) approaches that of a multivariate normal distribution in $p-1$ dimensions with a covariance matrix of $\kappa^{-1}\mathbf{I}_{p-1}$. Thus intuitively we can think of κ as σ^{-2}, that is think of κ as the inverse variance. As $\kappa \to \infty$, (31.47) approaches a singular multivariate normal distribution supported on the $(p-1)$-dimensional subspace $\theta^{\perp} \subset \mathbb{R}^p$. As a singular multivariate normal distribution in $\mathbb{R}^p$ its covariance matrix is $\kappa^{-1}(\mathbf{I}_p - \theta\theta^{\mathrm{T}})$.

For the circle Ω_1, (31.47) is due to von Mises. For general Ω_p, it is due (independently) to Fisher and to Langevin. More properties of the Fisher–von Mises–Langevin distribution can be found in *Watson* [31.10] or in *Fisher* et al. [31.11].

The distribution of an M-estimator $\widehat{\mathbf{A}}$ which minimizes an objective function of the form (31.14) is similar to the distribution given in Theorem 31.4.4:

- If $p = 2$, write $\widehat{\mathbf{A}} = \mathbf{A}\Psi_2(\widehat{h})$, for $\widehat{h} \in \mathbb{R}^1$. Then $\widehat{h}$ is normally distributed with mean 0 and variance $\frac{k}{n}$.
- If $p = 3$, write $\widehat{\mathbf{A}} = \mathbf{A}\Psi_3(\widehat{\boldsymbol{h}})$, for $\widehat{\boldsymbol{h}} \in \mathbb{R}^3$. Let $\boldsymbol{\Sigma} = \lambda_1\boldsymbol{e}_1\boldsymbol{e}_1^{\mathrm{T}} + \lambda_2\boldsymbol{e}_2\boldsymbol{e}_2^{\mathrm{T}} + \lambda_3\boldsymbol{e}_3\boldsymbol{e}_3^{\mathrm{T}}$ be the spectral decomposition of $\boldsymbol{\Sigma}$. Then $\widehat{\boldsymbol{h}}$ is distributed trivariate normal with mean $\mathbf{0}$ and covariance matrix

$$\begin{aligned}\frac{k}{n}\Big[&(\lambda_2+\lambda_3)^{-1}\boldsymbol{e}_1\boldsymbol{e}_1^{\mathrm{T}} + (\lambda_3+\lambda_1)^{-1}\boldsymbol{e}_2\boldsymbol{e}_2^{\mathrm{T}}\\ &+(\lambda_1+\lambda_2)^{-1}\boldsymbol{e}_3\boldsymbol{e}_3^{\mathrm{T}}\Big]\,.\end{aligned}$$

- For general p, write $\widehat{\mathbf{A}} = \mathbf{A}\exp(\widehat{\mathbf{H}})$, where $\widehat{\mathbf{H}}$ is $p \times p$ skew-symmetric. Then $\widehat{\mathbf{H}}$ has a multivariate normal density proportional to $\exp\left[-\frac{n}{2k}\mathrm{Tr}(\widehat{\mathbf{H}}^{\mathrm{T}}\boldsymbol{\Sigma}\widehat{\mathbf{H}})\right]$.

Let $\psi(t) = -\rho_0'(t)$. (The sign of ψ has been chosen to make $\psi(t)$ nonnegative, since ρ_0 is a decreasing function of t.) The constant k and its sample estimate $\widehat{k}$ are given by

$$k = \frac{(p-1)E[\psi(t)^2(1-t^2)]}{E^2[(p-1)\psi(t)t - \psi'(t)(1-t^2)]}\,,$$

$$\widehat{k} = \frac{n(p-1)\sum_i \psi(t_i)^2(1-t_i^2)}{\left\{\sum_i[(p-1)\psi(t_i)t_i - \psi'(t_i)(1-t_i^2)]\right\}^2}\,. \quad (31.48)$$

For the spherical case, the matrix $\boldsymbol{\Sigma} = \sum_i \boldsymbol{u}_i\boldsymbol{u}_i^{\mathrm{T}}$. Its dominant eigenvector $\boldsymbol{e}_1$ points in the direction of the center of the $\boldsymbol{u}_i$. The $\boldsymbol{e}_2$ is the vector perpendicular to $\boldsymbol{e}_1$ so that the two-dimensional plane spanned by $\boldsymbol{e}_1$ and $\boldsymbol{e}_2$ (and the origin) best fits the $\boldsymbol{u}_i$. This continues until $\boldsymbol{e}_1, \cdots, \boldsymbol{e}_{p-1}$ is the $(p-1)$-dimensional hyperplane, among the collection of all $(p-1)$-dimensional hyperplanes that bests fits the data. This latter hyperplane is, of course, the hyperplane perpendicular to $\boldsymbol{e}_p$. Except for this slight reinterpretation of the geometric meaning of the $\boldsymbol{e}_i$, our previous comments about the relationship of the uncertainties in $\widehat{\boldsymbol{h}}$ to the geometry of the $\boldsymbol{u}$-points, as summarized by the eigen-decomposition of $\boldsymbol{\Sigma}$, remain valid. Indeed the original Stock and Molnar insights about the uncertainties of tectonic plate reconstructions were actually in the spherical data context.

Thus, as before, the uncertainties in $\widehat{\mathbf{A}}$ are determined up to the constant k by the geometry of the $\boldsymbol{u}$-points. Only the constant k depends upon the underlying data distribution f_0 or upon the objective function ρ. We can define the asymptotic relative efficiency as in Sect. 31.4.7 without change. Its interpretation (31.39) also remains valid.

Equation (31.48) implies that we can, as before, define the asymptotic efficiency of the L_1 estimator relative to the least squares estimator, at the density f_0, as $\mathrm{ARE}(L_1, L_2; f_0) = k(f_0, L_2)/k(f_0, L_1)$. The interpretation (31.39) remains valid. The constants $k(f_0, L_2)$ and $k(f_0, L_1)$ come from (31.48) using the underlying density f_0 under consideration and $\rho_0(t) = 2 - 2t$ [refer to (31.9)], $\psi(t) = 2$, for the least squares case, or $\rho_0(t) = \arccos(t)$, $\psi(t) = (1-t^2)^{\frac{1}{2}}$, for the L_1 case. If f_0 is the Fisher–von Mises–Langevin density (31.47) on Ω_p (which we will denote by $F_{\kappa,p}$ in the following)

$$\mathrm{ARE}(L_1, L_2; F_{\kappa,p}) = \frac{\left[\int_{-1}^{1} \mathrm{e}^{\kappa t}(1-t^2)^{(p-2)/2}\,\mathrm{d}t\right]^2}{\left[\int_{-1}^{1} \mathrm{e}^{\kappa t}(1-t^2)^{(p-1)/2}\,\mathrm{d}t\right]} \times \frac{1}{\left[\int_{-1}^{1} \mathrm{e}^{\kappa t}(1-t^2)^{(p-3)/2}\,\mathrm{d}t\right]}\,. \quad (31.49)$$

As $\kappa \to \infty$, the limit of (31.49) is

$$\lim_{\kappa\to\infty}\mathrm{ARE}(L_1, L_2; F_{\kappa,p}) = \frac{2\Gamma^2(p/2)}{(p-1)\Gamma^2[(p-1)/2]}\,. \quad (31.50)$$

Comparing (31.40) with (31.50), we see that (31.50) is the same as (31.40) with p replaced by $p-1$. This is as expected because, as noted above, for large κ the Fisher–von Mises–Langevin distribution approaches a $(p-1)$-dimensional multivariate normal distribution. Figure 31.2 gives a graph of $\mathrm{ARE}(L_1, L_2; F_{\kappa,p})$ for $p = 2, 3$.

In particular for $p = 3$, $\mathrm{ARE}(L_1, L_2; F_\kappa, 3) \to \pi/4$. For the Fisher–von-Mises–Langevin distribution, least squares methods are optimal. Nevertheless, in standard error terms, the penalty for using L_1 methods is at most 13%.

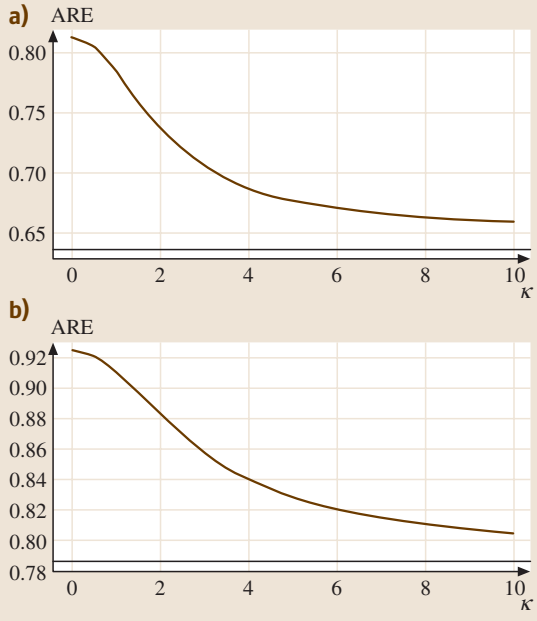

Fig. 31.2a,b Asymptotic efficiency of L_1 estimators relative to least squares estimators for Fisher–von Mises–Langevin distributions on Ω_p as a function of κ for **(a)** $p = 2$ and **(b)** $p = 3$. Horizontal lines are asymptotic limits as $\kappa \to \infty$.

31.5 Diagnostics

We discuss in this section influence function diagnostics for the Procrustes model. Suppose the registration provided by the estimates $(\widehat{\mathbf{A}}, \widehat{\gamma}, \widehat{\boldsymbol{b}})$ is unsatisfactory. These diagnostics will determine which points are influential for the estimated orthogonal matrix $\widehat{\mathbf{A}}$, which points are influential for the estimated scale change $\widehat{\gamma}$, and which are influential for the estimated translation $\widehat{\boldsymbol{b}}$.

31.5.1 Influence Diagnostics in Simple Linear Regression

As background discussion, we consider first the simple linear regression model

$$y_i = \alpha + \beta x_i + \text{error}\,, \tag{31.51}$$

where $x_i, y_i \in \mathbb{R}^1$. For simplicity, we will assume $\sum_i x_i = 0$. This can be accomplished by a centering transformation similar to that used in (31.29).

For the model (31.51), the least squares estimates are

$$\widehat{\alpha} = \overline{y}\,,$$
$$\widehat{\beta} = \left(\sum_i x_i^2\right)^{-1} \left(\sum_i x_i y_i\right)\,. \tag{31.52}$$

Suppose we delete the i-th observation (x_i, y_i) and recompute the estimates (31.52). The resulting estimates would be [see *Cook* and *Weisberg* [31.12], (3.4.6)]

$$\widehat{\alpha}_{(i)} = \widehat{\alpha} - (1 - v_{ii})^{-1} \frac{e_i}{n}\,,$$
$$\widehat{\beta}_{(i)} = \widehat{\beta} - (1 - v_{ii})^{-1} \frac{x_i e_i}{\sum_k x_k^2}\,, \tag{31.53}$$

where

$$e_i = y_i - \widehat{\alpha} - \widehat{\beta} x_i$$

is the residual, and

$$v_{ii} = \frac{1}{n} + \frac{x_i^2}{\sum_k x_k^2}$$

is the i-th diagonal entry of the so-called *hat* matrix. It can be shown that

$$0 \le v_{ii} \le 1\,,$$
$$\sum_i v_{ii} = 2\,. \tag{31.54}$$

If $|x_i|$ is big, $1 - v_{ii}$ can be close to zero, although because of (31.54), if n is large, this will usually not be the case. Ignoring the factor of $(1 - v_{ii})^{-1}$, it follows from (31.53) that deletion of (x_i, y_i) will be influential for $\widehat{\alpha}$ when the magnitude of the residual $|e_i|$ is big. Deletion of (x_i, y_i) will be influential for $\widehat{\beta}$ when both $|x_i|$ and $|e_i|$ are big. Points with large values of $|x_i|$ [typically, due to (31.54), $|x_i| > \frac{4}{n}$] are called *high-leverage* points, whereas points with large values of $|e_i|$ are called *outliers*. (Recall we have centered the data so that $\overline{x} = 0$.)

Thus influence on $\widehat{\alpha}$ and on $\widehat{\beta}$ are different. Outliers are influential for $\widehat{\alpha}$, whereas influence for $\widehat{\beta}$ is a combination of being an outlier and having high leverage. For the model (31.51) with the least squares estimators, the *influence function* works out to be

$$\mathrm{IF}\left[\widehat{\alpha}; (x_i, y_i)\right] = \frac{y_i - \alpha - \beta x_i}{n}\,, \tag{31.55}$$

$$\mathrm{IF}\left[\widehat{\beta}; (x_i, y_i)\right] = \frac{x_i(y_i - \alpha - \beta x_i)}{\sum_k x_k^2}\,, \tag{31.56}$$

where α and β are the 'true' population values in the model (31.51). We will not give a formal definition of the influence function here, but refer the reader to *Cook* and *Weisberg* [31.12] for a more comprehensive discussion of the influence function in the regression model.

It should be noted tthat to actually calculate (31.55) and (31.56) from a sample, it is necessary to estimate α and β. Thus, even though in the left-hand sides of (31.55) and (31.56), $\widehat{\alpha}$ and $\widehat{\beta}$ are least squares estimates, we should substitute in the right-hand sides of (31.55) and (31.56) better estimates, if available, of α and β. There is no contradiction in using L_1 estimates to estimate the influence function of the least squares estimators.

31.5.2 Influence Diagnostics for the Procrustes Model

Chang and *Ko* [31.3] calculated the *standardized influence functions* (SIF) for M-estimates (31.13) in the Procrustes model (31.29). (The influence functions of the estimates $\widehat{\mathbf{A}}$ and $\widehat{\beta}$ are vectors; the standardization calculates their square length in some metric.) Using their notation

$$||\mathrm{SIF}\left[\widehat{\beta}; (\boldsymbol{u}_i, \boldsymbol{v}_i)\right]||^2 = k_I \psi(s_i)^2\,, \tag{31.57}$$

where $s_i = ||\boldsymbol{v}_i - \gamma \mathbf{A}(\boldsymbol{u}_i - \overline{\boldsymbol{u}}) - \beta||$ and $\psi(s) = \rho_0'(s)$. Therefore

- the influence of $(\boldsymbol{u}_i, \boldsymbol{v}_i)$ on the estimate $\widehat{\beta}$ of the translation parameter depends only upon the length s_i of the residual.

This behavior is similar to that of simple linear regression (31.55). The constant k_I is given by

$$k_I = \frac{pE[g'(s)^2]}{E^2[\psi'(s)+(p-1)\psi(s)s^{-1}]} ,$$

where $g(s) = \log f_0(s)$ and $f_0(s)$ is defined in Sect. 31.4.3.

For the scale parameter γ, let $\mathbf{\Sigma} = n^{-1}\sum_i (\boldsymbol{u}_i - \overline{\boldsymbol{u}})(\boldsymbol{u}_i - \overline{\boldsymbol{u}})^{\mathrm{T}}$. Then

$$||\mathrm{SIF}[\widehat{\gamma}; (\boldsymbol{u}_i, \boldsymbol{v}_i)]||^2 = \frac{k_I \psi(s_i)^2}{\mathrm{Tr}(\mathbf{\Sigma})} \left[\boldsymbol{w}_i^{\mathrm{T}} \mathbf{A}(\boldsymbol{u}_i - \overline{\boldsymbol{u}})\right]^2 . \quad (31.58)$$

Here

$$\boldsymbol{w}_i = [\boldsymbol{v}_i - \gamma \mathbf{A}(\boldsymbol{u}_i - \overline{\boldsymbol{u}}) - \beta]/s_i .$$

Notice that $\boldsymbol{v}_i - \gamma\mathbf{A}(\boldsymbol{u}_i - \overline{\boldsymbol{u}}) - \beta$ is the residual of the i-th data point and s_i is its length. Thus $\boldsymbol{w}_i$ is a unit-length vector in the direction of the i-th data point. We conclude

- For a given length s_i of residual, a point $(\boldsymbol{u}_i, \boldsymbol{v}_i)$ will be influential for the estimate $\widehat{\gamma}$ of the scale parameter if $\boldsymbol{u}_i$ is far from the center $\overline{\boldsymbol{u}}$ of the data and if its residual is parallel to $\mathbf{A}(\boldsymbol{u}_i - \overline{\boldsymbol{u}})$.

For simplicity, we restrict the formulas of influence on the estimate of the orthogonal matrix $\mathbf{A}$ to the cases $p = 2, 3$. For $p = 2$,

$$||\mathrm{SIF}\left[\widehat{\mathbf{A}}; (\boldsymbol{u}_i, \boldsymbol{v}_i)\right]||^2 = \frac{k_I \psi(s_i)^2}{\mathrm{Tr}(\mathbf{\Sigma})} ||\boldsymbol{w}_i \times [\mathbf{A}(\boldsymbol{u}_i - \overline{\boldsymbol{u}})]||^2 . \quad (31.59)$$

The product on the right-hand side of (31.59) is the vector 'cross' product. Therefore

- For $p = 2$, for a given length s_i of residual, a point $(\boldsymbol{u}_i, \boldsymbol{v}_i)$ will be influential for the estimate $\widehat{\mathbf{A}}$ of the orthogonal matrix if $\boldsymbol{u}_i$ is far from the center $\overline{\boldsymbol{u}}$ of the data and if its residual is perpendicular to $\mathbf{A}(\boldsymbol{u}_i - \overline{\boldsymbol{u}})$. Thus points which are influential for $\widehat{\mathbf{A}}$ will not be influential for $\widehat{\gamma}$, and vice versa. Indeed

$$||\mathrm{SIF}[\widehat{\gamma}; (\boldsymbol{u}_i, \boldsymbol{v}_i)]||^2 + ||\mathrm{SIF}\left[\widehat{\mathbf{A}}; (\boldsymbol{u}_i, \boldsymbol{v}_i)\right]||^2 = \frac{k_I \psi(s_i)^2}{\mathrm{Tr}(\mathbf{\Sigma})} ||\boldsymbol{u}_i - \overline{\boldsymbol{u}}||^2 .$$

For $p = 3$, let $\lambda_1 \geq \lambda_2 \geq \lambda_3$ be the eigenvalues of Σ and let $\boldsymbol{e}_1, \boldsymbol{e}_2, \boldsymbol{e}_3$ be the corresponding eigenvectors. Write

$$\boldsymbol{w}_i \times \left(\mathbf{A}\frac{\boldsymbol{u}_i - \overline{\boldsymbol{u}}}{||\boldsymbol{u}_i - \overline{\boldsymbol{u}}||}\right) = x_1 \mathbf{A}\boldsymbol{e}_1 + x_2 \mathbf{A}\boldsymbol{e}_2 + x_3 \mathbf{A}\boldsymbol{e}_3 .$$

Then

$$\mathrm{SIF}\left[\widehat{\mathbf{A}}; (\boldsymbol{u}_i, \boldsymbol{v}_i)\right] = k_I \psi(s_i)^2 ||\boldsymbol{u}_i - \overline{\boldsymbol{u}}||^2 \times \left(\frac{x_1^2}{\lambda_2 + \lambda_3} + \frac{x_2^2}{\lambda_3 + \lambda_1} + \frac{x_3^2}{\lambda_1 + \lambda_2}\right) . \quad (31.60)$$

It follows

- For $p = 3$, for a given length s_i of residual and distance $||\boldsymbol{u}_i - \overline{\boldsymbol{u}}||$ of $\boldsymbol{u}_i$ from the center of the data, a point $(\boldsymbol{u}_i, \boldsymbol{v}_i)$ will be maximally influential for the estimate $\widehat{\mathbf{A}}$ of the orthogonal matrix if both $\boldsymbol{u}_i - \overline{\boldsymbol{u}}$ is perpendicular to the dominant eigenvector $\boldsymbol{e}_1$ of $\mathbf{\Sigma}$ and the residual

$$\boldsymbol{w}_i = \pm\mathbf{A}\left(\frac{\boldsymbol{u}_i - \overline{\boldsymbol{u}}}{||\boldsymbol{u}_i - \overline{\boldsymbol{u}}||} \times \boldsymbol{e}_1\right) .$$

- The influence of $(\boldsymbol{u}_i, \boldsymbol{v}_i)$ on $\widehat{\mathbf{A}}$ will be zero if

$$\boldsymbol{w}_i = \pm\mathbf{A}\left(\frac{\boldsymbol{u}_i - \overline{\boldsymbol{u}}}{||\boldsymbol{u}_i - \overline{\boldsymbol{u}}||}\right) .$$

- The maximum influence of the data on the estimate $\widehat{\mathbf{A}}$ of the orthogonal matrix can be minimized for fixed $\mathrm{Tr}(\mathbf{\Sigma})$ by making $\lambda_1 = \lambda_2 = \lambda_3$. Thus the optimal choice of landmarks would make the landmarks spherically symmetric around the center point $\overline{\boldsymbol{u}}$.

31.5.3 Example: Influence for the Hands Data

For the Procrustes model (31.29) and the hands data, we compare here the influence statistics for the least squares estimates $(\widehat{\mathbf{A}}_2, \widehat{\gamma}_2, \widehat{\boldsymbol{\beta}}_2)$ [given in (31.20) and (31.33)] to those for the the L_1 estimates $(\widehat{\mathbf{A}}_1, \widehat{\gamma}_1, \widehat{\boldsymbol{\beta}}_1)$ [in (31.34)]. These estimates correspond to $\psi_2(s) = s$ and $\psi_1(s) = 1$ respectively. In the right-hand sides of (31.57), (31.58), and (31.60), we substituted $s_i = ||\boldsymbol{v}_i - \widehat{\gamma}_1 \widehat{\mathbf{A}}_1(\boldsymbol{u}_i - \overline{\boldsymbol{u}}) - \widehat{\boldsymbol{\beta}}_1||$ to calculate the influence functions for both the L_1 and least squares estimates. Similarly the $\boldsymbol{w}_i$ were calculated using the L_1 estimates. Furthermore when (31.57), (31.58), and (31.60) were calculated for the i-th observation $(\boldsymbol{u}_i, \boldsymbol{v}_i)$, $\boldsymbol{u}_i$ was not used to calculate $\mathbf{\Sigma}$.

Using (31.57),

$$||\mathrm{SIF}[\widehat{\boldsymbol{\beta}}_2; (\boldsymbol{u}_i, \boldsymbol{v}_i)]||^2 \propto s_i^2 ,$$
$$||\mathrm{SIF}[\widehat{\boldsymbol{\beta}}_1; (\boldsymbol{u}_i, \boldsymbol{v}_i)]||^2 \propto 1 ,$$

so that E (top of thumb), followed by H (base of palm), are the most influential for $\widehat{\beta}_2$. All points are equally influential for $\widehat{\beta}_1$.

In what follows we will be interested in determining which data points are most influential for which estimates. In other words we will be interested in the relative values of $||\mathrm{SIF}||^2$. Thus, for each estimator, we renormalized the values of $||\mathrm{SIF}||^2$ so that their sum (over the 12 data points) equals 1. The results, together with the values of s_i, are shown in Fig. 31.3.

We have from (31.58) and (31.60)

$$||\mathrm{SIF}\,[\widehat{\gamma}_2;(\boldsymbol{u}_i,\boldsymbol{v}_i)]\,||^2 \propto s_i^2\left[\boldsymbol{w}_i^{\mathrm{T}}\mathbf{A}(\boldsymbol{u}_i-\overline{\boldsymbol{u}})\right]^2 ,$$

$$||\mathrm{SIF}\,[\widehat{\gamma}_1;(\boldsymbol{u}_i,\boldsymbol{v}_i)]\,||^2 \propto \left[\boldsymbol{w}_i^{\mathrm{T}}\mathbf{A}(\boldsymbol{u}_i-\overline{\boldsymbol{u}})\right]^2 ,$$

$$\left|\left|\mathrm{SIF}\left[\widehat{\mathbf{A}}_2;(\boldsymbol{u}_i,\boldsymbol{v}_i)\right]\right|\right|^2 \propto s_i^2\left|\left|\boldsymbol{u}_i-\overline{\boldsymbol{u}}\right|\right|^2 \left(\frac{x_1^2}{\lambda_2+\lambda_3}+\frac{x_2^2}{\lambda_3+\lambda_1}+\frac{x_3^2}{\lambda_1+\lambda_2}\right) ,$$

$$\left|\left|\mathrm{SIF}\left[\widehat{\mathbf{A}}_1;(\boldsymbol{u}_i,\boldsymbol{v}_i)\right]\right|\right|^2 \propto \left|\left|\boldsymbol{u}_i-\overline{\boldsymbol{u}}\right|\right|^2 \left(\frac{x_1^2}{\lambda_2+\lambda_3}+\frac{x_2^2}{\lambda_3+\lambda_1}+\frac{x_3^2}{\lambda_1+\lambda_2}\right) ,$$

$$\boldsymbol{w}_i\times\left[\widehat{\mathbf{A}}_1\frac{\boldsymbol{u}_i-\overline{\boldsymbol{u}}}{||\boldsymbol{u}_i-\overline{\boldsymbol{u}}||}\right] = x_1\widehat{\mathbf{A}}_1\boldsymbol{e}_1+x_2\widehat{\mathbf{A}}_1\boldsymbol{e}_2+x_3\widehat{\mathbf{A}}_1\boldsymbol{e}_3 .$$

Examining Fig. 31.3, we see that point E is by far the most influential point for $\widehat{\mathbf{A}}$. Its relative influence however can be somewhat diminished by using L_1 estimates. The value of $||\boldsymbol{u}_{\mathrm{E}}-\overline{\boldsymbol{u}}||$ is also the largest of the $||\boldsymbol{u}_i-\overline{\boldsymbol{u}}||$. It turns out that $\boldsymbol{u}_{\mathrm{E}}-\overline{\boldsymbol{u}}$ makes an angle of 13° with $\boldsymbol{e}_2$ and that the unit length $\boldsymbol{w}_{\mathrm{E}}$ makes an angle of 12° with $\widehat{\mathbf{A}}_1\boldsymbol{e}_3$. Thus x_1 will be relatively big and x_2, x_3 relatively small. This accounts for the strong influence of point E on both estimates of $\mathbf{A}$. Notice that s_{E} and $||\boldsymbol{u}_{\mathrm{E}}-\overline{\boldsymbol{u}}||$ are sufficiently big that, despite the directions of $\boldsymbol{w}_{\mathrm{E}}$ and $\widehat{A}_1(\boldsymbol{u}_{\mathrm{E}}-\overline{\boldsymbol{u}})$, E is still fairly influential for $\widehat{\gamma}_2$. However, its influence on $\widehat{\gamma}_1$, which does not depend upon s_{E}, is quite small.

The point H (base of the palm) is the most influential point for $\widehat{\gamma}$. H is perhaps the least well-defined point so that it is not surprising that its residual length s_{H} is relatively big. It also defines the length of the hand, so that its influence on $\widehat{\gamma}$ is not surprising. Indeed if H were completely deleted, $\widehat{\gamma}_2$ would change from 0.9925 to 1.0110 and $\widehat{\gamma}_1$ changes from 1.0086 to 1.0262.

One might think that C (top of the middle finger) would also be influential for $\widehat{\gamma}$. In a coordinate system of the eigenvectors of $\boldsymbol{\Sigma}$,

$$\boldsymbol{u}_{\mathrm{H}}-\overline{\boldsymbol{u}} = \begin{bmatrix} -3.98 & 1.15 & 0.33 \end{bmatrix}^{\mathrm{T}}$$

$$\boldsymbol{u}_{\mathrm{C}}-\overline{\boldsymbol{u}} = \begin{bmatrix} 3.55 & -0.77 & -0.03 \end{bmatrix}^{\mathrm{T}}$$

so that $\boldsymbol{u}_{\mathrm{H}}-\overline{\boldsymbol{u}} \approx -(\boldsymbol{u}_{\mathrm{C}}-\overline{\boldsymbol{u}})$. It is useful here to remember that $\boldsymbol{e}_1$ is approximately in the direction of the length of the left hand. Furthermore s_{C} and s_{H} are reasonably close.

However Fig. 31.3 indicates that C has negligible influence on both estimates of γ. Indeed if C were completely deleted, $\widehat{\gamma}_2$ would only change from 0.9925 to 0.9895 and $\widehat{\gamma}_1$ change from 1.0086 to 1.0047. These changes are much smaller than those caused by the deletion of H.

The difference is that $\widehat{\mathbf{A}}_1(\boldsymbol{u}_{\mathrm{C}}-\overline{\boldsymbol{u}})$ makes an angle of 88° with $\boldsymbol{w}_{\mathrm{C}}$. In other words $\widehat{\mathbf{A}}_1(\boldsymbol{u}_{\mathrm{C}}-\overline{\boldsymbol{u}})$ and $\boldsymbol{w}_{\mathrm{C}}$ are very close to perpendicular (Perhaps the close to perpendicularity of the residual at C to $\widehat{\mathbf{A}}_1(\boldsymbol{u}_{\mathrm{C}}-\overline{\boldsymbol{u}})$ is to be expected. The uncertainty in locating C is roughly tangential to the middle finger tip.) Hence the influence of C on $\widehat{\gamma}$ is negligible.

On the other hand, $\widehat{\mathbf{A}}_1(\boldsymbol{u}_{\mathrm{H}}-\overline{\boldsymbol{u}})$ makes an angle of 124° with $\boldsymbol{w}_{\mathrm{H}}$. This accounts for the greater influence of H.

Thus if the registration between the two hands is unsatisfactory in either the translation or rotation parameters, point E should be inspected. If it is unsatisfactory in the scale change, point H should be checked.

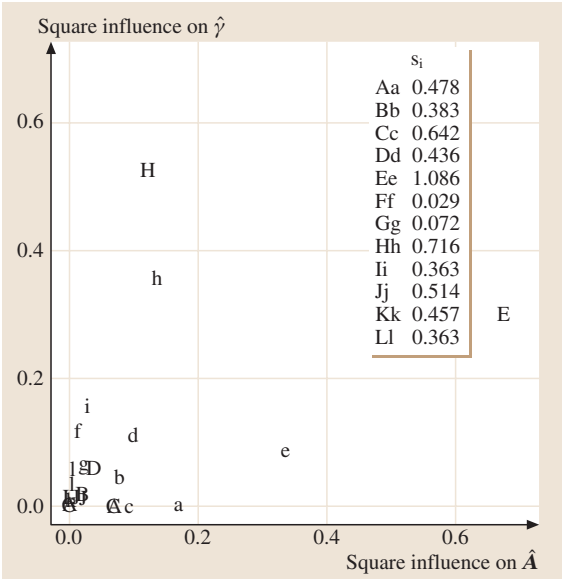

Fig. 31.3 Relative influence of hands data points on least squares (upper case) and L_1 estimates (lower case) of γ and $\mathbf{A}$

32. Statistical Genetics for Genomic Data Analysis

In this chapter, we briefly summarize the emerging statistical concepts and approaches that have been recently developed and applied to the analysis of genomic data such as microarray gene expression data. In the first section we introduce the general background and critical issues in statistical sciences for genomic data analysis. The second section describes a novel concept of statistical significance, the so-called false discovery rate, the rate of false positives among all positive findings, which has been suggested to control the error rate of numerous false positives in large screening biological data analysis. In the next section we introduce two recent statistical testing methods: significance analysis of microarray (SAM) and local pooled error (LPE) tests. The latter in particular, which is significantly strengthened by pooling error information from adjacent genes at local intensity ranges, is useful to analyze microarray data with limited replication. The fourth section introduces analysis of variation (ANOVA) and heterogenous error modeling (HEM) approaches that have been suggested for analyzing microarray data obtained from multiple experimental and/or biological conditions. The last two sections describe data exploration and discovery tools largely termed *supervised learning* and *unsupervised learning*. The former approaches include several multivariate statistical methods for the investigation of coexpression patterns of multiple genes, and the latter approaches are used as classification methods to discover genetic markers for predicting important subclasses of human diseases. Most of the statistical software packages for the approaches introduced in this chapter are freely available at the open-source bioinformatics software web site (Bioconductor; http://www.bioconductor.org/).

Accelerated by the Human Genome Project, recent advances in high-throughput biotechnologies have dramatically changed the horizon of biological and biomedical sciences. Large screening expression profiling techniques such as DNA microarrays, mass spectrometry, and protein chips offer great promise for functional genomics and proteomics research, and have the potential to transform the diagnosis and treatment of human diseases [32.1]. In particular, DNA microarray and GeneChip^{TM}gene expression approaches are becoming increasingly important in current biomedical studies [32.2–4].

Analysis of such genome-wide data, however, has brought extreme challenges not only in the biological sciences but also in the statistical sciences. Fundamental difficulties exist in applying traditional statistical approaches to genome-wide expression data, namely the *multiple comparisons issue* and the *small n–large p problem* [32.5]. The former problem arises because classical statistical hypothesis testing, modeling, and inference strategies are designed for studying a small number of candidate targets at a time, whereas one often investigates tens of thousands of genes' differential expression in a single microarray study. For example,

when a two-sample t-test is applied for evaluating statistical significance of thousands of genes' differential expression patterns in a microarray study, the p-values obtained from this within-gene test must be adjusted to take into account the random chance of all the candidate genes in the array data.

The latter difficulty, the small n–large p problem, arises due to the fact that many biological and biomedical microarray studies are performed with a small number of replicated arrays, or without replication. Unlike DNA sequence information, gene expression data are context-dependent and offer different interpretations depending on (patient) sample condition, time point, and treatment for a single subject [32.6]. In addition to the high costs of microarray experiments, certain biological or human patient specimens are often limited, thereby necessitating that microarray studies be performed with limited replication. Consequently, one must perform statistical inference on a small number of observations (n) compared to a large number of potential predictor genes (p). The latter number of tens of thousands of genes is simply too large to be considered in standard statistical testing and modeling, whereas the sample size (or number of replicated arrays at each condition) of a microarray study is typically small, a few tens at most and often only one or two replicates. This presents great difficulty for the application of traditional statistical approaches, which generally require a reasonably large sample size for maximal performance. As microarray (and similar high-throughput) technology becomes an important tool in biological and biomedical investigation, the lack of appropriate statistical methods for large screening microarray data will undoubtedly become a great obstacle in the current biological sciences. In this chapter, we will briefly summarize the statistical approaches that have been applied to microarray gene expression data analysis by avoiding these pitfalls.

We also introduce several multivariate statistical methods that have been used to investigate the coregulation structures of multiple genes as *unsupervised learning* and to discover genetic markers for predicting important subclasses of human diseases and biological targets as *supervised learning*. In particular, clustering approaches have been widely applied to the analysis of gene expression microarray data. The method of visualizing gene expression data based on cluster order, so-called cluster-image map (CIM) analysis, is found to be very efficient in summarizing the thousands of gene expression values and aiding in the identification of some interesting patterns of gene expression [32.3,7,8]. Since a clustering algorithm provides an efficient dimension reduction for extremely high-dimensional data based on their association, it is much easier to simultaneously screen thousands of gene expression values and to identify interesting patterns on the image maps. The statistical software packages for most of these approaches are freely available at the open-source bioinformatics development web site (Bioconductor; http://www.bioconductor.org/).

We note that this kind of microarray data analysis is implemented based on certain standard preprocessing procedures. Suppose we have gene expression data with n genes and p arrays. A matrix of this gene expression data is defined by $Y_{n\times p}$ with n rows and p columns. The data are then typically log2-transformed to remedy the right-skewed distribution, to make error components additive, and to aplly other statistical procedures that are based on underlying Gaussian distributional assumptions. Each column of the matrix (or each array) is scaled or normalized to a common baseline by matching interquartile ranges or by nonparametric regression methods, e.g., lowess.

32.1 False Discovery Rate

In order to avoid a large number of false positive findings (or type I errors) in genomic data analysis, the classical family-wise error rate (FWER) has initially been used to control for the random chance of multiple candidates by evaluating the probability that at most one false positive is included at a cutoff level of a statistic [32.9]. However, FWER adjustment has been found to be very conservative in microarray studies, resulting in a high false-negative error rate [32.10]. To avoid pitfalls such as this, a novel statistical significance concept, the so-called *false discovery rate* (FDR) and its refinement, the *q-value*, have been suggested [32.11, 12] (QVALUE package at Bioconductor). FDR is defined as follows. Consider a family of m simultaneously tested null hypotheses of which m_0 are true. For each hypothesis H_i a test statistic is calculated along with the corresponding p-value, P_i. Let R denote the number of hypotheses rejected by a procedure, V the number of true null

hypotheses erroneously rejected, and S the number of false hypotheses rejected as summarized in Table 32.1. Now let Q denote V/R when $R > 0$ and 0 otherwise. Then the FDR is defined as the expectation of Q, i. e. FDR$= E(Q)$.

As shown in [32.11], the FDR of a multiple comparison procedure is always smaller than or equal to the FWER, where equality holds if all null hypotheses are true. Thus, control of the FDR implies control of the FWER only when all null hypotheses are true, but it generally controls such an error rate much less conservatively than FWER because there exist quite a few true positives in practical data analysis. In the context of gene expression analysis, this result means that, if FDR is controlled at some level q, then the probability of erroneously detecting any differentially expressed genes among all genes identified by a certain selection criterion is less than or equal to q. Intuitively, FDR controls the expected proportion of false positives among all candidate genes identified significantly by a testing criterion. Therefore, based on FDR, researchers can now assess their statistical confidence among the identified targets with a much smaller false-negative error rate. FDR evaluation has been rapidly adopted for microarray data analysis including the significance analysis of microarrays (SAM) and local pooled error (LPE) approaches [32.9, 10, 13].

Table 32.1 Outcomes when testing m hypotheses

Hypothesis	Accept	Reject	Total
Null true	U	V	m_0
Alternative true	T	S	m_1
Total	W	R	m

32.2 Statistical Tests for Genomic Data

Each gene's differential expression pattern in a microarray experiment is usually assessed by (typically pairwise) contrasts of mean expression values among experimental conditions. Such comparisons have been routinely assessed as fold changes whereby genes with greater than two or three fold changes are selected for further investigation. It has been frequently found that a gene showing a high fold-change between experimental conditions might also exhibit high variability and hence its differential expression may not be significant. Similarly, a modest change in gene expression may be significant if its differential expression pattern is highly reproducible. A number of authors have pointed out this fundamental flaw in the fold-change-based approach [32.14]. In order to assess differential expression in a way that controls both false positives and false negatives, a standard approach is emerging based on statistical significance and hypothesis testing, with careful attention paid to the reliability of variance estimates and multiple comparison issues.

The classical two-sample t-statistic has initially been used for testing each gene's differential expression; procedures such as the Westfall–Young step-down method have been suggested to control FWER [32.9]. These t-test procedures, however, rely on reasonable estimates of reproducibility or within-gene error to be constructed, requiring a large number of replicated arrays. When a small number of replicates are available per condition, e.g. duplicate or triplicate, the use of naive, within-gene estimates of variability does not provide a reliable hypothesis-testing framework. For example, a gene may have very similar differential expression values in duplicate experiments by chance alone. This can lead to inflated signal-to-noise ratios for genes with low but similar expression values. Furthermore, the comparison of means can be misled by outliers with dramatically smaller or bigger expression intensities than other replicates. As such, error estimates constructed solely within genes may result in underpowered tests for differential expression comparisons and also result in large numbers of false positives.

A number of approaches to improving estimates of variability and statistical tests of differential expression have thus recently emerged. Several variance function methods have been proposed. Reference [32.15] suggested a simple regression estimation of local variances; [32.16] used a smoothing-spline pooled-error method by regressing standard error estimates on the mean log intensities; and [32.17] estimates a two-parameter variance function of mean expression intensity. Reference [32.18] compared some of these variance-estimation methods. Recently, [32.19] suggested the use of data-adapted robust estimate of array error based on a smoothing spline and standardized local median absolute deviation (MAD). The variance function methods described above borrow strength across genes in order to improve reliability of variance estimates in differential expression tests. This is conceptually similar to the SAM method of [32.10] and the empirical Bayes methods of [32.20] and [32.21].

These methods also shrink the within-gene variance estimate towards an estimate including more genes, and construct signal-to-noise ratios using the shrunken variance in a similar fashion to the local-pooled-error (LPE) test described below.

The local-pooled-error (LPE) estimation strategy has also been introduced for within-gene expression error, whereby variance estimates for genes are formed by pooling variance estimates for genes with similar expression intensities from replicated arrays within experimental conditions [32.13]. The LPE approach leverages the observations that genes with similar expression intensity values often show similar array-experimental variability within experimental conditions; and that variance of individual gene expression measurements within experimental conditions typically decreases as a (nonlinear) function of intensity [32.5,22]. The LPE approach handles the situation where a gene with low expression may have very low variance by chance and the resulting signal-to-noise ratio is unrealistically large. The pooling of errors within local intensities shrinks such variances to the variance of genes with similar intensities. In this chapter, two recent statistical testing procedures – SAM and LPE – are described in more detail while many classical testing and p-value adjustment strategies can be found elsewhere [32.9].

32.2.1 Significance Analysis of Microarrays

The significance analysis of microarrays (SAM) approach is based on analysis of random fluctuations in the data [32.10] (SIGGENES package at Bioconductor). Based on the observation that the signal-to-noise ratio decreases with decreasing gene expression, as shown in [32.13], fluctuations are considered to be gene specific even for a given level of expression in [32.10]. To account for gene-specific fluctuations, a statistic is defined based on the ratio of change in gene expression to standard deviation in the data for that gene. The *relative difference* $d(i)$ in gene expression is:

$$d(i) = \frac{\bar{x}_I(i) - \bar{x}_U(i)}{s(i) + s_0}\,, \tag{32.1}$$

where $x_I(i)$ and $x_U(i)$ are defined as the average levels of expression for gene (i) in states I and U, respectively. The *gene-specific scatter* $s(i)$ is the standard deviation of repeated expression measurements:

$$s(i) = \sqrt{a\left\{\sum_m [x_m(i) - \bar{x}_I(i)]^2 + \sum_n [x_n(i) - \bar{x}_U(i)]^2\right\}}\,, \tag{32.2}$$

where $\sum_m$ and $\sum_n$ are summations of the expression measurements in states I and U, respectively, $a = (1/n_1 + 1/n_2)/(n_1 + n_2 - 2)$, and n_1 and n_2 are the numbers of measurements in states I and U. To compare values of $d(i)$ across all genes, the distribution of $d(i)$ is assumed to be independent of the level of gene expression. At low expression levels, variance in $d(i)$ can be high because of small values of $s(i)$. To ensure that the variance of $d(i)$ is independent of gene expression, a small positive constant s_0 is added to the denominator of (32.1). The coefficient of variation of $d(i)$ is computed as a function of $s(i)$ in moving windows across the data. The value for s_0 was chosen to minimize the coefficient of variation.

32.2.2 The Local-Pooled-Error Test

The local-pooled-error (LPE) method has been introduced specifically for analysis of small-sample microarray data, whereby error variance estimates for genes are formed by pooling variance estimates for genes with similar expression intensities from replicated arrays within experimental conditions [32.13] (LPE package at Bioconductor). The LPE approach leverages the observations that genes with similar expression intensity values often show similar array-experimental variability within experimental conditions; and that variance of individual gene-expression measurements within experimental conditions typically decreases as a (nonlinear) function of intensity, as shown in Fig. 32.1. This is due, in part, to common background noise at each spot of the microarray. At high levels of expression intensity, this background noise is dominated by the expression intensity, while at low levels the background noise is a larger component of the observed expression intensity. The LPE approach controls the situation where a gene with low expression may have very low variance by chance and the resulting signal-to-noise ratio is unrealistically large. The LPE method borrows strength across genes in order to improve accuracy of error variance estimation in microarray data. This is conceptually similar to the SAM method above and the empirical Bayes methods of [32.20], which shrink the within-gene variance estimate towards an estimate including more genes in a similar fashion to LPE.

To take into account heterogeneous error variability across different intensity ranges in microarray data, the LPE method can be applied as follows (refer to [32.13] for a more detailed technical description). For oligo array data, let x_{ijk} be the observed expression intensity at gene j for array k and sample i. For duplicate

arrays, $k = 1, 2$, plots of $A = \log 2(x_{ij_1} x_{ij_2})/2$ versus $M = \log 2(x_{ij_1}/x_{ij_2})$, $j = 1, \ldots, J$, can facilitate the investigation of between-duplicate variability in terms of overall intensity. The A versus M (or AM) plot provides a very raw look at the data and is useful in detecting outliers and patterns of intensity variation as a function of mean intensity [32.9]. At each of the local intensity regions of the AM plot under a particular biological condition, the unbiased estimate of the local variance is obtained. A cubic spline is then fit to these local variance estimates to obtain a smoothing variance function. The optimal choice of the effective degree of freedom df_λ of the fitted smoothing spline is obtained by minimizing the expected squared prediction error. This two-stage error estimation approach – estimation of the error of M within quantiles and then nonparametric smoothing on these estimates – is used because direct nonparametric estimation often leads to unrealistic (small or large) estimates of error when only a small numbers of observations are available at a fixed-width intensity range.

Based on the LPE estimation above, statistical significance of the LPE-based test is evaluated as follows. First, each gene's medians under the two compared conditions are calculated to avoid artifacts from outliers. The approximate normality of medians can be assumed with a small number of replicates based on the fact that the individual log-intensity values within a local intensity range follow a normal distribution [32.13]. The LPE statistic for the median (log-intensity) difference z is then calculated as:

$$z = (m_1 - m_2)/s_{\text{pooled}} , \qquad (32.3)$$

where m_1 and m_2 are the median intensities in two the compared array-experimental conditions X and Y, and s_{pooled} is the pooled standard error, $\left[s_x^2(m_1)/n_1 + s_y^2(m_2)/n_2\right]^{1/2}$ from the LPE-estimated baseline variances of s_x^2 and s_y^2. The LPE approach shows a significantly better performance than two-sample t-test, SAM, and Westfall–Young permutation tests, especially when the number of replicates is smaller

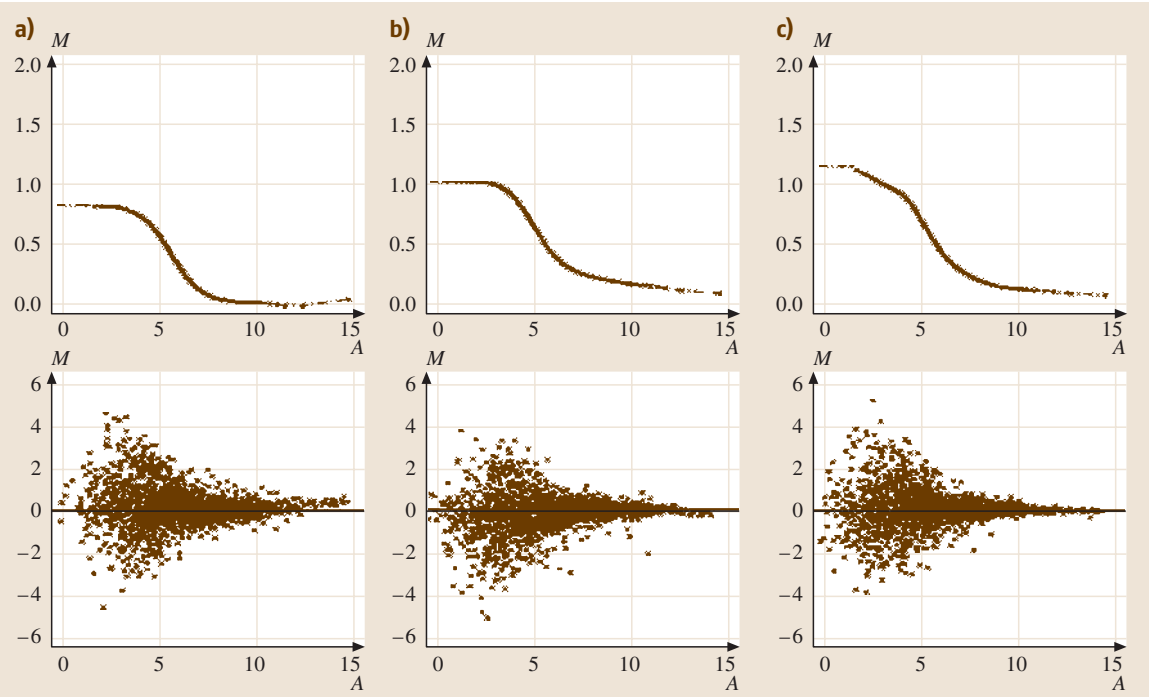

Fig. 32.1a–c Log intensity ratio $\log_2 \frac{X_{ij1}}{X_{ij2}}$ (M) as a function of average gene expression $\log_2 \sqrt{x_{ij1} x_{ij2}}$ (A). The *top row* of panels **(a)**, **(b)** and **(c)** represent local pooled error (LPE) for naive, 48 h activated, and T-cell clone D4 conditions, respectively, in the mouse immune-response microarray study in [32.13]. Variance estimates in percentile intervals are shown as *points*, and a *smoothed curve* superimposing these points is also shown. The *bottom row* of panels represent the corresponding M-versus-A graphs. The *horizontal line* represents identical expression between replicates

than ten. In a simulation study from a Gaussian distribution without extreme outliers, the LPE method showed a significant improvement of statistical power with three and five replicates (see Figure 2 in [32.13]).

32.3 Statistical Modeling for Genomic Data

Microarray gene-expression studies are also frequently performed for comparing complex, multiple biological conditions and pathways. Several linear modeling approaches have been introduced for analyzing microarray data with multiple conditions. Reference [32.23] considered an analysis of variance (ANOVA) model to capture the effects of dye, array, gene, condition, array–gene interaction, and condition–gene interaction separately on cDNA microarray data, and [32.24] proposed a two-stage mixed model that first models cDNA microarray data with the effects of array, condition, and condition–array interaction, and then fits the residuals with the effects of gene, gene–condition interaction, and gene–array interaction. Several approaches have also been developed under the Bayesian paradigm for analyzing microarray data including: the Bayesian parametric modeling [32.25], the Bayesian regularized t-test [32.21], the Bayesian hierarchical modeling with a multivariate normal prior [32.26], and the Bayesian heterogeneous error model (HEM) with two error components [32.27]. The ANOVA and HEM approaches are introduced in this chapter.

32.3.1 ANOVA Modeling

Reference [32.23] first suggested the use of analysis of variance (ANOVA) models to both estimate relative gene expression and to account for other sources of variation in microarray data. Even though the exact form of the ANOVA model depends on the particular data set, a typical ANOVA model for two-color-based cDNA microarray data can be defined as

$$y_{ijkg} = \mu + A_i + D_j + V_k + G_g + (AD)_{ij} + (AG)_{ig} + (DG)_{ig} + (VG)_{kg} + \epsilon_{ijkg} \,, \tag{32.4}$$

where y_{ijkg} is the measured intensity from array i, dye j, variety k, and gene g on an appropriate scale (typically the log scale). The generic term *variety* is often used to refer to the mRNA samples under study, such as treatment and control samples, cancer and normal cells, or time points of a biological process. The terms A, D, and AD account for all effects that are not gene-specific. The gene effects G_g capture the average levels of expression for genes and the array-by-gene interactions $(AG)_{ig}$ capture differences due to varying sizes of spots on arrays. The dye-by-gene interactions $(DG)_{jg}$ represent gene-specific dye effects. None of the above effects are of biological interest, but amount to a normalization of the data for ancillary sources of variation. The effects of primary interest are the interactions between genes and varieties, $(VG)_{kg}$. These terms capture differences from overall averages that are attributable to the specific combination of variety k and gene g. Differences among these variety-by-gene interactions provide the estimates for the relative expression of gene g in varieties 1 and 2 by

$$(VG)_{1g} - (VG)_{2g} \,.$$

Note that AV, DV, and other higher-order interaction terms are typically assumed to be negligible and considered together with the error terms. The error terms ϵ_{ijkg} are often assumed to be independent with mean zero and variance σ^2. However, such a *global* ANOVA model is difficult to implement in practice due to its computational restriction. Instead, one often considers gene-by-gene ANOVA models like:

$$y_{ijkg} = \mu_g + A_i + D_j + V_k + (AD)_{ij} + (VG)_{kg} + \epsilon_{ijkg} \,. \tag{32.5}$$

Alternatively, a two-stage ANOVA model is used [32.24]. The first layer is for the main effects that are not specific to the gene

$$y_{ijkg} = \mu + A_i + D_j + V_k + (AD)_{ij} + (AG)_{ig} + \epsilon_{ijkg} \,. \tag{32.6}$$

Let r_{ijkg} be the residuals from this first ANOVA fit. Then, the second-layer ANOVA model for gene-specific effects is considered as

$$r_{ijkg} = G_g + +(AG)_{ig} + (DG)_{ig} + (VG)_{kg} + \nu_{ijkg} \,. \tag{32.7}$$

Except the main effects of G and V and their interaction effects, the other terms A, D, (AD), (AG), and (DG) can be considered as random effects. These within-gene ANOVA models can be implemented using most standard statistical packages, such as R, SAS, or SPSS.

32.3.2 The Heterogeneous Error Model

Similarly to the statistical tests for comparing two sample conditions, the above within-gene ANOVA modeling methods are underpowered and have inaccurate error estimation in microarray data with limited replication. Using a Bayesian hierarchical approach with LPE-based (or error-pooling) empirical Bayes prior constructions, [32.27] have constructed a heterogeneous error model (HEM) with two layers of error to decompose the total error variability into the technical and biological error components in microarray data (HEM package at Bioconductor). Utilizing the LPE-estimated error-distribution information of microarray data for its empirical Bayes prior specifications, this modeling strategy provides separate estimates of the technical and biological error components in microarray data, especially the former error component, significantly more accurately. The first layer is constructed to capture the array technical variation due to many experimental error components, such as sample preparation, labeling, hybridization, and image processing

$$y_{ijkl} = x_{ijk} + \epsilon_{ijkl}\,, \quad \text{where}$$
$$\epsilon_{ijkl} \sim \text{iid Normal} \left[0, \sigma_\epsilon^2(x_{ijk})\right]\,, \tag{32.8}$$

where i = 1, 2, ..., G; j = 1, 2, ..., C; k = 1, 2, ..., m_{ij}; l = 1, 2, ..., n_{ijk}, and iid means independently and identically distributed. The second layer is then hierarchically constructed to capture the biological error component:

$$x_{ijk} = \mu + g_i + c_j + r_{ij} + b_{ijk}\,, \quad \text{where}$$
$$b_{ijk} \text{ iid Normal} \left[0, \sigma_b^2(ij)\right]\,. \tag{32.9}$$

Here, the genetic parameters are for the grand mean (shift or scaling) constant, gene, cell, interaction effects, and the biological error; the last error term varies and is heterogeneous for each combination of different genes and conditions. Note that the biological variability is individually assessed for discovery of biologically relevant expression patterns in this approach.

Bayesian posterior estimates and distributions are quite dependent on their prior specifications when the sample size is small in a microarray study. This difficulty in Bayesian applications to microarray data has been well-recognized and several authors have suggested the use of more-informative empirical Bayes priors [32.28, 29]. In these studies, empirical Bayes (EB) priors are used for defining distributions of genes with different expression patterns, e.g., distributions for equivalently and differentially expressed genes. Such specifications would be useful to determine each gene's expression pattern when the number of different expression patterns is small. However, as the number of conditions increases, the number of expression patterns increases exponentially, and these EB approaches quickly become impractical; many of these prior distributions also become unidentifiable. Conversely, the EB priors in HEM are used for specification of the two layers of error – technical and biological errors – which can be directly observed from each array data set, and can also be reliably estimated by the LPE method, pooling information from the genes with similar expression intensity. Thus, a nonparametric EB prior for the technical error $\sigma^2(x_{ijk})$ that is estimated by the LPE method and sampled by bootstrapping at each intensity x_{ijk}, whereas a parametric EB prior, Gamma (α, β_{ij}) is used because this error should freely vary to reflect the actual sampling variability of different biological subjects. Using these error-pooling-based prior specifications, HEM has demonstrated its improved performance in small sample microarray data analysis both in simulated and practical microarray data, see Fig. 32.2.

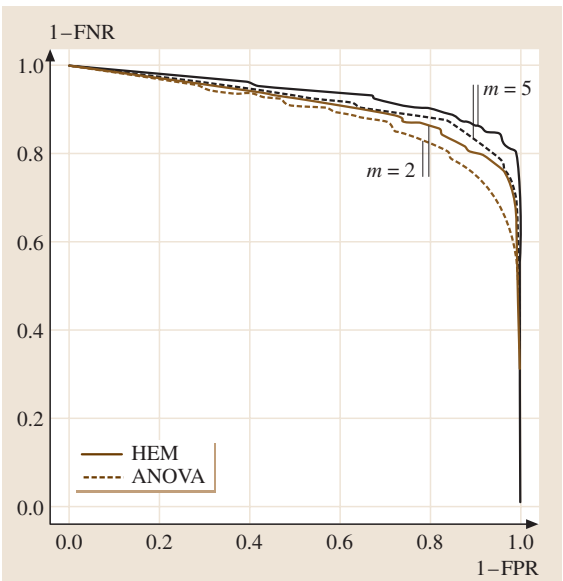

Fig. 32.2 ROC curves from HEM (*solid lines*) and ANOVA (*dotted lines*) models with two and five replicated arrays; The *horizontal axis* is 1 − FPR = 1 − Pr(positive|negative) and the *vertical axis* is 1 − FNR = 1 − Pr(negative|positive)

32.4 Unsupervised Learning: Clustering

Clustering analysis is widely applied to search for the groups (clusters) in microarray data because these techniques can effectively reduce the high-dimensional gene-expression data into a two-dimensional dendrogram organized by each gene's expression-association patterns. These clustering approaches first need to be defined by a measure or distance index of similarity or dissimilarity such as

- Euclidean: $d(x, y) = \sum_k (x_k - y_k)^2$;
- Manhattan: $d(x, y) = \sum |x_k - y_k|$;
- Correlation: $d(x, y) = 1 - r(x, y)$, where $r(x, y)$ is the Pearson or Spearman sample-correlation coefficient.

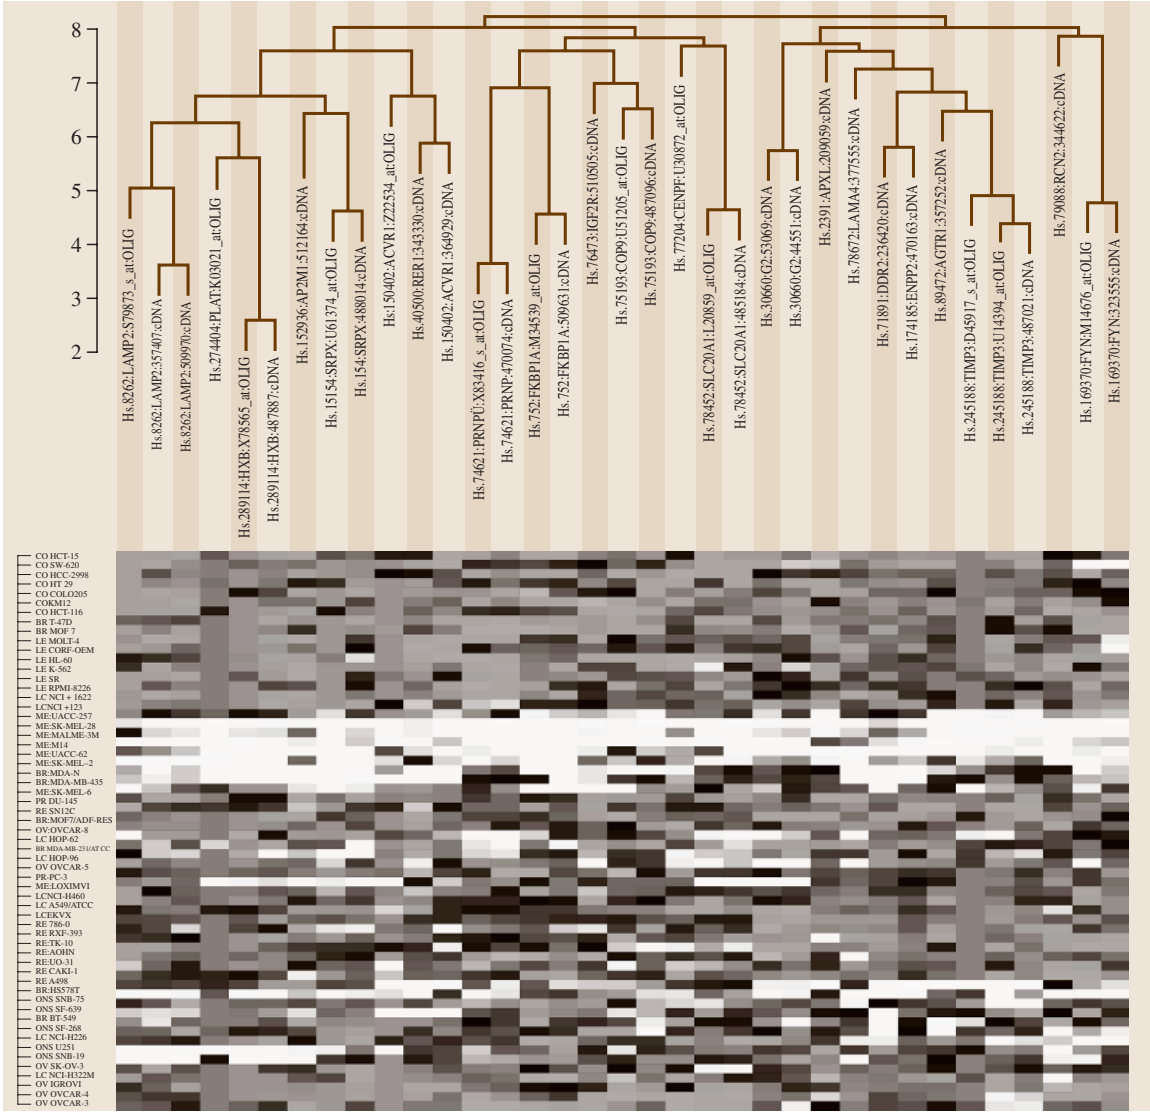

Fig. 32.3 Clustered image maps (CIMs) for hierarchical clustering of the cDNA and oligo array expression patterns. Each gene expression pattern is designated as coming from the cDNA or oligo array set. A region of CIM occupied by melanoma genes from the combined set of 3297 oligo and cDNA transcripts [32.3]

Note that if x and y are standardized, i. e., subtracted by each mean and divided by each standard deviation, then Euclidean and correlation distances can be easily shown to be mathematically equivalent:

$$\begin{aligned}\sum_k (x_k - y_k)^2 &= \sum_k \left(x_k^2 + y_k^2 - 2x_k y_k\right) \\ &= 2\left(1 - \sum_k x_k y_k\right) \\ &= 2[1 - r(x, y)] \,.\end{aligned}$$

Two classes of clustering algorithms have been used in genomic data analysis. The first class of clustering algorithms is based on hierarchical allocation including

1. Agglomerative methods:
   a) average linkage based on group average distance [32.3, 7]
   b) single linkage based on minimum nearest distance
   c) complete linkage based on maximum furthest distance.
2. Probability-based clustering: Bayes factor or posterior probability for choosing k clusters
3. Divisive methods: monothetic variable division, polythetic division

A cluster-image map is shown for the microarray data of the NCI 60 cancer cell lines in Fig. 32.3.

The second class is the partitioning algorithms that divide the data into a prespecified number of subsets including:

1. Self-organizing map: divides the data into a geometrically preset grid structure of subclusters [32.8];
2. Kmeans: iterative relocation clustering into a predefined number of subclusters;
3. Pam (partitioning around medoids) similar to, but more robust than Kmeans clustering;
4. Clara: clustering for applications to large data sets;
5. Fuzzy algorithm: provide fractions of membership, rather than deterministic allocations.

One of the most difficult aspects of using these clustering analyses is to interpret their heuristic, often unstable clustering results. To overcome this shortcoming, several refined clustering approaches have been suggested. For example, [32.23] suggest the use of bootstrapping to evaluate the consistency and confidence of each gene's membership to particular cluster groups. The *gene shaving* approach has been suggested to find the clusters directly relevant to major variance directions of an array data set [32.30]. Recently, *tight clustering*, a refined bootstrap-based hierarchical clustering is proposed to formally assess and identify the groups of genes that are most tightly clustered to each other [32.31].

32.5 Supervised Learning: Classification

Applications of microarray data have received considerable attention in many challenging classification problems in biomedical research [32.2, 32, 33]. In particular, such applications have been conducted in cancer research as alternative diagnostic techniques to the traditional ones such as classification by the origin of cancer tissues and/or the microscopic appearance; the latter are far from satisfaction for the prediction of many critical human disease subtypes [32.34]. Several different approaches to microarray classification modeling have been proposed, including gene voting [32.2], support vector machines (SVMs) [32.35, 36], Bayesian regression models [32.33], partial least squares [32.37], genetic-algorithm k-nearest-neighbor (GA/KNN) method [32.38], and between-group analysis [32.39].

Microarray data often have tens of thousands of genes on each chip whereas only a few tens of samples or replicated arrays are available in a microarray study. Therefore, it is desirable to avoid overfitting and to find a best subset of the thousands of genes for constructing classification rules and models that are robust to different choices of training samples and provide consistent prediction performance for future samples. In particular, to avoid inflated evaluation of prediction performance from a large screening search on many candidate models, feature selection must be simultaneously performed with classification model construction on a training set under a particular classification method. Evaluation of prediction performance should then be carefully conducted among the extremely large number of competing models, especially in using appropriate performance selection criteria and in utilizing the whole data for model training and evaluation.

32.5.1 Measures for Classification Model Performance

Several different measures are currently used to evaluate the performance of classification models: classification error rate, area under the receiver operating characteristics curve (AUC), and the product of posterior classification probabilities [32.40–42]. However, when a large number of candidate models, e.g., more than 10^8 two-gene models on 10 k array data, are compared in their performance, these measures are often quickly saturated; their maximum levels are achieved by many competing models, so that identification of the best prediction model among them is extremely difficult. Furthermore, these measures cannot capture an important aspect of classification model performance as follows. Suppose three samples are classified using two classification models (or rules). Suppose also that one model provides correct posterior classification probabilities 0.8, 0.9, and 0.4, and the other 0.8, 0.8, and 0.4 for the three samples. Assuming these were unbiased estimates of classification error probabilities (on future data), the former model would be preferred because this model will perform better in terms of the expected number of correctly classified samples in future data. Note that the two models provide the same misclassification error rate, 1/3. This aspect of classification performance cannot be captured by evaluating the commonly used error rate or AUC criteria, which simply add one count for each correctly classified sample ignoring its degree of classification error probability.

To overcome this limitation, the so-called *misclassification penalized posterior* (MiPP) criterion has recently been suggested [32.43]. This measure is the sum of the correct-classification (posterior) probabilities of correctly classified samples subtracted by the sum of the misclassification (posterior) probabilities of misclassified samples. Suppose there are m classes from populations π_i $(i = 1, \ldots, m)$ and a total of $N = \sum_{i=1}^{m} n_i$ samples. Let $\boldsymbol{X}_{ij}$, $j = 1, \ldots, n_i$, be the j-th sample vector from the i-th class under a particular prediction model (e.g., one-gene or two-gene model), denoted as R_{M} and a rule R, e.g., linear discriminant analysis (LDA) or SVMs. For sample vector $\boldsymbol{X}_{ij}$, the posterior classification probability to be assigned to class k (under R_{M}) is defined as $p_k(\boldsymbol{X}_{ij}) = P\left(\boldsymbol{X}_{ij} \in \pi_k | \boldsymbol{X}_{ij}\right)$. (We omit the notation R_{M} for simplicity.) For example, $p_k(\boldsymbol{X}_{kj})$ is thus the posterior probability of correct classification for the sample $\boldsymbol{X}_{kj}$. MiPP is then defined as:

$$\psi_p = \sum_{\text{correct}} p_k(\boldsymbol{X}_{kj}) - \sum_{\text{wrong}} \left[1 - p_k(\boldsymbol{X}_{kj})\right] . \tag{32.10}$$

Here correct and wrong correspond to the samples that are correctly and incorrectly classified, respectively. In the two-class problem, *correct* simply means $p_k(\boldsymbol{X}_{kj}) > 0.5$, but in general, it occurs when $p_k(\boldsymbol{X}_{kj}) = \max_{i=1,\ldots,m}[p_i(\boldsymbol{X}_{kj})]$.

It can be shown that MiPP is simply the sum of the posterior probabilities of correct classification penalized by the number of misclassified samples (N_{M})

$$\psi_p = \sum_{\text{correct}} p_k(\boldsymbol{X}_{kj}) + \sum_{\text{wrong}} p_k(\boldsymbol{X}_{kj}) - \sum_{\text{wrong}} 1 = \sum p_k(\boldsymbol{X}_{kj}) - N_{\mathrm{M}} . \tag{32.11}$$

That is, MiPP increases as the sum of correct-classification posterior probabilities increases, as the number of misclassified samples decreases, or both. Thus, MiPP is a continuous measure of classification performance that takes into account both the degree of classification certainty and the error rate, and is sensitive enough to distinguish subtle differences in prediction performance among many competing models. MiPP can be directly derived from the posterior classification probabilities of class membership in LDA, quadratic discriminant analysis (QDA), and logistic regression (LR), but it is slightly differently obtained for SVMs because they do not directly provide an estimate of posterior classification probability. In this case, a logit-link-based estimation can be used to derive a *pseudo* posterior classification probabilities as suggested by [32.44].

32.5.2 Classification Modeling

As described above, several classification modeling approaches are currently used in genomic data analysis. These approaches often adopt certain cross-validation techniques, such as leave-one-out or training-and-validation-set strategies for their modeling search and fitting.

Gene Voting

Adopting the idea of aggregating power by multiple predictors, the so-called *gene voting* classification method has been proposed for the prediction of subclasses of acute leukemia patients observed by microarray gene-expression data [32.2]. This method gains accuracy by

aggregating predictors built from a learning set and by casting their voting weights. For binary classification, each gene casts a vote for class 1 or 2 among p samples, and the votes are aggregated over genes. For gene g_j the vote is

$$v_j = a_j(g_j - b_j) ,$$

where $a_j = (\hat{\mu}_1 - \hat{\mu}_2)/(\hat{\sigma}_1 + \hat{\sigma}_2)$ and $b_j = (\hat{\mu}_1 + \hat{\mu}_2)/2$. Using this method based on 50 gene predictors, [32.2] has correctly classified 36 of 38 patients in an independent validation set between acute myeloid leukemia (AML) and acute lymphoblastic leukemia (ALL).

LDA and QDA

Linear discriminant analysis can be applied with leave-one-out classification as follow. Assume each of $f_k(x)$, $k = 1, \ldots, K$, follows a multivariate normal (μ_k, Σ) distribution with mean vector μ_k a common variance–covariance matrix Σ. Then,

$$\begin{aligned}
&\log Pr(G = k|X = x)/Pr(G = j|X = x) \\
&\quad = \log[f_k(x)/f_j(x)] + \log(\pi_k/\pi_j) \\
&\quad = \log(\pi_k/\pi_j) - \frac{1}{2}(\mu_k + \mu_j)^{\mathrm{T}} \Sigma^{-1}(\mu_k - \mu_j) \\
&\qquad + x^{\mathrm{T}} \Sigma^{-1}(\mu_k - \mu_j) .
\end{aligned}$$

A sample vector x_o will then be allocated to group k if the above equation is greater than zero or to group j otherwise.

The quadratic discriminant analysis can be similarly performed except that the variance–covariance matrix Σ is now considered differently for each subpopulation group. The differences between LDA and QDA are typically small, especially if polynomial factors are considered in LDA. In general, QDA requires more observations to estimate each variance–covariance matrix for each class. LDA and QDA have consistently shown high performance not because the data likely from Gaussian distributions, but more likely because simple boundaries such as linear or quadratic are sufficientto define the different classes in the data [32.42].

Logistic Regression (LR)

LR discriminant analysis requires less assumptions than the aforementioned LDA and QDA approaches. LR methods simply maximize the conditional likelihood $Pr(G = k|X)$, typically by a Newton–Raphson algorithm [32.45]. The allocation decision on a sample vector x_o by LR is based on the logit regression fit:

$$\mathrm{Logit}(p_i) = \log[p_i/(1 - p_i)] \sim \hat{\beta}^{\mathrm{T}} x ,$$

where $\hat{\beta}$ is the LR estimated coefficient vector for the microarray data. LR discriminate analysis is often used due to its flexible assumption about the underlying distribution, but if it is actually applied to a Gaussian distribution, LR shows a loss of 30% efficiency in the (misclassification) error rate compared to LDA.

Support Vector Machines (SVMs)

SVMs separate a given set of binary labeled training data with a hyperplane that is maximally distant from them; this is known as the maximal margin hyperplane [32.35]. Based on a kernel, such as a polynomial of dot products, the current data space will be embedded in a higher-dimensional space. The commonly used kernels are:

- Radial basis kernel: $K(x, y) = \exp\left(-\frac{|x-y|^2}{2\sigma^2}\right)$,
- Polynomial kernel: $K(x, y) = < x, y >^d$ or $K(x, y) = (< x, y > +c)^d$,

where $<$, $>$ denotes the inner-product operation. Note that the above polynomial kernel is of order d and is linear when $d = 1$. Using a training set, we derive a hyperplane with maximal separation and validate against a validation set.

SVMs often consider linear classifiers:

$$f_{w,b}(x) = < w, x > +b ,$$

which lead to linear prediction rules: $h_{w,b}(x) = \mathrm{sign}[f_{w,b}(x)]$ for the decision boundary of the hyperplane $f_{w,b}(x)$. SVMs maps each vector-valued example into a feature space:

$$x \to [\psi_1(x), \psi_2(x), \ldots, \psi_N(x)] .$$

32.5.3 Stepwise Cross-Validated Discriminant Analysis

Classification techniques must be carefully applied in prediction model training on genomic data. In particular, if all the samples are used both for model search/training and for model evaluation in a large screening search for classification models, a serious selection bias is inevitably introduced [32.46]. In order to avoid such a pitfall, a stepwise (leave-one-out) cross-validated discriminant procedure (SCVD) that gradually adds genes to the training set has been suggested [32.42, 47]. It is typically found that the prediction performance is continuously improved (or not decreased) by adding more features into the model. This is again due to a sequential search and selection

strategy against an astronomically large number of candidate models; some of them can show over-optimistic prediction performance for a particular training set by chance. Note also that even though a leave-one-out or similar cross-validation strategy is used in this search, the number of candidate models is too big to eliminate many random ones that survived from such a specific cross-validation strategy by chance. Thus, test data should be completely independent from the training data to obtain an unbiased estimate of each model's performance.

The SCVD Procedure

Using the MiPP criterion above, the SCVD classification model is constructed sequentially as follows. Given a classification rule R, the models are constructed on a training data set in a forward stepwise cross-validated discriminant fashion. Suppose we have a training data set consisting of N samples and g candidate features (genes). A schematic summary of the MiPP-based SCVD model construction is shown in Fig. 32.4.

The initial step begins by fitting each feature individually on the training set. For each of the G features, MiPP is calculated based on leave-one-out cross-validation (so MiPP for a gene is the average of MiPPs of the N leave-one-out fits for that particular gene). The gene with the maximal value of MiPP is then retained, and the optimal one-gene model O_1 is fit using all training samples. The second step adds each of the $G-1$ features and of these $G-1$ two-gene models, the one with the maximal value of MiPP is similarly retained and used to construct the optimal two-gene model O_2. This process continues adding features in this sequential fashion until the training model becomes saturated at the L-th step, i. e., MiPP converges to a certain maximum level and the L-gene MiPP is not bigger than the (L-1)-gene MiPP (note that MiPP has an upper bound of N).

Because of the sequential selection of features in this model construction, the performance of the prediction model improves when there a large number of features in a model and this cannot be used as an objective measure of classification performance. Therefore, the performance of each of the optimal models $O_1, \ldots, O_L$ is assessed on a completely independent test data set to determine the final robust prediction model. In this case, both MiPP and the error rate can be evaluated since the latter can be used among the small number of competing optimal models with different numbers of model features.

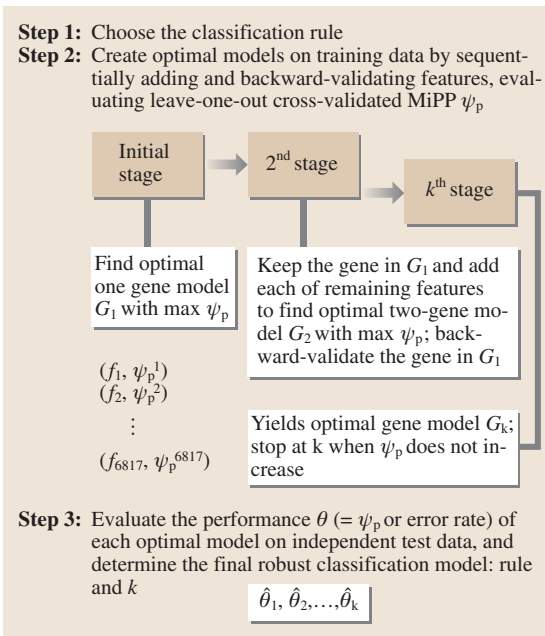

Fig. 32.4 A schematic diagram for classification modeling based on the stepwise cross-validated discriminant (SCVD) procedure

Comparison of Classification Methods

Using this SCVD strategy based on MiPP, several widely used classification rules such as linear discriminant analysis (LDA), quadratic discriminant analysis (QDA), logistic regression (LR), and support vector machines

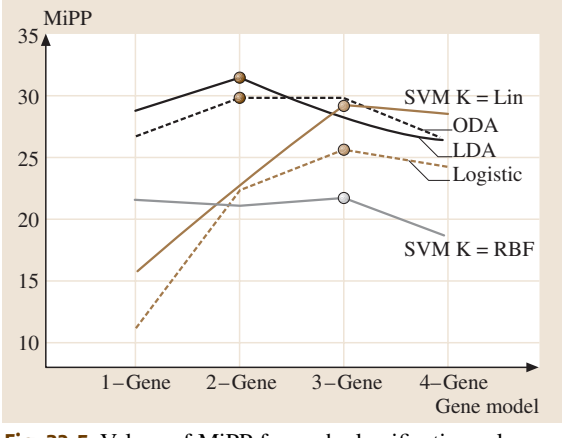

Fig. 32.5 Values of MiPP for each classification rule constructed for models with up to four genes. The best gene model of all the gene models for a given classification rule is denoted by a •

Table 32.2 Classification results of the classification rules and the corresponding gene model

Method	Model	Training data ER%	ψ_p	Test data ER %	ψ_p
LDA	1882+1144	0	37.91	2.94	31.46
QDA	4847+5062	0	37.96	5.88	29.81
Logistic	1807+4211+575	0	37.998	11.76	25.64
SVM K=Linear	2020+4377+1882	0	35.16	0	29.26
SVM K=RBF	4847+3867+6281	0	32.52	5.88	21.713

(SVMs) with linear or radial basis function (RBF) kernels have been compared. The leukemia microarray data in [32.2] had a training set of 27 ALL and 11 AML samples and an independent test set of 20 ALL and 14 AML samples. Since two distinct data sets exist, the model is constructed on the training data and evaluated on the test data set. Figure 32.5 shows the performance of each classification rule on the test data set. Each rule identified a different subset of features and the performance of the best subset for each classification rule along with its performance is shown in Table 32.2. This best subset is simply the point at which each line from Fig. 32.5 reaches its maximum value.

In terms of error rate, it appears as if the SVM with a linear kernel is the most accurate rule. However, LDA only misclassified one sample and the SVM with the RBF kernel and QDA misclassified two samples on the independent test data. Logistic regression does not seem to perform as well as the other rules, by misclassifying 4 out of 34 samples. Note again that comparing the rules on the basis of MiPP is somewhat tricky for SVMs since the estimated probabilities of correct classification from SVMs are based upon how far samples are from a decision boundary. As a result, unlike the LDA, QDA, and LR cases, these are not true posterior classification probabilities. In an application to a different microarray study on colon cancer, the RBF-kernel SVM model with three genes was found to perform best among these classification techniques.

Therefore, using the MiPP-based SCVS procedure, the most parsimonious classification models were derived with a very small number of features, only two or three genes from microarray data, outperforming many previous models with 50–100 features. This may imply that a set of a small number of genes may be sufficient to explain the discriminativeinformation of different types of a particular desease, even though it is often found that there exist multiple sets (of small numbers of genes) with similar classification prediction performance.

33. Statistical Methodologies for Analyzing Genomic Data

The purpose of this chapter is to describe and review a variety of statistical issues and methods related to the analysis of microarray data. In the first section, after a brief introduction of the DNA microarray technology in biochemical and genetic research, we provide an overview of four levels of statistical analyses. The subsequent sections present the methods and algorithms in detail.

In the second section, we describe the methods for identifying significantly differentially expressed genes in different groups. The methods include fold change, different *t*-statistics, empirical Bayesian approach and significance analysis of microarrays (SAM). We further illustrate SAM using a publicly available colon-cancer dataset as an example. We also discuss multiple comparison issues and the use of false discovery rate.

In the third section, we present various algorithms and approaches for studying the relationship among genes, particularly clustering and classification. In clustering analysis, we discuss hierarchical clustering, *k*-means and probabilistic model-based clustering in detail with examples. We also describe the adjusted Rand index as a measure of agreement between different clustering methods. In classification analysis, we first define some basic concepts related to classification. Then we describe four commonly used classification methods including linear discriminant analysis (LDA), support vector machines (SVM), neural network and tree-and-forest-based classification. Examples are included to illustrate SVM and tree-and-forest-based classification.

The fourth section is a brief description of the meta-analysis of microarray data in three different settings: meta-analysis of the same biomolecule and same platform microarray data, meta-analysis of the same biomolecule but different platform microarray data, and meta-analysis of different biomolecule microarray data.

We end this chapter with final remarks on future prospects of microarray data analysis.

Since the seminal work on microarray technology of *Schena* et al. [33.1], microarray data have attracted a great deal of attention, as reflected by the ever increasing number of publications on this technology in the past decade. The applications of the microarray technology encompass many fields of science from the search for differentially expressed genes [33.2], to the understanding of regulatory networks [33.3], DNA sequencing and mutation study [33.4], single nucleotide polymorphism (SNP) detection [33.5], cancer diagnosis [33.6], and drug discovery [33.7].

Accompanying the advancement of the microarray technology, analyzing microarray data has arguably become the most active research area of statistics and bioinformatics. Figure 33.1 provides a four-level overview of the analytic process. The first challenge in dealing with the microarray data is to preprocess the data, which involves background subtraction, array normalization, and probe-level data summarization. The purpose of this preprocessing is to remove noise and artifacts in order to enhance and extract hybridization signals. This data preprocessing is also often referred as

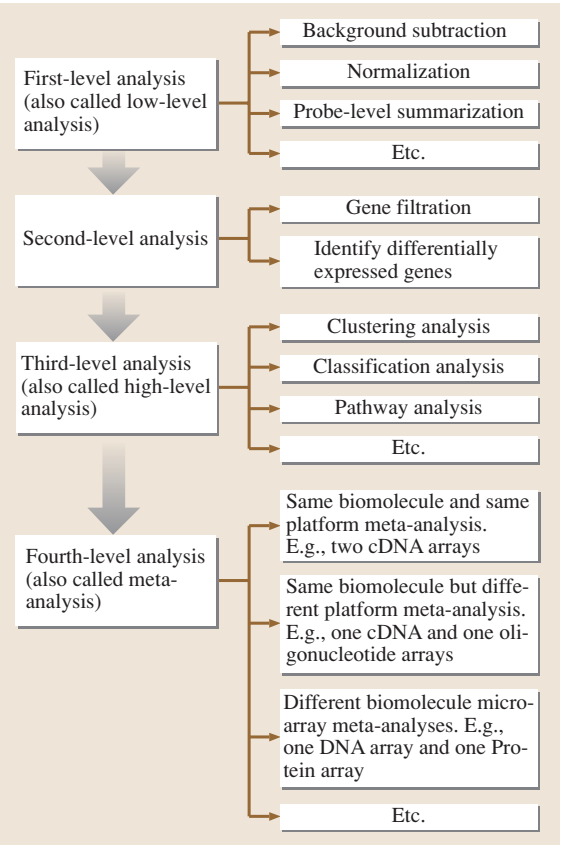

Fig. 33.1 Diagram of the four-level analysis of microarray data

the low-level analysis [33.8]. After the data are processed and cleaned, they are analyzed for different purposes. The focus of this article is on the methods for this postprocessing analysis.

The second-level analysis usually contains two steps: one is to filter *unusual* genes whose expression profiles are suspicious due to noise or are too extreme, and the other is to identify the differentially expressed genes across different samples. The gene filtration process is generally heuristic and specific to known biological contents. Thus, we will not discuss it here. To identify genes that have significantly different expression profiles, the commonly used approaches include the estimation of fold change, Student's T-test, the Wilcoxon rank sum test, the penalized T-test, empirical Bayes [33.9], and significance analysis of microarray (SAM, *Tusher* et al. [33.10]). We will review these methods in Sect. 33.1.

We will review the third-level analysis in Sect. 33.2. This type of analysis is also called high-level analysis [33.11], and it includes clustering, classification and pathway analysis. This is usually conducted on a subset of genes that are selected from the second-level analysis. To identify genes that may be correlated to each other, clustering analysis has become particularly popular, and the approaches include hierarchical clustering [33.12], k-means [33.13], self-organization maps (SOM) [33.14], principle-component analysis (PCA) [33.15], and probabilistic model-based clustering [33.16].

To classify tissue samples or diagnose diseases based on gene expression profiles, both classic discriminant analysis and contemporary classification methods have been used and developed. The methods include k-nearest neighbors (KNN) [33.17], linear discriminant analysis (LDA) [33.18], support vector machine (SVM) [33.19], artificial neural networks (ANN) [33.20], classification trees [33.21], and random and deterministic forests [33.18]. It is noteworthy that tree- and forest-based approaches can be easily applied to the entire microarray dataset without restricting our attention to a subset of selected genes.

To identify genes that may be on the same pathway of a particular biological process, relevance networks [33.22], linear differential equation [33.23], Boolean networks [33.24], Bayesian networks [33.25] and the probabilistic rational model (PRM) [33.26] have been used and developed.

The fourth-level analysis, also referred as meta-analysis, is a relative new topic for the analysis of microarray data. Because many different types and platforms of microarrays can be designed to address the same (or similar) biological problems, it is useful to compare and synthesize the results from different studies.

Before we introduce specific methods, we should point out that, as a result of high-throughput technology, the unique challenge from analyzing microarray data is the large number of genes (tens of thousands) and relatively small sample sizes (commonly on the order of tens or hundreds). In this article, n denotes the number of genes and m the number of arrays. n is generally much greater than m.

33.1 Second-Level Analysis of Microarray Data

33.1.1 Notation

For a two-channel cDNA microarray data [33.1], we have a $2n \times m$ matrix of imaging data reflecting the red (cy5) and green (cy3) signals for each of the n genes on m arrays. The log ratio of the red to green signal is usually taken for each gene, and the analysis will be based on an $n \times m$ data matrix.

For one-channel Affymetrix Oligonucleotide GeneChip data [33.27], we have a $2\sum_{i=1}^{n} p_i \times m$ matrix of raw image data where p_i is the number of probes for the i-th gene. Note that, for each probeset, Affymetrix uses a pair of perfect match (PM) and mismatch (MM). As for oligonucleotide microarrays, steps [differences, ratios, analysis of variance (ANOVA) models, etc.] can be taken to summarize the PM and MM signals for each gene, and we still have an $n \times m$ data matrix.

A major objective of microarray analysis is to infer significantly differentially expressed genes (abbreviated as SDE genes) across different samples, e.g., m_1 tumor samples versus m_2 normal samples.

Let $Y_{ij,k}$ be the expression level of the i-th gene on the j-th array in the k-th sample. Let $\overline{Y_{i.,1}}$ and $\overline{Y_{i.,2}}$ denote the average expression level of the i-th gene in samples 1 and 2, respectively.

33.1.2 Fold Change

Many studies identify SDE genes in two samples based on simple fold-change thresholds such as a two-fold change in means. Although the choice of a threshold is somewhat arbitrary, fold change is intuitive and biologically meaningful, and serves as an effective preliminary step to eliminate a large portion of genes whose data are of little interest in a particular study.

33.1.3 *t*-Statistic

As in many clinical studies, the t-statistic provides a simple, extremely useful tool to compare the data from two samples. Let $\overline{M}$ be the mean difference between the expression profiles of a gene in two groups and $\mathrm{se}(\overline{M})$ be the standard error of $\overline{M}$. The t-statistic, defined as

$$t = \frac{\overline{M}}{\mathrm{sd}(\overline{M})} ,$$

is useful to test a null hypothesis that the gene is not differentially expressed in the two groups against the alternative hypothesis that the gene is differentially expressed.

Unlike a typical clinical study, in which we have one pair or a very few pairs of hypotheses to test, in microarray analysis we have a pair of hypotheses for every gene of interest. This means that we inevitably deal with the multiple comparison issue. Although this issue is difficult and there is no clear-cut, ideal answer, many reasonable solutions have been proposed.

Efron et al. [33.9] proposed to inflate $\mathrm{se}(\overline{M})$ by adding a constant that equals the 90-th percentile of the standard errors of all the genes. *Tusher* et al. [33.10] call such a constant a fudge factor, and propose to estimate it by minimizing the coefficient of variation of the absolute t-values. We will discuss this approach in detail in Sect. 33.1.4. Other approaches have also been proposed; for example, *Smyth* [33.28] replaces $\mathrm{se}(\overline{M})$ with a Bayesian shrinkage estimator of the standard deviation.

The permutation test is also commonly used to compare the microarrays. Permutations are usually performed at the array level to create a situation similar to the null hypothesis while maintaining the dependence structure among the genes [33.10]. In every permutation, a t-statistic can be calculated for each gene. Once a large number of permutations are completed, we have an empirical distribution for the t-statistic under the null hypothesis, which then can be used to identify SDE genes.

33.1.4 The Multiple Comparison Issue

As we mentioned earlier, we have to control the type I error rate α while testing a large number of hypotheses simultaneously. There are two commonly used approaches to deal with this issue. One is to control the family-wise error rate (FWER) and the other is to control the false discovery rate (FDR).

The FWER controls the probability of making at least one false positive call at the desired significance level. FWER guarantees that the type I error rate is less than or equal to a specified value for any given set of genes. The most known example of FWER is Bonferroni correction that divides the desired significance level α by total number of hypotheses. If the desired significance level is 0.05 and we compare expression profiles in 10 000 genes, a gene is declared to have significantly different profiles in two groups if the P-value is not greater than $\frac{0.05}{10\,000} = 5 \times 10^{-6}$. Another FWER approach is the so-called *Šidák* correction in which the

adjusted type I error rate is at $1-(1-\alpha)^{\frac{1}{n}}$ [33.29], which is close to α/n. Clearly, Bonferroni and Šidák corrections are sufficient but not necessary conditions [33.30], and FWER approaches are generally very conservative and set a stringent bar to declare SDE genes.

Because of the conservative nature of the FWER approaches, the FDR concept has flourished since it was proposed by [33.31]). FDR is defined as the mean of the ratio of the number, denoted by V, of falsely rejected hypotheses to the total rejected hypotheses, denoted by R, namely,

$$\mathrm{FDR} = E\left(\frac{V}{R}|R>0\right)\Pr(R>0)\,,$$

where $\Pr(R>0)$ is the probability of rejecting at least one hypothesis.

The FDR can be controlled at a given α level through the following steps. First, for n genes, we have n null hypotheses and n p values, denoted by $p_1,\ldots,p_n$. Then, we sort the p-values in ascending order such that $p_{(1)}\le\cdots\le p_{(n)}$. We reject any gene i that satisfies the condition $p_{(i)}\le\frac{i}{n}\times\frac{\alpha}{p_0}$, where p_0 is the proportion of genes for which the null hypotheses are indeed true. Because p_0 is unknown in practice, the most conservative approach is to replace it with 1. Recently, attempts have been made to estimate p_0 as in Tusher et al.'s SAM, where they used a permutation procedure to estimate p_0. Similar to the classical p-values, the significance measures for each gene in terms of FDR are called q-values, a name that was introduced by *Storey* [33.32, 33].

In addition, the FDR concept has been generalized. For example, *Storey* and *Tibshirani* [33.9] and *Storey* et al. [33.32] proposed positive FDR (pFDR), which corrects the error rate only when they are positive findings. For microarray data, many gene profiles are correlated, *Troendle* [33.34] proposed an adjusted FDR to address the correlation and demonstrated the benefit in terms of gained power.

33.1.5 Empirical Bayesian Approach

Using microarray data from a breast cancer study, *Efron* et al. [33.9, 35] described the empirical Bayesian method. As an initial step, a summary statistic, Z, needs to be defined for every gene to reflect the scientific interest; this can be the t-statistic as described above, a Wilcoxon rank statistic, or another choice. All genes are perceived to belong to either the differentially or nondifferentially expressed group. The density of Z_i is $f_0(z_i)$ if gene i is in the nondifferentially expressed group, and $f_1(z_i)$ otherwise. Without knowing the group, Z_i has the following mixture distribution:

$$p_0 f_0(z_i)+p_1 f_1(z_i)\,,$$

where p_0 is the prior probability that gene i is not differentially expressed, and $p_1=1-p_0$.

Based on Bayes' theorem, the posterior probability that gene i is not differentially expressed given Z_i is

$$p_0(z_i)=p_0\frac{f_0(z_i)}{f(z_i)}\,.$$

We can estimate the mixture density $f(z_i)$ by the empirical distribution $\hat{f}(z_i)$ because the genes of interest are naturally a mixture of the two groups. In addition, the null density $f_0(z_i)$ can be estimated through the permutation that artificially generates data under the null hypothesis. In other words, we can derive the posterior probability $p_0(z_i)$ for a given prior p_0. The choice of p_0 can be subjective. One conservative possibility is to choose p_0 to be the minimum of $\hat{f}(z_i)/\hat{f}_0(z_i)$ so that the posterior probability $p_1(z_i)$ that gene i is differentially expressed is non-negative. Note that $p_1(z_i)=1-p_0(z_i)$. Finally, all genes can be ranked according to $p_1(z_i)$ and highly probably differentially expressed genes can be selected.

Efron et al. [33.9, 35] did not assume a specific form for $f(z_i)$. In contrast, *Lonnstedt* and *Speed* [33.36] assumed that the data comes from the mixture of normal distributions and used the conjugate priors for the variances and the means. Under those assumptions, they derived the log odds posterior test. *Smyth* [33.28] extended the hierarchical model of *Lonnstedt* and *Speed* [33.36] to deal with microarray experiments with more than two sample groups. The method is called the Limma algorithm.

33.1.6 Significance Analysis of Microarray (SAM)

Tusher et al. [33.10] introduced the SAM algorithm. SAM identifies genes with statistically significant changes in expression by assimilating a set of gene-specific t-tests in which the standard error is adjusted by adding a small positive constant. It performs a random permutation among experiments and declares the significant genes based on a selected threshold. For the given threshold, SAM estimates the FDR by comparing the number of genes significant in the permuted samples with the number of genes significant in the original sample.

SAM can be downloaded from http://www-stat.stanford.edu/~tibs/SAM/. Specifically, first, for each gene i, SAM computes a t-like statistic

$$t_i = \frac{r_i}{s_i + s_0} ,$$

where r_i is the difference between the expression means of gene i in the two groups (expression is on a logarithm scale), s_i is the standard error, and s_0 is the fudge factor to be estimated. Secondly, similarly to the FDR scheme, all t_i values are sorted into the order statistics

$$t_{(1)} \le t_{(2)} \le \ldots \le t_{(n)} .$$

To choose the significance threshold, the expression data are permuted in the two groups within each gene B times, and during each permutation, we repeat the first two steps, which leads to a set of order statistics:

$$t^b_{(1)} \le t^b_{(2)} \le \ldots \le t^b_{(n)} .$$

After the permutations, we calculate the mean of the order statistics for each gene as follows

$$\bar{t}_{(i)} = \frac{1}{B} \sum_{b=1}^{B} t^b_{(i)} .$$

For a given threshold Δ, a gene is considered significant if $|t_{(i)} - \bar{t}_{(i)}| > \Delta$, and the FDR is estimated by the ratio of the number of genes found to be significant in the permutation samples to the number of genes called significant in the original sample.

Example 1: Identification of SDE Genes Using SAM. In this example, we apply SAM to examine a publicly available colon-cancer dataset [33.37]. This dataset contains the expression profiles of 2000 genes using an Affymetrix oligonucleotide array in 22 normal and 40 colon-cancer tissues.

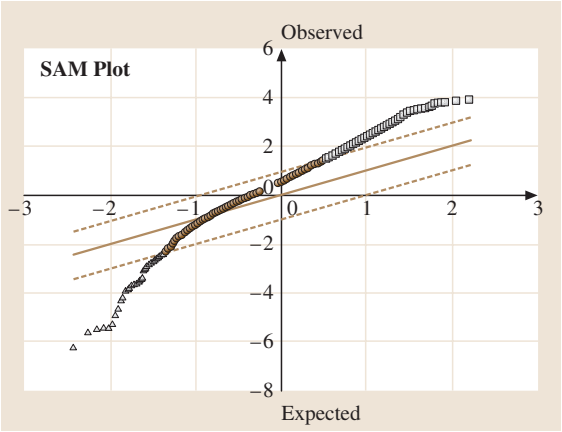

Fig. 33.2 The quantile–quantile plot from SAM for the colon-cancer dataset. Genes are declared significantly changed when their corresponding t-values are outside the two dashed lines. The white square and triangle points correspond to the genes that are significantly overexpressed and underexpressed, respectively

Figure 33.2 displays the quantile–quantile plot from SAM. The two dashed lines determine a boundary to call genes SDE depending on the choice of Δ. For example, Δ was chosen as 0.9857 in Fig. 33.2 to control the FDR at about 5%. The white square and triangle points in the figure correspond to the genes that are declared to be significantly overexpressed and underexpressed respectively. Out of the 490 declared SDE genes (440 overexpressed and 50 underexpressed), 25 genes are expected to be declared falsely.

33.2 Third-Level Analysis of Microarray Data

The third-level microarray analysis includes clustering, classification and pathway analysis. These approaches usually, though not always, follow the second-level microarray analysis because most of them can work effectively on only a small number of genes.

33.2.1 Clustering

Clustering is arguably the most commonly used approach at the third-level of analysis [33.38, 39]. It is an unsupervised learning algorithm from a machine-learning viewpoint, because the gene classes are unknown or not used, and need to be *discovered* from the data. Therefore, the goal of clustering analysis is to group genes (or arrays) based on their similarity in the feature space (e.g., expression pattern).

The underlying assumption behind clustering is that genes with similar expression profiles should share some common biological behaviors, e.g., belonging to the same protein complex or gene family [33.40], having common biological functions [33.41], being regulated by common transcription factors [33.3], belonging to the same genetic pathway, or coming from the same origin [33.39].

After the clusters are formed, a dendrogram or a tree of all genes will be viewed, although the views are not unique, because there is a left-or-right selection at each splitting step. Two popular programs for gene clustering are *Eisen* et al.'s TreeView program [33.12] and Li and Wong's dChip programs [33.8]. Routines are also available in standard statistical packages such as R, Splus, and SAS.

Distance

In order to group objects (genes or arrays) together, we need to define a measure to quantify the similarity among objects in the feature space. Such a measure of similarity is called a distance. There are several commonly used definitions of distance. Suppose that the expression profiles of two genes are $Y_i = (y_{i1}, y_{i2}, \ldots, y_{im})$ and $Y_j = (y_{j1}, y_{j2}, \ldots, y_{jm})$.

The Euclidean distance between Y_i and Y_j is

$$d_{\mathrm{E}}\left(Y_i, Y_j\right) = \left[\sum_{k=1}^{m}\left(y_{ik} - y_{jk}\right)^2\right]^{\frac{1}{2}} .$$

The city-block distance between Y_i and Y_j is

$$d_{\mathrm{C}}\left(Y_i, Y_j\right) = \sum_{k=1}^{m}\left|y_{i1} - y_{j1}\right| .$$

The Pearson correlation distance between Y_i and Y_j is

$$d_{\mathrm{R}}\left(Y_i, Y_j\right) = 1 - r_{Y_i Y_j} ,$$

where $r_{Y_i Y_j}$ is the Pearson correlation coefficient between Y_i and Y_j.

The Spearman correlation distance between Y_i and Y_j uses the rank-based correlation coefficient in which the expression levels are replaced with the ranks.

More definitions can be found in the book by *Draghici* [33.30]. We should note that the Euclidean and city-block distance look for similar expression numerical values while the Pearson and Spearman distances tend to emphasize similar expression patterns.

The distances defined above measure the gene-wise distance. When clusters are found, we also need to define the distance between two clusters. The four approaches are: single linkage distance (the minimum distance between any gene in one cluster and any gene in the other cluster), complete linkage distance (the maximum distance between any gene in one cluster and any gene in the other cluster), average linkage distance (the average of all pair-wise distances between any gene in one cluster and any gene in the other cluster), and centroid linkage distance (the distance between the centroids of the two clusters).

Clustering Methods

When a distance measure is chosen, there are different ways to execute the clustering process. The clustering methods broadly fall into two categories: hierarchical methods and partitioning methods. Hierarchical methods build up a hierarchy for clusters, from the lowest one (all genes are in one cluster) to the highest one (all genes are in their own clusters) while partitioning methods group the genes into the different clusters based on their expression profiles. Therefore, one does not need to provide the cluster number for hierarchical clustering methods but it is necessary for the partitioning clustering methods.

Hierarchical methods include agglomerative hierarchical methods and divisive hierarchical methods.

The agglomerative hierarchical methods use a bottom-up strategy by treating each individual gene as a cluster at the first step. Then two nearest genes are found and assigned into a cluster where the *nearest* is defined by the distance between these two genes, e.g., for a Pearson distance nearest means the two genes having the largest correlation coefficient. Then an agglomerative hierarchical method assigns a new expression profile for the formed clusters, and repeats these steps until there is only one cluster left.

The divisive hierarchical methods, on the other hand, treat all genes belonging to one cluster at the beginning. Then in each step they choose a partitioning method to divide all genes into a predecided number of clusters, e.g., using k-means to partition genes into two clusters at each single step. Therefore, the decisive hierarchical clustering methods employ the bottom-down strategy.

The k-means clustering is the simplest and fastest clustering algorithm [33.42] among the partitioning methods. It has been widely used in many microarray analyses. To form K clusters, the k-means algorithm allocates the observations into different groups in order to minimize the within-group sum of squares

$$\min_{S_K}\left[\sum_{k=1}^{K}\sum_{i\in S_K}\sum_{j=1}^{m}\left(y_{ij} - \overline{y}_{kj}\right)^2\right] ,$$

where K is the prespecified cluster number, S_k is the set of objects in the k-th cluster and $\overline{y}_{kj}$ is the mean of group j in cluster k. In other words, k-means clustering uses the Euclidean distance.

The k-means clusters are formed through iterations as follows: First, k center genes are randomly selected, and every other gene is assigned to the closest center gene. Then, the center is redefined for each cluster to

minimize the sum of squares toward the center. In fact, the coordinates of a cluster center are the mean expressions of all the genes in that cluster. After the centers are redefined, all genes are regrouped and the iteration process continues until it converges.

After analyzing a yeast cell-cycle expression dataset, *Duan* and *Zhang* [33.43] noted that it could be particularly useful to use a weighted sum of squares for gene clustering to take into account the loss of synchrony of cells. We refer to *Duan* and *Zhang* [33.43] for the details.

Another widely used partitioning clustering algorithm is *self-organizing maps* (SOMs) which were developed by *Kohonen* [33.44]. In essence, SOM clustering is a spatial version of the k-means clustering. For a prespecified grid (i. e., a 6×8 hexagonal grid), SOMs project high-dimensional gene expression data onto a two- or three-dimensional map and place similar genes close to each other. Here, the centroid positions of clusters are related to one another via a spatial topology (e.g., the squared map), and are also iteratively adjusted according to the data.

Both the k-means and SOMs are algorithmic methods and do not have a probabilistic justification. *Probabilistic model-based* clustering (PMC) analysis, on the other hand, assumes that the data is generated by a mixture of underlying probability distributions, and uses the maximum-likelihood method to estimate parameters that define the number of clusters as well as the clusters. Hence, we do not need to specify the number of clusters. Using the probabilistic model, we can even consider covariates while determining the clustering memberships of the genes. However, the model can quickly become complicated as the number of clusters increases. Thus, we must try to use parsimonious models as much as possible. Finally, PMC and k-means are also closely related. In fact, k-means can be interpreted as a parsimonious model of simple independent Gaussians [33.15, 45, 46].

Example 2: Clustering Analysis. In this example, first we perform a hierarchical clustering analysis on the 490 SDE genes from example 1. The clustering analysis is applied in two directions: clustering on samples and clustering on genes. Although we do not present the entire the clustering tree here, two major clusters are formed to distinguish tumor and normal samples. For clustering on the genes, there are roughly five major patterns in terms of the gene expressions. One pattern corresponds to the underexpressed genes and the other four corresponds to the overexpressed genes in the tumor samples versus the normal ones.

For illustration, we selected the first 10 normal arrays and the first 10 cancer arrays, and 20 overexpressed and 20 underexpressed genes randomly from the 490 SDE genes. Figure 33.3 is from the heatmap function in *R*. Though not perfect, two patterns are formed mostly along the line of normal versus tumor tissues. There are roughly five major patterns in terms of expression profiles. Overexpressed and underexpressed genes tend to belong to different clusters. For example, pattern 3 (P3) and pattern 4 (P4) are mainly composed of underexpressed genes while the other three clusters contain mainly overexpressed genes.

Following the hierarchical clustering analysis presented above, we also applied the k-means approach to the 490 SDE genes and set the number of clusters to five. Furthermore, we applied *probabilistic model-based* clustering (PMC) to the same dataset. We examined the BIC (Bayesian information criterion) for different numbers of clusters, and it turned out that the value of

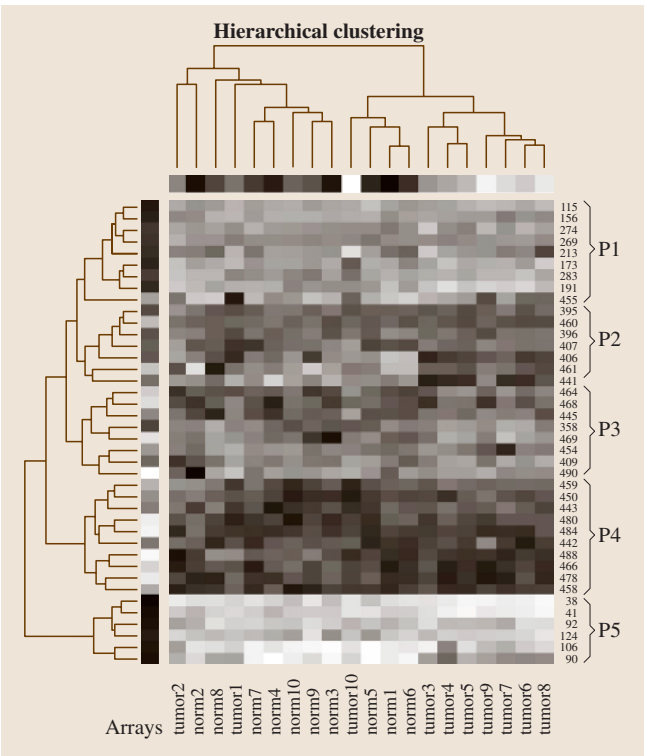

Fig. 33.3 Hierarchical clustering based on a subset of the colon-cancer dataset. Each column corresponds to a sample, and each row a gene. The underexpressed genes were assigned numbers above 440, and the overexpressed genes at or below 440

Table 33.1 The numbers of genes belonging to the intersects of the five k-means clusters and the 13 PMC clusters

k-Means Clusters	PMC Clusters												
	1	2	3	4	5	6	7	8	9	10	11	12	13
1	0	11	0	0	0	57	35	0	0	0	0	29	0
2	25	8	0	0	62	5	0	0	0	0	0	0	0
3	0	0	2	13	0	0	0	0	23	0	0	0	0
4	0	0	15	0	0	0	0	0	1	31	0	0	41
5	0	2	0	0	0	0	1	65	0	34	24	6	0

BIC reaches its minimum at 13 clusters, which is much more than heuristic choice of five. Table 33.1 displays the numbers of genes belonging to the intersects of the five k-means clusters and the 13 PMC clusters. Each of the five k-means clusters is a union of four or so PMC clusters. In fact, if we choose five PMC clusters, they are very similar to the formation of the five k-means clusters, and we will assess this similarity in the next section.

Measure of Agreement Between Two Sets of Clusters

From both the methodological and biologic points of view, there is a need to compare the clusters from different clustering methods. For example, to evaluate the performance of a new clustering approach, we need to compare the derived clusters with the underlying membership in a simulation study. We may also be interested in comparing clustering results derived from the same mRNA samples but being hybridized and analyzed in two different laboratories.

A commonly used measure of agreement between two sets of clusters is the so-called adjusted Rand index (ARI) [33.15, 47, 48]. Let us consider the partitions U and V, and let $\boldsymbol{n}_{ij}$ be the number of genes falling in the intersect of the i-th cluster in U and the j-th cluster in V. The ARI is defined as

$$\frac{\sum_{i,j}\binom{n_{ij}}{2}-\left[\sum_i\binom{n_{i\cdot}}{2}\sum_j\binom{n_{\cdot j}}{2}\right]/\binom{n}{2}}{\frac{1}{2}\left[\sum_i\binom{n_{i\cdot}}{2}+\sum_j\binom{n_{\cdot j}}{2}\right]-\left[\sum_i\binom{n_{i\cdot}}{2}\sum_j\binom{n_{\cdot j}}{2}\right]/\binom{n}{2}},$$

where $n_{i\cdot}$ and $n_{\cdot j}$ are the numbers of genes in the i-th cluster of U and the j-th cluster of V, respectively.

We suggested some similarity between the k-means and PMC clusters. In fact, the ARI value between the two sets of clusters is 0.425, and it increases to 0.94 if both methods use five clusters. This similarity is expected, because PMC and k-means are equivalent if PMC assumes an independent Gaussian covariance structure [33.15].

33.2.2 Classification

In most microarray experiments, we know the groups on the arrays. For example, some mRNA samples were extracted from tumor cells and the others from normal cells. This is similar to the situation in Sect. 33.1.1. Therefore, it is natural to use this information in analysis and to class cells based on the expression profiles. This is so-called supervised learning.

In Sect. 33.1.1, $Y_{ij,k}$ denotes the expression level of the i-th gene on the j-th array in the k-th sample. Here, we also use $(Y_{ij}, Z = k)$ to reflect the fact that the expression level Y_{ij} of the i-th gene on the j-th array comes from the k-th sample. In other words, the sample group is represented by Z, which is the response or dependent variable in classification.

The essence of classification is to define domains in the feature space spanned by Y_{ij} and to assign a class membership Z to each domain. Classification methods differ in the choice of the shape for the domain and in the algorithm to identify the domain. Some elementary concepts are useful to distinguish these differences. The first one is *linearity*. It refers to a linear combination of the features (expressions of different genes) that forms a hyperplane separating different domains in the feature space. The second term is *separability*. It reflects the extent that the different classes of samples are separable. The third concept is *misclassification*. Often, data are only partially separable, and misclassification is inevitable. In this circumstance, we may need to define a cost function to accommodate different classification errors.

In the machine-learning literature, there is also a distinction between the *learning* (i.e., training) and the *test* samples. The learning data are used to train the classification algorithm and the test data are used to test the predictive ability of the trained classification algorithm. In practice, however, we usually have one dataset and have to split the sample into the training and test samples by leaving a portion of data out during the learning process and saving it as the test data. This pro-

cedure is called cross-validation. More precisely, for a v-fold cross-validation, we first divide the data into v approximately equal sub-samples. Then, we use $v-1$ sub-samples as the training data to construct a classification rule and the left-over subsample as the test data to validate the classification rule. After rotating every sub-sample between training and test data, the performance of the classification rule is assessed through the average in the v runs of validation in the test sample.

In the next subsections, we will review four classification methods that are useful for classifying tissue samples based on gene expression profiles. The methods are linear discriminant analysis (LDA), support vector machines (SVM), artificial neural networks (ANN), and tree-based classification.

LDA

LDA was introduced by Fisher in 1936 for classifying samples by finding a hyperplane that maximizes the between-class variances. Let S_Y be the common sample covariance matrix of all gene expressions, $\bar{Y}_1$ and $\bar{Y}_2$ be the average expression levels of the genes in groups 1 and 2, respectively. The solution to LDA is $S_Y^{-1}(\bar{Y}_1 - \bar{Y}_2)$.

SVM

SVM was first proposed by *Boser* et al. [33.49] and *Cortes* and *Vapnik* [33.50]. SVM finds an optimal hyperplane to separate samples and to allow the maximum *separation* between different classes of samples. The margin of the region that separates samples is *supported* by a few vectors, termed support vectors.

In a two-class classification problem, let $Z = 1$ or -1 denote the two classes. If the two classes of samples are separable, we find a hyperplane $\{y : y^{\mathrm{T}}\beta + \beta_0 = 0, ||\beta|| = 1\}$ such that $(y^{\mathrm{T}}\beta + \beta_0)Z \geq C \geq 0$, where C is the margin optimized to allow the maximal space between the two classes of samples.

For nonseparable case, the procedure is much complicated. Some points will inevitably be on the wrong side of the hyperplane. The idea is to introduce a slack variable to reflect how far a sample is on the wrong side, and then look for the hyperplane at the condition of the total misclassification less than a user-selected limit (i. e., bound the sum of slack variables by a constant). We refer to *Vapnik* [33.51] for the details.

Example 3: Support Vector Machine (SVM). In this example, we perform a classification analysis on the colon-cancer data by SVM. We use M26697 and M63391, the two most significant genes that were identified by SAM from example 1. Specifically, M26697 is the most significant overexpressed gene and M63391 is the most significant underexpressed gene. We used the SVM function in *R* with the cost equal to 100, γ of 1 and tenfold cross-validation, where γ is the coefficient of the radial kernel used to form a hyperplane. Figure 33.4 displays the contour plot of the SVM result. The prediction model correctly classifies 37 cancer and 20 normal samples, but misclassifies three cancer and two normal samples.

Neural Network

The artificial neural network (ANN) is a very popular methodology in machine learning. Also referred to as connectionist architectures, parallel distributed processing, and neuromorphic systems, ANN is an information-processing paradigm with collections of mathematical models that emulate the densely interconnected, parallel structure of the mammalian brain and adaptive biological learning. It is composed of a large number of highly interconnected processing elements that are analogous to neurons and are tied together with

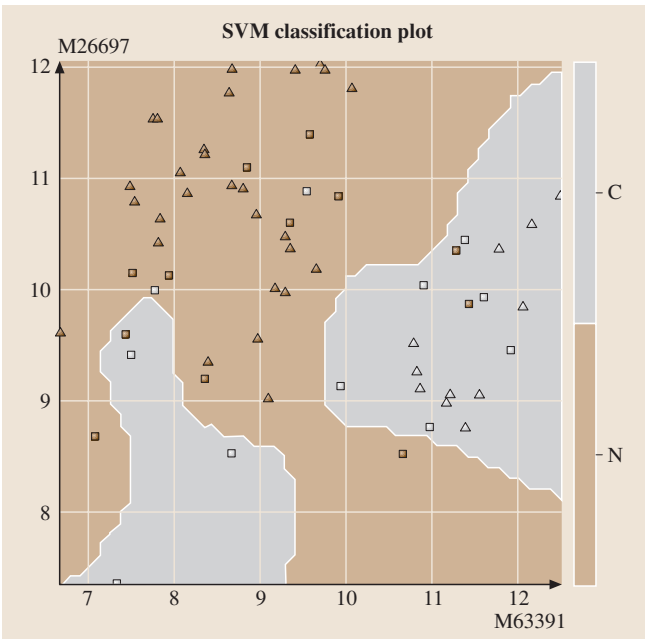

Fig. 33.4 Contour plot of the SVM result using two genes: M26997 and M63391 for the colon-cancer data. C represents cancer and N represents normal. The *light-gray area* is the cancer region and the *brown area* is the normal region. *Square points* represent the support vectors and the *triangle points* represent the data points other than support vectors. The *brown* and *white points* belong to the cancer and the normal regions, respectively

weighted connections that are analogous to synapses. Learning typically occurs by example through training, or exposure to a true set of input/output data where the training algorithm iteratively adjusts the connection weights (synapses). These connection weights store the knowledge necessary to solve specific problems.

ANN can be used for feature selection and feature extraction. The former amounts to variable selection and reduction in statistics and the latter is a generation of the statistical techniques such as principal component analysis, factor analysis, and linear discriminant analysis that are intended to identify lower-dimensional data structures such as linear directions. These lower-dimensional structures usually depend on all of the original variables (i. e., features). Thus, ANN is in essence a computationally intensive version of traditional statistical methods such as regression, classification, clustering, and factor analysis. However, ANN is designed in a way that mimics neural networks and is biologically intuitive and appealing in many applications. This is the major reason that we plan to consider ANN as one of the primary tools to explore the unknown relationship in our data, which is usually referred to as pattern recognition.

The advantage of ANNs lies in their resilience against distortions in the input data and their capability for learning. They are often good at solving problems that are too complex for conventional technologies (e.g., problems that do not have an algorithmic solution, or for which an algorithmic solution is too complex to be found), and are often well-suited to problems that people are good at solving, but for which traditional methods are not.

There are multitudes of different types of ANNs. Some of the more popular include the multilayer perceptron, which is generally trained with the back-propagation of error algorithm, learning vector quantization, radial basis functions, Hopfield, and Kohonen, to name a few. Some ANNs are classified as feed-forward while others are recurrent (i. e., implement feedback) depending on how data is processed through the network. Some ANNs employ supervised training while others are referred to as unsupervised or self-organizing.

Figure 33.5 illustrates a conventional three-layer neural network with n features and K classes. For this feed-forward neural network, the inputs are $y_1, \cdots, y_n$ which correspond to the gene expression profiles and the outputs are $z_1, \cdots, z_K$, which correspond to the K samples in the microarray data. The middle layer consists of many hidden units (also called neurons) and the number of hidden units can be freely chosen and determine the maximum nonlinearity. Each line in Fig. 33.5 indicates a weight—the edge—in the network. This weight represents how much the two neurons which are connected by it can interact. If the weight is larger, then the two neurons can interact more, that is, a stronger signal can pass through the edge. The nature of the interconnections between two neurons can be such that one neuron can either stimulate (a positive weight α) or inhibit (a negative weight α) the other. More precisely, in each hidden unit, we have

$$X_m = \sigma\left(\alpha_{0m} + \alpha_m^{\mathrm{T}} Y\right) ,$$

where σ is called the activation function or neural function and $(\alpha_{0m}, \alpha_m^{\mathrm{T}})$ are the weights. A common choice for σ is the sigmoid function,

$$\sigma(\upsilon) = \frac{1}{1 + \mathrm{e}^{-\upsilon}} .$$

The output function allows a final transformation of the linear combinations of the hidden unit variables,

$$f_k(z) = g_k\left(\beta_{0k} + \beta_k^{\mathrm{T}} X\right) .$$

For a K-class classification, a softmax (logistic) function is usually chosen for the output function

$$g_k(T) = \frac{\mathrm{e}^{T_k}}{\sum_{l=1}^{K} \mathrm{e}^{\mathrm{T}_l}} .$$

During the training period we present the perceptron with inputs one at a time and see what output it gives. If

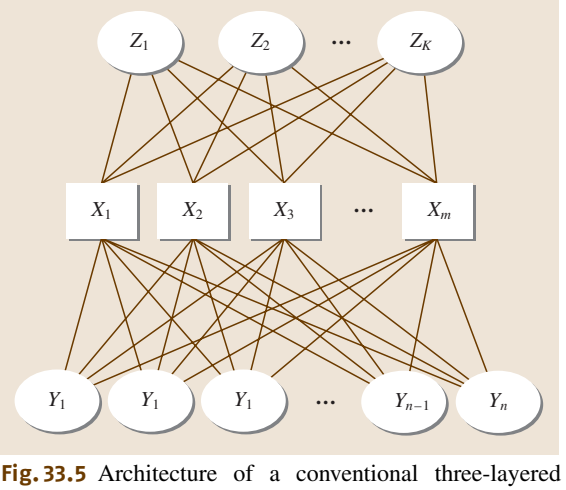

Fig. 33.5 Architecture of a conventional three-layered feed-forward neural network

the output is wrong, we will tell it that it has made a mistake. It should then change its weights and/or threshold properly to avoid making the same mistake later.

33.2.3 Tree- and Forest-Based Classification

One of the most convenient and intuitive approaches for classification is classification trees [33.52, 53]. Classification trees, and their expansion to forests, are based on the so-called recursive partitioning technique. The basic idea of recursive partitioning is to extract homogeneous strata of the tissue samples through expression profiles depending on the expression levels of a particular gene.

Zhang and *Yu* [33.54] reanalyzed the dataset from *Hedenfalk* et al. [33.55] to classify breast cancer mutations in either the BRCA1 or BRCA2 gene using gene expression profiles. *Hedenfalk* et al. [33.55] collected and analyzed biopsy specimens of primary breast cancer tumors from seven and eight patients with germline mutations of BRCA1 and BRCA2, respectively. In addition, seven patients with sporadic cases of primary breast cancer whose family history was unknown were also identified. They obtained cDNA microarrays from 5361 unique genes, of which 2905 are known genes and 2456 are unknown. Thus, in this dataset, Let $Z = 1, 2, 3$ denote BRCA1, BRCA2, and sporadic cases, respectively.

If we use this entire breast cancer dataset to construct a tree, these 22 samples form the initial learning sample, which is called the root node and labeled as node 1 in the tree diagram (Fig. 33.6). The tree structure is determined by recursively selecting a split to divide an upper layer node into two offspring nodes. To do this, we need to evaluate the homogeneity, or the impurity to its opposite,

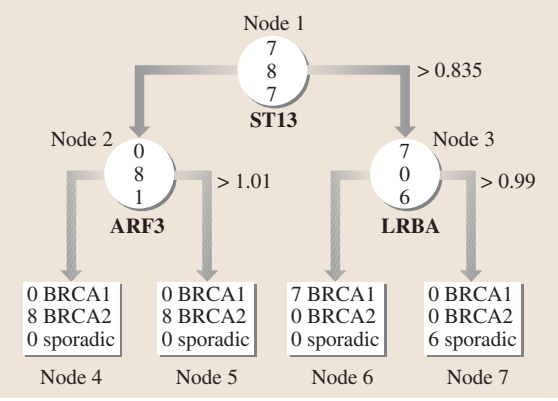

Fig. 33.6 Classification tree for breast-cancer data

of any node. A common measure of node impurity is the entropy function,

$$i_t = -\sum_{k=1}^{K} P(Z = k|\text{node } t) \log[P(Z = k|\text{node } t)] .$$

If node t is the root node, then $P(Z = 1|\text{node } t) = 7/22$, $P(Z = 2|\text{node } t) = 8/22$, and $P(Z = 3|\text{node } t) = 7/22$. Thus, the impurity i_t of the root node can be calculated easily as follows: $i_t = -(7/22)\log(7/22) - (8/22)\log(8/22) - (7/22)\log(7/22) = 1.097$.

How good is the root node? The impurity is zero for a perfect node in which $P(Z = k|\text{Node } t)$ is either 0 or 1, and reaches its worst level when $P(Z = k|\text{node } t) = \frac{1}{3}$ with $i_t = 1.099$. Therefore, the impurity of the root node is near the worst level by design, motivating us to partition the root node into small nodes to reduce the impurity.

The first step of the recursive partitioning process is to divide the root of 32 samples in Fig. 33.6 into two nodes, namely, nodes 2 and 3 in Fig. 33.6. There are many ways of partitioning the root node, because we can take any of the 5361 genes and split the root node according to whether the expression level of this chosen gene is greater than any threshold c. After comparing all possible partitions, we choose the gene and its threshold to keep both i_2 in node 2 and i_3 in node 3 at their lowest possible levels simultaneously. Mathematically, we achieve this goal by minimizing the weighted impurity $r_2 i_2 + r_3 i_3$, where r_2 and r_3 are the proportions of tissue samples in nodes 2 and 3, respectively. This is precisely how the first split (i. e., whether ST13 > 0.835) in Fig. 33.6 is determined.

Once the root is split into nodes 2 and 3, and we can apply the same procedure to potentially split nodes 2 and 3 further. Indeed, the tree in Fig. 33.6 divides the 22 samples into four groups using Heping Zhang's RTREE (http://peace.med.yale.edu). Nodes 2 and 3 are divided based on the expression levels of genes ARF3 and LRBA.

Using a variety of analytic techniques including a modified F- and t-test and a mutual-information scoring, *Hedenfalk* et al. [33.55] selected nine differentially expressed genes to classify BRCA1-mutation-positive and negative tumors and then 11 genes for BRCA2-mutation-positive and negative tumors. Clearly, the tree in Fig. 33.6 uses fewer genes and is a much simpler classification rule.

Although Fig. 33.6 is simple, it does not contain the potentially rich information in the dataset. To improve the reliability of the classification and to accommo-

date potentially multiple biological pathways, *Zhang* and *Yu* [33.54] and *Zhang* et al. [33.56] proposed expanding trees to forests. The large number of genes in microarray makes it an ideal application for these forests.

The most common approach to constructing forests is to perturb the data randomly, form a tree from the perturbed data, and repeat this process to form a series of trees; this is called a random forest. After a forest is formed, we aggregate information from the forest. One such scheme, called bagging (bootstrapping and aggregating), generates a bootstrap sample from the original sample. The final classification is then based on the majority vote of all trees in the forest [33.57].

It is well-known that random forests [33.18, 57] improve predictive power in classification. After observing the fact that there are typically many trees that are of equally high predictive quality in analyzing genomic data, *Zhang* et al. [33.18] proposed a method to construct forests in a deterministic manner. Deterministic forests eliminate the randomness in the random forests and maintain a similar, and sometimes improved, level of precision as the random forests.

The procedure for constructing the deterministic forests is simple. We can search and collect all distinct trees that have a nearly perfect classification or are better than any specified precision. This can be carried out by ranking the trees in deterministic forests. One limitation for the forests (random or deterministic) is that we cannot view all trees in the forests. However, we can examine the frequency of genes as they appear in the forests. Frequent and prominent genes may then be used and analyzed by any method as described above. In other words, forest construction offers a mechanism for data reduction. For the breast-cancer data, one of the most prominent genes identified in the forests is ERBB2. *Kroll* et al. [33.58] analyzed the gene expression patterns of four breast-cancer cell lines: MCF-7, SK-BR-3, T-47D, and BT-474, and reported unique high levels of expressions in the receptor tyrosine kinase ERBB2.

33.3 Fourth-Level Analysis of Microarray Data

Nowadays, different types and platforms of microarray have been developed to address the same (or similar) biological problems. How to integrate and exchange the information contained in different sources of studies effectively is an important and challenging topic for both biologists and statisticians [33.59]. The strategy depends on the situation. When all studies of interest were conducted under the same experimental conditions, this is a standard situation for meta-analysis. There are situations where the experiments are similar, but different platforms were measured, such as the integration of one cDNA array-based study and one oligonucleotide array-based study. There are also situations where different biomolecule microarrays were collected, such as the integration of a genomic array study and a proteomic array study.

Integrating a cDNA array and an Affymetrix chip is complicated because genes on a cDNA array may correspond to several genes (or probesets) on the Affymetrix chip based on the Unigene cluster-matching criteria [33.60]. Instead of matching by genes, matching by the sequence-verified probes may increase the correlation between two studies [33.61].

Most meta-analyses of microarray data have been performed in a study-by-study manner. For example, *Yauk* et al. [33.62] use the Pearson coefficient to measure the correlation across studies, *Rhodes* et al. [33.63] and *Wang* et al. [33.64] use the estimations from one study as prior knowledge while analyzing other studies, and *Welsh* et al. [33.65] treat DNA microarrays as a screening tool and then use protein microarrays to identify the biomarker in cancer research. While they are convenient, these strategies are not ideal [33.63, 66]. Thus, it is imperative and useful to develop better methods to synthesize information from different genomic and proteomic studies [33.59, 62, 67].

33.4 Final Remarks

The technology of gene and protein chips is advancing rapidly, and the entire human genome can be simultaneously monitored on a single chip. The analytic methodology is evolving together with the technology development, but is far from satisfactory. This article reviews some of the commonly used methods in ana-

lyzing microarrays. Analyzing microarray data is still challenging; some of the important issues include how to interpret the results in the biological context, how to improve the reproducibility of the conclusions, and how to integrate information from related but different studies.

34. Statistical Methods in Proteomics

Proteomics technologies are rapidly evolving and attracting great attention in the post-genome era. In this chapter, we review two key applications of proteomics techniques: disease biomarker discovery and protein/peptide identification. For each of the applications, we state the major issues related to statistical modeling and analysis, review related work, discuss their strengths and weaknesses, and point out unsolved problems for future research.

We organize this chapter as follows. Section 34.1 briefly introduces mass spectrometry (MS) and tandem MS/MS with a few sample plots showing the data format. Section 34.2 focuses on MS data preprocessing. We first review approaches in peak identification and then address the problem of peak alignment. After that, we point out unsolved problems and propose a few possible solutions.

Section 34.3 addresses the issue of feature selection. We start with a simple example showing the effect of a large number of features. Then we address the interaction of different features and discuss methods of reducing the influence of noise. We finish this section with some discussion on the application of machine learning methods in feature selection. Section 34.4 addresses the problem of sample classification. We describe the random forest method in detail in Sect. 34.5.

In Sect. 34.6 we address protein/peptide identification. We first review database searching methods in Sect. 34.6.1 and then focus on de novo MS/MS sequencing in Sect. 34.6.2. After reviewing major protein/peptide identification programs like SEQUEST and MASCOT in Sect. 34.6.3, we conclude the section by pointing out some major issues that need to be addressed in protein/peptide identification.

Proteomics technologies are considered the major player in the analysis and understanding of protein function and biological pathways. The development of statistical methods and software for proteomics data analysis will continue to be the focus of proteomics for years to come.

34.1 Overview

In the post-genome era, proteomics has attracted more and more attention due to its ability to probe biological functions and structures at the protein level. Although recent years have witnessed great advancement in the collection and analysis of gene expression microarray data, proteins are in fact the functional units that

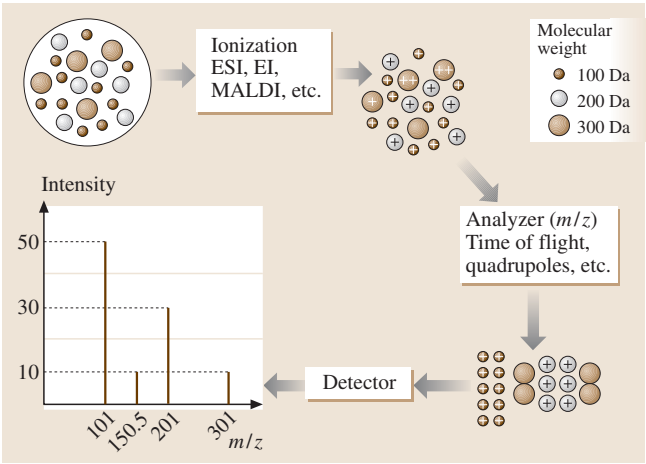

Fig. 34.1 The principle of MS data generation. Molecules are ionized into peptides in the ionizer. The peptides are accelerated and separated by the analyzer and then detected by the detector

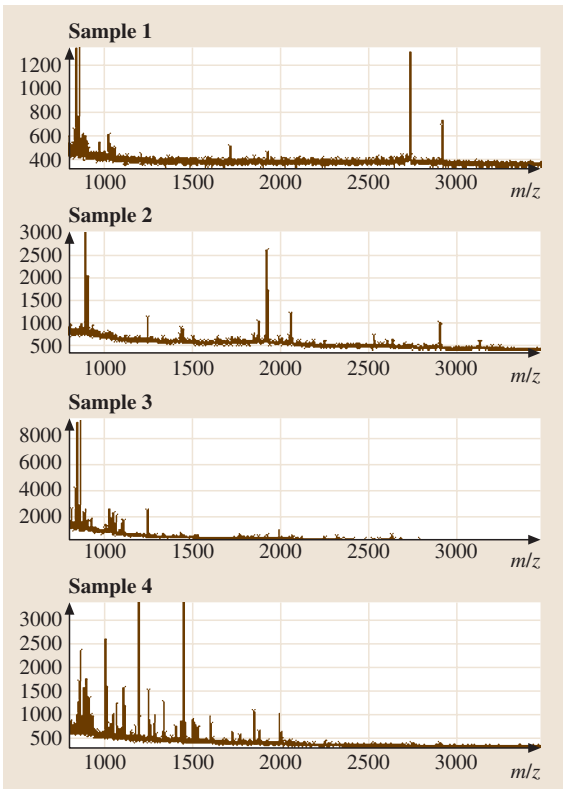

Fig. 34.2 A few examples of MS raw data. The horizontal axis denotes the m/z ratio and the vertical axis denotes the intensity value

are of biological relevance. The often poor correlation that exists between levels of mRNA versus protein expression [34.1], and the rapid advances in mass spectrometry (MS) instrumentation and attendant protein profiling methodologies have substantially increased interest in using MS approaches to identify peptide and protein biomarkers of disease. This great level of interest arises from the high potential of biomarkers to provide earlier diagnosis, more accurate prognosis and disease classification; to guide treatment; and to increase our understanding at the molecular level of a wide range of human diseases. This chapter focuses on two key applications of proteomics technologies: disease biomarker discovery and protein identification through MS data. We anticipate that statistical methods and computer programs will contribute greatly to the discovery of disease biomarkers as well as the identification of proteins and their modification sites. These methods should help biomedical researchers to better realize the potential contribution of rapidly evolving and ever more sophisticated MS technologies and platforms.

The study of large-scale biological systems has become possible thanks to emerging high-throughput mass spectrometers. Basically, a mass spectrometer consists of three components: ion source, mass analyzer, and detector. The ion source ionizes molecules of interest into charged peptides, the mass analyzer accelerates these peptides with an external magnetic field and/or electric field, and the detector generates a measurable signal when it detects the incident ions. This procedure of producing MS data is illustrated in Fig. 34.1. Data resulting from MS sources have a very simple format consisting entirely of paired mass-to-charge ratio (m/z value) versus intensity data points. Figure 34.2 shows a few examples of the raw MALDI-MS data.

The total number of measured data points is extremely large (about 10^5 for a conventional MALDI-TOF instrument, as compared to perhaps 10^6 for a MALDI-FTICR instrument covering the range from 700–28 000 Da), while the sample size is usually on the order of hundreds. This very high ratio of data size to sample size poses unique statistical challenges in MS data analysis. It is desirable to find a limited number of potential peptide/protein biomarkers from the vast amount of data in order to distinguish cases from controls and enable classification of unknown samples. This process is often referred to as biomarker discovery. In this chapter, we review key steps in biomarker discovery: preprocessing, feature selection, and sample classification.

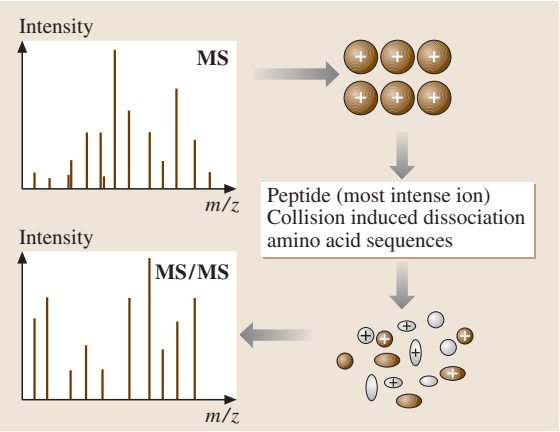

Fig. 34.3 The principle of MS/MS data generation. Peptides are further fragmented through collision-induced dissociation (CID) and detected in the tandem MS equipment

A biomarker discovered in the MS data may correspond to many possible biological sources (so a spectral peak can arise from different proteins). Therefore, it is necessary to identify peptides and their parent proteins in order to fully understand the relation between protein structure and disease development. This understanding can also be very useful in drug design and development.

In order to identify proteins in complex mixtures, the tandem MS technique (MS/MS) coupled with database searching has become the method of choice for the rapid and high-throughput identification, characterization, and quantification of proteins. In general, a protein mixture of interest is enzymatically digested, and the resulting peptides are then further fragmented through collision-induced dissociation (CID). The resulting tandem MS spectrum contains information about the constituent amino acids of the peptides and therefore information about their parent proteins. This process is illustrated in Fig. 34.3.

Many MS/MS-based methods have been developed to identify proteins. The identification of peptides containing mutations and/or modifications, however, is still a challenging problem. Statistical methods need to be developed to improve identification of modified proteins in samples consisting of only a single protein and also in samples consisting of complex protein mixtures.

We organize the rest of the chapter as follows: Section 34.2 describes MS data preprocessing methods. Section 34.3 focuses on feature selection. Section 34.4 reviews general sample classification methodology and Sect. 34.5 mainly describes the random forest algorithm. Section 34.6 surveys different algorithms/methods for protein/peptide identification, each with its strengths and weaknesses. It also points out challenges in the future research and possible statistical approaches to solving these challenges. Section 34.7 summarizes the chapter.

34.2 MS Data Preprocessing

When analyzing MS data, only the spectral peaks that result from the ionization of biomolecules such as peptides and proteins are biologically meaningful and of use in applications. Different data preprocessing methods have been proposed to detect and locate spectral peaks. A commonly used protocol for MS data preprocessing consists of the following steps: spectrum calibration, baseline correction, smoothing, peak identification, intensity normalization and peak alignment [34.2–4].

Preprocessing starts with aligning individual spectra. Even with the use of internal calibration, the maximum observed intensity for an internal calibrant may not occur at exactly the same m/z value in all spectra. This challenge can be addressed by aligning spectra based on the maximum observed intensity of the internal calibrant. For the sample collected, the distance between each pair of consecutive m/z ratios is not constant. Instead, the increment in m/z values is approximately a linear function of the m/z values. Therefore, a log-transformation of m/z values is needed before any analysis is performed so that the scale on the predictor is roughly comparable across the range of all m/z values. In addition to transforming the m/z values, we also need to log-transform intensities to reduce the dynamic range of the intensity values. In summary, log-transformations are needed for both m/z values and intensities as the first step in MS data analysis. Figure 34.4 shows an example of MS data before and after the log-transformation.

Chemical and electronic noise produce background fluctuations, and it is important to remove these background fluctuations before further analysis. Local smoothing methods have been utilized for baseline

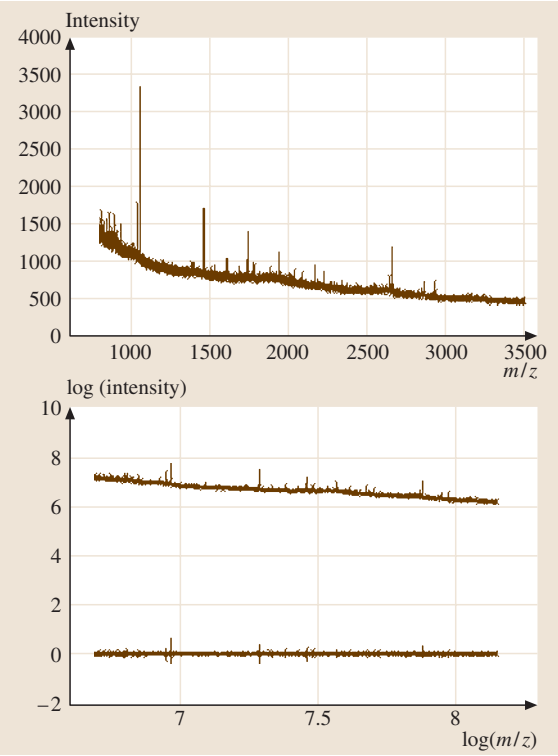

Fig. 34.4 ***Top:*** Original raw data. ***Bottom:*** MS data after the log-transformation (*top*). The result of baseline correction is also shown (*bottom*)

subtraction to remove high frequency noise, which is apparent in MALDI-MS spectra. In the analysis of MALDI data, *Wu* et al. [34.5] used a local linear regression method to estimate the background intensity values, and then subtracted the fitted values from the local linear regression result. *Baggerly* et al. [34.4] proposed a semi-monotonic baseline correction method in their analysis of SELDI data. *Liu* et al. [34.6] computed the convex hull of the spectrum, and subtracted the convex hull from the original spectrum to get the baseline-corrected spectrum. An example of baseline correction is shown in Fig. 34.4 as well.

Among the above steps, peak identification and alignment are arguably the most important ones. The inclusion of non-peaks in the analysis will undoubtedly reduce our ability to identify true biomarkers, while the peaks identified need to be aligned so that the same peptide corresponds to the same peak value.

In the following, we give an overview of the existing approaches related to peak detection and peak alignment.

34.2.1 Peak Detection/Finding

Normally, spectral peaks are local maxima in MS data. Most published algorithms on peak identification use local intensity values to define peaks; in other words peaks are mostly defined with respect to nearby points. For example, *Yasui* et al. [34.3, 7] defined a peak as the m/z value that has the highest intensity value within its neighborhood, where the neighbors are the points within a certain range from the point of interest. In addition, a peak must have an intensity value that is higher than the average intensity level of its broad neighborhood. *Coombes* et al. [34.4] considered two peak identification procedures. For simple peak finding, local maxima are first identified. Then, those local maxima that are likely noise are filtered out, and nearby maxima that likely represent the same peptides are merged. There is a further step needed to remove unlikely peak points. In simultaneous peak detection and baseline correction, peak detection is first used to obtain a preliminary list of peaks, and then the baseline is calculated by excluding candidate peaks. The two steps are iterated and some peaks are further filtered out if the signal-to-noise ratio is smaller than a threshold. Similarly, *Liu* et al. [34.6] declared a point in the spectrum to be a peak if the intensity is a local maximum, its absolute value is larger than a particular threshold, and the intensity is larger than a threshold times the average intensity in the window surrounding this point.

All of these methods are based on similar intuitions and heuristics. Several parameters need to be specified beforehand in these algorithms, such as the number of neighboring points and the intensity threshold value. In fact, the parameter settings in the above algorithms are related to our understanding/modeling of the underlying noise. To address this issue, *Coombes* et al. [34.4] defined noise as the median absolute value of intensity. *Satten* et al. [34.8] used the negative part of the normalized MS data to estimate the variance of the noise. Wavelet-based approaches [34.9, 10] have also been proposed to remove noise in the MS data before peak detection. Based on the observation that there are substantial measurement errors in the measured intensities, *Yasui* and colleagues [34.3] argued that binary peak/non-peak data is more useful than the absolute values of intensity, while they still used a local maximum search method to detect peaks. Clearly, the success of noise-estimation-plus-threshold methodology depends largely on the validity of the noise model, which remains to be seen.

Another issue in peak detection is to avoid false positive detections. This is often done by adding an additional constraint (such as the peak width constraint [34.3]) or by choosing a specific scale level after wavelet decomposition of the original MS data (*Randolph* and *Yasui*) [34.10]. In the case of high-resolution data, it has been proposed that more than one isotopic variant of a peptide peak should be present before a spectral peak is considered to result from peptide ionization (*Yu* et al.) [34.11]. It may also be possible to use prior information about the approximate expected peak intensity distribution of different isotopes arising from the same peptide during peak detection; the theoretical relative abundance of the first peptide isotope peak may range from 60.1% for polyGly (n=23, MW 1329.5 Da) to 90.2% for poly Trp (n=7, MW 1320.5 Da) (personal communication 11/1/04 from Dr. Walter McMurray, Keck Laboratory). Certainly we also have to consider the issue of limited resolution and the consequent overlapping effect of neighboring peaks.

34.2.2 Peak Alignment

After peaks have been detected, we have to align them together before comparing peaks in different data sets. Previous studies have shown that the variation of peak locations in different data sets is nonlinear [34.12, 13]. The example in *Yu* et al. [34.11] shows that this variation still exists even when we use technical replicates. The reasons that underlie data variation are extremely complicated, including differences in sample preparation, chemical noise, cocrystallization and deposition of the matrix-sample onto the MALDI-MS target, laser position on the target, and other factors. Although it is of interest to identify these reasons, we are more interested in finding a framework to reduce the variation and align these peaks together.

Towards this direction, some methods have been proposed. *Coombes* et al. [34.4] pooled the list of detected peaks that differed in location by three clock ticks or by 0.05% of the mass. *Yasui* et al. [34.3] believed that the m/z axis shift of the peaks is approximately $\pm$ 0.1% to $\pm$0.2% of the m/z value. Thus, they expanded each peak to its local neighborhood with the width equal to 0.4% of the m/z value of the middle point. This method certainly oversimplifies the problem. In another study (*Yasui* et al.) [34.7], they first calculated the number of peaks in all samples allowing certain shifts, and selected m/z values using the largest number of peaks. This set of peaks is then removed from all spectra and the procedure is iterated until all peaks are exhausted from all the samples. In a similar spirit, *Tibshirani* et al. [34.14] proposed to use complete linkage hierarchical clustering in one dimension to cluster peaks, and the resulting dendrogram is cut off at a given height. All of the peaks in the same cluster are considered to be the same peak in further analysis.

Randolph and *Yasui* [34.10] used wavelets to represent the MS data in a multiscale framework. They used a coarse-to-fine method to first align peaks at a dominant scale and then refine the alignment of other peaks at a finer scale. From a signal representation point of view, this approach is very interesting. But it remains to be determined whether the multiscale representation is biologically reasonable.

Johnson et al. [34.15] assumed that the peak variation is less than the typical distance between peaks and they used a closest point matching method for peak alignment. The same idea was also used in *Yu* et al. [34.11] to address the alignment of multiple peak sets. Certainly, this method is limited by the data quality and it cannot handle large peak variation.

Dynamic programming (DP) based approaches [34.12, 16] have also been proposed. DP has been used in gene expression analysis to warp one gene expression time series to another similar series obtained from a different biological replicate [34.17], where the correspondence between the two gene expression time series is guaranteed. In MS data analysis, however, the situation is more complicated since a one-to-one correspondence between two data sets does not always exist. Although it is still possible to apply DP to deal with the lack-of-correspondence problem, some modifications are necessary (such as adding an additional distance penalty term to the estimation of correspondence matrix). It also remains unclear how DP can identify and ignore outliers during the matching.

Eilers [34.13] proposed a parametric warping model with polynomial functions or spline functions to align chromatograms. In order to fix warping parameters, he added calibration example sequences into chromatograms. While the idea of using a parametric model is interesting, it is difficult to repeat the same parameter estimation method in MS data since we cannot add many calibrator compounds into the MS samples. Also, it is unclear whether a second-order polynomial would be enough to describe the nonlinear shift in the MS peaks.

Although all of these methods are ad hoc, the relatively small number of peaks (compared to the number of collected points) and the relatively small shifts from spectrum to spectrum ensure that these heuristic peak alignments should work reasonably well in practice.

34.2.3 Remaining Problems and Proposed Solutions

Current peak detection methods (such as the local maximum search plus threshold method) export detection results simply as peaks or non-peaks. Given the noisy nature of MS data, this simplification is prone to being influenced by noise (noise may also produce some local maximal values) and is very sensitive to specific parameter settings (including the intensity threshold value). In addition, a uniform threshold value may exclude some weak peaks in the MS data, while the existence/nonexistence of some weak peaks may be the most informative biomarkers.

Instead of using a binary output, it would be better to use both peak width and intensity information as quantitative measures of how likely it is that a candidate is a true peak. We can use a distribution model to describe the typical peak width and intensity. The parameters of the distribution can be estimated using training samples. Then a likelihood ratio test can be used to replace the binary peak detection result (either as peak (one) or as non-peak (zero)) with a real value. This new measure should provide richer information about peaks. We believe this will help us to better align multiple peak sets.

The challenge in peak alignment is that current methods may not work if we have large peak variation [like with LC/MS (liquid chromatography/mass spectrometry) data]. Another unsolved problem is that it may not be valid to assume that the distribution of peaks is not corrupted by noise (false positive detection).

To address these problems, we may consider the "true" locations of peaks as random variables and regard the peak detection results as sampling observations. Then, the problem of aligning multiple peak sets is converted to the problem of finding the mean (or median) values of random variables since we can assume that the majority of peaks should be located close to the "true" locations, with only a few outliers not obeying this assumption. After the mean/median values have been found/estimated, the remaining task is to simply align peaks w.r.t. the mean/median standard. Intuitively, the relative distance between a peak and its mean/median standard may also be used as a confidence measure in alignment.

34.3 Feature Selection

For current large-scale genomic and proteomic datasets, there are usually hundreds of thousands of features (also called variables in the following discussion) but limited sample size, which poses a unique challenge for statistical analysis. Feature selection serves two purposes in this context: biological interpretation and to reduce the impact of noise.

Suppose we have n_1 samples from one group (e.g. cancer patients) and n_0 samples from another group (e.g. normal subjects). We have m variables $(X_1, \ldots, X_m)$ (e.g. m/z ratios). For the kth variable, the observations are

$$X_k^1 = (x_{k1}, \ldots, x_{kn_1})$$

for the first group and

$$X_k^0 = \left(x_{k(n_1+1)}, \ldots, x_{k(n_1+n_0)}\right)$$

for the second group. They can be summarized in a data matrix, $X = (x_{ij})$. Assume X_k^1 are n_1 i.i.d. samples from one distribution $f_{k1}(x)$ and X_k^0 are n_0 i.i.d. samples from another distribution $f_{k0}(x)$.

Two sample t-test statistics or variants thereof are often used to quantify the difference between two groups in the analysis of gene expression data [34.18–20]

$$T_i = \frac{\bar{x}_{i1} - \bar{x}_{i0}}{\sqrt{\frac{1}{n_1}\hat{\sigma}_{i1}^2 + \frac{1}{n_0}\hat{\sigma}_{i0}^2}}, \tag{34.1}$$

where

$$\bar{x}_{i1} = \sum_{k=1}^{n_1} x_{ik}, \quad \bar{x}_{i0} = \sum_{k=n_1+1}^{n_1+n_0} x_{ik},$$

$$\hat{\sigma}_{i1}^2 = \frac{1}{n_1 - 1}\sum_{k=1}^{n_1}(x_{ik} - \bar{x}_{i1})^2,$$

$$\hat{\sigma}_{i0}^2 = \frac{1}{n_0 - 1}\sum_{k=n_1+1}^{n_1+n_0}(x_{ik} - \bar{x}_{i0})^2.$$

T_i can be interpreted as the standardized difference between these two groups. It is expected that the larger the standardized difference, the more separated the two groups are. One potential problem with using t-statistics is its lack of robustness, which may be a serious drawback when hundreds of thousands of features are being screened to identify informative ones.

34.3.1 A Simple Example of the Effect of Large Numbers of Features

Although there are hundreds of thousands of peaks representing peptides, we expect the number of peaks that provide information on disease classification to be limited. This, coupled with the limited number of samples available for analysis, poses great statistical challenges for the identification of informative peaks. Consider the following simple example: suppose that there are $n_1 = 10, n_2 = 10$, $m_0 = 10^3$ peptides showing no difference, and $m_1 = 40$ peptides showing differences between the two groups with $\lambda = \mu/\sigma = 1.0$. We can numerically calculate the expected number of significant features for these two groups

$$N_0 = 2m_0[1 - T(x, df = 18)] ,$$
$$N_1 = m_1[T(-x, df = 18, \lambda = 1.0) + 1 - T(x, df = 18, \lambda = 1.0)] ,$$

where $T(x, df)$ is the t-distribution function with df degrees of freedom, $T(x, df, \lambda)$ is the t-distribution function with df degrees of freedom and noncentral parameter λ, and the significance cut-off values are chosen as $|T| > x$. Figure 34.5 gives a comparison of true and false positives for this example, where a diagonal line is also shown. We can clearly see the dominant effect of noise in this example.

This artificial example reveals the difficulty that extracting useful features among a large number of noisy features entails. In practice, due to the noisy nature of MS data, the variance σ for individual peptide intensity will be very large, reflecting the difficulties with reproducibility that are commonly observed for MS data. Also, the number of noisy features m_0 (mostly uninformative) are increasing exponentially with the advance of technology (e.g. MALDI-FTICR data). The combination of these two factors will increase the ratio of false/true positives.

In this simple example, we ignore the interaction of different proteins. For complex diseases, such as cancer, it is quite possible that the effects result from the joint synergy of multiple proteins, while they individually show nonsignificant differences. Novel statistical methods are needed to account for the effects of noise and interactions among features.

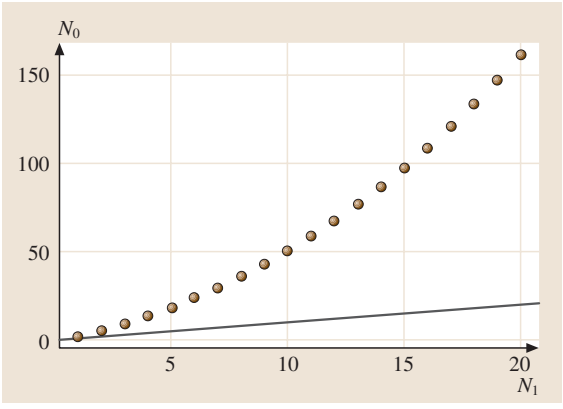

Fig. 34.5 Comparison of true positive and false positive for the simulation example. N_1 is the number of true positive, N_0 false positive. The diagonal line is also plotted as a *solid line*. Different points correspond to different settings of critical values in the t-test

34.3.2 Interaction

In ordinary or logistic regression models, we describe the interaction of different variables by including the interaction terms. This approach quickly becomes unfeasible with an increasing number of variables. Therefore, standard regression models are not appropriate due to $n \ll p$.

Instead of using univariate feature selection methods, it may be useful to consider multivariate feature selection methods. *Lai* et al. [34.21] analyzed the co-expression pattern of different genes using a prostate cancer microarray dataset, where the goal is to select genes that have differential gene–gene coexpression patterns with a target gene. Some interesting genes have been found to be significant and reported to be associated with prostate cancer, yet none of them showed marginal significant differential gene expressions.

Generally, multivariate feature selection is a combinatorial approach. To analyze two genes at a time we need to consider n^2 possibilities instead of n for the univariate feature selection. To analyze the interaction of K genes we need to consider n^K possibilities, which quickly becomes intractable.

A classification and regression tree (CART) [34.22] naturally models the interaction among different variables, and it has been successfully applied to genomic and proteomic datasets where $n \ll p$ is expected [34.23].

There are several new developments that are generalizations of the tree model. Bagging stands for bootstrap aggregating. Intuitively, bagging uses bootstrap to produce pseudoreplicates to improve prediction

accuracy [34.24]. The boosting method [34.25] is a sequential voting method, which adaptively resamples the original data so that the weights are increased for those most frequently misclassified samples. A boosting model using a tree as the underlying classifier has been successfully applied to genomic and proteomic datasets [34.26, 27].

34.3.3 Reducing the Influence of Noise

For most statistical models, the large number of variables may cause an overfitting problem. Just by chance, we may find some combinations of noise that can potentially discriminate samples with different disease status. We can incorporate some additional information into our analysis. For MS data, for instance, we only want to focus on peaks resulting from peptide/protein ionization. In previous sections we have addressed and emphasized the importance of MS data preprocessing.

34.3.4 Feature Selection with Machine Learning Methods

Isabelle et al. [34.28] have reported using SVM to select genes for cancer classification from microarray data. *Qu* et al. [34.29] applied a boosting tree algorithm to classify prostate cancer samples and to select important peptides using MS analysis of sera. *Wu* et al. [34.5] reported using random forest to select important biomarkers from ovarian cancer data based on MALDI-MS analysis of patient sera.

One distinct property of these learning-based feature selection methods compared to traditional statistical methods is the coupling of feature selection and sample classification. They implicitly approach the feature selection problem from a multivariate perspective. The significance of a feature depends strongly upon other features. In contrast, the feature selection methods employed in *Dudoit* et al. [34.30] and *Golub* et al. [34.31] are univariate and interactions among genes are ignored.

34.4 Sample Classification

There are many well established discriminant methods, including linear and quadratic discriminant analysis, and k-nearest neighbor, which have been compared in the context of classifying samples using microarray and MS data [34.5, 30]. The majority of these methods were developed in the pregenome era, where the sample size n was usually very large while the number of features p was very small. Therefore, directly applying these methods to genomic and proteomic datasets does not work. Instead, feature selection methods are usually applied to select some "useful" features at first and then the selected features are used to carry out sample classification based on traditional discriminant methods. This two-step approach essentially divides the problem into two separate steps: feature selection and sample classification, unlike the recently developed machine learning methods where the two parts are combined together.

The previously mentioned bagging (*Breiman*) [34.24], boosting (*Freund* and *Schapire*) [34.25], random forest (*Breiman*) [34.32], and support vector machine (*Vapnik*) [34.33] approaches have all been successfully applied to high-dimension genomic and proteomic datasets.

Due to the lack of a genuine testing dataset, cross-validation (CV) has been widely used to estimate the error rate for the classification methods. Inappropriate use of CV may seriously underestimate the real classification error rate. *Ambroise* and *McLachlan* [34.34] discussed the appropriate use of CV to estimate classification error rate, and recommended the use of K-fold cross-validation, e.g. $K = 5$ or 10.

34.5 Random Forest: Joint Modelling of Feature Selection and Classification

Wu et al. [34.5] compared the performance of several classical discriminant methods and some recently developed machine learning methods for analyzing an ovarian cancer MS dataset. In this study, random forest was shown to have good performance in terms of feature selection and sample classification. Here we design an algorithm to get an unbiased estimation of the classification error using random forest and at the same time efficiently extract useful features.

Suppose the preprocessed MS dataset has n samples and p peptides. We use $\{X_k \in \mathbb{R}^p,\ k = 1, 2, \cdots, n\}$ to represent the intensity profile of the kth individ-

ual, and $\{Y_k, k = 1, 2, \cdots, n\}$ to code the sample status.

The general idea of random forest is to combine random feature selection and bootstrap resampling to improve sample classification. We can briefly summarize the general idea as the following algorithm.

General random forest algorithm

1. Specify the number of bootstrap samples B, say 10^5.
2. For $b = 1, 2, \cdots, B$,
   a) Sample with replacement n samples from $\{X_k\}$ and denote the bootstrap samples by $\boldsymbol{X}^b = \{X_{b_1}, \cdots, X_{b_n}\}$, the corresponding response being $\boldsymbol{Y}^b = \{Y_{b_1}, \cdots, Y_{b_n}\}$.
   b) Randomly select m out of p peptides. Denote the selected subset of features by $\{r_1, \cdots, r_m\}$, and the bootstrap samples restricted to this subset by $\boldsymbol{X}_m^b$. Build a tree classifier T_b using $\boldsymbol{Y}^b$ and $\boldsymbol{X}_m^b$. Predict those samples not in the bootstrap samples using T_b.
3. Average the prediction over bootstrap samples to produce the final classification.

For the random forest algorithm from *Breiman* [34.32], randomness is introduced at each node split. Specifically, at each node split, a fixed number of features is randomly selected from all of the features and the best split is chosen among these selected features. For the random subspace method developed by *Ho* [34.35], a fixed number of features is selected at first and is used for the same original data to produce a tree classifier. Thus, both models have the effect of randomly using a fixed subset of features to produce a classifier, but differ in the underlying tree-building method.

Figure 34.6 shows a simple comparison of the two methods. We selected 78 peptides from the ovarian cancer MS data reported by *Wu* et al. [34.5]. Then we apply the two algorithms to numerically evaluate their sample classification performance using the selected subset of features. We want to emphasize that the calculated classification error rate is not a true error rate because we have used the sample status to select 78 peptides first. Our purpose here is just to show a simple numerical comparison of these two methods.

Other important issues in the analysis of MS data include specification of the number of biomarkers and the sample size being incorporated into the experimental design. To estimate the classification error Err, as discussed in *Cortes* et al. [34.36], the inverse power law learning curve relationship between Err and sample size N,

$$\mathrm{Err}(N) = \beta_0 N^{-\alpha} + \beta_1 \,, \tag{34.2}$$

is approximately true for large sample size datasets (usually about tens of thousands of samples); β_1 is the asymptotic classification error and (α, β_0) are positive constants.

Current MS data usually have a relatively small sample size ($N \approx 10^2$) compared to the high-dimension feature space ($p \approx 10^5$). In this situation, it may not be appropriate to rely on the learning curve model to extrapolate β_1, which corresponds to an infinite training sample size $N = \infty$. But within a limited range, this model may be useful to extrapolate the classification error. To estimate parameters $(\alpha, \beta_0, \beta_1)$, we need to obtain at least three observations.

Obviously the classification error Err also depends on the selected number of biomarkers m. We are going to use the inverse-power-law (34.2) to model $\mathrm{Err}(N, m)$.

We proposed the following algorithm to get an unbiased estimate for the classification error rate, which also provides an empirical method to select the number of biomarkers (Wu et al.) [34.37].

CV error estimation using random forest algorithm

1. Specify the number of folders K, say 5, and the range for the number of biomarkers m, say $M = \{20, 21, \cdots, 100\}$. Randomly divide all N samples into balanced K groups.
2. For $k = 1, 2, \cdots, K$ do the following:
   a) Use samples in the kth group as the testing set Ts and all the other samples as the training set Tr.

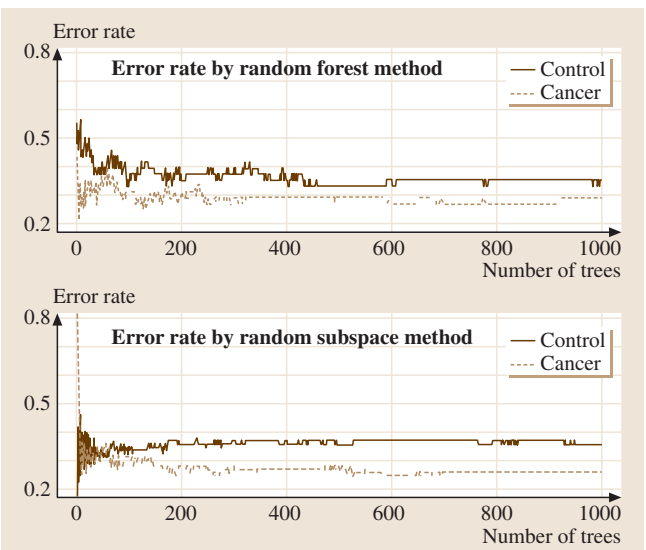

Fig. 34.6 Comparison of the error rates of two random forest algorithms on an ovarian cancer data set. 78 features selected by t-test are used in both algorithms. The two methods give similar performances

b) Apply the random forest algorithm (or any other feature selection method) to the training data Tr. Rank all of the features according to their importance.

c) Use the first $m \in M$ most important features and construct a classifier based on the training set Tr and predict samples in the testing set Ts. We will get a series of error estimates

$$\left\{\epsilon\left(k, m, \frac{K-1}{K}N\right), m \in M\right\} ,$$

where $\frac{K-1}{K}N$ is the effective size of the training set.

d) Use samples in the ith and jth group as the testing set and other $K-2$ groups as the training set. Repeat steps (2.2) and (2.3) to get the error estimate

$$\left\{\epsilon\left(k, m, \frac{K-2}{K}N\right), m \in M\right\} ,$$

where $\frac{K-2}{K}N$ is the effective size of the training set.

e) We can repeat step (2.4) using n of the groups as a testing set and get the error rate

$$\left\{\epsilon\left(k, m, \frac{K-n}{K}N\right), m \in M\right\} ,$$
$$n = 1, 2, \cdots, K-1 .$$

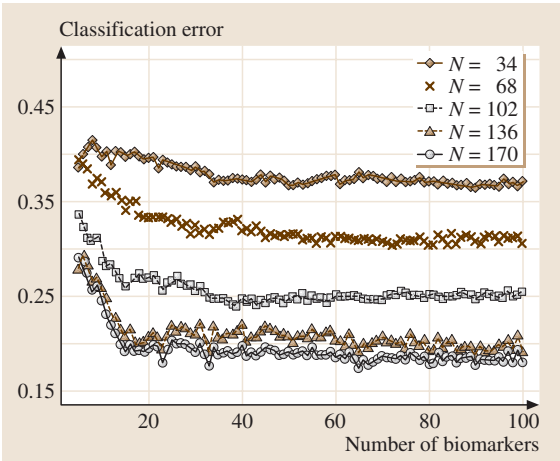

Fig. 34.7 Fivefold cross-validation estimation of classification error rate achieved by applying a random forest algorithm to the ovarian dataset. The error rates for sample size $N = 34, 68, 102, 136$ are obtained from the fivefold CV and the error rate for $N = 170$ is extrapolated from the inverse power law model fitting

3. Average $\epsilon[k, m, N(K-n)/K]$ over K folders to get the final error estimation $\bar{\epsilon}[m, N(K-n)/K]$ for m biomarkers and sample size $N(K-n)/K$.
4. Fit the inverse power law model (34.2) to $\bar{\epsilon}[m, N(K-n)/K]$ for every fixed m and extrapolate the error rate to N samples, $\bar{\epsilon}(m, N)$.

The estimated error rate curve $\bar{\epsilon}(m, n)$ can be used as a guidance for sample size calculation and to select the number of biomarkers.

For K folders, the previous algorithm will involve a total of 2^K training set fittings. If K is relatively large, say 10, the total number of fittings will be very large $(2^K = 1024)$. Note that in the inverse power law model (34.2) we only have three parameters $(\alpha, \beta_0, \beta_1)$. We can carry out just enough training data fitting, say 10, to estimate these three parameters. Then we can use the fitted model to interpolate or extrapolate the classification error rate for other sample size.

Figure 34.7 displays the fivefold CV estimate of the classification error rate achieved by applying the random forest algorithm to the serum mass spectrometry dataset for 170 ovarian cancer patients reported in *Wu* et al. [34.5], where the error rates for the training sample size $N = 34, 68, 102, 136$ are derived from the fivefold CV, and the error rate for $N = 170$ is extrapolated from the inverse power law model fitting.

34.5.1 Remaining Problems in Feature Selection and Sample Classification

As we discussed before, the univariate feature selection based on t-statistics is very sensitive to noise. We can reduce the influence of noise marginally by using additional biological information. But more importantly, we need to develop robust statistical methods. It is conjectured that random forest (*Breiman*) [34.32] does not over-fit. Our experience shows that we can dramatically reduce the classification error rate by incorporating feature selection with the random forest algorithm.

Intuitively, the sample classification error rate will increase with too much noise in the data. In this sense, feature selection will help us to improve the performance of algorithm classification. However, feature selection is usually affected by the small sample size $(n \ll p)$ in genomic and proteomic datasets. If we only select a small number of features, we may miss many "useful" features. One approach would be to couple the fast univariate feature selection with computationally intensive machine learning methods. For example, we can first use univariate feature selection to reduce the number of

features to a manageable size M_0. Then, we can apply the machine learning methods to refine our selection to a small number of target features M_1. Certainly, determining M_0 is a trade-off issue: if M_0 is too small, we will miss many informative features; if M_0 is too large, we will have a heavy computing burden for the following machine learning methods and also make the feature selection unstable.

For the genomic and proteomic data, the large n and small p will make the majority of the traditional statistical methods unusable. Most recently developed machine learning methods are computationally intensive and are often evaluated by empirical performance on some datasets. Statistical methods needed to be developed to bridge the traditional model-based principles and the newly developed machine learning methods.

34.6 Protein/Peptide Identification

34.6.1 Database Searching

MS in combination with database searching has emerged as a key platform in proteomics for high-throughput identification and quantification of proteins. A single stage MS provides a "mass fingerprint" of the peptide products of the enzymatically digested proteins, and this can be used to identify proteins [34.38–45]. This approach is useful for identifying purified proteins (such as proteins in dye-stained spots from 2-D polyacrylamide gels), and may also succeed with simple mixtures containing only 2–3 major proteins. Protein identification based on peptide mass database searching requires both high mass accuracy and that observed peptide masses be matched to a sufficient fraction (e.g. >25%) of the putatively identified protein. The latter task will be made more difficult if the protein has been post-translationally modified at multiple sites. Alternatively, the resulting peptide ions from the first stage MS can be isolated in the mass spectrometer and individually fragmented through CID to produce a tandem MS. In addition to the parent peptide mass, tandem MS provides structural information that can be used to deduce the amino acid sequences of individual peptides. Since tandem MS often identifies proteins using the CID-induced spectrum obtained from a single peptide, this technology is capable of identifying proteins in very complex mixtures such as cell extracts [34.43, 44, 46–61]. In general, database searching methods compare the experimentally observed tandem MS with features predicted for hypothetical spectra from candidate peptides (of equal mass) in the database and then return a ranked listing of the best matches, assuming that the query peptide exists in the protein sequence database. The statistical challenge in MS- and MS/MS-based protein identification is to assess the probability that a putative protein identification is indeed correct. In the case of MS/MS-based approaches, a commonly used criterion is that the observed MS/MS spectra must be matched to at least two different peptides from each identified protein.

34.6.2 De Novo Sequencing

An alternative approach to database searching of uninterpreted tandem MS for peptide identification is De Novo MS/MS sequencing [34.62–65], which attempts to derive a peptide sequence directly from tandem MS data. Although de novo MS/MS sequencing can handle situations where a target sequence is not in the protein database searched, the utility of this approach is highly dependent upon the quality of tandem MS data, such as the number of predicted fragment ion peaks that are observed and the level of noise, as well as the high level of expertise of the mass spectroscopist in interpreting the data, as there is no currently accepted algorithm capable of interpreting MS/MS spectra in terms of a de novo peptide sequence without human intervention. Because of the availability of DNA sequence databases, many of which are genome-level, and the very large numbers of MS/MS spectra (e.g., tens of thousands) generated in a single isotope coded affinity tag or another MS-based protein profiling analysis of a control versus experimental cell extract, highly automated database searching of uninterpreted MS/MS spectra is by necessity the current method of choice for high-throughput protein identification [34.43, 46, 49].

34.6.3 Statistical and Computational Methods

Due to the large number of available methods/alogrithms for MS- and MS/MS-based protein identification, we focus on what we believe are currently the most widely used approaches in the field.

- SEQUEST (Eng et al.) [34.46]

SEQUEST is one of the foremost yet sophisticated algorithms developed for identifying proteins from tandem

MS data. The analysis strategy can be divided into four major steps: data reduction, search for potential peptide matches, scoring peptide candidates and cross-correlation validation. More specifically, it begins with computer reduction of the experimental tandem MS data and only retains the most abundant ions to eliminate noise and to increase computational speed. It then chooses a protein database to search for all possible contiguous sequences of amino acids that match the mass of the peptide with a predetermined mass tolerance. Limited structure modifications may be taken into account as well as the specificity of the proteolytic enzyme used to generate the peptides. After that, SEQUEST compares the predicted fragment ions from each of the peptide sequences retrieved from the database with the observed fragment ions and assigns a score to the retrieved peptide using several criteria such as the number of matching ions and their corresponding intensities, some immonium ions, and the total number of predicted sequence ions. The top 500 best fit sequences are then subjected to a correlation-based analysis to generate a final score and ranking for the sequences.

SEQUEST correlates MS spectra predicted for peptide sequences in a protein database with an observed MS/MS spectrum. The cross-correlation score function provides a measure of the similarity between the predicted and observed fragment ions and a ranked order of relative closeness of fit of predicted fragment ions to other isobaric sequences in the database. However, since the cross-correlation score does not have probabilistic significance, it is not possible to determine the probability that the top-ranked and/or other matches result from random events and are thus false positives. Although lacking a statistical basis, *Eng* et al. [34.46] suggest that a difference greater than 0.1 between the normalized cross-correlation functions of the first- and second-ranked peptides indicates a successful match between the top-ranked peptide sequence and the observed spectrum. A commonly used guideline for Sequest-based protein identification is that observed MS/MS spectra are matched to two or more predicted peptides from the same protein and that each matched peptide meets the 0.1 difference criterion.

- MASCOT (*Perkins* et al.) [34.43]

MASCOT is another commonly used database searching algorithm, which incorporates a probability-based scoring scheme. The basic approach is to calculate the probability (via an approach that is not well described in the literature) that a match between the experimental MS/MS data set and each sequence database entry is a chance event. The match with the lowest probability of resulting from a chance event is reported as the best match. MASCOT considers many key factors, such as the number of missed cleavages, both quantitative and nonquantitative modifications (the number of nonquantitative modifications is limited to four), mass accuracy, the particular ion series to be searched, and peak intensities. Hence, MASCOT iteratively searches for the set with the most intense ion peaks, which provide the highest score – with the latter being reported as $-10\log(P)$, where P is the probability of the match resulting from a random, chance event. *Perkins* et al. [34.43] suggested that the validity of MASCOT probabilities should be tested by repeating the search against a randomized sequence database and by comparing the MASCOT results with those obtained via the use of other search engines.

- Other Methods

In addition to SEQUEST and MASCOT, many other methods have been proposed to identify peptides and proteins from tandem MS data. They range from the development of probability-based scoring schemes, the identification of modified peptides, and checking the identities of peptides and proteins in other miscellaneous fields. Here we give a brief review of these approaches.

Bafna and *Edwards* [34.49] proposed the use of SCOPE to score a peptide with a conditional probability of generating the observed spectrum. SCOPE models the process of tandem MS spectrum generation using a two-step stochastic process. Then SCOPE searches a database for the peptide that maximizes the conditional probability. The SCOPE algorithm works only as well as the probabilities assumed for each predicted fragment of a peptide. Although *Bafna* and *Edwards* [34.49] proposed using a human-curated database of identified spectra to compute empirical estimates of the fragmentation probabilities required by this algorithm, to our knowledge this task has not yet been carried out. Thus, SCOPE is not yet a viable option for most laboratories.

Pevzner et al. [34.48] implemented spectral convolution and spectral alignment approaches to identifying modified peptides without the need for exhaustive generation of all possible mutations and modifications. The advantages of these approaches come with a tradeoff in the accuracy of their scoring functions, and they usually serve as filters to identify a set of "top-hit" peptides for further analysis. *Lu* and *Chen* [34.60] developed a suffix tree approach to reduce search time when identifying modified peptides, but the resulting scores do not have direct probabilistic interpretations.

PeptideProphet [34.53] and ProteinProphet (*Nesvizhskii* et al.) [34.61] were developed at the Institute for

Systems Biology (ISB) to validate peptide and protein identifications using robust statistical models. After scores are derived from the database search, PeptideProphet models the distributions of these scores as a mixture of two distributions, with one consisting of correct matches, and the other consisting of incorrect matches. ProteinProphet takes as input the list of peptides along with probabilities from PeptideProphet, adjusts the probabilities for observed protein grouping information, and then discriminates correct from incorrect protein identifications.

Mann and *Wilm* [34.47] proposed a "peptide sequence tag" approach to extracting a short, unambiguous amino acid sequence from the peak pattern that, when combined with the mass information, infers the composition of the peptide. *Clauser* et al. [34.44] considered the impact of measurement accuracy in protein identification. *Kapp* et al. [34.66] proposed two different statistical methods, the cleavage intensity ratio (CIR) and a linear model, to identify the key factors that influence peptide fragmentation. It has been known for a long time that peptides do not fragment equally and that some bonds are more likely to break than others. However, the chemical mechanisms and physical processes that govern the fragmentation of peptides are highly complex. One can only take results from previous experiments and try to find indicators about such mechanisms. The use of these statistical methods demonstrates that proton mobility is the most important factor. Other important factors include local secondary structure and conformation as well as the position of a residue within a peptide.

34.7 Conclusion and Perspective

While the algorithms for protein identification from tandem MS mentioned above have different emphases, they contain the elements of the following three modules [34.49]:

1. Interpretation [34.67], where the input MS/MS data are interpreted and the output may include parent peptide mass and possibly a partial sequence.
2. Filtering, where the interpreted MS/MS data are used as templates in a database search in order to identify a set of candidate peptides.
3. Scoring, where the candidate peptides are ranked with a score.

Among these three modules, a good scoring scheme is the mainstay. Most database searching algorithms assign a score function by correlating the uninterpreted tandem MS with theoretical/simulated tandem MS for certain peptides derived from protein sequence databases. An emerging issue is the significance of the match between a peptide sequence and tandem MS data. This is especially important in multidimensional LC/MS-based protein profiling where, for instance, our isotope-coded affinity tag studies on crude cell extracts typically identify and quantify two or more peptides from only a few hundred proteins as compared to identifying only a single peptide from a thousand or more proteins. Currently, we require that two or more peptides must be matched to each identified protein. However, if statistically sound criteria could be developed to permit firm protein identifications based on only a single MS/MS spectrum, the useable data would increase significantly. Therefore, it is important and necessary to develop the best possible probability-based scoring schemes, particularly in the case of the automated high-throughput protein analyses used today.

Even for the probability-based algorithms, the efficiencies of score functions can be further improved by incorporating other important factors. For example, statistical models proposed by *Kapp* et al. [34.66] may be used to predict the important factors that govern the fragmentation pattern of peptides and subsequently improve the fragmentation probability as well as the score function in SCOPE [34.49]. In addition, some intensity information can be added to improve score function.

One common drawback of all of these algorithms is the lack of ability to detect modified peptides. Most of the database search methods are not mutation- and modification-tolerant. They are not effective at detecting types and sites of sequence variations, leading to low score functions. A few methods have incorporated mutation and modification into their algorithms, but they can only handle at most two or three possible modifications. Therefore, the identification of modified peptides remains a challenging problem. Theoretically, one can generate a virtual database of all modified peptides for a small set of modifications and match the spectrum against this virtual database. But the size of this virtual database increases exponentially with the number of modifications allowed, making this approach unfeasible. Markov chain Monte Carlo is an appealing approach to identifying mutated and modified peptides. The algorithm may start from a peptide corresponding

to a protein and a "new" candidate peptide with modifications/mutations is proposed according to a set of prior probabilities for different modifications and mutations. The proposed "new" peptide is either rejected or accepted and the procedure can be iterated to sample the posterior distribution for protein modification sites and mutations. However, the computational demands can also be enormous for this approach. Parallel computation and better-constructed databases are necessary to make this approach more feasible.

35. Radial Basis Functions for Data Mining

This chapter deals with the design and applications of the radial basis function (RBF) model. It is organized into three parts. The first part, consisting of Sect. 35.1, describes the two data mining activities addressed here: classification and regression. Next, we discuss the important issue of bias–variance tradeoff and its relationship to model complexity. The second part consists of Sects. 35.2 to 35.4. Section 35.2 describes the RBF model architecture and its parameters. In Sect. 35.3.1 we briefly describe the four common algorithms used for its design: clustering, orthogonal least squares, regularization, and gradient descent. In Sect. 35.3.2 we discuss an algebraic algorithm, the SG algorithm, which provides a step-by-step approach to RBF design. Section 35.4 presents a detailed example to illustrate the use of the SG algorithm on a small data set. The third part consists of Sects. 35.5 and 35.6. In Sect. 35.5 we describe the development of RBF classifiers for a well-known benchmark problem to determine whether Pima Indians have diabetes. We describe the need for and importance of partitioning the data into training, validation, and test sets. The training set is employed to develop candidate models, the validation set is used to select a model, and the generalization performance of the selected model is assessed using the test set. Section 35.6 describes a recent data mining application in bioinformatics, where the objective is to analyze the gene expression profiles of Leukemia data from patients whose classes are known to predict the target cancer class. Finally, Sect. 35.7 provides concluding remarks and directs the reader to related literature. Although the material in this chapter is applicable to other types of basis funktions, we have used only the Gaussian function for illustrations and case studies because of its popularity and good mathematical properties.

Neural networks have been used extensively to model unknown functional relationships between input and output data. The radial basis function RBF model is a special type of neural network consisting of three layers: input, hidden, and output. It represents two sequential mappings. The first nonlinearly maps the input data via basis functions in the hidden layer. The second, a weighted mapping of the basis function outputs, generates the model output. The two mappings are usually treated separately, which makes RBF a very versatile modeling technique. There has been some debate about whether RBF is biologically plausible, and hence whether it really is a neural network model. Nevertheless, it has become an established model for diverse classification and regression problems. For example, it has been successfully employed in areas such as data mining, medical diagnosis, face and speech recognition, robotics, forecasting stock prices, cataloging objects in the sky, and bioinformatics.

RBF networks have their theoretical roots in regularization theory and were originally developed by Russian mathematicians in the 1960s. They were used for strict interpolation among multidimensional data [35.1], where it is required that every input be mapped to a corresponding output. *Broomhead* and *Lowe* [35.2] used the RBF model for approximation. The relation-

ship between the use of RBF for strict interpolation and approximation is of special interest in this chapter. Further, they have been shown to possess very important mathematical properties of universal and best approximation [35.3]. A function approximation scheme is said to have the property of universal approximation if the set of functions supported by the approximation scheme is dense in the space of the continuous functions defined on the input domain, and it has the property of best approximation if there is one function among this set that has the lowest approximating error for any given function to be approximated. This provides a strong mathematical justification for their practical application, since the popular multilayer perceptrons approach, for example, does not possess the property of best approximation.

In this chapter we describe the radial basis network architecture, its design and applications. The data mining problem we address is described in Sect. 35.1. The RBF model and its parameters are described in Sect. 35.2. Sect. 35.3 presents some common design algorithms. An important design problem relates to determining the number of basis functions in the hidden layer and their parameters. A new algebraic algorithm, the SG algorithm, provides a systematic methodology for doing so and is also discussed in Sect. 35.3. An illustrative modeling example is described in Sect. 35.4, and a benchmark case study about diabetes classification is presented in Sect. 35.5. An important data mining application for cancer class prediction based on microarray data analysis is described in Sect. 35.6. Finally, some concluding remarks are presented in Sect. 35.7.

35.1 Problem Statement

Knowledge discovery applications are aimed at extracting accurate, previously unknown, useful, and actionable information from databases, and the related discipline is known as knowledge discovery in databases KDD. The usual steps in this process, often followed iteratively, are: selection of the target data from the raw databases; its processing and transformation; information extraction (called "data mining") using algorithmic approaches; interpretation of the information gained; and its useful application. Data mining is the key phase in this process and is main interest in this chapter. For a detailed description of this discipline, see [35.4–6].

The data available is a collection of records, each record itself being a collection of fields or data items. This tabular data is the input to a data mining algorithm, the output of which is the desired information or the knowledge sought. Usual data mining applications include data characterization, pattern recognition, rule extraction, clustering, trend analysis, and visualization. In this chapter, we address only pattern recognition. The pattern recognition task can be described as the construction of a model for input-output mapping on the basis of available tabular data. Such data are called the training sample. The inputs are d-dimensional independent variables or features ($\boldsymbol{x}$'s), and the output is a one-dimensional dependent variable (y). The two common pattern recognition tasks are classification and regression. In the case of classification, y represents one of a possible L classes. Most applications, however, are binary classification problems; in other words $L = 2$ in most practical cases. In regression problems y is a continuous variable. The constructed model is employed to predict the output y for future observed input $\boldsymbol{x}$'s. The objective is to seek a data mining algorithm that predicts y as accurately as possible. In other words, we seek to minimize the prediction error on future data.

In classification problems, a commonly used prediction error measure is the "classification error" (CE), which is defined as the ratio of misclassified objects to the total number of objects. For regression problems, the mean squared error (MSE) is generally employed. It is the averaged sum of squared discrepancies between the actual and the predicted values. The model performance is computed for the training data. An independent data set that is representative of the data used for training and is called the "validation set" is employed to compare the performance of the derived models. Then, yet another independent data set, called the "test set", is employed to assess the test error of the selected model as a performance measure on future data, for which the model was developed in the first place.

In the design and selection of RBF models, we prefer a parsimonious model; in other words, one with the smallest number of terms that provides the desired performance. However, it is well known that a model with too few terms can suffer from underfitting, while one with too many can result in overfitting and will therefore fail to generalize well on future data. This problem

is also known as the "bias-variance dilemma" in machine learning and statistics literature [35.5,7,8]. Simple models tend to have high bias and low variance, while complex models tend to have low bias and high variance. A graphical illustration of this phenomenon is shown in Fig. 35.1. The objective of modeling is to seek a compromise or tradeoff between bias and variance, and to find a model of just the right complexity. For the RBF model, as we discuss below, this means that we seek a model with just enough basis functions in the hidden layer. In other words, we seek a model that has a low training error and a low generalization error as assessed by the error on test data. In Fig. 35.1 this idealized situation is labeled as the "best model".

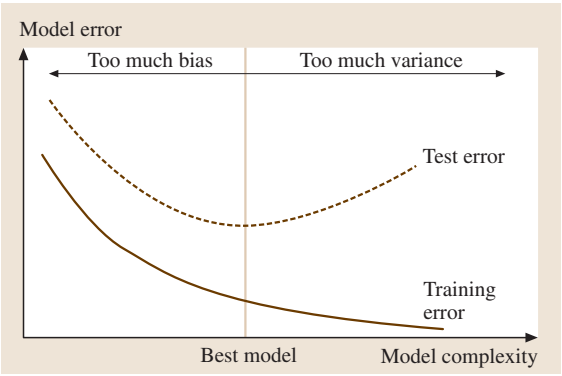

Fig. 35.1 Typical behavior of training error and test error

35.2 RBF Model and Parameters

A typical RBF network is shown in Fig. 35.2. It has three layers: input, hidden and output. The input layer consists of an $n \times d$ input data matrix $\mathbf{X}$:

$$\mathbf{X} = (\boldsymbol{x}_1, \boldsymbol{x}_2, ..., \boldsymbol{x}_n)^T \in \mathbb{R}^{n \times d} , \tag{35.1}$$

where $\boldsymbol{x}_i$, i= 1, 2, . . . , n are the d-dimensional vectors and n is the size of the data. The hidden layer has m basis functions $\phi_1(\cdot)$, $\phi_2(\cdot)$, . . . , $\phi_m(\cdot)$ centered at basis function centers $\boldsymbol{\mu}_1, \boldsymbol{\mu}_2, \ldots, \boldsymbol{\mu}_m$, respectively, and connected to the output layer with weights $w_1, w_2, \ldots, w_m$, respectively. The basis functions transform the input data matrix via nonlinear mappings based on using the Euclidean distance between the input vector $\boldsymbol{x}$ and the prototype vectors $\boldsymbol{\mu}_j, j = 1, \ldots,$ m. This mapping can be represented as follows, where $\|\cdot\|$ is the Euclidean norm:

$$\phi_j(\boldsymbol{x}) = \phi\left(\left\|\boldsymbol{x} - \boldsymbol{\mu}_j\right\|\right), j = 1, 2, ..., m. \tag{35.2}$$

The $n \times d$ input matrix is thus transformed by the m basis functions into the following $n \times m$ design matrix $\boldsymbol{\Phi}$. In this matrix, the jth column represents the outputs from the jth basis function, $j = 1, 2, \ldots,$m.

$$\boldsymbol{\Phi} = \begin{array}{c} \begin{matrix} \Phi_1 & \hbar & \Phi_j & \hbar & \Phi_m \end{matrix} \\ \begin{pmatrix} \phi_1(x_1) & \hbar & \phi_j(x_1) & \hbar & \phi_m(x_1) \\ \phi_1(x_2) & \hbar & \phi_j(x_2) & \hbar & \phi_m(x_2) \\ \hbar & \hbar & \hbar & \hbar & \hbar \\ \phi_1(x_n) & \hbar & \phi_j(x_n) & \hbar & \phi_m(x_n) \end{pmatrix} \end{array} . \tag{35.3}$$

Several types of basis function have been considered in the literature. The common ones are Gaussian, thin plate spline, inverse multiquadratic, and cubic [35.7,9]. However, the basis function most commonly used for most applications is the Gaussian. Its form is $\phi(r) = \exp\left(-\frac{r^2}{2\sigma^2}\right)$, where σ is a parameter that controls the smoothness properties of the approximating function. The expression for the jth Gaussian function mapping can be explicitly written as

$$\phi_j(\boldsymbol{x}) = \exp\left(-\frac{\left\|\boldsymbol{x} - \boldsymbol{\mu}_j\right\|^2}{2\sigma_j^2}\right) , \tag{35.4}$$

where $\boldsymbol{\mu}_j$ is the center and σ_j is the width of the jth basis function, $j = 1, 2, \ldots,$m. On substituting in (35.3), we

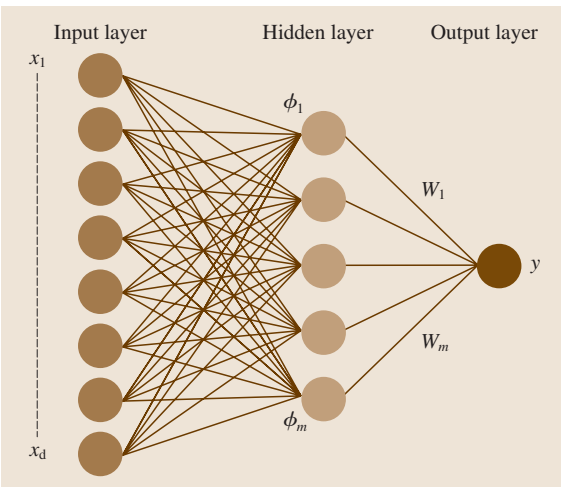

Fig. 35.2 Radial basis function network

can write the expression for a Gaussian design matrix, $\boldsymbol{\Phi}$, as

$$\boldsymbol{\Phi} = \begin{array}{c} \begin{array}{ccccc} \Phi_1 & \hbar & \Phi_j & \hbar & \Phi_m \end{array} \\ \begin{pmatrix} \exp\left(-\frac{\|\boldsymbol{x}_1-\boldsymbol{\mu}_1\|^2}{2\sigma_1^2}\right) & \hbar & \exp\left(-\frac{\|\boldsymbol{x}_1-\boldsymbol{\mu}_j\|^2}{2\sigma_j^2}\right) & \hbar & \exp\left(-\frac{\|\boldsymbol{x}_1-\boldsymbol{\mu}_m\|^2}{2\sigma_m^2}\right) \\ \exp\left(-\frac{\|\boldsymbol{x}_2-\boldsymbol{\mu}_1\|^2}{2\sigma_1^2}\right) & \hbar & \exp\left(-\frac{\|\boldsymbol{x}_2-\boldsymbol{\mu}_j\|^2}{2\sigma_j^2}\right) & \hbar & \exp\left(-\frac{\|\boldsymbol{x}_2-\boldsymbol{\mu}_m\|^2}{2\sigma_m^2}\right) \\ \hbar & \hbar & \hbar & \hbar & \hbar \\ \exp\left(-\frac{\|\boldsymbol{x}_n-\boldsymbol{\mu}_1\|^2}{2\sigma_1^2}\right) & \hbar & \exp\left(-\frac{\|\boldsymbol{x}_n-\boldsymbol{\mu}_j\|^2}{2\sigma_j^2}\right) & \hbar & \exp\left(-\frac{\|\boldsymbol{x}_n-\boldsymbol{\mu}_m\|^2}{2\sigma_m^2}\right) \end{pmatrix} \end{array} \tag{35.5}$$

For the special case where the number of basis functions equals the number of data vectors (when $m = n$), and if we use the n input data vectors as the basis function centers, the matrix in (35.5) is called the interpolation matrix. It is this matrix that is employed for the strict interpolation problem mentioned earlier and is of special interest in the SG algorithm. To compute the output, the entries in the matrix given by (35.5) are combined linearly according to the weights. The resulting values at the output node are then given by

$$f(\boldsymbol{x}) = \sum_{j=1}^{m} w_j \exp\left(-\frac{\|\boldsymbol{x}-\boldsymbol{\mu}_j\|^2}{2\sigma_j^2}\right), \tag{35.6}$$

where $f(\boldsymbol{x})$ represents the Gaussian RBF output for the input vector $\boldsymbol{x}$. Thus, for n input vectors $(\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_n)^{\mathrm{T}}$, the output layer consists of n outputs, one for each $\boldsymbol{x}$, as indicated below,

$$\left[f(\boldsymbol{x}_1),\, f(\boldsymbol{x}_2),\, \ldots,\, f(\boldsymbol{x}_n)\right]^{\mathrm{T}} = \boldsymbol{\Phi}\boldsymbol{w}\,. \tag{35.7}$$

Thus, we see that a Gaussian RBF model is fully defined by the number of basis functions (m), their centers $[\boldsymbol{\mu} = (\mu_1, \mu_2, \ldots, \mu_m)]$, widths $[\boldsymbol{\sigma} = (\sigma_1, \sigma_2, \ldots, \sigma_m)]$, and the weights $[\boldsymbol{w} = (w_1, w_2, \ldots, w_m)]$ to the output layer. In most applications, and in this chapter, a global width σ is used for each basis function. The parameters m, $\boldsymbol{\mu}$ and $\boldsymbol{\sigma}$ define the hidden layer (the nonlinearity of the RBF model). The weights ($\boldsymbol{w}$) define the linear part as indicated in Fig. 35.2. This completes discussion of the radial basis function model and its parameters. We now move on to discuss RBF model development; in other words, the determination of its parameters from the training sample or the given input-output data set.

35.3 Design Algorithms

A common characteristic of most design or training algorithms used for RBF models is that they employ a two-stage training procedure. In the first stage, only the input data is used to determine the basis function parameters. For the Gaussian case, these are the number of basis functions, their centers, and their widths. Once the basis function parameters are determined, the weights are found in the second stage to minimize some error measure. There are a large number of procedures available in the literature for RBF design. We first describe the four commonly used ones and then a relatively new algorithm called the SG algorithm.

35.3.1 Common Algorithms

Clustering: [35.10] A set of centers for basis functions can be obtained by employing clustering techniques on the input data. The k-means clustering algorithm [35.5] is used to locate a set of k basis function centers. For a specified k, the algorithm seeks to partition the input data into k disjoint subsets, each of which corresponds to a cluster. Once the cluster membership is determined, the averages of the data points in these clusters are chosen as the centers of the k basis functions in the RBF model, and m is taken to equal k. Next, the widths of the basis functions are determined by a P-nearest neighbor heuristic [35.5]. Thus, if P=1, the width of the jth basis function is set to be the Euclidean distance between its own center and the center of its nearest neighbor.

Orthogonal Least Square: [35.11] In this procedure a set of vectors is constructed in the space spanned by the vectors of hidden unit outputs for the training set and then by directly finding the center of an additional basis function such that it gives the greatest reduction in residual sum-of-square error. The stopping criterion employed is a threshold on the fraction of the variance explained by the model.

Regularization: [35.7] These procedures are motivated by the theory of regularization. A regularization parameter is used to control the smoothness properties of a mapping function by adding an extra term to the minimized error function that is designed to penalize mappings that are not smooth.

Gradient Descent: [35.10] Such training algorithms are fully supervised gradient-descent methods over some error measure. Specifically, the model parameters are updated as a function of this error measure according to some specified learning rates associated with the RBF parameters.

35.3.2 SG Algorithm

In the SG algorithm, the parameters $(m, \boldsymbol{\sigma}, \boldsymbol{\mu})$ of the nonlinear mapping are first determined from the input matrix $\mathbf{X}$ without referencing the output values. Then, the linear parameters $(\boldsymbol{w})$ are determined by referencing the output y's. The SG algorithm consists of four steps, given below. These steps are shown schematically in Fig. 35.3.

- Step 1: Select a range of values for global width, $\boldsymbol{\sigma}$, and a representation capability measure, δ, according to the heuristics given below.
- Step 2: Determine a value of m that satisfies the δ criterion. This step involves singular value decomposition of the interpolation matrix computed from the input data matrix $\mathbf{X}$ for a chosen $\boldsymbol{X}\sigma$.
- Step 3: Determine centers for the m basis functions that maximize structural stability provided by the selected model complexity, m. This step involves the use of QR factorization.
- Step 4: Compute weights using the pseudoinverse and estimate the output values.

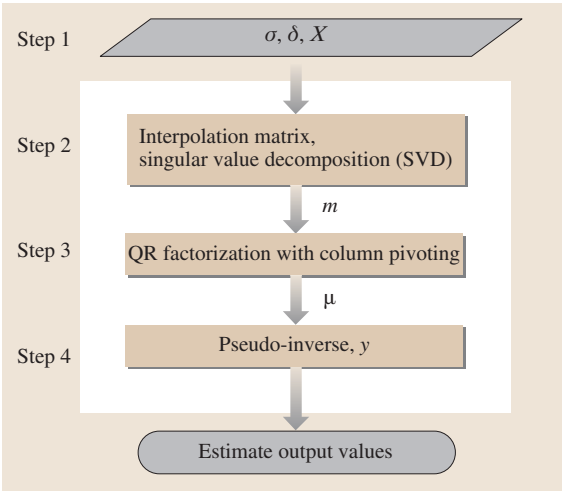

Fig. 35.3 The four steps of the SG RBF modeling algorithm

Note that the choice of parameters in Step 1 affects the quality of the developed model. Heuristically, we take $\boldsymbol{\sigma}$ to be approximately in the range of 0 to $0.75\sqrt{d/2}$, and δ is taken to be in the range 0.1% to 1.0% [35.12], where d is the dimensionality of the input data points. RBF models are then developed for a few judicially chosen values of these parameters. The performance of these models is assessed using some prespecified approach, and the most appropriate model is selected. This process is illustrated in Sects. 35.5 and 35.6 for two real-world data sets.

35.4 Illustrative Example

In this section we illustrate the use of the SG algorithm on a small data set generated from the following sine function [35.7]:

$$h(x) = 0.5 + 0.4\sin(2\pi x)\,.$$

Five values of the above function are computed at equal intervals of x in the range 0.0 to 1.0. Then random noise values, generated from a Gaussian distribution with mean zero and variance 0.25, are added to $h(x)$ to obtain five data points. The data set is listed in Table 35.1 along with the true $h(x)$ values. Our objective is to seek a good approximation for the unknown function $h(x)$, based only on the x and observed y data. A plot of the true $h(x)$ and the observed y values is shown in Fig. 35.4. Also shown is an approximated or estimated function found using interpolation, as discussed next.

Table 35.1 Dataset for illustrative example

i	x_i	$h(x_i)$	y_i
1	0.00	0.50	0.5582
2	0.25	0.90	0.9313
3	0.50	0.50	0.5038
4	0.75	0.10	0.1176
5	1.00	0.50	0.4632

First, we consider the strict interpolation problem for this data set, then we illustrate the use of the SG algorithm for approximation. The interpolation problem is to determine a Gaussian RBF that gives exact outputs for each x; in other words, we seek a model whose output is exactly equal to the y value corresponding to that x given in Table 35.1. For this we construct an inter-

polation matrix with five basis functions, one centered at each input value x. Suppose we use a global width $\sigma = 0.4$. Then the five Gaussian basis functions, each with $\sigma = 0.4$, will be centered at the five x values of Table 35.1 and will map the input data into an interpolation matrix according to the expressions in (35.5) with $m = n = 5$. For example, the column $\boldsymbol{\Phi}_2$ in matrix $\boldsymbol{\Phi}$ is obtained according to (35.3) and (35.4) by substituting $\boldsymbol{\mu} = 0.25$ and the five x values given below.

$$\Phi_2(x) = \begin{pmatrix} \phi_2(x_1) \\ \phi_2(x_2) \\ \phi_2(x_3) \\ \phi_2(x_4) \\ \phi_2(x_5) \end{pmatrix} = \begin{pmatrix} \exp\left(-\frac{\|0.00-0.25\|^2}{2(0.4)^2}\right) \\ \exp\left(-\frac{\|0.25-0.25\|^2}{2(0.4)^2}\right) \\ \exp\left(-\frac{\|0.50-0.25\|^2}{2(0.4)^2}\right) \\ \exp\left(-\frac{\|0.75-0.25\|^2}{2(0.4)^2}\right) \\ \exp\left(-\frac{\|1.00-0.25\|^2}{2(0.4)^2}\right) \end{pmatrix}$$

$$= \begin{pmatrix} 0.8226 \\ 1.0000 \\ 0.8226 \\ 0.4578 \\ 0.1724 \end{pmatrix} .$$

Other columns of the matrix are similarly computed for different $\boldsymbol{\mu}$'s. The final 5×5 interpolation matrix is given below.

$$\boldsymbol{\Phi} = \begin{array}{ccccc} \Phi_1 & \Phi_2 & \Phi_3 & \Phi_4 & \Phi_5 \\ 1.0000 & 0.8226 & 0.4578 & 0.1724 & 0.0439 \\ 0.8226 & 1.0000 & 0.8226 & 0.4578 & 0.1724 \\ 0.4578 & 0.8226 & 1.0000 & 0.8226 & 0.4578 \\ 0.1724 & 0.4578 & 0.8226 & 1.0000 & 0.8226 \\ 0.0439 & 0.1724 & 0.4578 & 0.8226 & 1.0000 \end{array} \quad (35.8)$$

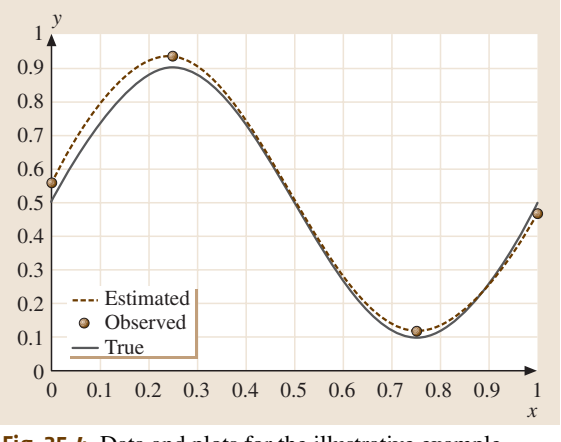

Fig. 35.4 Data and plots for the illustrative example

This matrix is symmetric because we have chosen a global width for the basis functions. Also, its diagonal values are 1.0 because the x values are listed in increasing order and because the height of the basis function at its center is always 1.0. The above interpolation matrix and the y_i vector in Table 35.1 are used to compute weights $\boldsymbol{w} = (w_1, w_2, \ldots, w_5)^T$ of the links to the output node using the pseudoinverse. Finally, the interpolated function is obtained from (35.6) and (35.7) as

$$\begin{aligned} \hat{y} = & -2.09 \exp\left(-\frac{\|x-0.0\|^2}{2(0.4)^2}\right) \\ & +3.87 \exp\left(-\frac{\|x-0.25\|^2}{2(0.4)^2}\right) \\ & -0.06 \exp\left(-\frac{\|x-0.50\|^2}{2(0.4)^2}\right) \\ & +3.63 \exp\left(-\frac{\|x-0.75\|^2}{2(0.4)^2}\right) \\ & +2.91 \exp\left(-\frac{\|x-1.0\|^2}{2(0.4)^2}\right) . \end{aligned}$$

Note that here $\hat{y}$ is the weighted sum of the basis function outputs and consists of five terms, one corresponding to each basis function. A plot of this function is shown in Fig. 35.4, where the estimated values are exactly equal to the observed y's since we are dealing with exact interpolation.

In practical problems, exact interpolation is undesirable because it represents extreme overfitting. Referring to Fig. 35.1, this indicates a very complex model that will not perform well on new data in the sense that it will exhibit a high generalization error. In practice, we seek an approximate model according to the guidelines discussed in Sect. 35.1. To achieve this goal we use the SG algorithm, where the user controls the tradeoff between underfitting and overfitting or between bias and variance by specifying the values of δ [35.12]. As indicated above, for practical applications, $\delta = 0.1\%$ to 1% seems to be a good set of values to consider. The RBF model is then designed according to the above four-step procedure. We provide a description of this procedure for the sine data below. However, details of the singular value decomposition and QR factorization are beyond the scope of this chapter and can be found in [35.12, 13].

The starting point in the SG algorithm is the selection of σ and δ. For the sine data, suppose

$\sigma = 0.4$ and $\delta = 0.01$. The 5×5 interpolation matrix for this σ is computed as shown above. In step 2, its singular value decomposition yields five singular values. Using these and $\delta = 0.01$, for this example data, we obtain $m = 4$. Then, in step 3, QR factorization identifies the four centers for the basis functions as being $\mu_1 = 1.00$, $\mu_2 = 0.00$, $\mu_3 = 0.75$ and $\mu_4 = 0.25$. Finally, the weights are obtained in step 4 as $w_1 = -2.08$, $w_2 = 3.82$, $w_3 = -3.68$ and $w_4 = 2.92$. Thus, an approximation of the unknown function $h(x)$ based on the available data x and y in Table 35.1 is provided by an RBF model

$$\hat{y} = \sum_{j=1}^{4} w_j \exp\left(-\frac{\|x - \mu_j\|^2}{2\sigma_j^2}\right),$$

where w_j and μ_j are as listed above and $\sigma_j = 0.4$ for $j = 1, 2, 3, 4$. This estimate of y is based on the four basis functions selected by the SG algorithm for $\delta = 0.01$. Note that in this simple example we obtained a value of m that is almost the same as n. However, in practical applications with real-world data, the design value of m is generally much smaller than the n as seen in Sects. 35.5 and 35.6.

35.5 Diabetes Disease Classification

This benchmark problem is taken from the Proben1 data set of the UCI repository [35.14]. It was studied in Lim [35.15] using the SG algorithm. The objective is to develop a classification model to determine whether diabetes of Pima Indians is positive or negative, based on personal data such as age, number of times pregnant, and so on. Other factors considered include the results from medical examinations, such as data on blood pressure, body mass index, and results of glucose tolerance tests. There are eight inputs, two outputs, 768 examples, and no missing values in this data set. A summary of the input and output attributes and the encoding scheme employed for data processing is given in Table 35.2. Here, all inputs are continuous and each is normalized to a range of 0 to 1 for data preprocessing. Attribute number 9 is the output, consisting of two values, diabetes or no diabetes. Before proceeding with RBF model development we need to decide upon an approach to model evaluation. This point is discussed next.

The generalization performance of an RBF model relates to its predictive ability on some future data. Therefore, we need to be able to assess this performance during the model building process. For applications where we have adequate data, the best approach is to randomly divide the available data into three sets: training set, validation set, and test set [35.5]. We use the training set for model development, the validation set to compare the developed models and, usually, select the model with the smallest error on the validation set. The test set is not used until after the final model is selected. The performance of the selected model on the test set is used as a measure of its generalization performance. A common practice is to split the data into 50% for training and 25% each for validation and test sets. Using this

Table 35.2 Data description for the diabetes example

Inputs (8)			
Attribute No.	**No. of attributes**	**Attribute meaning**	**Values and encoding**
1	1	Number of times pregnant	0 ... 17 → 0 ... 1
2	1	Plasma glucose concentration after 2 h in an oral glucose tolerance test	0 ... 199 → 0 ... 1
3	1	Diastolic blood pressure (mm Hg)	0 ... 122 → 0 ... 1
4	1	Triceps skin fold thickness (mm)	0 ... 99 → 0 ... 1
5	1	2-hour serum insulin (mu U/ml)	0 ... 846 → 0 ... 1
6	1	Body mass index (weight in kg/(height in m)^2)	0 ... 67.1 → 0 ... 1
7	1	Diabetes pedigree function	0.078 ... 2.42 → 0 ... 1
8	1	Age (years)	21 ... 81 → 0 ... 1
Output (2)			
9	2	No diabetes Diabetes	1 0 0 1

Table 35.3 RBF models for the diabetes example

$\delta = 0.01$ Model	m	σ	Classification error (CE) (%)		
			Training	Validation	Test
A	18	0.6	20.32	23.44	24.48
B	9	0.7	21.88	21.88	22.92
C	9	0.8	22.66	21.35	23.44
D	8	0.9	22.92	21.88	25.52

G	6	1.2	25.78	28.13	28.13
H	5	1.3	25.26	31.25	30.73

split for this application, we divide the set of 768 patients into 384 for training, 192 for validation and 192 for the test set.

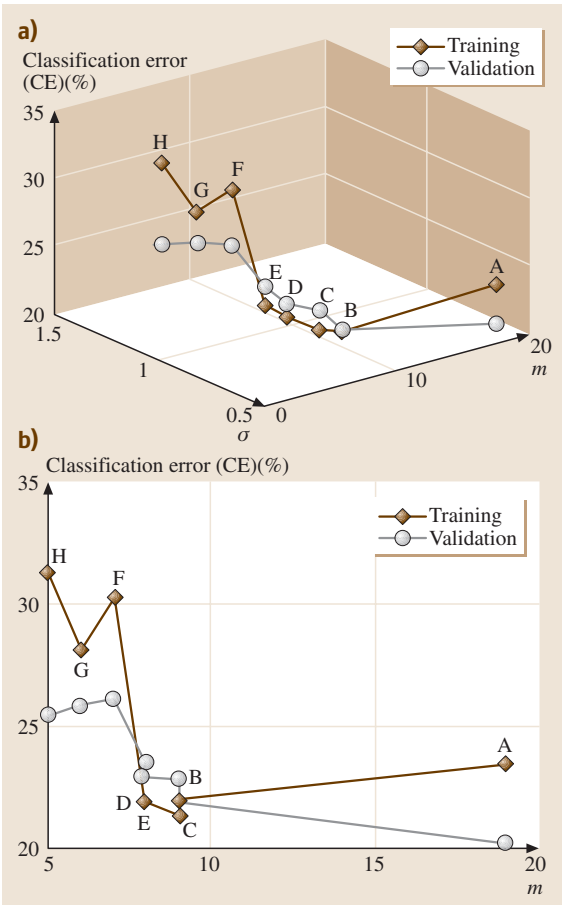

Fig. 35.5 Plots of training and validation errors for the diabetes example ($\delta = 0.01$)

We employ the heuristics given in Sect. 35.3 and select values of width (σ) in the range 0.6 to 1.3. Also, we use $\delta = 0.01$, 0.005 and 0.001. The algorithm is then executed to develop RBF models. For each model, the training and validation classification errors(CE) are also computed. However, to provide a better insight, the test error is also computed here. The classification results for eight models (A to H) for $\delta = 0.01$ are shown in Table 35.3. We note that as σ decreases from 1.3 to 0.6, the m value increases, and the training CE decreases from 25.26% to 20.32%. However, the validation CE first decreases from 31.25% to 21.35% and then increases to 23.44%. The test error first decreases with increasing m and then begins to increase. The validation errors, though used for different purposes, tend to exhibit similar behavior with respect to m. The pattern of CE error behavior is shown graphically in Fig. 35.5. Here, the errors are shown with respect to m and σ in Fig. 35.5a and as a function of m alone in Fig. 35.5b. We note that the training and validation error behavior is quite similar to the theoretical pattern discussed above and that depicted in Fig. 35.1. However, for some models the validation error is smaller than the training error. Also, the error behavior is not monotonic. This can and does happen in practical applications due to random variations in the real-world data assigned to the training, validation, and test sets.

To select the model, we evaluate the validation CE for models A to H. The minimum value occurs for model C, and hence this model is selected as the preferred model. The test CE for this model is 23.44. Next, models were developed for $\delta = 0.005$ and 0.001. However, the details of these models are not shown here. The best models for these two cases and for $\delta = 0.01$ are listed in Table 35.4.

To select the final model, we consult the results in Table 35.4 and note that the RBF model with the smallest

Table 35.4 Selected models and error values for the diabetes example

Classification error (CE) (%)					
δ	m	σ	Training	Validation	Test
0.01	9	0.8	22.66	21.35	23.44
0.005	9	0.8	22.66	21.35	23.44
0.001	10	1.2	22.66	20.83	23.96

validation error is the model with $m = 10, \sigma = 1.2$. This is our final choice for modeling the classification of diabetes. Its test error is 23.96. What this says is that when this model is used to evaluate future patients for diabetes or no diabetes, the model will misclassify, on average, about 24% of the patients. Also, note that the design value of m, the number of basis functions, is only 10, while $n = 384$ for the training data. Thus, we see that a much simpler model than strict interpolation requires provides a good classifier. If we were to use $m = n = 384$ in this case, all patients in the training set would be correctly classified with $CE = 0.0$. However, the n performance of such a model on the validation and test sets is likely to be very poor.

35.6 Analysis of Gene Expression Data

Now we describe a data mining application of the RBF model to binary cancer classification based on gene expression data from DNA microarray hybridization experiments [35.16]. Cancer class prediction is crucial to its treatment, and developing an automated analytical approach for classification based upon the microarray expression is an important task [35.16]. A generic approach to classifying two types of acute leukemia based on the monitoring of gene expression by DNA microarrays was originally pioneered by [35.17]. We employ their data set to illustrate the classifier development process and use sensitivity analyses in order to select an appropriate cancer classification model. The goal is to construct a classifier that distinguishes between two cancer classes based on gene expression data from patients whose class, AML (acute myeloid leukemia) or ALL (acute lymphoblastic leukemia), is known. This classifier will be used to predict the cancer class of a future patient about whom only the gene expression will be known, not the class.

The dataset consists of 72 samples. The number of gene expression levels for each patient in this dataset is 7129. In other words, 7129 attributes or features are used to describe a patient in this dataset. Since the set is relatively small, it is split into 38 training samples and 34 test samples, where each sample represents a patient [35.17]. The test set error is used for model selection here.

The classification results for the training data set, using the SG algorithm of Sect. 35.3, are summarized in Table 35.5 for $\delta = 0.01$. Results for test data are also included. Here we have seven models (A to G) for σ ranging from 32 to 20, and the design values of m vary from 12 to 38.

The CE for the training set varies from 0% to 5.26% and for the test set from 14.71% to 26.47%. Next, the behavior of the training and test error in the $(m–\sigma)$ plane is shown in Fig. 35.6. Comparing it to Fig. 35.1, we note that the training error decreases as m increases, becoming 0% at $m = n = 38$. This happens when the classification model represents exact interpolation.

Table 35.5 Classification results for the cancer gene example

Model	σ	m	Classification error (%)	
			Training	Test
A	32	12	5.26	26.47
B	30	15	2.63	20.59
C	28	21	2.63	17.65
D	26	29	0	14.71
E	24	34	0	14.71
F	22	38	0	17.65
G	20	38	0	17.65

Next, we discuss model selection based on the test CE in Table 35.5. This error first decreases with increasing m and then increases, a pattern similar to the theoretical behavior depicted in Fig. 35.1. Based on the discussion in Sect. 35.2, the best model is D. Note that here we have a somewhat degenerate case, where the training error is zero and the test error is minimum for the selected model.

35.7 Concluding Remarks

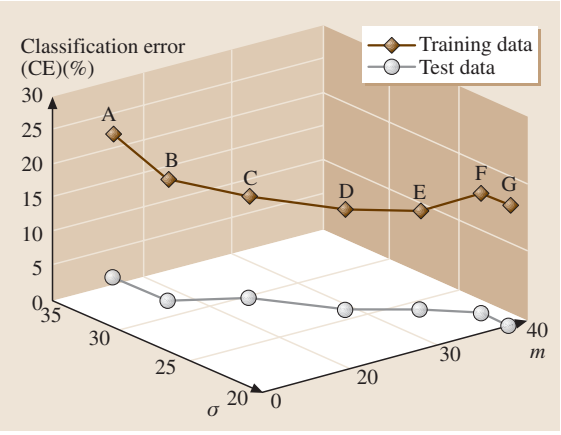

Fig. 35.6 Classification errors for the cancer gene example

In this chapter we introduced the RBF model and provided a detailed discussion of its design by evaluating the training, validation and test errors as surrogates for bias-variance phenomena. A simple example was used for illustration and then a benchmark data set was analyzed. Finally, the RBF model was used for a recent data mining application, cancer class prediction based on gene expression data. In our presentation we used only Gaussian basis functions because of their popularity and good mathematical properties. The methodology, however, is applicable to several other types of basis functions.

There is a vast body of literature on the topic of radial basis functions. The chapters in *Bishop* [35.7], *Haykin* [35.9], and *Kecman* [35.18] provide good coverage. *Buhmann* [35.19] is a rather theoretical book on this subject. A recent collection of methodologies and applications of the RBF model appears in (see *Howlett* and *Jain* [35.20]). Some other applications can be found in *Shin* and *Goel* [35.13, 21]. New developments in the theory and applications of radial basis functions can also be found in most journals and conference proceedings on neural networks and machine learning.

36. Data Mining Methods and Applications

In this chapter, we provide a review of the knowledge discovery process, including data handling, data mining methods and software, and current research activities. The introduction defines and provides a general background to data mining knowledge discovery in databases. In particular, the potential for data mining to improve manufacturing processes in industry is discussed. This is followed by an outline of the entire process of knowledge discovery in databases in the second part of the chapter.

The third part presents data handling issues, including databases and preparation of the data for analysis. Although these issues are generally considered uninteresting to modelers, the largest portion of the knowledge discovery process is spent handling data. It is also of great importance since the resulting models can only be as good as the data on which they are based.

The fourth part is the core of the chapter and describes popular data mining methods, separated as supervised versus unsupervised learning. In supervised learning, the training data set includes observed output values ("correct answers") for the given set of inputs. If the outputs are continuous/quantitative, then we have a regression problem. If the outputs are categorical/qualitative, then we have a classification problem. Supervised learning methods are described in the context of both regression and classification (as appropriate), beginning with the simplest case of linear models, then presenting more complex modeling with trees, neural networks, and support vector machines, and concluding with some methods, such as nearest neighbor, that are only for classification. In unsupervised learning, the training data set does not contain output values. Unsupervised learning methods are described under two categories: association rules and clustering. Association rules are appropriate for business applications where precise numerical data may not be available while clustering methods are more technically similar to the supervised learning methods presented in this chapter. Finally, this section closes with a review of various software options.

The fifth part presents current research projects, involving both industrial and business applications. In the first project, data is collected from monitoring systems, and the objective is to detect unusual activity that may require action. For example, credit card companies monitor customers' credit card usage to detect possible fraud. While methods from statistical process control were developed for similar purposes, the difference lies in the quantity of data. The second project describes data mining tools developed by Genichi Taguchi, who is well known for his industrial work on robust design. The third project tackles quality and productivity improvement in manufacturing industries. Although some detail is given, considerable research is still needed to develop a practical tool for today's complex manufacturing processes.

Finally, the last part provides a brief discussion on remaining problems and future trends.

Data mining (DM) is the process of exploration and analysis, by automatic or semiautomatic means, of large quantities of data to discover meaningful patterns and rules [36.1]. Statistical DM is exploratory data analysis with little or no human interaction using computationally feasible techniques, i. e., the attempt to find *unknown interesting* structure [36.2]. Knowledge discovery in databases (KDD) is a multidisciplinary research field for nontrivial extraction of implicit, previously unknown, and potentially useful knowledge from data [36.3]. Although some treat DM and KDD equivalently, they can be distinguished as follows. The KDD process employs DM methods (algorithms) to extract knowledge according to the specifications of measures and thresholds, using a database along with any necessary preprocessing or transformations. DM is a step in the KDD process consisting of particular algorithms (methods) that, under some acceptable objective, produces particular patterns or knowledge over the data. The two primary fields that develop DM methods are statistics and computer science. Statisticians support DM by mathematical theory and statistical methods while computer scientists develop computational algorithms and relevant software [36.4]. Prerequisites for DM include: (1) Advanced computer technology (large CPU, parallel architecture, etc.) to allow fast access to large quantities of data and enable computationally intensive algorithms and statistical methods; (2) knowledge of the business or subject matter to formulate the important business questions and interpret the discovered knowledge.

With competition increasing, DM and KDD have become critical for companies to retain customers and ensure profitable growth. Although most companies are able to collect vast amounts of business data, they are often unable to leverage this data effectively to gain new knowledge and insights. DM is the process of applying sophisticated analytical and computational techniques to discover exploitable patterns in complex data. In many cases, the process of DM results in actionable knowledge and insights. Examples of DM applications include fraud detection, risk assessment, customer relationship management, cross selling, insurance, banking, retail, etc.

While many of these applications involve customer relationship management in the service industry, a potentially fruitful area is performance improvement and cost reduction through DM in industrial and manufacturing systems. For example, in the fast-growing and highly competitive electronics industry, total revenue worldwide in 2003 was estimated to be $900 billion, and the growthrate is estimated at 8% per year (www.selectron.com). However, economies of scale, purchasing power, and global competition are making the business such that one must either be a big player or serve a niche market. Today, extremely short life cycles and constantly declining prices are pressuring the electronics industry to manufacture their products with high quality, high yield, and low production cost.

To be successful, industry will require improvements at all phases of manufacturing. Figure 36.1 illustrates the three primary phases: design, ramp-up, and production. In the production phase, maintenance of a high performance level via improved system diagnosis is needed. In the ramp-up phase, reduction in new product development time is sought by achieving the required performance as quickly as possible. Market demands have been forcing reduced development time for new product and production system design. For example, in the computer industry, a product's life cycle has been shortened to 2–3 years recently, compared to a life cycle of 3–5 years a few years ago. As a result, there are a number of new concepts in the area of production systems, such as flexible and reconfigurable manufacturing systems. Thus, in the design phase, improved system performance integrated at both the ramp-up and production phases is desired. Some of the most critical factors and barriers in the competitive development of modern manufacturing systems lie in the largely uncharted area of predicting system performance during the design phase [36.5, 6]. Consequently, current systems necessitate that a large number of design/engineering changes be made after the system has been designed.

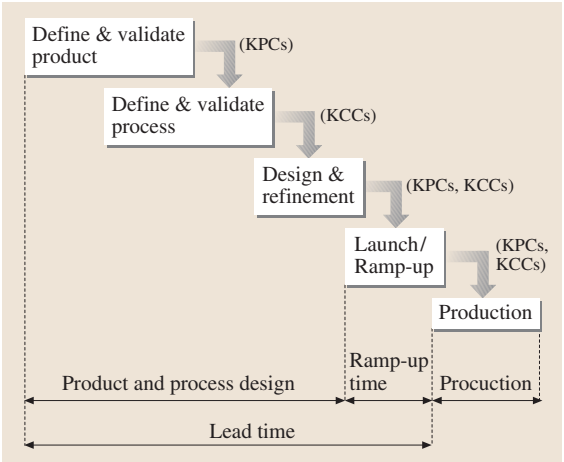

Fig. 36.1 Manufacturing system development phases. KPCs = Key product characteristics. KCCs = Key control characteristics

At all phases, system performance depends on many manufacturing process stages and hundreds or thousands of variables whose interactions are not well understood. For example, in the multi-stage printed circuit board (PCB) industry, the stages include process operations such as paste printing, chip placement, and wave soldering; and also include test operations such as optical inspection, vision inspection, and functional test. Due to advancements in information technology, sophisticated software and hardware technologies are available to record and process huge amounts of daily data in these process and testing stages. This makes it possible to extract important and useful information to improve process and product performance through DM and quality improvement technologies.

36.1 The KDD Process

The KDD process consists of four main steps:

1. Determination of business objectives,
2. Data preparation,
   a) Create target data sets,
   b) Data quality, cleaning, and preprocessing,
   c) Data reduction and projection,
3. Data mining
   a) Identify DM tasks,
   b) Apply DM tools,
4. Consolidation and application,
   a) Consolidate discovered knowledge,
   b) Implement in business decisions.

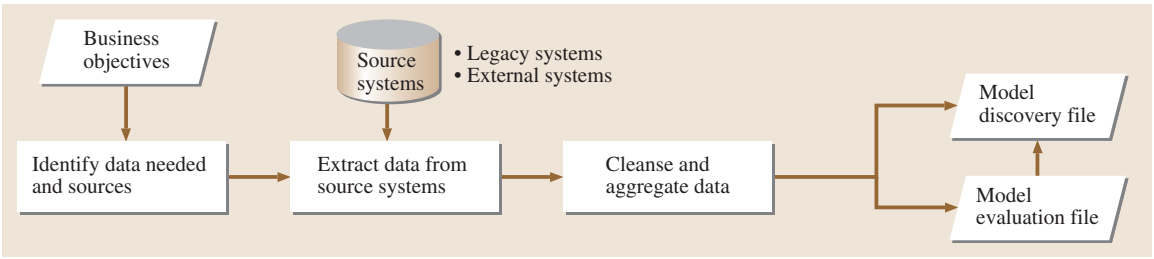

Fig. 36.2 Data preparation flow chart

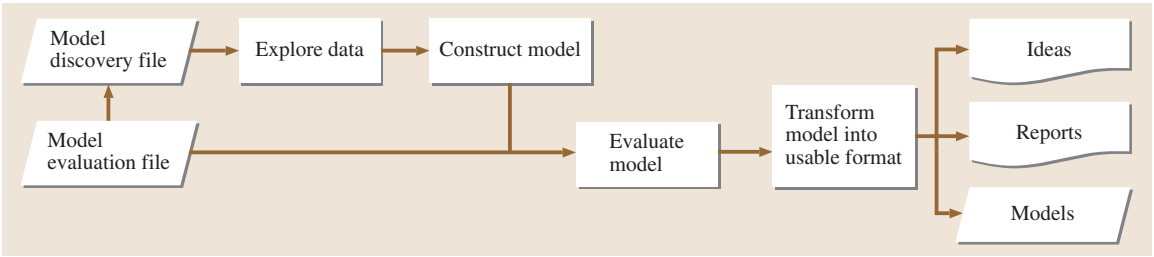

Fig. 36.3 Data mining flow chart

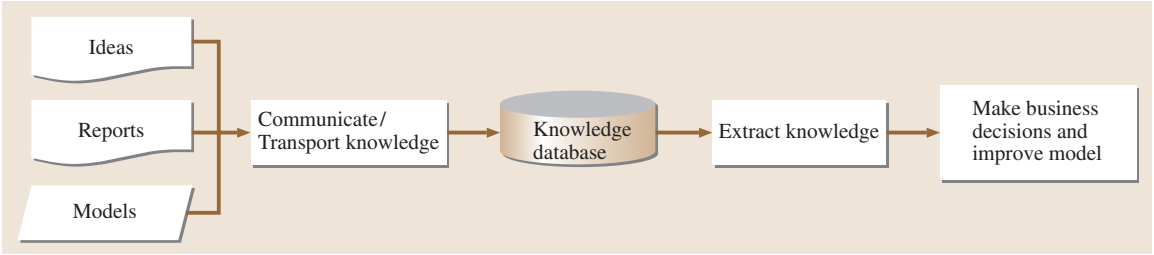

Fig. 36.4 Consolidation and application flow chart

As an example of formulating business objectives, consider a telecommunications company. It is critically important to identify those customer traits that retain profitable customers and predict fraudulent behavior, credit risks and customer churn. This knowledge may be used to improve programs in target marketing, marketing channel management, micro-marketing, and cross selling. Finally, continually updating this knowledge will enable the company to meet the challenges of new product development effectively in the future. Steps 2–4 are illustrated in figs. 36.2–36.4. Approximately 20–25% of effort is spent on determining business objectives, 50–60% of effort is spent on data preparation, 10–15% of is spent on DM, and about 10% is spent on consolidation/application.

36.2 Handling Data

The largest percentage effort of the KDD process is spent on processing and preparing the data. In this section, common forms of data storage and tools for accessing the data are described, and the important issues in data preparation are discussed.

36.2.1 Databases and Data Warehousing

A *relational database* system contains one or more objects called tables. The data or information for the database are stored in these tables. Tables are uniquely identified by their names and are comprised of columns and rows. Columns contain the column name, data type and any other attributes for the column. Rows contain the records or data for the columns. The structured query language (SQL) is the communication tool for relational database management systems. SQL statements are used to perform tasks such as updating data in a database, or retrieving data from a database. Some common relational database management systems that use SQL are: Oracle, Sybase, Microsoft SQL Server, Access, and Ingres. Standard SQL commands, such as *Select*, *Insert*, *Update*, *Delete*, *Create*, and *Drop*, can be used to accomplish almost everything that one needs to do with a database.

A *data warehouse* holds local databases assembled in a central facility. A *data cube* is a multidimensional array of data, where each dimension is a set of sets representing domain content, such as time or geography. The dimensions are scaled categorically, for example, region of country, state, quarter of year, week of quarter. The cells of the cube contain aggregated measures (usually counts) of variables. To explore the data cube, one can *drill down*, *drill up*, and *drill through*. Drill down involves splitting an aggregation into subsets, e.g., splitting region of country into states. Drill up involves consolidation, i. e., aggregating subsets along a dimension. Drill through involves subsets crossing multiple sets, e.g., the user might investigate statistics within a state subset by time. Other databases and tools include object-oriented databases, transactional databases, time series and spatial databases, online analytical processing (OLAP), multidimensional OLAP (MOLAP), and relational OLAP using extended SQL (ROLAP). See Chapt. 2 of *Han* and *Kamber* [36.7] for more details.

36.2.2 Data Preparation

The purpose of this step in the KDD process is to identify data quality problems, sources of noise, data redundancy, missing data, and outliers. Data quality problems can involve inconsistency with external data sets, uneven quality (e.g., if a respondent fakes an answer), and biased opportunistically collected data. Possible sources of noise include faulty data collection instruments (e.g., sensors), transmission errors (e.g., intermittent errors from satellite or internet transmissions), data entry errors, technology limitations errors, misused naming conventions (e.g., using the same names for different meanings), and incorrect classification.

Redundant data exists when the same variables have different names in different databases, when a raw variable in one database is a derived variable in another, and when changes in a variable over time are not reflected in the database. These irrelevant variables impede the speed of the KDD process because dimension reduction is needed to eliminate them. Missing data may be irrelevant if we can extract useful knowledge without imputing the missing data. In addition, most statistical methods for handling missing data may fail for massive data sets, so new or modified methods still need to be developed. In detecting outliers, sophisticated methods like the Fisher information matrix or convex hull peeling are available, but are too complex for massive data sets. Although outliers may be easy to visualize in low dimensions, high-dimensional outliers may not show up in low-dimensional projections.

Currently, clustering and other statistical modeling are used.

The data preparation process involves three steps: data cleaning, database sampling, and database reduction and transformation. Data cleaning includes removal of duplicate variables, imputation of missing values, identification and correction of data inconsistencies, identification and updating of stale data, and creating a unique record (case) identification (ID). Via database sampling, the KDD process selects appropriate parts of the databases to be examined. For this to work, the data must satisfy certain conditions (e.g., no systematic biases). The sampling process can be expensive if the data have been stored in a database system such that it is difficult to sample the data the way you want and many operations need to be executed to obtain the targeted data. One must balance a trade-off between the costs of the sampling process and the mining process. Finally, database reduction is used for data cube aggregation, dimension reduction, elimination of irrelevant and redundant attributes, data compression, and encoding mechanisms via quantizations, wavelet transformation, principle components, etc.

36.3 Data Mining (DM) Models and Algorithms

The DM process is illustrated in Fig. 36.5. In this process, one will start by choosing an appropriate class of models. To fit the best model, one needs to split the sample data into two parts: the training data and the testing data. The training data will be used to fit the model and the testing data is used to refine and tune the fitted model. After the final model is obtained, it is recommended to use an independent data set to evaluate the goodness of the final model, such as comparing the prediction error to the accuracy requirement. (If independent data are not available, one can use the cross-validation method to compute prediction error.) If the accuracy requirement is not satisfied, then one must revisit earlier steps to reconsider other classes of models or collect additional data.

Before implementing any sophisticated DM methods, data description and visualization are used for initial exploration. Tools include descriptive statistical measures for central tendency/location, dispersion/spread, and distributional shape and symmetry; class characterizations and comparisons using analytical approaches, attribute relevance analysis, and class discrimination and comparisons; and data visualization using scatter-plot matrices, density plots, 3-D stereoscopic scatter-plots, and parallel coordinate plots. Following this initial step, DM methods take two forms: supervised versus unsupervised learning. Supervised learning is described as
textitlearning with a teacher, where the *teacher* provides data with correct answers. For example, if we want to classify online shoppers as buyers or non-buyers using an available set of variables, our data would include actual instances of buyers and non-buyers for training a DM method. Unsupervised learning is described as

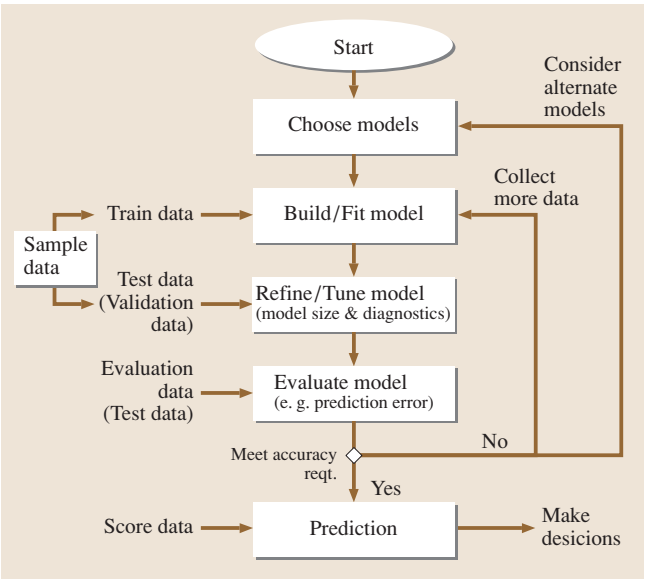

Fig. 36.5 Data mining process

learning without a teacher. In this case, correct answers are not available, and DM methods would search for patterns or clusters of similarity that could later be linked to some explanation.

36.3.1 Supervised Learning

In supervised learning, we have a set of *input* variables (also known as predictors, independent variables, $\boldsymbol{x}$) that are measured or preset, and a set of *output* variables (also known as responses, dependent variables, $\boldsymbol{y}$) that are measured and assumed to be influenced by the in-

puts. If the outputs are continuous/quantitative, then we have a *regression* or *prediction* problem. If the outputs are categorical/qualitative, then we have a *classification* problem. First, a DM model/system is established based on the collected input and output data. Then, the established model is used to predict output values at new input values. The predicted values are denoted by $\hat{\boldsymbol{y}}$.

The DM perspective of *learning with a teacher*, follows these steps:

- Student presents an answer ($\hat{\boldsymbol{y}}_i$ given $\boldsymbol{x}_i$);
- Teacher provides the correct answer $\boldsymbol{y}_i$ or an error $\boldsymbol{e}_i$ for the student's answer;
- The result is characterized by some *loss function* or *lack-of-fit criterion*:LOF($\boldsymbol{y}$, $\hat{\boldsymbol{y}}$);
- The objective is to minimize the expected loss.

Supervised learning includes the common engineering task of function approximation, in which we assume that the output is related to the input via some function $f(\boldsymbol{x}, \epsilon)$, where ϵ represents a random error, and seek to approximate $f(\cdot)$.

Below, we describe several supervised learning methods. All can be applied to both the regression and classification cases, except for those presented below under Other Classifikation Methods. We maintain the following notation. The j-th input variable is denoted by x_j (or random variable X_j) and the corresponding boldface $\boldsymbol{x}$ (or $\boldsymbol{X}$) denotes the vector of p input variables $(x_1, x_2, \ldots, x_p)^{\mathrm{T}}$, where boldface $\boldsymbol{x}_i$ denotes the i-th sample point; N is the number of sample points, which corresponds to the number of observations of the response variable; the response variable is denoted by y (or random variable Y), where y_i denotes the i-th response observation. For the regression case, the response y is quantitative, while for the classification case, the response values are indices for C classes ($c = 1, \ldots, C$). An excellent reference for these methods is *Hastie* et al. [36.8].

Linear and Additive Methods

In the regression case, the basic linear method is simply the *multiple linear* regression model form

$$\mu(\boldsymbol{x}; \beta) = E[Y \mid \boldsymbol{X} = \boldsymbol{x}] = \beta_0 + \sum_{m=1}^{M} \beta_m b_m(\boldsymbol{x}),$$

where the model terms $b_m(\boldsymbol{x})$ are pre-specified functions of the input variables, for example, a simple linear term $b_m(\boldsymbol{x}) = x_j$ or a more complex interaction term $b_m(\boldsymbol{x}) = x_j x_k^2$. The key is that the model is *linear in the parameters* $\boldsymbol{\beta}$. Textbooks that cover linear regression are abundant (e.g., [36.9, 10]). In particular, *Neter* et al. [36.11] provides a good background on residual analysis, model diagnostics, and model selection using best subsets and stepwise methods. In model selection, insignificant model terms are eliminated; thus, the final model may be a subset of the original pre-specified model. An alternate approach is to use a shrinkage method that employs a penalty function to *shrink* estimated model parameters towards zero, essentially reducing the influence of less important terms. Two options are ridge regression [36.12], which uses the penalty form $\sum \beta_m^2$, and the lasso [36.13], which uses the penalty form $\sum |\beta_m|$.

In the classification case, linear methods generate *linear decision boundaries* to separate the C classes. Although a direct linear regression approach could be applied, it is known not to work well. A better method is *logistic regression* [36.14], which uses log-odds (or logit transformations) of the posterior probabilities $\mu_c(\boldsymbol{x}) = P(Y = c|\boldsymbol{X} = \boldsymbol{x})$ for classes $c = 1, \ldots, C-1$ in the form

$$\log \frac{\mu_c(\boldsymbol{x})}{\mu_C(\boldsymbol{x})} = \log \frac{P(Y = c|\boldsymbol{X} = \boldsymbol{x})}{P(Y = C|\boldsymbol{X} = \boldsymbol{x})} = \beta_{c0} + \sum_{j=1}^{p} \beta_{cj} x_j \,,$$

where the C posterior probabilities $\mu_c(\boldsymbol{x})$ must sum to one. The decision boundary between class $c < C$ and class C is defined by the hyperplane $\{\boldsymbol{x} \mid \beta_{c0} + \sum \beta_{cj} x_j = 0\}$, where the log-odds are zero. Similarly, the decision boundary between classes $c \neq C$ and $d \neq C$, derived from the log-odds for classes c and d, is defined by $\{\boldsymbol{x} \mid \beta_{c0} + \sum \beta_{cj} x_j = \beta_{d0} + \sum \beta_{dj} x_j\}$. In the binary case ($C = 2$), if we define $\mu(\boldsymbol{x}) = P(Y = 1|\boldsymbol{X} = \boldsymbol{x})$, then $1 - \mu(\boldsymbol{x}) = P(Y = 2|\boldsymbol{X} = \boldsymbol{x})$. The logit transformation is then defined as $g(\mu) = \mu/(1 - \mu)$.

Closely related to logistic regression is *linear discriminant analysis* [36.15], which utilizes exactly the same linear form for the log-odds ratio, and defines linear *discriminant functions* $\delta_c(\boldsymbol{x})$, such that $\boldsymbol{x}$ is classified to class c if its maximum discriminant is $\delta_c(\boldsymbol{x})$. The difference between the two methods is how the parameters are estimated. Logistic regression maximizes the conditional likelihood involving the posterior probabilities $P(Y = c|\boldsymbol{X})$ while linear discriminant analysis maximizes the full log-likelihood involving the unconditional probabilities $P(Y = c, \boldsymbol{X})$. More general forms of discriminant analysis are discussed below under Other Classifikation Methods.

Finally, it should be noted that the logistic regression model is one form of *generalized linear model*

(GLM) [36.16]. GLM forms convert what appear to be nonlinear models into linear models, using tools such as transformations (e.g., logit) or conditioning on nonlinear parameters. This then enables the modeler to use traditional linear modeling analysis techniques. However, real data often do not satisfy the restrictive conditions of these models.

Rather than using pre-specified model terms, as in a linear model, a *generalized additive model* (GAM) [36.17], provides a more flexible statistical method to enable modeling of nonlinear patterns in each input dimension. In the regression case, the basic GAM form is

$$\mu(\boldsymbol{x}) = \beta_0 + \sum_{j=1}^{p} f_j(x_j) \,,$$

where the $f_j(\cdot)$ are unspecified (smooth) univariate functions, one for each input variable. The additive restriction prohibits inclusion of any interaction terms. Each function is fitted using a *nonparametric regression* modeling method, such as running-line smoothers (e.g., *lowess*, [36.18]), smoothing splines or kernel smoothers [36.19–21]. In the classification case, an additive logistic regression model utilizes the logit transformation for classes $c = 1, \ldots, C-1$ as above

$$\begin{aligned} \log \frac{\mu_c(\boldsymbol{x})}{\mu_C(\boldsymbol{x})} &= \log \frac{P(Y=c|\boldsymbol{X}=\boldsymbol{x})}{P(Y=C|\boldsymbol{X}=\boldsymbol{x})} \\ &= \beta_0 + \sum_{j=1}^{p} f_j(x_j) \,, \end{aligned}$$

where an additive model is used in place of the linear model. However, even with the flexibility of nonparametric regression, GAM may still be too restrictive. The following sections describe methods that have essentially no assumptions on the underlying model form.

Trees and Related Methods

One DM decision tree model is *chi-square automatic interaction detection* (CHAID) [36.22, 23], which builds non-binary trees using a chi-square test for the classification case and an F-test for the regression case. The CHAID algorithm first creates categorical input variables out of any continuous inputs by dividing them into several categories with approximately the same number of observations. Next, input variable categories that are not statistically different are combined, while a Bonferroni p-value is calculated for those that are statistically different. The best split is determined by the smallest p-value. CHAID continues to select splits until the smallest p-value is greater than a pre-specified significance level (α).

The popular *classification and regression trees* (CART) [36.24] utilize recursive partitioning (binary splits), which evolved from the work of *Morgan* and *Sonquist* [36.25] and *Fielding* [36.26] on analyzing survey data. CARTs have a forward stepwise procedure that adds model terms and backward procedure for pruning. The model terms partition the $\boldsymbol{x}$-space into disjoint hyper-rectangular regions via indicator functions: $b^+(x;t) = 1\{x > t\}$, $b^-(x;t) = 1\{x \le t\}$, where the *split-point* t defines the borders between regions. The resulting model terms are:

$$f_m(\boldsymbol{x}) = \prod_{l=1}^{L_m} b^{s_{l,m}}(x_{v(l,m)}; t_{l,m}) \,, \tag{36.1}$$

where, L_m is the number of univariate indicator functions multiplied in the m-th model term, $x_{v(l,m)}$ is the input variable corresponding to the l-th indicator function in the m-th model term, $t_{l,m}$ is the split-point corresponding to $x_{v(l,m)}$, and $s_{l,m}$ is $+1$ or -1 to indicate the direction of the partition. The CART model form is then

$$f(\boldsymbol{x};\beta) = \beta_0 + \sum_{m=1}^{M} \beta_m f_m(\boldsymbol{x}) \,. \tag{36.2}$$

The partitioning of the $\boldsymbol{x}$-space does not keep the parent model terms because they are redundant. For example, suppose the current set has the model term:

$$f_a(\boldsymbol{x}) = 1\{x_3 > 7\} \cdot 1\{x_4 \le 10\} \,,$$

and the forward stepwise algorithm chooses to add

$$\begin{aligned} f_b(\boldsymbol{x}) &= f_a(\boldsymbol{x}) \cdot 1\{x_5 > 13\} \\ &= 1\{x_3 > 7\} \cdot 1\{x_4 \le 10\} \cdot 1\{x_5 > 13\} \,. \end{aligned}$$

Then the model term $f_a(\boldsymbol{x})$ is dropped from the current set. Thus, the recursive partitioning algorithm follows a binary tree with the current set of model terms $f_m(\boldsymbol{x})$ consisting of the M leaves of the tree, each of which corresponds to a different region R_m.

In the regression case, CART minimizes the squared error loss function,

$$\mathrm{LOF}(\hat{f}) = \sum_{i=1}^{N} \left[y_i - \hat{f}(\boldsymbol{x}_i)\right]^2 \,,$$

and the approximation is a piecewise-constant function. In the classification case, each region R_m is classified into one of the C classes. Specifically, define the

proportion of class c observations in region R_m as

$$\hat{\delta}_{mc} = \frac{1}{N_m} \sum_{\boldsymbol{x}_i \in R_m} 1\{y_i = c\} ,$$

where N_m is the number of observations in the region R_m. Then the observations in region R_m are classified into the class c corresponding to the maximum proportion $\hat{\delta}_{mc}$. The algorithm is exactly the same as for regression, but with a different loss function. Appropriate choices include minimizing the misclassification error (i. e., the number of misclassified observations), the Gini index, $\sum_{c=1}^{C} \hat{\delta}_{mc}(1-\hat{\delta}_{mc})$, or the deviance $\sum_{c=1}^{C} \hat{\delta}_{mc}\log(\hat{\delta}_{mc})$.

The exhaustive search algorithms for CART simultaneously conduct variable selection (x) and split-point selection (t). To reduce computational effort, the *fast algorithm for classification trees* [36.27] separates the two tasks. At each existing model term (leaf of the tree), F-statistics are calculated for variable selection. Then linear discriminant analysis is used to identify the split-point. A version for logistic and Poisson regression was presented by *Chaudhuri* et al. [36.28].

The primary drawback of CART and FACT is a bias towards selecting higher-order interaction terms due to the property of keeping only the leaves of the tree. As a consequence, these tree methods do not provide robust approximations and can have poor prediction accuracy. *Loh* and *Shih* [36.29] address this issue for FACT with a variant of their classification algorithm called QUEST that clusters classes into superclasses before applying linear discriminant analysis. For CART, *Friedman* et al. [36.30] introduced to the statistics literature the concepts of *boosting* [36.31] and *bagging* [36.32] from the machine learning literature. The bagging approach generates many bootstrap samples, fits a tree to each, then uses their average prediction. In the framework of boosting, a model term, called a *base learner*, is a *small* tree with only L disjoint regions (L is selected by the user), call it $B(\boldsymbol{x}, \boldsymbol{a})$, where $\boldsymbol{a}$ is the vector of tree coefficients. The boosting algorithm begins by fitting a small tree $B(\boldsymbol{x}, \boldsymbol{a})$ to the data, and the first approximation, $\hat{f}_1(\boldsymbol{x})$, is then this first small tree. In the m-th iteration, residuals are calculated, then a small tree $B(\boldsymbol{x}, \boldsymbol{a})$ is fitted to the residuals and combined with the latest approximation to create the m-th approximation:

$$\hat{f}_m(\boldsymbol{x}; \beta_0, \beta_1, \ldots, \beta_m) = \hat{f}_{m-1}(\boldsymbol{x}; \beta_0, \beta_1, \ldots, \beta_{m-1}) + \beta_m B(\boldsymbol{x}, \boldsymbol{a}) ,$$

where a line search is used to solve for β_m. The resulting boosted tree, called a *multiple additive regression tree* (MART) [36.33], then consists of much lower-order interaction terms. *Friedman* [36.34] presents *stochastic gradient boosting*, with a variety of loss functions, in which a bootstrap-like bagging procedure is included in the boosting algorithm.

Finally, for the regression case only, *multivariate adaptive regression splines* (MARS) [36.35] evolved from CART as an alternative to its piecewise-constant approximation. Like CART, MARS utilizes a forward stepwise algorithm to select model terms followed by a backward procedure to prune the model. A univariate version (appropriate for additive relationships) was presented by *Friedman* and *Silverman* [36.36]. The MARS approximation bends to model curvature at *knot* locations, and one of the objectives of the forward stepwise algorithm is to select appropriate knots. An important difference from CART is that MARS maintains the parent model terms, which are no longer redundant, but are simply lower-order terms.

MARS model terms have the same form as (36.1), except the indicator functions are replaced with truncated linear functions,

$$[b^+(x; t) = [+(x-t)]_+, \quad b^-(x; t) = [-(x-t)]_+ ,$$

where $[q]_+ = \max(0, q)$ and t is an univariate knot. The search for new model terms can be restricted to interactions of a maximum order (e.g., $L_m \leq 2$ permits up through two-factor interactions). The resulting MARS approximation, following (36.2), is a continuous, piecewise-linear function. After selection of the model terms is completed, smoothness to achieve a certain degree of continuity may be applied.

Hastie et al. [36.8] demonstrate significant improvements in accuracy using MART over CART. For the regression case, comparisons between MART and MARS yield comparable results [36.34]. Thus, the primary decision between these two methods is whether a piecewise-constant approximation is satisfactory or if a continuous, smooth approximation would be preferred.

Artificial Neural Networks

Artificial neural network (ANN) models have been very popular for modeling a variety of physical relationships (for a general introduction see *Lippmann* [36.37] or *Haykin* [36.38]; for statistical perspectives see *White* [36.39], *Baron* et al. [36.40], *Ripley* [36.23], or *Cheng* and *Titterington* [36.41]). The original motivation for ANNs comes from how *learning* strengthens connections along neurons in the brain. Commonly, an ANN model is represented by a diagram of nodes in vari-

ous layers with weighted connections between nodes in different layers (Fig. 36.6). At the input layer, the nodes are the input variables and at the output layer, the nodes are the response variable(s). In between, there is usually at least one *hidden* layer which induces flexibility into the modeling. *Activation functions* define transformations between layers (e.g., input to hidden). Connections between nodes can *feed back* to previous layers, but for supervised learning, the typical ANN is *feedforward* only with at least one hidden layer.

The general form of a feedforward ANN with one hidden layer and activation functions $b_1(\cdot)$ (input to hidden) and $b_2(\cdot)$ (hidden to output) is

$$f_c(\boldsymbol{x};\boldsymbol{w},\boldsymbol{v},\boldsymbol{\theta},\gamma_c) = b_2\left[\sum_{h=1}^{H} w_{hc}\cdot b_1\left(\sum_{j=1}^{p} v_{jh}x_j+\theta_h\right)+\gamma_c\right], \tag{36.3}$$

where $c = 1,\ldots,C$ and C is the number of output variables, p is the number of input variables, H is the number of hidden nodes, the weights v_{jh} link input nodes j to hidden nodes h and w_{hc} link hidden nodes h to output nodes c, and θ_h and γ_c are constant terms called bias nodes (like intercept terms). The number of coefficients to be estimated is $(p+1)H+(H+1)C$, which is often larger than N. The simplest activation function is a linear function $b(z) = z$, which reduces the ANN model in (36.3) with one response variable to a multiple linear regression equation. For more flexibility, the recommended activation functions between the input and hidden layer(s) are the S-shaped *sigmoidal* functions or

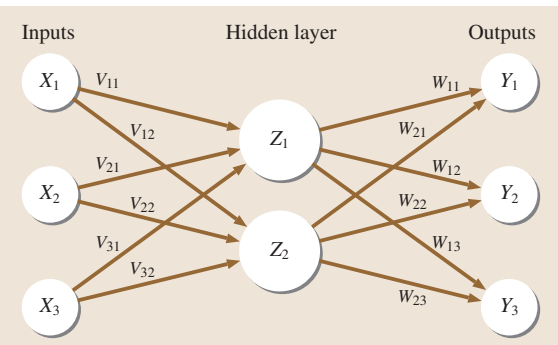

Fig. 36.6 Diagram of a typical artificial neural network for function approximation. The input nodes correspond to the input variables, and the output node(s) correspond to the output variable(s). The number of hidden nodes in the hidden layer must be specified by the user

the bell-shaped *radial basis functions*. Commonly used sigmoidal functions are the logistic function

$$b(z) = \frac{1}{1+\mathrm{e}^{-z}}$$

and the hyperbolic tangent

$$b(z) = \tanh(z) = \frac{1-\mathrm{e}^{-2x}}{1+\mathrm{e}^{-2x}}\,.$$

The most common radial basis function is the Gaussian probability density function.

In the regression case, each node in the output layer represents a quantitative response variable. The output activation function may be either a linear, sigmoidal, or radial basis function. Using a logistic activation function from input to hidden and from hidden to output, the ANN model in (36.3) becomes

$$f_c(\boldsymbol{x};\boldsymbol{w},\boldsymbol{v},\boldsymbol{\theta},\gamma_c) = \left[1+\exp\left(-\sum_{h=1}^{H} w_{hc}z_h+\gamma_c\right)\right]^{-1},$$

where for each hidden node h

$$z_h = \left[1+\exp\left(-\sum_{j=1}^{p} v_{jh}x_j+\theta_h\right)\right]^{-1}.$$

In the classification case with C classes, each class is represented by a different node in the output layer. The recommended output activation function is the *softmax* function. For output node c, this is defined as

$$b(z_1,\ldots,z_C;c) = \frac{\mathrm{e}^{z_c}}{\sum_{d=1}^{C}\mathrm{e}^{z_d}}\,.$$

This produces output values between zero and one that sum to one and, consequently, permits the output values to be interpreted as posterior probabilities for a categorical response variable.

Mathematically, an ANN model is a nonlinear statistical model, and a nonlinear method must be used to estimate the coefficients (weights v_{jh} and w_{hc}, biases θ_h and γ_c) of the model. This estimation process is called network training. Typically, the objective is to minimize the squared error lack-of-fit criterion

$$\mathrm{LOF}(\hat{f}) = \sum_{c=1}^{C}\sum_{i=1}^{N}\left[y_i-\hat{f}_c(\boldsymbol{x}_i)\right]^2.$$

The most common method for training is *backpropagation*, which is based on gradient descent. At each

iteration, each coefficient (say w) is adjusted according to its contribution to the lack-of-fit

$$\Delta w = \alpha \frac{\partial(\text{LOF})}{\partial w} ,$$

where the user-specified α controls the step size; see *Rumelhart* et al. [36.42] for more details. More efficient training procedures are a subject of current ANN research.

Another major issue is the network *architecture*, defined by the number of hidden nodes. If too many hidden nodes are permitted, the ANN model will overfit the data. Many model discrimination methods have been tested, but the most reliable is validation of the model on a testing data set separate from the training data set. Several ANN architectures are fitted to the training data set and then prediction error is measured on the testing data set. Although ANNs are generally flexible enough to model anything, they are computationally intensive, and a significant quantity of representative data is required to both fit and validate the model. From a statistical perspective, the primary drawback is the overly large set of coefficients, none of which provide any intuitive understanding for the underlying model structure. In addition, since the nonlinear model form is not motivated by the true model structure, too few training data points can result in ANN approximations with extraneous nonlinearity. However, given enough good data, ANNs can outperform other modeling methods.

Support Vector Machines

Referring to the linear methods for classification described earlier, the decision boundary between two classes is a hyperplane of the form $\{\boldsymbol{x} \mid \beta_0 + \sum \beta_j x_j = 0\}$. The *support vectors* are the points that are most critical to determining the optimal decision boundary because they lie close to the points belonging to the other class. With *support vector machines* (SVM) [36.43,44], the linear decision boundary is generalized to the more flexible form

$$f(\boldsymbol{x};\boldsymbol{\beta}) = \beta_0 + \sum_{m=1}^{M} \beta_m g_m(\boldsymbol{x}), \qquad (36.4)$$

where the $g_m(\boldsymbol{x})$ are transformations of the input vector. The decision boundary is then defined by $\{\boldsymbol{x} \mid f(\boldsymbol{x};\boldsymbol{\beta}) = 0\}$. To solve for the optimal decision boundary, it turns out that we do not need to specify the transformations $g_m(\boldsymbol{x})$, but instead require only the *kernel function* [36.21,45]:

$$K(\boldsymbol{x},\boldsymbol{x}') = \langle [g_1(\boldsymbol{x}), \ldots, g_M(\boldsymbol{x})], [g_1(\boldsymbol{x}'), \ldots, g_M(\boldsymbol{x}')] \rangle .$$

Two popular kernel functions for SVM are polynomials of degree d, $K(\boldsymbol{x},\boldsymbol{x}') = (1 + \langle \boldsymbol{x},\boldsymbol{x}' \rangle)^d$, and radial basis functions, $K(\boldsymbol{x},\boldsymbol{x}\prime) = \exp(-\|\boldsymbol{x}-\boldsymbol{x}'\|^2/c)$.

Given $K(\boldsymbol{x},\boldsymbol{x}')$, we maximize the following Lagrangian dual-objective function:

$$\max_{\alpha_1,\ldots\alpha_N} \sum_{i=1}^{N} \alpha_i - \frac{1}{2} \sum_{i=1}^{N} \sum_{i'=1}^{N} \alpha_i \alpha_{i'} y_i y_{i'} K(\boldsymbol{x}_i, \boldsymbol{x}_i')$$
$$\text{s.t.} \quad 0 \le \alpha_i \le \gamma , \text{ for } i = 1, \ldots, N \text{ and}$$
$$\sum_{i=1}^{N} \alpha_i y_i = 0 ,$$

where γ is an SVM tuning parameter. The optimal solution allows us to rewrite $f(\boldsymbol{x};\boldsymbol{\beta})$ as

$$f(\boldsymbol{x};\boldsymbol{\beta}) = \beta_0 + \sum_{i=1}^{N} \alpha_i y_i K(\boldsymbol{x},\boldsymbol{x}_i) ,$$

where β_0 and $\alpha_1, \ldots, \alpha_N$ are determined by solving $f(\boldsymbol{x};\boldsymbol{\beta}) = 0$. The support vectors are those $\boldsymbol{x}_i$ corresponding to nonzero α_i. A smaller SVM tuning parameter γ leads to more support vectors and a smoother decision boundary. A testing data set may be used to determine the best value for γ.

The SVM extension to more than two classes solves multiple two-class problems. SVM for regression utilizes the model form in (36.4) and requires specification of a loss function appropriate for a quantitative response [36.8,46]. Two possibilities are the ϵ-insensitive function

$$V_\epsilon(e) = \begin{cases} 0 & \text{if } |e| < \epsilon , \\ |e| - \epsilon & \text{otherwise} , \end{cases}$$

which ignores errors smaller than ϵ, and the *Huber* [36.47] function

$$V_{\text{H}}(e) = \begin{cases} e^2/2 & \text{if } |e| \le 1.345 , \\ 1.345|e| - e^2/2 & \text{otherwise} , \end{cases}$$

which is used in robust regression to reduce model sensitivity to outliers.

Other Classification Methods

In this section, we briefly discuss some other concepts that are applicable to DM classification problems. The basic intuition behind a good classification method is derived from the *Bayes classifier*, which utilizes the posterior distribution $P(Y = c|\boldsymbol{X} = \boldsymbol{x})$. Specifically, if $P(Y = c|\boldsymbol{X} = \boldsymbol{x})$ is the maximum over $c = 1, \ldots, C$, then $\boldsymbol{x}$ would be classified to class c.

Nearest neighbor (NN) [36.48] classifiers seek to estimate the Bayes classifier directly without specification of any model form. The k-NN classifier identifies the k closest points to $\boldsymbol{x}$ (using Euclidean distance) as the *neighborhood* about $\boldsymbol{x}$, then estimates $P(Y = c|\boldsymbol{X} = \boldsymbol{x})$ with the fraction of these k points that are of class c. As k increases, the decision boundaries become smoother; however, the *neighborhood* becomes less local (and less relevant) to $\boldsymbol{x}$. This problem of local representation is even worse in high dimensions, and modifications to the distance measure are needed to create a practical k-NN method for DM. For this purpose, *Hastie* and *Tibshirani* [36.49] proposed the discriminant adaptive NN distance measure to reshape the neighborhood adaptively at a given $\boldsymbol{x}$ to capture the critical points to distinguish between the classes.

As mentioned earlier, linear discriminant analysis may be too restrictive in practice. *Flexible discriminant analysis* replaces the linear decision boundaries with more flexible regression models, such as GAM or MARS. *Mixture discriminant analysis* relaxes the assumption that that classes are more or less spherical in shape by allowing a class to be represented by multiple (spherical) clusters; see *Hastie* et al. [36.50] and *Ripley* [36.23] for more details.

K-means clustering classification applies the K-means clustering algorithm separately to the data for each of the C classes. Each class c will then be represented by K clusters of points. Consequently, nonspherical classes may be modeled. For a new input vector $\boldsymbol{x}$, determine the closest cluster, then assign $\boldsymbol{x}$ to the the class associated with that cluster.

Genetic algorithms [36.51, 52] use processes such as genetic combination, mutation, and natural selection in an optimization based on the concepts of natural evolution. One generation of models competes to pass on characteristics to the next generation of models, until the best model is found. Genetic algorithms are useful in guiding DM algorithms, such as neural networks and decision trees [36.53].

36.3.2 Unsupervised Learning

In unsupervised learning, correct answers are not available, so there is no clear measure of success. Success must be judged subjectively by the value of discovered knowledge or the effectiveness of the algorithm. The statistical perspective is to observe N vectors from the population distribution, then conduct direct inferences on the properties (e.g. relationship, grouping) of the population distribution. The number of variables or attributes is often very high (much higher than that in supervised learning). In describing the methods, we denote the j-th variable by x_j (or random variable X_j), and the corresponding boldface $\boldsymbol{x}$ (or $\boldsymbol{X}$) denotes the vector of p variables $(x_1, x_2, \ldots, x_p)^{\mathrm{T}}$, where boldface $\boldsymbol{x}_i$ denotes the i-th sample point. These variables may be either quantitative or qualitative.

Association Rules

Association rules or *affinity groupings* seek to find associations between the values of the variables $\boldsymbol{X}$ that provide knowledge about the population distribution. *Market basket analysis* is a well-known special case, for which the extracted knowledge may be used to link specific products. For example, consider all the items that may be purchased at a store. If the analysis identifies that items A and B are commonly purchased together, then sales promotions could exploit this to increase revenue.

In seeking these associations, a primary objective is to identify variable values that occur together with high probability. Let S_j be the the set of values for X_j, and consider a subset $s_j \subseteq S_j$. Then we seek subsets $s_1, \ldots, s_p$ such that

$$P\left[\bigcap_{j=1}^{p}(X_j \in s_j)\right] \tag{36.5}$$

is large. In market basket analysis, the variables $\boldsymbol{X}$ are converted to a set of binary variables $\boldsymbol{Z}$, where each attainable value of each X_j corresponds to a variable Z_k. Thus, the number of Z_k variables is $K = \sum |S_j|$. If binary variable Z_k corresponds to $X_j = v$, then $Z_k = 1$ when $X_j = v$ and $Z_k = 0$ otherwise. An *item set* κ is a realization of $\boldsymbol{Z}$. For example, if the Z_k represent the possible products that could be purchased from a store, then an item set would be the set of items purchased together by a customer. Note that the number of $Z_k = 1$ in an item set is at most p. Equation (36.5) now becomes

$$P\left[\bigcap_{k\in\kappa}(Z_k = 1)\right],$$

which is estimated by

$$T(\kappa) = \frac{\text{Number of observations for which item set } \kappa \text{ occurs}}{N}.$$

$T(\kappa)$ is called the *support* for the rule. We can select a lower bound t such that item sets with $T(\kappa) > t$ would be considered to have large support.

Further knowledge may be extracted via the a priori algorithm [36.54] in the form of if–then statements. For an item set κ, the items with $Z_k = 1$ would be partitioned into two disjoint item subsets such that $A \bigcup B = \kappa$. The association rule would be stated as "if A, then B" and denoted by $A \Rightarrow B$, where A is called the *antecedent* and B is called the *consequent*. This rule's support $T(A \Rightarrow B)$ is the same as $T(\kappa)$ calculated above, an estimate of the joint probability. The *confidence* or *predictability* of this rule is

$$C(A \Rightarrow B) = \frac{T(A \Rightarrow B)}{T(A)} ,$$

which is an estimate of the conditional probability $P(B|A)$. The *expected confidence* is the support of B, $T(B)$, and an estimate for the unconditional probability $P(B)$. The *lift* is the ratio of the confidence over the expected confidence,

$$L(A \Rightarrow B) = \frac{C(A \Rightarrow B)}{T(B)} ,$$

which, if greater than , can be interpreted as the increased prevalence of B when associated with A. For example, if $T(B) = 5\%$, then B is estimated to occur unconditionally 5% of the time. If $C(A \Rightarrow B) = 40\%$, then given A occurs, B is estimated to occur 40% of the time. This results in a lift of 8, implying that B is 8 times more likely to occur if we know that A occurs.

Cluster Analysis

The objective of cluster analysis is to partition the N observations of $\boldsymbol{x}$ into groups or clusters such that the dissimilarities within each cluster are smaller than the dissimilarities between different clusters [36.55]. Typically the variables $\boldsymbol{x}$ are all quantitative, and a distance measure (e.g., Euclidean) is used to measure dissimilarity. For categorical x variables, a dissimilarity measure must be explicitly defined. Below, we describe some of the more common methods.

K-means [36.56] is the best-known clustering tool. It is appropriate when the variables $\boldsymbol{x}$ are quantitative. Given a prespecified value K, the method partitions the N observations of $\boldsymbol{x}$ into exactly K clusters by minimizing within-cluster dissimilarity. Squared Euclidean distance

$$d(\boldsymbol{x}_i, \boldsymbol{x}_i') = \sum_{j=1}^{p} (x_{ij} - x_{i'j})^2$$

is used to measure dissimilarity. For a specific clustering assignment $\boldsymbol{C} = (C_1, \ldots, C_K)$, the within-cluster dissimilarity is measured by calculating $d(\boldsymbol{x}_i, \boldsymbol{x}_i')$ for all points $\boldsymbol{x}_i, \boldsymbol{x}_i'$ within a cluster C_k, then summing over the K clusters. This is equivalent to calculating

$$W(\boldsymbol{C}) = \sum_{k=1}^{K} \sum_{i \in C_k} d(\boldsymbol{x}_i, \bar{\boldsymbol{x}}_k) ,$$

where the cluster mean $\bar{\boldsymbol{x}}_k$ is the sample mean vector of the points in cluster C_k. Given a current set of cluster means, the K-means algorithm assigns each point to the closest cluster mean, calculates the new cluster means, and iterates until the cluster assignments do not change.

Unfortunately, because of its dependence on the squared Euclidean distance measure, K-means clustering is sensitive to outliers (i. e., is not robust). *K-mediods* [36.57] is a generalized version that utilizes an alternately defined cluster *center* in place of the cluster means and an alternate distance measure.

Density-based clustering (DBSCAN) [36.58] algorithms are less sensitive to outliers and can discover clusters of irregular (p-dimensional) shapes. DBSCAN is designed to discover clusters and noise in a spatial database. The advantage of DBSCAN over other clustering methods is its ability to represent specific structure in the analysis explicitly. DBSCAN has two key parameters: neighborhood size (ϵ) and minimum cluster size ($n_{\min}$). The neighborhood of an object within a radius ϵ is called the ϵ-neighborhood of the object. If the ϵ-neighborhood of an object contains at least $n_{\min}$ objects, then the object is called a core object. To find a cluster, DBSCAN starts with an arbitrary object o in the database. If the object o is a core object w.r.t. ϵ and $n_{\min}$, then a new cluster with o as the core object is created. DBSCAN continues to retrieve all density-reachable objects from the core object and add them to the cluster.

GDBSCAN [36.59] generalizes the two key parameters of the DBSCAN algorithm such that it can cluster point objects and spatially extended objects according to an arbitrarily selected combination of attributes. The neighborhood of an object is now defined by a binary predicate η on a data set that is reflexive and symmetric. If η is true, then the neighborhood of an object is called the η-neighborhood of an object. In other words, the η-neighborhood of an object is a set of objects, S, which meet the condition that η is true. Corresponding to $n_{\min}$, another predicate, $w_{\min}$ of the set of objects, S, is defined such that it is true if and only if the weighted cardinality for the set, wCard(S), is greater or equal to the minimum cardinality (MinCard), i. e. wCard(S) $\geq$ MinCard.

Finally, ordering points to identify the clustering structure (OPTICS) [36.60] is a method of cluster analysis that produces an augmented ordering of the database representing its density-based clustering structure. This method by itself does not produce a clustering of a data set explicitly. The information produced by OPTICS includes representative points, arbitrarily shaped clusters and intrinsic clustering structure, which can then be used by a clustering algorithm when selecting clustering settings. This same information can also be used by a human expert to gain insight into the clustering structure of the data.

Self-Organizing (Feature) Maps (SOMs) [36.61] belong to the class of ANNs called *unsupervised learning networks*. SOMs can be organized as a single layer or as two layers of neuron nodes. In this arrangement, the input layer consists of p nodes corresponding to the real-valued input vector of dimension p. The input layer nodes are connected to a second layer of nodes U. By means of lateral connections, the nodes in U form a lattice structure of dimensionality M. Typically M is much smaller than p. By means of a learning algorithm, the network *discovers* the clusters within the data. It is possible to alter the discovered clusters by varying the learning parameters of the network. The SOM is especially suitable for data survey because it has appealing visualization properties. It creates a set of prototype vectors representing the data set and carries out a topology-preserving projection of the prototypes from the p-dimensional input space onto a low-dimensional (typically two-dimensional) grid. This ordered grid can be used as a convenient visualization surface for showing different features of the SOM (and thus of the data), for example, the cluster structure. While the axes of such a grid do not correspond to any measurement, the spatial relationships among the clusters do correspond to relationships in p-dimensional space. Another attractive feature of the SOM is its ability to discover arbitrarily shaped clusters organized in a nonlinear space.

36.3.3 Software

Several DM software packages are available at a wide range of prices, of which six of the most popular packages are:

- SAS Enterprise Miner (www.sas.com/technologies/analytics/datamining/miner/),
- SPSS Clementine (www.spss.com/clementine/),
- XLMiner in Excel (www.xlminer.net),
- Ghostminer (www.fqspl.com.pl/ghostminer/),
- Quadstone (www.quadstone.com/),
- Insightful Miner (www.splus.com/products/iminer/).

Haughton et al. [36.62] present a review of the first five listed above. The SAS and SPSS packages have the most complete set of KDD/DM tools (data handling, DM modeling, and graphics), while Quadstone is the most limited. Insightful Miner was developed by *S+* [www.splus.com], but does not require knowledge of the *S+* language, which is only recommended for users that are familiar with statistical modeling. For statisticians, the advantage is that Insightful Miner can be integrated with more sophisticated DM methods available with *S+*, such as flexible and mixture discriminant analysis. All six packages include trees and clustering, and all except Quadstone include ANN modeling. The SAS, SPSS, and XLMiner packages include discriminant analysis and association rules. Ghostminer is the only one that offers SVM tools.

SAS, SPSS, and Quadstone are the most expensive (over $ 40 000) while XLMiner is a good deal for the price (under $ 2 000). The disadvantage of XLMiner is that it cannot handle very large data sets. Each package has certain specializations, and potential users must carefully investigate these choices to find the package that best fits their KDD/DM needs. Below we describe some other software options for the DM modeling methods presented.

GLM or linear models are the simplest of DM tools and most statistical software can fit them, such as SAS, SPSS, *S+*, and Statistica [www.statsoftinc.com/]. However, it should be noted that Quadstone only offers a regression tool via scorecards, which is not the same as statistical linear models. GAM requires access to more sophisticated statistical software, such as *S+*.

Software for CART, MART, and MARS is available from Salford Systems [www.salford-systems.com]. SAS Enterprise Miner includes CHAID, CART, and the machine learning program C4.5 [www.rulequest.com] [36.63], which uses classifiers to generate decision trees and if–then rules. SPSS Clementine and Insightful Miner also include CART, but Ghostminer and XLMiner utilize different variants of decision trees. QUEST [www.stat.wisc.edu/~loh/quest.html] is available in SPSS's AnswerTree software and Statistica.

Although ANN software is widely available, the most complete package is Matlab's [www.mathworks.com] Neural Network Toolbox. Information on SVM software is available at [www.support-vector.net/software.html]. One good option is Matlab's SVM Toolbox.

36.4 DM Research and Applications

Many industrial and business applications require modeling and monitoring processes with real-time data of different types: real values, categorical, and even text. DM is an effective tool for extracting process knowledge and discovering data patterns to provide a control aid for these processes. Advanced DM research involves complex system modeling of heterogeneous objects, where adaptive algorithms are necessary to capture dynamic system behavior.

36.4.1 Activity Monitoring

One important DM application is the development of an effective data modeling and monitoring system for understanding customer profiles and detecting fraudulent behavior. This is generally referred to as *activity monitoring for interesting events requiring action* [36.64]. Other activity monitoring examples include credit card or insurance fraud detection, computer intrusion detection, some forms of fault detection, network performance monitoring, and news story monitoring.

Although activity monitoring has only recently received attention in the information industries, solutions to similar problems were developed long ago in the manufacturing industries, under the moniker *statistical process control* (SPC). SPC techniques have been used routinely for online process control and monitoring to achieve process stability and to improve process capability through variation reduction. In general, all processes are subject to some natural variability regardless of their state. This natural variability is usually small and unavoidable and is referred to as *common cause variation*. At the same time, processes may be subject to other variability caused by improper machine adjustment, operator errors, or low-quality raw material. This variability is usually large, but avoidable, and is referred to as *special cause variation*. The basic objective of SPC is to detect the occurrence of special cause variation (or process shifts) quickly, so that the process can be investigated and corrective action may be taken before quality deteriorates and defective units are produced. The main ideas and methods of SPC were developed in the 1920s by Walter Shewhart of Bell Telephone Laboratories and have had tremendous success in manufacturing applications [36.65, 66]. *Montgomery* and *Woodall* [36.67] provide a comprehensive panel discussion on SPC, and multivariate methods are reviewed by *Hayter* and *Tsui* [36.68] and *Mason* et al. [36.69].

Although the principle of SPC can be applied to service industries, such as business process monitoring, fewer applications exist for two basic reasons that *Montgomery* [36.65] identified. First, the system that needs to be monitored and improved is obvious in manufacturing applications, while it is often difficult to define and observe in service industries. Second, even if the system can be clearly specified, most non-manufacturing operations do not have natural measurement systems that reflect the performance of the system. However, these obstacles no longer exist, due to the many natural and advanced measurement systems that have been developed. In the telecommunications industry, for example, advanced software and hardware technologies make it possible to record and process huge amounts of daily data in business transactions and service activities. These databases contain potentially useful information to the company that may not be discovered without knowledge extraction or DM tools.

While SPC ideas can be applied to business data, SPC methods are not directly applicable. Existing SPC theories are based on small or medium-sized samples, and the basic hypothesis testing approach is intended to detect only simple shifts in a process mean or variance. Recently, *Jiang* et al. [36.70] successfully generalized the SPC framework to model and track thousands of diversified customer behaviors in the telecommunication industry. The challenge is to develop an integrated strategy to monitor the performance of an entire multi-stage system and to develop effective and efficient techniques for detecting the systematic changes that require action.

A dynamic business process can be described by the dynamic linear models introduced by *West* [36.71],

$$\begin{aligned} &\textit{Observation equation}: X_t = A_t\theta_t + \Delta_t \,, \\ &\textit{System evolution equation}: \theta_t = B_t\theta_{t-1} + \Lambda_t \,, \\ &\textit{Initial information}: \pi(S_0) \,, \end{aligned}$$

where A_t and B_t represent observation and state transition matrices, respectively, and Δ_t and Λ_t represent observation and system transition errors, respectively. Based on the dynamic system model, a model-based process monitoring and root-cause identification method can be developed. Monitoring and diagnosis includes fault pattern generation and feature extraction, isolation of the critical processes, and root-cause identification. *Jiang* et al. [36.70] utilize this for individual customer prediction and monitoring. In general, individual modeling is computationally intractable and

cluster models should be developed with mixture distributions [36.72].

One particularly competitive industry is telecommunications. Since divestiture and government deregulation, various telephone services, such as cellular, local and long distance, domestic and commercial, have become battle grounds for telecommunication service providers. Because of the data and information oriented nature of the industry, DM methods for knowledge extraction are critical. To remain competitive, it is important for companies to develop business planning systems that help managers make good decisions. In particular, these systems will allow sales and marketing people to establish successful customer loyalty programs for churn prevention and to develop fraud detection modules for reducing revenue loss through market segmentation and customer profiling.

A major task in this research is to develop and implement DM tools within the business planning system. The objectives are to provide guidance for targeting business growth, to forecast year-end usage volume and revenue growth, and to value risks associated with the business plan periodically. Telecommunication business services include voice and non-voice services, which can be further categorized to include domestic, local, international, products, toll-free calls, and calling cards. For usage forecasting, a minutes growth model is utilized to forecast domestic voice usage. For revenue forecasting, the average revenue per minute on a log scale is used as a performance measure and is forecasted by a double exponential smoothing growth function. A structural model is designed to decompose the business growth process into three major subprocesses: add, disconnect, and base. To improve explanatory power, the revenue unit is further divided into different customer groups. To compute confidence and prediction intervals, bootstrapping and simulation methods are used.

To understand the day effect and seasonal effect, the concept of bill-month equivalent business days (EBD) is defined and estimated. To estimate EBD, the factor characteristics of holidays (non-EBD) are identified and eliminated and the day effect is estimated. For seasonality, the US Bureau of the Census X-11 seasonal adjustment procedure is used.

36.4.2 Mahalanobis–Taguchi System

Genichi Taguchi is best known for his work on robust design and design of experiments. The Taguchi robust design methods have generated a considerable amount of discussion and controversy and are widely used in manufacturing [36.73–77]. The general consensus among statisticians seems to be that, while many of Taguchi's overall ideas on experimental design are very important and influential, the techniques he proposed are not necessarily the most effective statistical methods. Nevertheless, Taguchi has made significant contributions in the area of quality control and quality engineering. For DM, Taguchi has recently popularized the *Mahalanobis–Taguchi System* (MTS), a new set of tools for diagnosis, classification, and variable selection. The method is based on a Mahalanobis distance scale that is utilized to measure the level of abnormality in *abnormal* items as compared to a group of *normal* items. First, it must be demonstrated that a Mahalanobis distance measure based on all available variables is able to separate the abnormal from the normal items. Should this be successfully achieved, orthogonal arrays and signal-to-noise ratios are used to select an *optimal* combination of variables for calculating the Mahalanobis distances.

The MTS method has been claimed to be very powerful for solving a wide range of problems, including manufacturing inspection and sensing, medical diagnosis, face and voice recognition, weather forecasting, credit scoring, fire detection, earthquake forecasting, and university admissions. Two recent books have been published on the MTS method by *Taguchi* et al. [36.78] and *Taguchi* and *Jugulum* [36.79]. Many successful case studies in MTS have been reported in engineering and science applications in many large companies, such as Nissan Motor Co., Mitsubishi Space Software Co., Xerox, Delphi Automotive Systems, ITT Industries, Ford Motor Company, Fuji Photo Film Company, and others. While the method is getting a lot of attention in many industries, very little research [36.80] has been conducted to investigate how and when the method is appropriate.

36.4.3 Manufacturing Process Modeling

One area of DM research in manufacturing industries is quality and productivity improvement through DM and knowledge discovery. Manufacturing systems nowadays are often very complicated and involve many manufacturing process stages where hundreds or thousands of in-process measurements are taken to indicate or initiate process control of the system. For example, a modern semiconductor manufacturing process typically consists of over 300 steps, and in each step, multiple pieces of equipment are used

to process the wafer. Inappropriate understanding of interactions among in-process variables will create inefficiencies at all phases of manufacturing, leading to long product/process realization cycle times and long development times, and resulting in excessive system costs.

Current approaches to DM in electronics manufacturing include neural networks, decision trees, Bayesian models and rough set theory [36.81, 82]. Each of these approaches carries certain advantages and disadvantages. Decision trees, for instance, produce intelligible rules and hence are very appropriate for generating process control or design of experiments strategies. They are, however, generally prone to outlier and imperfect data influences. Neural networks, on the other hand, are robust against data abnormalities but do not produce readily intelligible knowledge. These methods also differ in their ability to handle high-dimensional data, to discover arbitrarily shaped clusters [36.58] and to provide a basis for intuitive visualization [36.83]. They can also be sensitive to training and model building parameters [36.60]. Finally, the existing approaches do not take into consideration the localization of process parameters. The patterns or clusters identified by existing approaches may include parameters from a diverse set of components in the system. Therefore, a combination of methods that complement each other to provide a complete set of desirable features is necessary.

It is crucial to understand process structure and yield components in manufacturing, so that problem localization can permit reduced production costs. For example, semiconducture manufacturing practice shows that over 70% of all fatal detects and close to 90% of yield excursions are caused by problems related to process equipment [36.84]. Systematic defects can be attributed to many categories that are generally associated with technologies and combinations of different process operations. To implement DM methods successfully for knowledge discovery, some future research for manufacturing process control must include yield modeling, defect modeling and variation propagation.

Yield Modeling

In electronics manufacturing, the ANSI standards [36.85] and practice gene rally assume that the number of defects on an electronics product follows a Poisson distribution with mean λ. The Poisson random variable is an approximation of the sum of independent Bernoulli trials, but defects on different components may be correlated since process yield critically depends on product groups, process steps, and types of defects [36.86]. Unlike traditional defect models, an appropriate logit model can be developed as follows. Let the number of defects of category X on an electronics product be

$$U_X = \sum Y_X$$

and

$$\text{logit}\big[E(Y_X)\big] = \alpha_X^0 + \alpha_X^O \cdot O_X + \alpha_X^C \cdot C_X + \alpha_X^{OC} \cdot O_X \cdot C_X \,,$$

where $\text{logit}(z) = \log[z/(1-z)]$ is the link function for Bernoulli distributions, and Y_X is a Bernoulli random variable representing a defect from defect category X. The default logit of the failure probability is α_X^0, and α_X^O and α_X^C are the main effects of operations (O_X) and components (C_X). Since the Y_Xs are correlated, this model will provide more detailed information about defects.

Multivariate Defect Modeling

Since different types of defects may be caused by the same operations, multivariate Poisson models are necessary to account for correlations among different types of defects. The *trivariate reduction method* suggests an additive Poisson model for the vector of Poisson counts $\boldsymbol{U} = (U_1, U_2, \cdots, U_k)'$,

$$\boldsymbol{U} = \boldsymbol{AV} \,,$$

where $\boldsymbol{A}$ is a matrix of zeros and ones, and $\boldsymbol{V} = (v_1, v_2, \cdots, v_p)'$ consists of independent Poisson variables v_i. The variance–covariance matrix takes the form $\text{Var}(U) = A\Sigma A' = \boldsymbol{\Phi} + \nu\nu'$, where $\boldsymbol{\Phi} = \text{diag}(\mu_i)$ is a diagonal matrix with the mean of the individual series, and ν is the common covariance term. Note that the v_i are essentially latent variables, and a factor analysis model can be developed for analyzing multivariate discrete Poisson variables such that

$$\log[E(\boldsymbol{U})] = \mu + \boldsymbol{L} \cdot \boldsymbol{F} \,,$$

where $\boldsymbol{U}$ is the vector of defects, $\boldsymbol{L}$ is the matrix of factor loadings, and $\boldsymbol{F}$ contains common factors representing effects of specific operations. By using factor analysis, it is possible to relate product defects to the associated packages and operations.

Multistage Variation Propagation

Inspection tests in an assembly line usually have functional overlap, and defects from successive inspection

stations exhibit strong correlations. Modeling serially correlated defect counts is an important task for defect localization and yield prediction. Poisson regression models, such as the generalized event-count method [36.87] and its alternatives, can be utilized to account for serial correlations of defects in different inspection stations. Factor analysis methods based on hidden Markov models [36.88] can also be constructed to investigate how variations are propagated through assembly lines.

36.5 Concluding Remarks

While DM and KDD methods are gaining recognition and have become very popular in many companies and enterprises, the success of these methods is still somewhat limited. Below, we discuss a few obstacles.

First, the success of DM depends on a close collaboration of subject-matter experts and data modelers. In practice, it is often easy to identify the right subject-matter expert, but difficult to find the qualified data modeler. While the data modeler must be knowledgeable and familiar with DM methods, it is more important to be able to formulate real problems such that the existing methods can be applied. In reality, traditional academic training mainly focuses on knowledge of modeling algorithms and lacks training in problem formulation and interpretation of results. Consequently, many modelers are very efficient in fitting models and algorithms to data, but have a hard time determining when and why they should use certain algorithms. Similarly, the existing commercial DM software systems include many sophisticated algorithms, but lack of guidance on which algorithms to use.

Second, implementation of DM is difficult to apply effectively across an industry. Although it is clear that extracting hidden knowledge and trends across an industry would be useful and beneficial to all companies in the industry, it is typically impossible to integrate the detailed data from competing companies due to confidentiality and proprietary issues. Currently, the industry practice is that each company will integrate their own detailed data with the more general, aggregated industry-wide data for knowledge extraction. It is obvious that this approach will be significantly less effective than the approach of integrating the detailed data from all competing companies. It is expected that, if these obstacles can be overcome, the impact of the DM and KDD methods will be much more prominent in industrial and commercial applications.

Part E Modeling and Simulation Methods

Part E contains ten chapters and focuses on statistical methods and modeling. Chapt. 37 provides an overview of several well-known bootstrap methods, including Efron's bootstrap and Studentized bootstrap interval for constructing confidence intervals and introduces some recently developed bootstrap methods such as the estimation-function bootstrap and the Markov-chain marginal bootstrap. Chapter 38 discusses generalized linear mixed models for correlated non-normal data and various methods for random-effect model parameters including the EM algorithms, penalized quasi-likelihood, the Markov-chain Newton–Raphson, the stochastic approximation, and the S–U algorithm. Chapter 39 focuses on the design and analysis of cluster randomized trials. This chapter also describes cost-efficiency models with covariates and the robustness of optimal designs, including both the number of clusters and cluster size. Chapter 40 discuss a semiparametric estimation method for an extension of the semiparametric regression model, called the two-way semilinear model, for normalization to estimate normalization curves and its applications to microarray data. Chapter 41 covers the development of latent-variable models for longitudinal data such as the generalized linear latent and mixed model, hierarchical latent-variable models, the linear mixed model for multivariate longitudinal responses as well as structural-equation models with latent variables for longitudinal data.

The next two chapters focus on genetic algorithms and scan statistics. Chapter 42 provides an overview of the concept of genetic algorithms, including hybrid genetic algorithms, adaptive genetic algorithms and fuzzy-logic controllers, and their applications in scheduling problems, network design, reliability design-optimization problems, logistic network, and transportation-related problems. Chapter 43 describes the concepts of scan statistics and the various types used to localize large clusters in continuous time, space, and on a two-dimensional lattice. It also discusses recent double-scan statistics methods that allow practitioners to test for some unusual lagged clustering of different types of events and complex systems.

The final three chapters focus on various issues in maintenance modeling. Chapter 44 describes a condition-based failure-prediction method consisting of both a computer simulation and an experiment on a DC motor for preventive maintenance using the Kalman filter. The applications of the method and experimental set ups with related system parameters and experimental results are also discussed. Chapter 45 gives a brief introduction to maintenance modeling and discusses generalized multistate maintenance models for repairable systems as well as condition-based inspection strategies for degraded systems with multiple, competing failure processes such as degradation processes and random shocks, while Chapt. 46 presents a review of major maintenance models and policies in the maintenance literature that are commonly used in practice and discusses various recent maintenance models with consideration of repair policies and inspection with human errors.

37. Bootstrap, Markov Chain and Estimating Function

In this chapter, we first review bootstrap methods for constructing confidence intervals (regions). We then discuss the following three important properties of these methods: (i) invariance under reparameterization; (ii) automatic computation; and (iii) higher order accuracy. The greatest potential value of the bootstrap lies in complex situations, such as nonlinear regression or high-dimensional parameters for example. It is important to have bootstrap procedures that can be applied to these complex situations, but still have the three desired properties. The main purpose of this chapter is to introduce two recently developed bootstrap methods: the estimation function bootstrap, and the Markov chain marginal bootstrap method. The estimating function bootstrap has all three desired properties and it can also be applied to complex situations. The Markov chain marginal bootstrap is designed for high-dimensional parameters.

37.1 Overview

For a statistical model involving an unknown parameter θ, the two main statistical inference issues are usually: (i) point estimation $\hat{\theta}$ (how to estimate the unknown parameter θ); and (ii) how to assess the accuracy of this estimator $\hat{\theta}$ (in terms of the standard deviation or confidence interval of the unknown θ). Statisticians usually try to find the exact distribution or asymptotic distribution of the estimator $\hat{\theta}$. However, it is difficult to obtain the exact distribution or asymptotic distribution in a lot of situations. Sometimes the asymptotic distribution can be obtained, but the distribution of $\hat{\theta}$ is not well approximated. Bootstrap provides a general methodology for constructing confidence intervals for unknown parameters.

In this chapter, we first discuss bootstrap methods in terms of the following three important properties: (1) invariance under reparameterization, (2) automatic computation, and (3) higher order accuracy. To illustrate these three properties, let's consider the following simple model. Assume that $Y_1, \ldots, Y_n$ is a random sample from some unknown distribution F. Let $y = (y_1, \ldots, y_n)$ be the realization of Y. Suppose that $\theta = \theta(F)$ is the unknown parameter of interest. This θ could be the mean, or variance, or some other function of the distribution F. Let $\hat{\theta} = \hat{\theta}(y_1, \ldots, y_n)$ be the estimator of θ based on the observation y.

37.1.1 Invariance under Reparameterization

Suppose θ is a scale parameter and that $h(\theta)$ is a strictly monotonic function in the parameter space of θ. Then the new reparameterized statistical model is based on $(Y_1, \ldots, Y_n)$ and the parameter $\xi = h(\theta)$. Suppose that an estimation procedure gives $\hat{\theta}$ as the estimator of θ based on $(Y_1, \ldots, Y_n)$ and parameter θ, and $\hat{\xi}$ as the

estimator of ξ based on $(Y_1, \ldots, Y_n)$ and parameter ξ respectively. This procedure is said to be *invariant* under reparameterization if $\hat{\xi} = h(\hat{\theta})$. It is well known that the maximum likelihood procedure is invariant under reparameterization. But the moment estimation procedure is usually not invariant under reparameterization. A confidence interval procedure is *invariant* under reparameterization, if $[\hat{\theta}(\alpha/2), \hat{\theta}(1-\alpha/2)]$ is the $1-\alpha$ level confidence interval of θ based on this procedure, and $[h(\hat{\theta}[\alpha/2]), h(\hat{\theta}[1-\alpha/2])]$ is the $1-\alpha$ level confidence interval of ξ based on this procedure. Here we assume that $h(\theta)$ is a strictly increasing function. When a procedure is not invariant under reparameterization, it is usually very important to select a good transformation and perform statistical inference after transformation. This has been a topic of research in classical statistics.

37.1.2 Automatic Computation

One of the most important advantages of the bootstrap method is its automatic computation; in other words it does not depend on theoretical calculation. A procedure is called an "automatic computation" if it does not depend on any extra analytical inference. In many applications, it is very difficult (sometimes impossible) to perform analytical calculations.

37.1.3 First and Higher Order Accuracy

Suppose that θ is a scale parameter and that $\hat{\theta}[\alpha]$ is the α confidence limit of θ, based on a certain procedure. Then the procedure is said to be *first-order accurate* if $P\big(\theta < \hat{\theta}[\alpha]\big) = \alpha + O(n^{-1/2})$. It is *second-order-accurate* if $P\big(\theta < \hat{\theta}[\alpha]\big) = \alpha + O(n^{-1})$. Higher order accuracy is defined in the same way. It is well known that the standard confidence interval,

$$\left[\hat{\theta} - \hat{\sigma} z_{(\alpha/2)}\,,\ \hat{\theta} + \hat{\sigma} z_{(\alpha/2)}\right],$$

is only first-order-accurate under some conditions. Here $z_{(\alpha/2)}$ is defined by $P(Z \geq z_{(\alpha)}) = \alpha$ for a standard normal random variable Z, while $\hat{\sigma}$ is an estimator of the standard deviation of $\hat{\theta}$. One advantage of using the bootstrap method is getting confidence intervals that are accurate to the second order.

In Sect. 37.2 we will introduce Efron's bootstrap for iid samples. To construct a second-order-accurate confidence interval, four different bootstrap methods are reviewed and discussed in terms of the three properties described above. We then consider three bootstrap methods for a linear model and discuss their properties.

In some more complex situations, the observations could be heteroscedastic; in other words the variances of Y_i are different. It is important to have a bootstrap procedure that remains consistent under heteroscedasticity. When θ is a high-dimensional vector it is usually more difficult to apply a bootstrap procedure because it is: (i) computational intensive; (ii) difficult to construct a good confidence region. For high dimension problems, it is often important to have reliable computational results. Some new bootstrap methods have been proposed for these complex situations.

The main propose of this chapter is to introduce some recent developments in bootstrap methodology. We consider two bootstrap methods. The first is the estimating function (EF) bootstrap proposed in *Hu* and *Kalbfleisch* [37.1]. Instead of resampling the data itself, the EF bootstrap resamples some functions of the data in order to achieve robustness to heteroscedasticity. This EF bootstrap is often the simplest computationally and it is straightforward to define studentized versions of the EF bootstrap which are invariant under reparameterization and require very little additional calculation. This method can be used to get confidence regions that are accurate to higher orders for multidimensional parameters. When the estimating function is differentiable, it can be easily extended to deal with nuisance parameter problems. Another method is called the Markov chain marginal bootstrap (MCMB), which is useful for constructing confidence intervals or regions for high dimension parameters. The MCMB is different from most bootstrap methods in two aspects: first, it solves only one-dimensional equations for a problem with any number of dimensions; second, it produces a Markov chain rather than a (conditionally) independent sequence.

In Sect. 37.3, we introduce the EF bootstrap and discuss the properties of the EF bootstrap. Some examples are used to illustrate the procedure. The Markov chain marginal bootstrap method is introduced in Sect. 37.4. In Sect. 37.5, we use the simple linear model to illustrate the MCMB algorithm and its properties. We also apply the EF bootstrap and MCMB method to different examples. In Sect. 37.6, we discuss some issues with using bootstrap methods.

37.2 Classical Bootstrap

37.2.1 Efron's Bootstrap

To start, let's consider the simplest case. Assume that $Y_1, \ldots, Y_n$ is a random sample from some unknown distribution F. Let $y = (y_1, \ldots, y_n)$ be the realization of Y. Suppose that $\theta = \theta(F)$ is the unknown parameter (scale) of interest. This θ could be the mean, the variance, or some other function of the distribution F. Let $\hat{\theta} = \hat{\theta}(y_1, \ldots, y_n)$ be the estimator of θ based on the observation y.

The main statistical goal is to find the distribution of $\hat{\theta} - \theta$. If we know this distribution, then we can do all kinds of statistical inference, (including deriving standard deviations and confidence intervals). Before Efron's bootstrap paper [37.2], researchers focused on finding the exact distribution or asymptotical distribution based on different theoretical approaches. Most of these methods depended on certain assumptions for the distribution F.

Efron's basic idea was to use computer simulation to investigate the distribution of $\hat{\theta} - \theta$. If F is a given (known) distribution, then we can use Monte Carlo simulation to get the distribution of $\hat{\theta} - \theta$. When F is unknown, the best nonparametric estimator of F is the empirical distribution, $\hat{F}$, which gives a weight of $1/n$ to each y_i. The bootstrap procedure can be summarized as follows:

- [i.] Draw a bootstrap sample $z_1^*, \ldots, z_n^*$ from distribution $\hat{F}$, which is the same as drawing $z_1^*, \ldots, z_n^*$ from $(y_1, \ldots, y_n)$ with replacement;
- [ii.] Calculate the bootstrap estimator $\hat{\theta}^* = \hat{\theta}(z_1^*, \ldots, z_n^*)$;
- [iii.] Repeat steps (i) and (ii) B (the bootstrap sample size) times to get $\hat{\theta}_1^*, \ldots, \hat{\theta}_B^*$. Now we define the empirical distribution:

$$\hat{G}(x) = B^{-1} \sum_{i=1}^{n} I(\hat{\theta}_i^* \le x) .$$

  Where $I(\cdot)$ is the indication function.
- [iv.] Use the empirical distribution of $\hat{\theta}^* - \hat{\theta}$ to approximate the distribution of $\hat{\theta} - \theta$.

In early work, the bootstrap estimators described above were used to estimate the bias of the estimator $\hat{\theta}$ [37.2, 3]. However, the main contribution of the bootstrap method is to provide a new way to assess the accuracy of the estimator $\hat{\theta}$. Here we discuss two main applications: (i) estimating the standard deviation of $\hat{\theta}$, and (ii) estimating the confidence interval of θ.

Standard Deviation

A commonly used measure of the accuracy of $\hat{\theta}$ is the standard deviation of $\hat{\theta}$. Based on the bootstrap estimators, we can easily calculate the bootstrap variance estimator as:

$$\hat{\sigma}^* = \left[(B-1)^{-1} \sum_{j=1}^{B} \left(\hat{\theta}_j^* - \bar{\theta}^* \right)^2 \right]^{1/2} ,$$

where $\bar{\theta}^* = B^{-1} \sum_{j=1}^{B} \hat{\theta}_j^*$. Under very general conditions, this is a consistent estimator of the true standard deviation [37.3]. The advantage of this bootstrap standard deviation, $\hat{\sigma}^*$, is that it does not depend on analytical inference. Instead, we can get it by computer simulation. When $\hat{\sigma}$ is not available, this $\hat{\sigma}^*$ can be used as the estimator of the standard deviation of $\hat{\theta}$.

Based on $\hat{\sigma}^*$, we can construct an approximate confidence interval for the unknown parameter θ as

$$\left[\hat{\theta} - \hat{\sigma}^* z_{(\alpha/2)} , \hat{\theta} + \hat{\sigma}^* z_{(\alpha/2)} \right] .$$

While this confidence interval conforms to "automatic computation", it is not "invariant under reparameterization", and is only first-order-accurate.

Confidence Interval

First we consider the following two distributions: (i) the distribution of the estimator $\hat{\theta}$,

$$H(t) = P\left[n^{-1/2} \left(\hat{\theta} - \theta \right) \le t \right] ;$$

and the corresponding distribution of the bootstrap estimator $\hat{\theta}^*$,

$$\hat{H}(t) = P\left[n^{-1/2} \left(\hat{\theta}^* - \hat{\theta} \right) \le t \right] .$$

Under certain conditions, it can be shown that [37.4]

$$\max_{t \in [-\infty, \infty]} |H(t) - \hat{H}(t)| = O_p\left(n^{1/2} \right) .$$

By using the distribution of $\hat{\theta}^* - \hat{\theta}$ to approximate the distribution of $\hat{\theta} - \theta$, we can construct the level $1 - \alpha$ confidence interval of θ as

$$\left[2\hat{\theta} - \hat{\theta}^*(1 - \alpha/2), 2\hat{\theta} - \hat{\theta}^*(\alpha/2) \right] ,$$

where $\hat{\theta}^*(\alpha)$ is the αth quantile of the bootstrap distribution $\hat{G}$. This confidence interval is also obtained via

"automatic computation", but it is not "invariant under reparameterization", and is only first-order-accurate.

Another way to construct the confidence interval is by using the distribution of $\hat{\theta}^*$ directly. The confidence interval is defined as

$$\left[\hat{\theta}^*(\alpha/2), \hat{\theta}^*(1-\alpha/2)\right] .$$

This interval is obtained via "automatic computation" and is "invariant under reparameterization", but is only first-order-accurate.

37.2.2 Second-Order-Accurate Confidence Intervals

One of the problems that has been studied the most in bootstrap literature is how to construct higher accurate bootstrap confidence intervals; see for example [37.5–8]. Here we review four commonly used methods: (i) studentized bootstrap interval; (ii) bias-corrected and accelerated method (BC_a method); (iii) approximated bootstrap confidence (ABC) interval; and (iv) prepivoting bootstrap interval. The advantages and disadvantages of these four methods are also discussed.

Studentized Bootstrap Interval

Instead of considering $n^{1/2}\left(\hat{\theta}-\theta\right)$ directly, we use the studentized statistic

$$T = \frac{n^{1/2}(\hat{\theta}-\theta)}{\hat{\sigma}(y_1, \ldots, y_n)} ,$$

where $\hat{\sigma}^2 = \hat{\sigma}^2(y_1, \ldots, y_n)$ is an estimate of the asymptotic variance $\mathrm{Var}\left(n^{1/2}\hat{\theta}\right)$. The corresponding bootstrap studentized statistic is then

$$T^* = \frac{n^{1/2}\left(\hat{\theta}^*-\hat{\theta}\right)}{\hat{\sigma}^*(z_1^*, \ldots, z_n^*)} .$$

A large number (B, say) of independent replications give the following estimated percentiles:

$$\hat{T}^{(\alpha)} = \alpha_{th} \text{ quantile of } (T^*(b), b = 1, \ldots, B) .$$

The $100\alpha_{th}$ bootstrap-t confidence endpoint $\hat{\theta}_T[\alpha]$ is then defined to be

$$\hat{\theta}_T[\alpha] = \hat{\theta} - \hat{\sigma}\hat{T}^{(1-\alpha)} .$$

Based on Edgeworth expansions of the statistics T and T^*, *Hall* [37.9] showed that

$$P(T < v) - P(T^* < v) = O_p(n^{-1}) ,$$

where the second probability is under the bootstrap distribution, so the bootstrap-t intervals are usually second-order-accurate. The advantage of this studentized bootstrap is that it is intuitive and easy to understand.

But this method is not "automatic computation"; it depends on the existence of a reliable estimator of the standard deviation, $\hat{\sigma}(y_1, \ldots, y_n)$. In a lot of applications, this may not be available. Secondly, as pointed in [37.8], even with a reliable estimator of the standard deviation, the studentized bootstrap algorithm can be numerically unstable, resulting in very long confidence intervals. Third, the studentized bootstrap intervals are not "invariant under reparameterization".

BC_a Interval

The distribution of $\hat{\theta}^*$ is usually not symmetric but instead skewed to one side. The BC_a ("bias-corrected and accelerated") intervals were studied in [37.5–8] based on the bootstrap distribution. The BC_a intervals depend on two numerical parameters: a bias-correction parameter z_0 and an acceleration a. The upper endpoint $\hat{\theta}_{BC_a}[\alpha]$ of a one-sided level-α BC_a interval is defined as

$$\hat{\theta}_{BC_a}[\alpha] = \hat{G}^{-1}\left[\Psi\left(z_0 + \frac{z_0 + z^\alpha}{1 - a(z_0 + z^\alpha)}\right)\right] ,$$

where $\hat{G}$ is the empirical distribution function of the bootstrap samples, and Ψ is the standard normal cdf with $z^\alpha = \Psi^{-1}(\alpha)$.

The bias-correction parameter z_0 is usually estimated from the bootstrap sample as

$$\hat{z}_0 = \Psi^{-1}\left\{B^{-1}\sum_{b=1}^{B} I\left[\hat{\theta}^*(b) < \hat{\theta}\right]\right\} .$$

On the other hand, the acceleration parameter a is more subtle and cannot be estimated as directly from the bootstrap sample. *Di Ciccio* and *Efron* [37.8] presented several ways to estimate the acceleration parameter a. The second-order accuracy of the BC_a intervals is discussed in [37.8].

The BC_a intervals are "invariant under reparameterization". Under some conditions, the BC_a intervals are second-order-accurate. However, the BC_a intervals depend on the acceleration parameter a, which cannot be estimated directly from the bootstrap replications. The need to estimate a makes the BC_a method less intuitive to users. Therefore, the BC_a intervals are not obtained via "automatic computation".

ABC Method

The ABC method (short for "approximate bootstrap confidence" interval) is an analytic version of BC_a applied to smoothly defined parameters in exponential families. Instead of estimating z_0 using a bootstrap distribution as in the BC_a method, the ABC method estimates z_0 and the acceleration parameter a analytically. The ABC method requires one further estimate of a nonlinearity parameter. Based on these estimates, we can then construct ABC intervals. *DiCiccio* and *Efron* [37.8] provide the details of this ABC method, and they also show the second-order accuracy of this method. The ABC intervals are "invariant under reparameterization", but are not obtained via "automatic computation".

Prepivoting Method (Bootstrap Calibration)

Calibration is a bootstrap technique for getting confidence intervals accurate to higher orders. Concepts related to it have been proposed and studied in [37.9–12].

Suppose that $\hat{\theta}[\alpha]$ is the upper endpoint of a one-side level-α approximate confidence bound for parameter θ. Let

$$\gamma(\alpha) = P\left[\theta < \hat{\theta}(\alpha)\right]$$

be the calibration curve. If the approximation is perfect, then $\gamma(\alpha) = \alpha$ for any given α. Otherwise, we can use the calibration curve. For example, if $\gamma(0.03) = 0.025$ and $\gamma(0.96) = 0.975$, then we can use $\left(\hat{\theta}[0.03], \hat{\theta}[0.96]\right)$ instead of $\left(\hat{\theta}[0.025], \hat{\theta}[0.975]\right)$ as our approximate 0.95-level confidence interval.

In applications, we do not usually know the calibration curve $\gamma(\alpha)$. But we can use the bootstrap method to estimate $\gamma(\alpha)$ as follows:

$$\hat{\gamma}(\alpha) = P_*\left(\hat{\theta} < \hat{\theta}[\alpha]^*\right) ,$$

where P_* indicates the bootstrap sample and $\hat{\theta}[\alpha]^*$ is the upper α bound based on the bootstrap sample.

We can use bootstrap calibration asymptotically to obtain a higher order confidence interval from a given system of confidence intervals. Therefore, it can be applied to all of the methods reviewed in this chapter. For example, we can use bootstrap calibration to obtain third-order-accurate confidence intervals from studentized bootstrap intervals. However, bootstrap calibration involves more computation. For example, if we use $B = 1000$ (bootstrap sample size), then the bootstrap calibration will require 1 000 000 recomputations of the original statistic $\hat{\theta}$. In practice, the sample size n is usually not very large, so we can usually use one bootstrap calibration.

37.2.3 Linear Regression

The bootstraps discussed so far are based on iid samples, but in many applications this assumption does not hold. Consider the linear model

$$Y_i = \boldsymbol{x}_i\boldsymbol{\beta} + e_i ,$$

where $\boldsymbol{x}_i$ is a $k\times 1$ vector which may be a random or fixed variable. Here $\boldsymbol{\beta}$ is the $k\times 1$ parameter vector of interest, and $e_1, \ldots, e_n$ are uncorrelated errors with means of zero and variances of $\mathrm{Var}(e_i) = \sigma_i^2$, $i = 1, \ldots, n$, respectively. We assume that e_i and $\boldsymbol{x}_i$ are uncorrelated for all i when $\boldsymbol{x}_1, ..., \boldsymbol{x}_n$ are random. Let

$$\boldsymbol{Y} = (Y_1, \ldots, Y_n)^{\mathrm{T}} , \boldsymbol{e} = (e_1, \ldots, e_n)^{\mathrm{T}} ,$$
$$\text{and } \mathbf{X} = (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n)^{\mathrm{T}}$$

The least square estimator is then

$$\hat{\boldsymbol{\beta}} = \left(\mathbf{X}^{\mathrm{T}}\mathbf{X}\right)^{-1}\mathbf{X}^{\mathrm{T}}\boldsymbol{Y} .$$

Here $\mathbf{X}^{\mathrm{T}}\mathbf{X}$ is assumed to be nonsingular. Let $\boldsymbol{y} = (y_1, \ldots, y_n)$ denote the observed $\boldsymbol{Y}$.

When $e_1, \ldots, e_n$ are independent and identically distributed $\left(\sigma_i^2 = \sigma^2 \text{ for all } i\right)$, [37.2] proposed the following bootstrap method based on residuals. Let $r_i = y_i - \boldsymbol{x}_i^{\mathrm{T}}\hat{\boldsymbol{\beta}}$, $i = 1, \ldots, n$. We can treat $r_1, \ldots, r_n$ as observations of $e_1, \ldots, e_n$. We can resample $r_1^*, \ldots, r_n^*$ from $(r_1, \ldots, r_n)$ with replacement. Now define the bootstrap sample as

$$y_i^* = \boldsymbol{x}_i^{\mathrm{T}}\hat{\boldsymbol{\beta}} + r_i^* , i = 1, \ldots, n .$$

Let $\boldsymbol{Y}^* = (y_1^*, \ldots, y_n^*)^{\mathrm{T}}$. The corresponding bootstrap estimator is

$$\hat{\boldsymbol{\beta}}^* = \left(\mathbf{X}^{\mathrm{T}}\mathbf{X}\right)^{-1}\mathbf{X}^{\mathrm{T}}\boldsymbol{Y}^* .$$

Based on these bootstrap estimators, we can then apply the techniques in Sect. 37.2.1 and Sect. 37.2.2 to estimate the standard deviation of $\hat{\boldsymbol{\beta}}$ and the confidence intervals for $\boldsymbol{\beta}$. However, when $\boldsymbol{x}_i$ are random and the σ_i^2 values are not the same, Efron's bootstrap, which is based on resampling the residuals, does not provide a consistent result.

To deal with this heteroscedasticity, *Freedman* [37.13] suggests the following "Pair" bootstrap: resample $\left(\boldsymbol{x}_1^*, y_1^*\right), \ldots, \left(\boldsymbol{x}_n^*, y_n^*\right)$ from $(\boldsymbol{x}_1, y_1), \ldots, (\boldsymbol{x}_n, y_n)$ with replacement and compute the bootstrap least squares estimate

$$\hat{\boldsymbol{\beta}}^* = \left(\mathbf{X}^{*\mathrm{T}}\mathbf{X}^*\right)^{-1}\mathbf{X}^{*\mathrm{T}}\boldsymbol{Y}^* ,$$

where $\mathbf{X}^* = \left(\boldsymbol{x}_1^*, \ldots \boldsymbol{x}_n^*\right)^{\mathrm{T}}$ and $\boldsymbol{Y}^* = \left(y_1^*, \ldots, y_n^*\right)^{\mathrm{T}}$. This method is consistent for heteroscedastic errors.

Hu and *Zidek* [37.14] propose another bootstrap method based on the observation that the estimator $\hat{\boldsymbol{\beta}}$ can be rewritten as

$$\hat{\boldsymbol{\beta}} = \left(\mathbf{X}^{\mathrm{T}}\mathbf{X}\right)^{-1}\mathbf{X}^{\mathrm{T}}\boldsymbol{Y} = \left(\mathbf{X}^{\mathrm{T}}\mathbf{X}\right)^{-1}\sum_{i=1}^{n}\boldsymbol{x}_i y_i = \boldsymbol{\beta} + (\mathbf{X}^{\mathrm{T}}\mathbf{X})^{-1}\sum_{i=1}^{n}\boldsymbol{x}_i e_i \,.$$

If we treat $z_i = \boldsymbol{x}_i r_i$ $(i = 1, \ldots, n)$ as an estimate of $\boldsymbol{x}_i e_i$, it is natural to suggest that the bootstrap estimator is:

$$\hat{\boldsymbol{\beta}}^* = \hat{\boldsymbol{\beta}} + \left(\mathbf{X}^{\mathrm{T}}\mathbf{X}\right)^{-1}\sum_{i=1}^{n} z_i^* \,,$$

where $z_1^*, \ldots, z_n^*$ is the bootstrap sample, which is drawn from $(z_1, \ldots, z_n)$ with replacement. This bootstrap method is also consistent for heteroscedastic errors.

As pointed out in [37.14], the numerical result of Freedman's "pair" bootstrap can be unstable. This is because the design matrix $\mathbf{X}^*$ changes for each bootstrap sample. For the bootstrap method proposed by *Hu* and *Zidek* [37.14], the design matrix $\mathbf{X}$ maintains the sample for each bootstrap sample. This is very important for cases with a small sample size n. When we applied the studentized bootstrap to both methods with heteroscedastic errors, *Hu* and *Zidek's* bootstrap was found to be easy to extend and has substantial numerical advantages over the "pair" bootstrap [37.14].

37.2.4 Some Remarks

We have discussed four second-order-accurate bootstrap methods. These methods are mainly useful for simple situations. However, resample methods are often needed in complex situations, such as nonlinear estimators and models with high-dimensional parameters. In these situations, there are clearly several difficulties that are encountered when using the traditional bootstraps: (i) it is difficult to derive an estimate for the acceleration parameter for the $\mathrm{BC_a}$ and ABC methods; (ii) for models with high-dimensional parameters, it is difficult to apply the studentized bootstrap and the prepivoting method; (iii) models with high-dimensional parameters are computationally intensive; (iv) the bootstrap sample may be quite different from the original sample which may produce unstable results.

In the following two sections, we will describe two recent proposals intended for complex models. The estimating function (EF) bootstrap is designed for estimates obtained from estimating equations. We show that the studentized estimating function bootstrap has the three desired properties. The Markov chain marginal bootstrap (MCMB) is mainly used to reduce computation in models with high-dimensional parameters.

37.3 Bootstrap Based on Estimating Equations

The traditional bootstrap methods based involve resampling the original data over and over again. Typically, the estimator is obtained from some estimating equation (*Godambe* and *Kale* [37.15]). The estimating function (EF) bootstrap proposed by [37.1, 14, 16] emphasizes the estimating function and the equation from which the estimator is obtained.

Following the same notations used by *Hu* and *Kalbfleisch* [37.1], let $\boldsymbol{y}_1, \ldots, \boldsymbol{y}_n$ be a sequence of independent random vectors of dimension q, and $\boldsymbol{\theta} \in \Omega \subset \mathbb{R}^p$ be an unknown parameter vector. For specified functions $\{\boldsymbol{g}_i\} : R^q \to R^p$, suppose that $E[\boldsymbol{g}_i(\boldsymbol{y}_i, \boldsymbol{\theta})] = 0$ for all $i = 1, \ldots, n$ and $\boldsymbol{\theta} \in \Omega$. We suppose that $\hat{\theta}$ is the solution of the following *unbiased linear estimating equation*

$$\boldsymbol{S}(\boldsymbol{y}, \boldsymbol{\theta}) = n^{-1/2}\sum \boldsymbol{g}_i(\boldsymbol{y}_i, \boldsymbol{\theta}) = 0 \,. \tag{37.1}$$

Here the normalizing constant $\left(n^{-1/2}\right)$ is chosen for the convenience of expressing asymptotic results. For simplicity, we also assume that $\boldsymbol{S}(\boldsymbol{y}, \boldsymbol{\theta})$ is a $1:1$ function of $\boldsymbol{\theta}$ and our main consideration will be the construction of confidence regions for the whole parameter vector $\boldsymbol{\theta}$, or for components or some functions of $\boldsymbol{\theta}$.

When the random vector $\boldsymbol{S}(\boldsymbol{y}, \boldsymbol{\theta})$ is exactly pivotal [37.17, 18], we can use exact methods to obtain confidence intervals or regions. However, in most cases, $\boldsymbol{S}(\boldsymbol{y}, \boldsymbol{\theta})$ is only approximately pivotal and we rely on asymptotic normality and χ^2 approximations to obtain the confidence intervals or regions of $\boldsymbol{\theta}$. Here we propose to use resampling methods to approximate the distribution of $\boldsymbol{S}(\boldsymbol{y}, \boldsymbol{\theta})$.

37.3.1 EF Bootstrap and Studentized EF Bootstrap

The EF Bootstrap

Let $\boldsymbol{z}_i = \boldsymbol{g}_i\left(\boldsymbol{y}_i, \hat{\theta}\right)$.

1. Draw a bootstrap sample $(z_1^*, \ldots, z_n^*)$ from $(z_1, \ldots, z_n)$ with replacement.
2. Compute $S^* = n^{-1/2} \sum z_i^*$. The bootstrap distribution of S^* can be used to approximate the distribution of $S(y, \theta)$.
3. Compute θ^* by solving $S(y, \theta) = S^*$.

The EF bootstrap generates a bootstrap sequence θ_j^* $(j = 1, \ldots, B$ where B is the bootstrap sample size) by repeating the above process B times. Based on θ_j^* $(j = 1, \ldots, B)$, we can then construct confidence regions of the parameter of interest (some functions of θ). Like Efron's bootstrap, this usually produces confidence intervals that are accurate only to the first order. *Hu* and *Kalbfleisch* [37.16] proposed one type of studentization. This studentization gives an approximation to second-order accuracy, but it is not invariant under reparameterization.

Here we introduce the studentized EF bootstrap proposed in [37.1]. We define

$$\mathbf{V}(y, \theta) = n^{-1} \sum [g_i(y_i, \theta) - \bar{g}][g_i(y_i, \theta) - \bar{g}]^{\mathrm{T}} , \tag{37.2}$$

where $\bar{g} = n^{-1} \sum g_i(y_i, \theta)$. In practice, we use the variance estimate

$$\hat{\mathbf{V}} = \mathbf{V}(y, \hat{\theta}) . \tag{37.3}$$

Instead of approximating the distribution of $S(y, \theta)$, we use a bootstrap method to approximate the distribution of

$$S_t(y, \theta) = \mathbf{V}(y, \theta)^{-1/2} S(y, \theta) . \tag{37.4}$$

In most cases, $S_t(y, \theta)$ is a better approximated pivotal.

Studentized EF Bootstrap

First we obtain $(z_1^*, \ldots, z_n^*)$ as in the EF bootstrap; compute

$$S_t^* = \mathbf{V}^{*-1/2} S^* ,$$

where $\mathbf{V}^* = n^{-1} \sum \left(z_i^* - \bar{z}^*\right)\left(z_i^* - \bar{z}^*\right)^{\mathrm{T}}$ and $\bar{z}^* = n^{-1} \sum z_i^*$, and finally solve

$$S_t(y, \theta) = S_t^* .$$

Under fairly general conditions [37.1], the studentized EF bootstrap is second-order-accurate and also invariant under reparameterization. The simplicity of its computation is discussed in the following two subsections.

37.3.2 The Case of a Single Parameter

When the parameter θ is a scalar and $S(y, \theta)$ is a monotonic function of θ, confidence intervals for θ based on the EF bootstrap are obtained as follows. For any specified α, we can find $S_{(\alpha)}^*$, the αth quantile of the bootstrap distribution of S^*. The two-sided interval $\left(\theta_{(\alpha/2)}^*, \theta_{(1-\alpha/2)}^*\right)$ obtained from

$$S\left(y, \theta_{(\alpha/2)}^*\right) = S_{(\alpha/2)}^*$$
$$\text{and} \quad S\left(y, \theta_{(1-\alpha/2)}^*\right) = S_{(1-\alpha/2)}^* ,$$

is the $100(1-\alpha)\%$ EF bootstrap confidence interval for θ. To obtain this interval, the equation $S(y, \theta) = S^*$ needs to be solved at only two points.

We can obtain higher order accuracy by using the studentized version based on (37.4). To do this, let $S_{t(\alpha)}^*$ be the αth quantile of the distribution of S_t^*. If $S_t(y, \theta)$ is monotonic in θ, then the equation $S_t(y, \theta) = S_{t(\alpha)}^*$ yields an endpoint for the interval. The confidence intervals obtained using the studentized EF bootstrap are usually second-order-accurate, and their performances are comparable to those of the $\mathrm{BC_a}$ and ABC methods [37.1].

From this simple model, we can see that the EF bootstrap has several advantages over Efron's bootstrap: (i) it is often computationally simpler, because we just have to solve the equation at two points; (ii) the studentized EF bootstrap is straightforward, while the classical studentized bootstrap requires a stable estimate of the variance; (iii) the studentized statistic $S_t(y, \theta)$ is invariant under reparameterization, as are the confidence intervals or regions based on studentized EF bootstrap. By contrast, the EF bootstrap is not invariant and it is usually first-order-accurate.

37.3.3 The Multiparameter Case

For a p-dimensional vector parameter θ, we use the approximate pivotal

$$\begin{aligned} Q(y, \theta) &= S(y, \theta)^{\mathrm{T}} \mathbf{V}(y, \theta)^{-1} S(y, \theta) \\ &= S_t(y, \theta)^{\mathrm{T}} S_t(y, \theta) . \end{aligned} \tag{37.5}$$

The distribution of $Q(y, \theta)$ can be approximated by the bootstrap distribution of

$$Q^* = S^{*\mathrm{T}} \mathbf{V}^{*-1} S^{*\mathrm{T}} = S_t^{*\mathrm{T}} S_t^*$$

using the calculations described in Sect. 37.3.1.

We define q^*_α to be the αth quantile of Q^*, which is determined by $P^*(Q^* > q^*_\alpha) = \alpha$. An approximate $100(1-\alpha)\%$ confidence region for $\boldsymbol{\theta}$ is then given by

$$C_{1-\alpha}(y) = \{\boldsymbol{\theta} : Q(y, \theta) \le q^*_\alpha\} . \tag{37.6}$$

This is based on the approximation

$$\begin{aligned} P[\boldsymbol{\theta} \in C_{1-\alpha}(y)] &= P[Q(\boldsymbol{y}, \boldsymbol{\theta}) \le q_\alpha] \\ &\approx P^*(Q^* \le q_\alpha) = 1-\alpha . \end{aligned} \tag{37.7}$$

Hu and *Kalbfleisch* [37.1] show that the confidence region in (37.7) is accurate up to order $O_p\left(n^{-3/2}\right)$. This improves on the usual χ^2 approximation, which is accurate up to order $O_p\left(n^{-1}\right)$. To construct the confidence region for a given confidence coefficient $1-\alpha$, one only needs to solve (37.6) for the relevant contour. This method is invariant under reparameterization.

The above approach does not generally work for inference on components or functions of $\boldsymbol{\theta}$. When $\boldsymbol{S}(\boldsymbol{y}, \boldsymbol{\theta})$ is a differentiable function of $\boldsymbol{\theta}$, *Hu* and *Kalbfleisch* [37.1] proposed a simple method based on some projections. However, the proposed method is usually accurate up to order $O_p\left(n^{-1}\right)$, and it is not invariant under reparameterization. When $\boldsymbol{S}(\boldsymbol{y}, \boldsymbol{\theta})$ is not differentiable, one needs to use the Markov chain marginal bootstrap (MCMB) proposed by *He* and *Hu* [37.19], which is introduced in Sect. 37.4.

37.3.4 Some Examples

Example 1. Estimating the population mean. Observations $y_1, \ldots, y_n$ are made on independent and identically distributed random variables, each with an unspecified distribution function, F. Interest focuses on the mean, μ, of F which is estimated with $\hat{\mu} = \bar{y}$. In the usual classical bootstrap (Efron's bootstrap), we (i) draw the bootstrap sample $\{y^*_1, \ldots, y^*_n\}$ from $\{y_1, \ldots, y_n\}$ and (ii) calculate the bootstrap sample mean $\hat{\mu}^*_C = n^{-1} \sum y^*_i$. These steps are repeated and the empirical distribution of the $\left(\hat{\mu}^*_C - \hat{\mu}\right)$ is the bootstrap approximation to the sampling distribution of $\hat{\mu} - \mu$.

In contrast, the EF bootstrap begins with the estimating equation $\sum(y_i - \mu) = 0$, whose solution is $\hat{\mu} = \bar{y}$. The component functions $y_i - \mu$ are estimated with $z_i = y_i - \bar{y}$, $i = 1, \ldots, n$. The method proceeds as follows: (i) draw a bootstrap sample $\{z^*_1, \ldots, z^*_n\}$ from $\{z_1, \ldots, z_n\}$; (ii) calculate $S^* = n^{-1/2} \sum z^*_i$. The bootstrap distribution of S^* approximates the sampling distribution of $S(\boldsymbol{y}, \mu) = \sqrt{n}(\hat{\mu} - \mu)$. Note that if μ^* is the solution to $S(\boldsymbol{y}, \mu) = S^*$, the bootstrap distribution of $\mu^* - \hat{\mu}$ approximates the distribution of $\mu - \hat{\mu}$.

The difference between the methods is evident, even though they give, in the end, identical results. With the classical bootstrap, $\hat{\mu}^*_C - \hat{\mu}$ approximates $\hat{\mu} - \mu$, whereas in the EF procedure, $\mu^* - \hat{\mu}$ approximates $\mu - \hat{\mu}$. As a consequence, μ^* is "bias corrected". The comparison between the studentized versions is similar.

Example 2. Common mean with known and unknown variances. Suppose that $y_1, \ldots, y_n$ are from populations with $Ey_i = \mu$ and $var(y_i) = \sigma^2_i$. When σ^2_i are known, the estimating equation,

$$\sum \frac{y_i - \mu}{\sigma^2_i} = 0$$

gives rise to the weighted least squares estimator,

$$\hat{\mu} = \left(\sum y_i/\sigma^2_i\right) / \left(\sum 1/\sigma^2_i\right) .$$

The EF and classical bootstraps can be applied to this problem in a straightforward way. (As noted above, the classical bootstrap is equivalent to the classical procedure of resampling $(y_i, \sigma_i), i = 1, \ldots, n$.) *Hu* and *Kalbfleisch* [37.16] compare the EF bootstrap with the classical bootstrap and the asymptotic normal approximation assuming normal and uniform errors. All methods do reasonably well, though the studentized versions of the EF and classical bootstraps do somewhat better than the other methods with abnormal errors.

Suppose there are k independent strata and in the ith stratum $y_{ij} \sim N\left(\mu, \sigma^2_i\right)$, $j = 1, \ldots, n_i$ independently, where $n_i \ge 3$ and $i = 1, \ldots, k$. The variances σ^2_i are unknown and interest centers on the estimation of μ. This problem has received much attention in the literature [37.20–24] [Bartlett (1936), Neyman and Scott (1948), Kalbfleisch and Sprott (1970), Barndorff-Nielsen (1983). *Neyman* and *Scott* (1948) showed that the maximum likelihood estimator can be inefficient. They (and many others) proposed the estimating equation

$$\sum_{i=1}^{k} \frac{n_i(n_i - 2)(\bar{y}_i - \mu)}{T_i(\mu)} = 0 ,$$

where $T_i(\mu) = \sum_{j=1}^{n_i}(y_{ij} - \mu)^2$ and $\bar{y}_i = \sum_{j=1}^{n_i} y_{ij}/n_i$. More generally, we could relax the condition of normal errors and still use the above equation to estimate μ.

When the number of strata k is large and the individual n_i's are small, usual inferential techniques can cause substantial difficulty. This is the case considered here, although other situations are also of interest and will be discussed elsewhere.

Let $y_i = (y_{i1}, \ldots, y_{in_i})$ and $g_i(y_i, \mu) = n_i(n_i - 2)(\bar{y}_i - \mu)/T_i(\mu)$. The estimating equation can therefore be rewritten as

$$\sum_{i=1}^{k} g_i(y_i, \mu) = 0 ,$$

and the EF bootstrap can now be applied in a straightforward manner.

37.4 Markov Chain Marginal Bootstrap

For statistical models with high-dimensional parameters, it is usually difficult to apply the bootstrap method because it is computationally intensive. For example, if one needs one minute to obtain the estimator, then one needs 1000 min to apply the bootstrap method to a sample of size $B = 1000$. To reduce the computational complexity of applying common bootstrap methods to high-dimensional parameters, *He* and *Hu* [37.19] propose the Markov chain marginal bootstrap (MCMB). In this section, we only review the MCMB for M-estimators of a linear model. Please see [37.19] for more general models and estimators.

Consider the linear regression problem $Y_i = \boldsymbol{x}_i'\boldsymbol{\beta} + e_i$, $(i = 1, \cdots, n)$ with independently and identically distributed errors e_i. An M-estimator, $\hat{\boldsymbol{\beta}}$, solves

$$n^{-1} \sum_{i=1}^{n} \psi\left(Y_i - \boldsymbol{x}_i'\boldsymbol{\beta}\right) \boldsymbol{x}_i = 0 \qquad (37.8)$$

for a score function ψ. In most applications, the function ψ is bounded and continuous. An important exception is the least absolute deviation estimator with $\psi(r) = \mathrm{sgn}(r)$. In this case, the equation (37.8) may not be solved exactly, but minimizing $\sum_{i=1}^{n} |Y_i - \boldsymbol{x}_i'\boldsymbol{\beta}|$ over $\boldsymbol{\beta} \in \mathbb{R}^p$ guarantees a solution so that (37.8) holds approximately.

Under some suitable conditions [37.25], the estimator $\hat{\boldsymbol{\beta}}$ is consistent and asymptotically normal,

$$n^{1/2}\left(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}\right) \to N\left(0, \left\{E\psi^2(e)/[E\psi'(e)]^2\right\}\left(\mathbf{X}'\mathbf{X}\right)^{-1}\right) ,$$

where $\mathbf{X}$ is the design matrix. A direct estimate of the variance does not always produce reliable confidence levels for inference. This is because it is difficult to estimate the constant $\left[E\psi'(e)\right]^2$ in a lot of cases.

For example, consider the minimum L_d-norm estimator that minimizes $\sum_{i=1}^{n} |y_i - \boldsymbol{x}_i'\boldsymbol{\beta}|^d$ $(d = 1.5)$. In this case, $E\psi'(e) = 0.5E|e|^{-0.5}$. One needs to estimate the constant $E|e|^{-0.5}$ to construct a confidence interval based on the asymptotic variance. A natural estimator is the average of n absolute residuals $r_i = y_i - \boldsymbol{x}_i'\hat{\beta}_n$. When $n = 20$ and e has a standard normal distribution and the residuals resemble a random sample drawn from it, then a simple simulation shows that the average of $|r_i|^{-0.5}$ has a mean of 1.71 and standard error of 0.80. When one or a few residuals are very close to 0, the estimate could be very large. Therefore, the confidence intervals constructed from this estimated asymptotic variance would be poor.

To avoid estimating the asymptotic variance directly, one can use the usual bootstrap methods (residual bootstrap or pair-wise bootstrap). In this case, a p-dimensional nonlinear system has to be solved for each bootstrap sample. This can become a computational burden for large p. Also, the pair-wise bootstrap can be numerical unstable, because the design matrix changes for each bootstrap sample. The EF bootstrap or studentized EF bootstrap is often more stable because it uses all of the design points in each resample, but its computational complexity is no less than that of the usual bootstrap methods. When ψ is differentiable, one can solve the computational problem using projection [37.1]. However, ψ is not differentiable in a lot of cases.

MCMB overcomes the computational complexity by breaking up the p-dimensional system into p marginal (one-dimensional) equations. The algorithm proceeds as follows. Let subscript β_j be the jth component of $\boldsymbol{\beta}$ and subscript $\boldsymbol{\beta}^{(k)}$ be the kth iteration of the algorithm. Suppose that $\hat{\boldsymbol{\beta}}$ is the estimate from (37.8) and $r_i = y_i - \boldsymbol{x}_i\hat{\boldsymbol{\beta}}$ are the residuals. Let $z_i = \psi(r_i)\boldsymbol{x}_i$ be the scores. The jth component of z_i will be denoted by z_{ij} $(i = 1, \ldots, n$ and $j = 1, \ldots, p)$. For the kth iteration with $k = 0, 1, \ldots$, we perform

1. For the jth component, we resample $\left\{z_{ij}^*, i = 1, \ldots, n\right\}$ from $\left\{z_{ij}, i = 1, \ldots, n\right\}$ without replacement.

2. Let $s_j^{(k)} = \sum_{i=1}^n z_{ij}^*$ and solve $\beta_j^{(k)}$ from

$$\sum_i^n \psi(y_i - \sum_{l=1}^{j-1} x_{il}\beta_l^{(k)} - x_{ij}\beta_j - \sum_{l=j+1}^{n} x_{il}\beta_l^{(k-1)})x_{ij} = s_j^{(k)} . \quad (37.9)$$

These two steps are performed for $j = 1, \ldots, p$.

This algorithm yields a sequence $\boldsymbol{\beta}^{(0)} = \hat{\boldsymbol{\beta}}$, $\boldsymbol{\beta}^{(1)}, \ldots \boldsymbol{\beta}^{(k)}, \ldots$. It is clearly a Markov chain. This method is called the Markov chain marginal bootstrap (MCMB), since a resampling process (bootstrap) is used with each marginal equation (37.9). In fact, the MCMB shares two properties with MCMC. That is, both methodologies aim to break up a high-dimensional problem into several one-dimensional ones, and both yield Markov chains as products. However, we must note that MCMB does not use any MCMC algorithm, and it is not derived from the MCMC framework.

Now we explain why the MCMB method reduces the computational complexity of the usual bootstrap method. To generate an additional variate $\beta_j^{(k)}$, one needs to resample and solve a one-dimensional equation, both of which are of the complexity $O(n)$. For $\boldsymbol{\beta}^{(k)}$, the complexity is $O(np)$ for large n and p. However, common bootstrap methods have to solve a p-dimensional system. Even the simplest system (a linear system) requires of the order of $O(np^2)$ computations. Therefore, the MCMB method reduces the computational complexity for large p. Some other studies have been discussed in [37.19].

Like the EF bootstrap, the MCMB method has another advantage; that all of the design points are used in each iteration. This leads to more reliable numerical results, especially when there are leverage points present in the data, as compared to the pairwise bootstrap method that can suffer from poor bootstrap estimates when a leverage point is excluded or duplicated in a resample.

The MCMB method can be used for the maximum likelihood estimators from general parametric models. The asymptotic validity of the MCMB method for general parametric models has been given in [37.19]. The use of MCMB for general M-estimators (or GEE estimators) is explored in [37.26].

The MCMB is usually not invariant under reparameterization. *He* and *Hu* [37.19] also show that the MCMB is first-order-accurate. However, it is unknown whether MCMB is second-order-accurate. Future research is clearly needed to understand the MCMB method.

37.5 Applications

In this section, we will apply the above bootstraps to two examples. The first example is a simple linear model. We use this example to illustrate the MCMB algorithm and show why the MCMB bootstrap works. The second example involves a linear estimating equation from L_q estimation. For more discussions of these examples, please refer to [37.1, 19].

Example 1. Simple linear model. First, we consider a simple regression model with sample size n and $p = 2$. In this special case, we have

$$n^{-1/2}\sum_{i=1}^n \left(Y_i - \boldsymbol{x}_{i1}\hat{\beta}_1^{(k)} - \boldsymbol{x}_{i2}\hat{\beta}_2^{(k-1)}\right)\boldsymbol{x}_{i1} = d_1^{(k)}$$

and

$$n^{-1/2}\sum_{i=1}^n \left(Y_i - \boldsymbol{x}_{i1}\hat{\beta}_1^{(k)} - \boldsymbol{x}_{i2}\hat{\beta}_2^{(k)}\right)\boldsymbol{x}_{i2} = d_2^{(k)} ,$$

where $d_1^{(k)} = n^{-1/2}\sum_{i=1}^n x_{i1}e_{i1}^{*(k)}$ and $d_2^{(k)} = n^{-1/2} \times \sum_{i=1}^n \boldsymbol{x}_{i2}e_{i2}^{*(k)}$, and both $e_{i1}^{*(k)}$ and $e_{i2}^{*(k)}$ are drawn independently with replacement from $r_i = Y_i - \hat{\beta}_1\boldsymbol{x}_{i1} - \hat{\beta}_2\boldsymbol{x}_{i2}$ $(i = 1, \cdots, n)$, the residuals from the parameter estimate $(\hat{\beta}_1, \hat{\beta}_2)$. Now let $s_{11} = n^{-1}\sum_{i=1}^n \boldsymbol{x}_{i1}^2$, $s_{12} = n^{-1}\sum_{i=1}^n \boldsymbol{x}_{i1}\boldsymbol{x}_{i2}$ and $s_{22} = n^{-1}\sum_{i=1}^n \boldsymbol{x}_{i2}^2$. Then the two equations can be written as

$$s_{11}n^{1/2}\left(\hat{\beta}_1 - \hat{\beta}_1^{(k)}\right) = d_1^{(k)} - s_{12}n^{1/2}\left(\hat{\beta}_2 - \hat{\beta}_2^{(k-1)}\right) ,$$

$$s_{22}n^{1/2}\left(\hat{\beta}_2 - \hat{\beta}_2^{(k)}\right) = d_2^{(k)} - s_{12}n^{1/2}\left(\hat{\beta}_1 - \hat{\beta}_1^{(k)}\right) .$$

Note that the right hand sides of the above equations are sums of two independent variables, so by using variance–covariance operation and assuming that the covariance matrix of $n^{1/2}\left(\hat{\beta} - \hat{\beta}^{(k)}\right)$ stabilizes to $V = (v_{ij})_{2\times 2}$ as $k \to \infty$, we have

$$s_{11}^2 v_{11} = s_{11}\sigma^2 + s_{12}^2 v_{22} ,$$
$$s_{22}^2 v_{22} = s_{22}\sigma^2 + s_{12}^2 v_{11} ,$$
$$s_{22}v_{12} = -s_{12}v_{11} .$$

Using some simple calculations, we can show that $\mathbf{V} = \sigma^2[(s_{ij})_{2\times 2}]^{-1}$. That is, the bootstrap variance–

covariance of $n^{1/2}\left(\hat{\boldsymbol{\beta}}-\hat{\boldsymbol{\beta}}^{(k)}\right)$ stabilizes to the desired asymptotic covariance matrix for the least squares estimator.

Now we move to a real example about grade point prediction. The director of admissions of a small college administered a newly designed entrance test to eight students selected at random from the new freshman class in a study to determine whether a student's grade point average (GPA) at the end of the freshman year (Y) can be predicted from their entrance test score (x).

The eight pairs of scores were: (5.5, 3.1), (4.8, 2.3), (4.7, 3.0), (5.9, 3.8), (4.1, 2.2), (4.7, 1.5), (4.5, 3.0) and (5.3, 3.6). After we fit the linear regression, we get the estimated regression line

$$\hat{Y} = -1.646 + 0.903x\,.$$

The residuals are $r = (-0.22, -0.39, 0.53, 0.12, 0.14, -1.10, 0.57, 0.45)$. For the above MCMB algorithm, we have $n = 8$, $x_{i1} = 1$ for $i = 1, \ldots, 8$, $(x_{12}, \ldots, x_{82}) = (5.5, \ldots, 5.3)$. Then we can apply the MCMB algorithm to $k = 200$ to get the 95% confidence intervals: β_1: $[-5.526, 2.134]$ and β_2: [0.138,1.668]. In this example, it is very easy to calculate the confidence intervals from other methods, but we are just using it to show how MCMB can be applied. In this simple example, there is no advantage to using the MCMB method. As we mentioned earlier, the main advantage of the MCMB is that it works well for the following two cases: (i) high-dimensional parameters, and (ii) estimating equations that are not differentiable. More complete simulation studies can be found in [37.19].

Example 2. The L_q estimation. Consider a linear estimating equation in which $g_i(y_i, \theta)$ is not differentiable with respect to θ. Such situations are quite common in nonparametric and semiparametric models [37.27, 28] and in robust regression [37.25]. Estimating functions that are not differentiable can give rise to various difficulties. Classical statistical results do not apply in general, and other methods (bootstrap methods) for confidence interval estimation are needed.

We consider the general regression model

$$y_i = \beta_0 + \beta_1 x_{1i} + \beta_2 x_{2i} + e_i, i = 1, \ldots, n\,, \quad (37.10)$$

and suppose that β is to be estimated by minimizing

$$\sum_{i=1}^{n} |y_i - (\beta_0 + \beta_1 x_{1i} + \beta_2 x_{2i})|^{1.5}\,.$$

The corresponding estimating equation

$$\sum_{i=1}^{n} \operatorname{sgn}\left(y_i - \boldsymbol{x}_i^{\mathrm{T}}\beta\right)\, \boldsymbol{x}_i\, |y_i - \boldsymbol{x}_i^{\mathrm{T}}\boldsymbol{\beta}|^{1/2} = 0\,, \quad (37.11)$$

where $\boldsymbol{x}_i = (1, x_{1i}, x_{2i})^{\mathrm{T}}$ and $\boldsymbol{\beta} = (\beta_0, \beta_1, \beta_2)^{\mathrm{T}}$. The EF bootstrap procedure for estimating the whole parameter $\boldsymbol{\beta}$ or components of $\boldsymbol{\beta}$ can be applied to this problem in a straightforward manner.

Consider a fixed design where $n = 20$, $\boldsymbol{x}_1 = (1.27, -1.10, 2.19, 0.73, -0.07, 0.42, 0.37, 0.45, -0.78, 0.76, 0.44, 1.32, -0.40, 0.33, -0.40, 0.55, 0.51, -0.11, -1.15, 1.71)$, and $\boldsymbol{x}_2 = (1.60, 1.09, -0.02, -0.83, 3.05, 0.34, -0.87, 0.45, -0.78, 0.76, 0.44, 1.32, -0.40, 0.33, -1.85, 0.69, 0.11, 1.47, 0.87, 0.12)$, and y_i are generated from (37.10) with $\beta_0 = \beta_1 = \beta_2 = 1$.

For the whole parameter vector $\boldsymbol{\beta}$, the studentized estimating function bootstrap method can be used to obtain a highly accurate $O_p\left(n^{-3/2}\right)$ confidence region. Here we just report a result based on 1000 simulations. For each simulation, we can construct a 95% confidence region for $\boldsymbol{\beta}$. Of the 1000 confidence regions, 963 confidence regions cover the true parameter $\boldsymbol{\beta} = (1, 1, 1)$.

For single parameters, the estimating function bootstrap method depends on whether the estimating function is differentiable. In this example, the estimating function is not differentiable at the point 0, so we cannot use the simple method proposed by *Hu* and *Kalbfleisch* [37.1]. In this case, the MCMB method can be used to construct the confidence interval for each component of $\boldsymbol{\beta}$.

The average confidence interval in Table 37.1 is obtained by taking the averages of the two end points of the intervals over 500 cases. We consider three methods here. NORM represents the usual confidence interval

Table 37.1 Minimum L_q distance estimator ($q = 1.5$). Simulated coverage probabilities and average confidence intervals (fixed design)

	β_0		β_1		β_2	
MCMB	90.8	[0.56, 1.43]	89.0	[0.55, 1.46]	87.6	[0.66, 1.33]
NORM	76.8	[0.63, 1.35]	76.4	[0.62, 1.38]	75.6	[0.72, 1.29]
PAIR	88.0	[0.53, 1.43]	86.0	[0.52, 1.50]	86.2	[0.62, 1.38]

based on normal approximation. PAIR represents the paired bootstrap introduced in Sect. 37.2.

For each of the 500 samples there is an estimate of β_0, β_1 and β_2. Based on these estimators, we can calculate the standard deviations, and they are 0.24, 0.28 and 0.22 respectively. The confidence intervals, constructed from these estimators using the standard formula of the average plus or minus 1.64 times the SD, are [0.56,1.42], [0.55,1.48] and [0.66,1.34], respectively. We may use these three intervals as benchmarks for the other methods under consideration. It is clear from Table 37.1 that MCMB performed well.

37.6 Discussion

We have reviewed different bootstrap methods for independent observations. However, for a lot of applications, the observations may depend on each other. For stationary processes, several bootstrap procedures have been proposed, which include the block bootstrap and others. The estimating function bootstrap can also be extended to dependent observations. *Hu* and *Kalbfleisch* [37.29] considered linear and nonlinear autoregressive models.

One important application of bootstrap is in longitudinal data analysis. In this application, a generalized estimating equation (GEE) is usually available. Within each stratum (for each patient), the observations are dependent. But the observations are independent between stratums. The estimating function bootstrap can be applied as in the common mean problem in Sect. 37.3. However, some modifications are necessary to apply the classical bootstrap procedures.

Major problems with using bootstrap for high-dimensional parameters include that it is computationally intensive and can produce unreliable numerical results. The estimating function bootstrap method solves this problem by fixing one side of the estimating equation. When the estimating function is differentiable, we can use EF bootstrap to construct confidence intervals (regions). When the estimating function is not differentiable, we can then use the MCMB to solve this problem by considering a one-dimensional equation at each step.

In applications, it is also important to choose the bootstrap sample size B appropriately. When the original process (to get the estimator, $\hat{\theta}$) does not involve intensive computation, $B = 1000$ or 2000 is recommended. In general, to estimate the variance–covariance matrix, we may only need a bootstrap sample size of 100 to 200. For confidence intervals based on quantiles, it would be better to use $B = 1000$ or 2000.

38. Random Effects

This chapter includes well-known as well as state-of-the-art statistical modeling techniques for drawing inference on correlated data, which occur in a wide variety of studies (during quality control studies of similar products made on different assembly lines, community-based studies on cancer prevention, and familial research of linkage analysis, to name a few).

The first section briefly introduces statistical models that incorporate random effect terms, which are increasingly being applied to the analysis of correlated data. An effect is classified as a random effect when inferences are to be made on an entire population, and the levels of that effect represent only a sample from that population.

The second section introduces the linear mixed model for clustered data, which explicitly models complex covariance structure among observations by adding random terms into the linear predictor part of the linear regression model. The third section discusses its extension – generalized linear mixed models (GLMMs) – for correlated nonnormal data.

The fourth section reviews several common estimating techniques for GLMMs, including the EM and penalized quasi-likelihood approaches, Markov chain Newton-Raphson, the stochastic approximation, and the S-U algorithm. The fifth section focuses on some special topics related to hypothesis tests of random effects, including score tests for various models. The last section is a general discussion of the content of the chapter and some other topics relevant to random effects models.

38.1 Overview

Classical linear regression models are a powerful tool for exploring the dependence of a response (such as blood pressure) on explanatory factors (such as weight, height and nutrient intake). However, the normality assumption required for these response variables has severely limited its applicability. To accommodate a wide variety of independent nonnormal data, *Nelder* and *Wedderburn* [38.1] and *McCullagh* and *Nelder* [38.2] introduced generalized linear models (GLMs), a natural generalization of linear regression models. The GLMs allow responses to have nonGaussian distributions. Hence, data on counts and proportions can be conveniently fitted into this framework. In a GLM, the mean of a response is typically linked to linear predictors via a nonrandom function, termed the *link function*. For analytical convenience, the link function is often determined by

the response's distribution. As an example, for Poisson data, the link is routinely chosen as log, whereas for Bernoulli responses, the link is usually chosen to be logit.

In many applications, however, responses are correlated due to unobservable factors, such as circumstantial or genetic factors. Consider the problem of investigating the strength of the beams made by randomly selected manufacturers. Beams made at the same factory are likely to be correlated because the were made using the same manufacturing procedures. Other examples include a longitudinal study of blood pressure, where repeated observations taken from the same individuals are likely be correlated, and a familial study in cardiovascular disease, where the incidents of heart failure from family members are likely to be related. In the last two decades, random effects models have emerged as a major tool for analyzing these kinds of correlated data (see [38.3–7] among others).

Indeed, using random effects in the modeling of correlated data provides several benefits. First, it provides a framework for performing data modeling in unbalanced designs, especially when measurements are made at arbitrary irregularly spaced intervals over many observational studies (as opposed to ANOVA, which requires a balanced dataset). Secondly, random effects can be used to model subject-specific effects, and they offer a neat way to separately model within- and between-subject variations. Thirdly, the framework of random effects provides a systematic way to estimate or predict individual effects.

Though conceptually attractive, GLMMs are often difficult to fit because of the intractability of the underlying likelihood functions. Only under special circumstances, such as when both response and random effects are normally or conjugately distributed, will the associated likelihood function have a closed form. Cumbersome numerical integrations often have to be performed. To alleviate this computational burden, various modeling techniques have been proposed. For example, *Stiratelli* et al. [38.4] proposed an EM algorithm for fitting serial binary data; *Schall* [38.5] developed an iterative Newton-Raphson algorithm; *Zeger* and *Karim* [38.6] and *McCulloch* [38.7] considered Monte Carlo EM methods. All of these commonly used inferential procedures will be presented and discussed in this chapter.

The rest of this chapter is structured as follows. Section 38.2 introduces the linear mixed model for clustered data and Sect. 38.3 discusses its extension, generalized linear mixed models, for correlated nonnormal data. Section 38.4 reviews several common estimating techniques for GLMMs, including the EM approach, penalized quasi-likelihood, Markov chain Newton-Raphson, the stochastic approximation and the S–U algorithm. Section 38.5 focuses on some special topics related to hypothesis tests of random effects. Section 38.6 concludes this chapter with discussion and some other topics relevant to random effects models.

Throughout this chapter, $f(\cdot)$ and $F(\cdot)$ denote the probability density (or probability mass) function (with respect to some dominating measure, such as the Lebesgue measure) and the cumulative distribution function, respectively. If the context is clear, we do not use separate notations for random variables and their actual values.

38.2 Linear Mixed Models

A clustered data structure is typically characterized by a series of observations on each of a collection of observational clusters. Consider the problem of investigating whether the beam produced from iron is more resilient than that from an alloy. To do this, we measure the strength of the beams made of iron and alloy from randomly selected manufacturers. Each manufacturer may contribute multiple beams, in which case each manufacturer is deemed as a cluster, while each beam contributes to a unit of observation. Other examples include the measurements of products produced by a series of assembly lines, and blood pressure taken weekly on a group of patients, in which cases the clusters are assembly lines and patients respectively. Clustering typically induces dependence among observations. A linear mixed model [38.3] explicitly models the complex covariance structure among observations by adding random terms into the linear predictor part of a linear regression model. Thus, both random and fixed effects will be present in an LMM. In data analysis, the decision on whether a factor should be fixed or random is often made on the basis of which effects vary with clusters. That is, clusters are deemed to be a random sample of a larger population, and therefore any effects that are not constant for all clusters are regarded as random.

As an example, let's say that $\boldsymbol{Y}_i$ denotes the response vector for the ith of a total of m clusters, where n_i measurements of blood pressure were taken for the

ith patient. $\mathbf{X}_i$ the known covariate matrix ($n_i \times p$) associated with the observations, such as the patient's treatment assignment and the time when the observation was taken, $\boldsymbol{b}_i$ is the vector of random effects and $\mathbf{Z}_i$ is the known design matrix associated with the random effects. Usually, the columns of $\mathbf{Z}_i$ are vectors of ones and a subset of those of $\mathbf{X}_i$ for modeling random intercepts and slopes. A linear mixed model can thus be specified as

$$\boldsymbol{Y}_i = \mathbf{X}_i\boldsymbol{\beta} + \mathbf{Z}_i\boldsymbol{b}_i + \boldsymbol{\epsilon}_i \,, \tag{38.1}$$

where we typically assume that the random error vector $\boldsymbol{\epsilon}_i \sim MVN(0, \sigma^2\mathbf{I}_{n_i})$ and $\boldsymbol{\epsilon}_i$ is independent of $\boldsymbol{b}_i$, which is assumed to have an expectation of zero for model identifiability. Here, $\mathbf{I}_{n_i}$ is an identity matrix of order n_i. In practice, we often assume $\boldsymbol{b}_i \sim MVN(0, \boldsymbol{\Sigma}(\boldsymbol{\theta}))$, where its variance–covariance matrix is dependent on a fixed q-dimensional (a finite number) parameter, say, $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_q)'$, termed "variance components". These variance components convey information about the population that the clusters are randomly selected from and are often of interest to practitioners, aside from the fixed effects.

To encompass all data, we denote the concatenated collections of $\boldsymbol{Y}_i$'s, $\mathbf{X}_i$'s, $\boldsymbol{b}_i$'s and $\boldsymbol{\epsilon}_i$'s by $\boldsymbol{Y}, \mathbf{X}, \boldsymbol{b}, \boldsymbol{\epsilon}$. For example, $\boldsymbol{Y} = (\mathbf{Y}_1', \ldots, \mathbf{Y}_m')'$. We now denote a block diagonal matrix whose ith diagonal block is $\mathbf{Z}_i$ by $\mathbf{Z}$. In this case (38.1) can be rewritten compactly as

$$\boldsymbol{Y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\boldsymbol{b} + \boldsymbol{\epsilon} \,, \tag{38.2}$$

where $\boldsymbol{b} \sim MVN(0, \mathbf{D})$, $\boldsymbol{\epsilon} \sim MVN(0, \sigma^2\mathbf{I}_{\mathcal{N}})$ and $\boldsymbol{b}$ and $\boldsymbol{\epsilon}$ are independent. Here, $\mathbf{D}$ is a block diagonal matrix whose diagonal blocks are $\boldsymbol{\Sigma}(\boldsymbol{\theta})$, and $\mathbf{I}_{\mathcal{N}}$ is an identity matrix of order $\mathcal{N}$, where $\mathcal{N}$ is the total number of observations (so $\mathcal{N} = \sum_{i=1}^{m} n_i$).

Indeed, model (38.2) accommodates a much more general data structure beyond clustered data. For example, with properly defined $\mathbf{Z}$ and random effects $\boldsymbol{b}$, model (38.2) encompasses crossed factor data [38.8] and Gaussian spatial data [38.9].

38.2.1 Estimation

Fitting model (38.1) or its generalized version (38.2) is customarily likelihood-based. A typical maximum likelihood estimation procedure is as follows.

First observe that $\boldsymbol{Y}$ is normally distributed, $\boldsymbol{Y} \sim MVN(\mathbf{X}\boldsymbol{\beta}, \mathbf{V})$, where $\mathbf{V} = \mathbf{Z}\mathbf{D}\mathbf{Z}' + \sigma^2\mathbf{I}_{\mathcal{N}}$, so that the log-likelihood for the observed data is

$$\ell = -\frac{1}{2}(\boldsymbol{Y} - \mathbf{X}\boldsymbol{\beta})'\mathbf{V}^{-1}(\boldsymbol{Y} - \mathbf{X}\boldsymbol{\beta}) - \frac{1}{2}\log|\mathbf{V}| - \frac{\mathcal{N}}{2}\log 2\pi \,. \tag{38.3}$$

Denote the collection of unknown parameters in the model by $\boldsymbol{\gamma} = (\boldsymbol{\beta}', \boldsymbol{\theta}', \sigma^2)'$. Setting $\partial\ell/\partial\boldsymbol{\gamma} = 0$ gives the maximum likelihood equation. Specifically, a direct calculation of $\partial\ell/\partial\boldsymbol{\beta}$ yields the ML equation for $\boldsymbol{\beta}$:

$$\boldsymbol{\beta} = (\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^{-1}\mathbf{X}'\mathbf{V}^{-1}\boldsymbol{Y} \,. \tag{38.4}$$

Denote by θ_k the kth element of the variance components $(\boldsymbol{\theta}, \sigma^2)$, where we label $\theta_{q+1} = \sigma^2$. Equating $\partial\ell/\partial\theta_k = 0$ gives

$$-\frac{1}{2}\left[\mathrm{tr}\left(\mathbf{V}^{-1}\frac{\partial\mathbf{V}}{\partial\theta_k}\right) - (\boldsymbol{Y} - \mathbf{X}\boldsymbol{\beta})' \times \mathbf{V}^{-1}\frac{\partial\mathbf{V}}{\partial\theta_k}\mathbf{V}^{-1}(\boldsymbol{Y} - \mathbf{X}\boldsymbol{\beta})\right] = 0 \,, \tag{38.5}$$

where $\mathrm{tr}(\cdot)$ denotes the trace of a square matrix. In practice, iterations are required between (38.4) and (38.5) to obtain the MLEs. Furthermore the asymptotic sampling variance is routinely obtained from the inverse of the information matrix, which is minus the expected value of the matrix of second derivatives of the log-likelihood (38.3).

It is, however, worth pointing out that the MLEs obtained from (38.4, 5) are biased, especially for the variance components when the sample size is small. This is because the estimating equation (38.5) for the variance components fails to account for the loss of degrees of freedom when the true $\boldsymbol{\beta}$ is replaced by its estimate, $\hat{\boldsymbol{\beta}}$. To address this issue, an alternative maximum likelihood procedure, called the restricted maximum likelihood procedure, has been proposed for estimating the variance components [38.10]. The key idea is to replace the original response $\boldsymbol{Y}$ by a linear transform, so that the resulting 'response' contains no information about $\boldsymbol{\beta}$. The variance components can then be estimated based on this transformed response variable.

More specifically, choose a vector $\boldsymbol{a}$ such that $\boldsymbol{a}'\mathbf{X} = 0$. For more efficiency we use the maximum number, $\mathcal{N} - p$, of linearly independent vectors $\boldsymbol{a}$ and write $\mathbf{A} = (\boldsymbol{a}_1, \ldots, \boldsymbol{a}_{\mathcal{N}-p})$, which has a full row rank of $\mathcal{N} - p$. The restricted MLE will essentially apply the MLE procedure on $\mathbf{A}'\boldsymbol{Y}$, in lieu of the original $\boldsymbol{Y}$.

To proceed, we note that $\mathbf{A}'\boldsymbol{Y} \sim MVN(0, \mathbf{A}'\mathbf{V}\mathbf{A})$. The ML equations for the variance components can now be derived in a similar way to those for the original

$\boldsymbol{Y} \sim MVN(\mathbf{X}\boldsymbol{\beta}, \mathbf{V})$, namely by replacing $\boldsymbol{Y}$, $\mathbf{X}$ and $\mathbf{V}$ with $\mathbf{A}'\boldsymbol{Y}$, 0 and $\mathbf{AVA}'$ respectively in (38.5).

Caution must be exercised if the MLEs or the RMLEs of the variance components fall outside of the parameter space, as in the case of a negative estimate for a variance, in which case those solutions must be adjusted to yield estimates in the parameter space; see a more detailed discussion in *McCulloch* and *Searle* [38.11].

38.2.2 Prediction of Random Effects

A fixed effect differs from a random effect in that the former is considered to be constant and is often the main parameter we wish to estimate. In contrast, a random effect is considered to be an effect deriving from a population of effects. Consider again the aforementioned study of beam strength. Aside from the differences between the beams made from iron and alloy, there should be at least two sources of variability: (1) among beams produced by the same manufacturer; (2) between manufacturers. A simple random effects model can be specified as

$$E(Y_{ij}|b_i) = X_{ij}\beta + b_i \,,$$

where Y_{ij} is the strength of the j-th beam produced by the ith manufacturer and X_{ij} indicates whether iron or alloy was used to produce such a beam. Note that b_i is the effect on the strength of the beams produced by the i-th manufacturer, and this manufacturer was just the one among the selected manufacturers that happened to be labeled i in the study. The manufacturers were randomly selected as representative of the population of all manufacturers in the nation, and inferences about random effects were to be made about that population. Hence, estimating the variance components is of substantial interest for this purpose. On the other hand, one may wish to gain information about the performance of particular manufacturers. For instance, one may want to rank various manufacturers in order to select the best (or worst) ones. In these cases we are interested in predicting b_i.

In general the 'best' prediction of $\boldsymbol{b}$ in (38.2) based on observed response $\boldsymbol{Y}$ is required to minimize the mean squared error

$$\int (\hat{\boldsymbol{b}} - \boldsymbol{b})' \mathbf{G} (\hat{\boldsymbol{b}} - \boldsymbol{b}) f(\boldsymbol{Y}, \boldsymbol{b}) \mathrm{d}\boldsymbol{Y} \mathrm{d}\boldsymbol{b} \,, \tag{38.6}$$

where the predictor $\hat{\boldsymbol{b}}$ depends only on $\boldsymbol{Y}$, $f(\boldsymbol{Y}, \boldsymbol{b})$ is the joint density function of $\boldsymbol{Y}$ and $\boldsymbol{b}$, and $\mathbf{G}$ is a given nonrandom positive definite matrix. It can be shown for any given $\mathbf{G}$ that the minimizer is $E(\boldsymbol{b}|\boldsymbol{Y})$; in other words the conditional expectation of $\boldsymbol{b}$ given the observed response $\boldsymbol{Y}$.

If the variance components are known, an analytical solution exists based on the linear mixed model (38.2). That is, assuming $\boldsymbol{Y}$ and $\boldsymbol{b}$ follow a joint multinormal distribution, it follows that

$$E(\boldsymbol{b}|\boldsymbol{Y}) = \mathbf{DZ}'\mathbf{V}^{-1}(\boldsymbol{Y} - \mathbf{X}\boldsymbol{\beta}) \,.$$

Replacing $\boldsymbol{\beta}$ by its MLE

$$\hat{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^{-1}\mathbf{X}'\mathbf{V}^{-1}\boldsymbol{Y}$$

would yield the Best linear unbiased predictor (BLUP) of random effects [38.12]. Because $\mathbf{D}$ and $\mathbf{V}$ are usually unknown, they are often replaced by their MLEs or RMLEs when calculating the BLUP, namely

$$\hat{\boldsymbol{b}} = \hat{\mathbf{D}}\hat{\mathbf{Z}}'\hat{\mathbf{V}}^{-1}(\boldsymbol{Y} - \mathbf{X}\hat{\boldsymbol{\beta}}) \,.$$

Extensive derivation for the variance of the BLUP when the variance components are known has been given by *Henderson* et al. [38.12]. The variance of the BLUP with unknown variance components is not yet fully available.

38.3 Generalized Linear Mixed Models

Nonnormal data frequently arise from engineering studies. Consider again the beam study, where we now change the response to be a binary variable, indicating whether a beam has satisfied the criteria of quality control. For such nonnormal data, statistical models can be traced back to as early as 1934, when *Bliss* [38.13] proposed the first probit regression model for binary data. However, it took another four decades before *Nelder* and *Wedderburn* [38.1] and *McCullagh* and *Nelder* [38.2] proposed generalized linear models (GLMs) that could unify models and modeling techniques for analyzing more general data (such as counted data and polytomous data). Several authors [38.3–5] have considered a natural generalization of the GLMs to accommodate correlated nonnormal data. Their approach was to add random terms to the linear predictor parts, and the resulting models are termed generalized linear mixed models (GLMMs).

As an example, let $\boldsymbol{Y_{ij}}$ denote the status (such as a pass or a fail from the quality assurance test) of the

jth beam from the i-th manufacturer. We might create a model such as

$$\begin{aligned} Y_{ij}|b_i &\overset{\text{iid}}{\sim} \text{Bernoulli}\left(\mu_{ij}^{\text{b}}\right) ; \\ & i = 1, \ldots, m,\ j = 1, \ldots, n_i , \\ \text{logit}\left(\mu_{ij}^{\text{b}}\right) &= \boldsymbol{X}_{ij}'\boldsymbol{\beta} + b_i , \\ b_i &\overset{\text{iid}}{\sim} N\left(0, \sigma_u^2\right) , \end{aligned}$$

where $\text{logit}(\mu) = \log[\mu/(1-\mu)]$ is the link function that bridges the conditional probability and the linear predictors. The normal assumption for the random effects b_i is reasonable because the logit link carries the range of parameter space of μ_{ij} from $[0, 1]$ into the whole real line. Finally, we use independent b_i's to model the independent cluster effects and the within-cluster correlations among observations.

It is straightforward to generalize the above formulation to accommodate more general data. Specifically, let $\boldsymbol{X}_{ij}$ be a $p \times 1$ covariate vector associated with response Y_{ij}. Conditional on an unobserved cluster-specific random variable $\boldsymbol{b}_i$ (an $r \times 1$ vector), Y_{ij} are independent and follow a distribution of exponentials, that is

$$Y_{ij}|\boldsymbol{b}_i \overset{\text{iid}}{\sim} f(Y_{ij}|\boldsymbol{b}_i) , \tag{38.7}$$

$$f(Y_{ij}|\boldsymbol{b}_i) = \exp\left\{[Y_{ij}\alpha_{ij} - h(\alpha_{ij})]/\tau^2 - c(Y_{ij}, \tau)\right\} . \tag{38.8}$$

The conditional mean of $Y_{ij}|\boldsymbol{b}_i$, μ_{ij}^{b}, is related to α_{ij} through the identity $\mu_{ij}^{\text{b}} = \partial h(\alpha_{ij})/\partial\alpha_{ij}$, the transformation of which is to be modeled as a linear model in both the fixed and random effects:

$$g\left(\mu_{ij}^{\text{b}}\right) = \boldsymbol{X}_{ij}'\boldsymbol{\beta} + \boldsymbol{Z}_{ij}'\boldsymbol{b}_i , \tag{38.9}$$

where $g(\cdot)$ is termed a *link function*, often chosen to be invertible and continuous, and $\boldsymbol{Z}_{ij}$ is an $r \times 1$ design vector associated with the random effect. The random effects $\boldsymbol{b}_i$ are mutually independent with a common underlying distribution $F(\cdot; \boldsymbol{\theta})$ [or density $f(\cdot; \boldsymbol{\theta})$], where the variance components $\boldsymbol{\theta}$ is an unknown scalar or vector.

Model (38.9) is comprehensive and encompasses a variety of models. For continuous outcome data, by setting

$$h(\alpha) = \frac{1}{2}\alpha^2, \quad c(y, \tau^2) = \frac{1}{2}y^2/\tau^2 - \frac{1}{2}\log(2\pi\tau^2)$$

and $g(\cdot)$ to be an identity function, model (38.9) reduces to a linear mixed model. For binary outcome data, let

$$h(\alpha) = \log[1 + \exp(\alpha)] .$$

Choosing $g(\mu) = \text{logit}(\mu)$ yields a logit random effects model, while choosing $g(\mu) = \Phi^{-1}(\mu)$, where $\Phi(\cdot)$ is the CDF for a standard normal, gives a probit random effects model.

From (38.7) and (38.8) it is easy to construct the likelihood that the inference will be based on. That is,

$$\ell = \sum_{i=1}^{m} \log \int \prod_{j=1}^{n_i} f(Y_{ij}|\boldsymbol{b}_i; \boldsymbol{\beta}) f(\boldsymbol{b}_i; \boldsymbol{\theta}) \mathrm{d}\boldsymbol{b}_i ,$$

where the integration is over the r-dimensional random effect $\boldsymbol{b}_i$ and the summation results from independence across clusters.

We can also reformulate model (38.9) in a compact form that encompasses all of the data from all of the clusters. Using $\boldsymbol{Y}$, $\mathbf{X}$, $\mathbf{Z}$, $\boldsymbol{b}$ as defined in the previous section, we write

$$g[E(\boldsymbol{Y}|\boldsymbol{b})] = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\boldsymbol{b} . \tag{38.10}$$

Hence, the log-likelihood function can be rewritten as

$$\begin{aligned} \ell(\boldsymbol{Y}; \boldsymbol{\beta}, \boldsymbol{\theta}) &= \log L(\boldsymbol{Y}; \boldsymbol{\beta}, \boldsymbol{\theta}) \\ &= \log \int f(\boldsymbol{Y}|\boldsymbol{b}; \boldsymbol{\beta}) f(\boldsymbol{b}; \boldsymbol{\theta}) \mathrm{d}\boldsymbol{b} , \end{aligned} \tag{38.11}$$

where $f(\boldsymbol{Y}|\boldsymbol{b}; \boldsymbol{\beta})$ is the conditional likelihood for $\boldsymbol{Y}$ and $f(\boldsymbol{b}; \boldsymbol{\theta})$ is the density function for $\boldsymbol{b}$, often assumed to have a mean of zero.

Model (38.10) is not a simple reformat – it accommodates more complex data structures than clustered data. For example, with a properly defined $\mathbf{Z}$ and random effects $\boldsymbol{b}$ it encompasses crossed factor data [38.8] and nonnormal spatial data [38.14]. Hence, for more generality, the inferential procedures that we encounter in Sect. 38.4 will be based on (38.10, 11).

The GLMM is advantageous when the objective is to make inferences about individuals rather than the population average. Within its framework, random effects can be estimated and each individual's profile or growth curve can be obtained. The best predictor of random effects minimizing (38.6) is $E(\boldsymbol{Y}|\boldsymbol{b})$, which is not necessarily linear in $\boldsymbol{Y}$. However, if we confine our interest to the predictors that are linear in $\boldsymbol{Y}$, or of the form

$$\hat{\boldsymbol{b}} = \boldsymbol{c} + \mathbf{Q}\boldsymbol{Y}$$

for some conformable vector $\boldsymbol{c}$ and matrix $\mathbf{Q}$, minimizing the mean squared error (38.6) with respect to $\boldsymbol{c}$ and $\mathbf{Q}$ leads to the best *linear* predictor

$$\hat{\boldsymbol{b}} = E(\boldsymbol{b}) + \text{cov}(\boldsymbol{b}, \boldsymbol{Y})\text{var}(\boldsymbol{Y})[\boldsymbol{Y} - E(\boldsymbol{Y})] , \tag{38.12}$$

which holds true without any normality assumptions [38.11].

For example, consider a beta-binomial model for clustered binary outcomes such that

$$Y_{ij}|b_i \sim \text{Bernoulli}(b_i)$$

and the random effect $b_i \sim \text{Beta}(\alpha, \eta)$, where $\alpha, \eta > 0$. Using (38.12) we obtain the best linear predictor for b_i,

$$\hat{b}_i = \frac{\alpha + \bar{Y}_i}{\alpha + \beta + 1} ,$$

where $\bar{Y}_i = \sum_{j=1}^{n_i} Y_{ij}/n_i$.

38.4 Computing MLEs for GLMMs

A common theme when fitting a GLMM has been the difficulty involved with computating likelihood-based inference. Indeed, computing the likelihood itself is often challenging for GLMMs, mostly because of intractable integrals. This section presents various commonly used likelihood-based approaches to estimating the coefficients and variance components in GLMMs.

38.4.1 The EM Approach

The EM algorithm [38.15] is a widely used approach to calculating MLEs with missing observations. The basic idea behind its application to the random effects models is to treat the random terms as 'missing' data, and to impute the missing information based on the observed data. Imputations are often made via conditional expectations.

When drawing inference, our goal is to maximize the marginal likelihood of the observed data in order to obtain the MLEs for unknown $\boldsymbol{\beta}$ and variance components $\boldsymbol{\theta}$. If random effects ($\boldsymbol{b}$) were observed, we would be able to write the 'complete' data as ($\boldsymbol{Y}, \boldsymbol{b}$) with a joint log-likelihood

$$\ell(\boldsymbol{Y}, \boldsymbol{b}; \boldsymbol{\beta}, \boldsymbol{\theta}) = \log f(\boldsymbol{Y}|\boldsymbol{b}; \boldsymbol{\beta}) + \log f(\boldsymbol{b}; \boldsymbol{\theta}) . \tag{38.13}$$

However, since $\boldsymbol{b}$ is unobservable, directly computing (38.13) is not feasible. Instead, the EM algorithm adopts a two-step iterative process. The expectation step ("E" step) computes the expectation of (38.13) conditional on the observed data. That is,

$$\tilde{\ell} = E\{\ell(\boldsymbol{Y}, \boldsymbol{b}; \boldsymbol{\beta}, \boldsymbol{\theta})|\boldsymbol{Y}, \boldsymbol{\beta}_0, \boldsymbol{\theta}_0\} ,$$

where $\boldsymbol{\beta}_0, \boldsymbol{\theta}_0$ are the current values, followed by the maximization step ("M" step), which maximizes $\tilde{\ell}$ with respect to $\boldsymbol{\beta}$ and $\boldsymbol{\theta}$. The E and M steps are iterated until convergence is achieved. Generally, the E step is computationally intensive, because it still needs to calculate a high-dimensional integral.

Indeed, since the conditional distribution of $\boldsymbol{b}|\boldsymbol{Y}$ involves the marginal distribution $f(\boldsymbol{Y})$, which is an intractable integral, a direct Monte Carlo simulation cannot fulfill the expectation step. In view of this difficulty, *McCulloch* [38.7] utilized the Metropolis–Hastings algorithm to make random draws from $\boldsymbol{b}|\boldsymbol{Y}$ without calculating the marginal density $f(\boldsymbol{Y})$.

The Metropolis–Hastings algorithm, dated back to the papers by *Metropolis* et al. [38.16] and *Hastings* [38.17], can be summarized as follows. Choose an auxiliary function $q(\boldsymbol{u}, \boldsymbol{v})$ such that $q(., \boldsymbol{v})$ is a pdf for all $\boldsymbol{v}$. This function is often called a *jumping distribution* from point $\boldsymbol{v}$ to $\boldsymbol{u}$. Draw $\boldsymbol{b}^*$ from $q(., \boldsymbol{b})$, where $\boldsymbol{b}$ is the current value of the Markov chain. Compute the ratio of importance

$$\omega = \frac{f(\boldsymbol{b}|\boldsymbol{Y})q(\boldsymbol{b}^*, \boldsymbol{b})}{f(\boldsymbol{b}^*|\boldsymbol{Y})q(\boldsymbol{b}, \boldsymbol{b}^*)} .$$

Set the current value of the Markov chain as $\boldsymbol{b}^*$ with probability $\min(1, \omega)$, and $\boldsymbol{b}$ has a probability $\max(0, 1 - \omega)$. It can be shown that, under mild conditions, the distribution of $\boldsymbol{b}$ drawn from such a procedure converges weakly to $f(\boldsymbol{b}|\boldsymbol{Y})$ (see, for example, [38.18]). Since the unknown density $f(\boldsymbol{Y})$ cancels out in the calculation of ω, the Metropolis–Hastings algorithm has successfully avoided computing $f(\boldsymbol{Y})$.

The ideal Metropolis–Hastings algorithm jumping rule is to sample the point directly from the target distribution. That is, in our case, $q(\boldsymbol{b}^*, \boldsymbol{b}) = f(\boldsymbol{b}^*|\boldsymbol{Y})$ for all $\boldsymbol{b}$. Then the ratio of importance, ω, is always 1, and the iterations of $\boldsymbol{b}^*$ are a sequence of independent draws from $f(\boldsymbol{b}^*|\boldsymbol{Y})$. In general, however, iterative simulation is applied to situations where direct sampling is not possible. Efficient jumping rules have been addressed by *Gelman* et al. [38.19].

We can now turn to the Monte Carlo EM algorithm, which takes the following form.

1. Choose initial values $\boldsymbol{\beta}^0$ and $\boldsymbol{\theta}^0$.

2. Denote the updated value at iteration s by $(\boldsymbol{\beta}^s, \boldsymbol{\theta}^s)$. Generate n values of $\boldsymbol{b}^1, \ldots, \boldsymbol{b}^n$ from $f(\boldsymbol{b}|\boldsymbol{Y}; \boldsymbol{\beta}^s, \boldsymbol{\theta}^s)$.
3. At iteration $s+1$, choose $\boldsymbol{\beta}^{s+1}$ to maximize $\frac{1}{n}\sum_{k=1}^{n} \log f(\boldsymbol{Y}|\boldsymbol{b}^k; \boldsymbol{\beta})$.
4. Find $\boldsymbol{\theta}^{s+1}$ to maximize $\frac{1}{n}\sum_{k=1}^{n} \log f(\boldsymbol{b}^k; \boldsymbol{\theta})$.
5. Repeat steps 2–4 until convergence.

While computationally intensive, this algorithm is relatively stable since the log marginal likelihood increases at each iteration step and it is convergent at a linear rate [38.15].

38.4.2 Simulated Maximum Likelihood Estimation

Implementation of the EM is often computationally intensive. A naive approach would be to numerically approximate the likelihood (38.11) and maximize it directly. For example, when the random effects ($\boldsymbol{b}$) follow a normal distribution, we may use Gaussian quadrature to evaluate (38.11) and its derivatives. However, this approach quickly fails when the dimensions of $\boldsymbol{b}$ are large. We now consider a simulation technique, namely, simulated maximum likelihood estimation, to approximate the likelihood directly and, further, to obtain the MLEs. The key idea behind this approach is to approximate (38.11) and its first- and second-order derivatives by Monte Carlo simulations while performing Newton-Raphson iterations.

We begin with the likelihood approximation. Following *Geyer* and *Thompson* [38.20] and *Gelfand* and *Carlin* [38.21], one notices that for any density function $h(\boldsymbol{b})$ with the same support as $f(\boldsymbol{b}; \boldsymbol{\theta})$,

$$L(\boldsymbol{Y}; \boldsymbol{\beta}, \boldsymbol{\theta}) = \int \frac{f(\boldsymbol{Y}|\boldsymbol{b}; \boldsymbol{\beta}) f(\boldsymbol{b}; \boldsymbol{\theta})}{h(\boldsymbol{b})} h(\boldsymbol{b}) \mathrm{d}\boldsymbol{b} \,. \quad (38.14)$$

Hence, Monte Carlo simulations can be applied to evaluate $L(\boldsymbol{Y}; \boldsymbol{\beta}, \boldsymbol{\theta})$. Explicitly, if $\boldsymbol{b}^1, \ldots, \boldsymbol{b}^n$ are generated independently from $h(\boldsymbol{b})$ (termed an *importance sampling distribution*), (38.14) can be approximated by

$$1/n \sum_{i=1}^{n} \frac{f(\boldsymbol{Y}|\boldsymbol{b}^i; \boldsymbol{\beta}) f(\boldsymbol{b}^i; \boldsymbol{\theta})}{h(\boldsymbol{b}^i)} \quad (38.15)$$

with an accuracy of order $O_p(n^{-1/2})$. The optimal (in the sense that the Monte Carlo approximation has zero variance) importance sampling distribution is $f(\boldsymbol{b}|\boldsymbol{Y})$, evaluated at the MLEs [38.22]. However, since the MLEs are unknown and the conditional distribution cannot be evaluated, such an optimal distribution is never meaningful practically. Nevertheless, we can find a distribution (such as a normal distribution) to approximate $f(\boldsymbol{b}|\boldsymbol{Y})$.

More specifically, notice that

$$\begin{aligned} f(\boldsymbol{b}|\boldsymbol{Y}) &= c \times f(\boldsymbol{Y}|\boldsymbol{b}; \boldsymbol{\beta}) f(\boldsymbol{b}; \boldsymbol{\theta}) \\ &= c \times \exp[-K(\boldsymbol{Y}, \boldsymbol{b})] \,, \end{aligned}$$

where c (which does not depend on $\boldsymbol{b}$) is used to ensure a proper density function. We use

$$\begin{aligned} h(\boldsymbol{b}; \boldsymbol{\beta}, \boldsymbol{\theta}) =& ||2\pi \hat{\boldsymbol{\Sigma}}||^{-1/2} \\ & \times \exp\left[-\frac{1}{2}(\boldsymbol{b} - \hat{\boldsymbol{b}})' \hat{\boldsymbol{\Sigma}}^{-1} (\boldsymbol{b} - \hat{\boldsymbol{b}})\right] \,, \end{aligned}$$

where $||\cdot||$ denotes the determinant of a square matrix, $\hat{\boldsymbol{b}} = \mathrm{argmin}_{\boldsymbol{b}}[K(\boldsymbol{Y}, \boldsymbol{b})]$ and $\hat{\boldsymbol{\Sigma}} = [\frac{\partial}{\partial \boldsymbol{b} \partial \boldsymbol{b}'} K(\boldsymbol{Y}, \hat{\boldsymbol{b}})]^{-1}$, to approximate the conditional density $f(\boldsymbol{b}|\boldsymbol{Y})$ evaluated at $\boldsymbol{\beta}$ and $\boldsymbol{\theta}$. Similarly, the derivatives of $L(\boldsymbol{Y}; \boldsymbol{\beta}, \boldsymbol{\theta})$ can also be approximated by Monte Carlo simulations.

Then the algorithm proceeds as follows:

1. Choose the initial values $\boldsymbol{\gamma}^0 = (\boldsymbol{\beta}^0, \boldsymbol{\theta}^0)$ for $\boldsymbol{\gamma} = (\boldsymbol{\beta}, \boldsymbol{\theta})$.
2. Denote the current value at the sth step by $\boldsymbol{\gamma}^s$. Generate $\boldsymbol{b}^1, \ldots, \boldsymbol{b}^n$ based on $h(\boldsymbol{b}|\boldsymbol{\gamma}^s)$.
3. Calculate the approximate derivatives of the marginal likelihood function $L(\boldsymbol{Y}; \boldsymbol{\beta}, \boldsymbol{\theta})$ evaluated at $\boldsymbol{\gamma}^s$:

$$\mathcal{B}_\beta^s = \frac{1}{n}\sum_{k=1}^{n} \frac{f(\boldsymbol{b}^k; \boldsymbol{\theta}^s)}{h(\boldsymbol{b}^k; \boldsymbol{\gamma}^s)} \frac{\partial}{\partial \boldsymbol{\beta}} f(\boldsymbol{Y}|\boldsymbol{b}^k; \boldsymbol{\beta})|_{\boldsymbol{\beta}^s} \,,$$

$$\mathcal{B}_\theta^s = \frac{1}{n}\sum_{k=1}^{n} \frac{f(\boldsymbol{Y}|\boldsymbol{b}^k; \boldsymbol{\beta}^s)}{h(\boldsymbol{b}^k; \boldsymbol{\gamma}^s)} \frac{\partial}{\partial \boldsymbol{\theta}} f(\boldsymbol{b}^k; \boldsymbol{\theta})|_{\boldsymbol{\beta}^s} \,,$$

$$\mathcal{A}_{\beta\beta}^s = \frac{1}{n}\sum_{k=1}^{n} \frac{f(\boldsymbol{b}^k; \boldsymbol{\theta}^s)}{h(\boldsymbol{b}^k; \boldsymbol{\gamma}^s)} \frac{\partial^2}{\partial \boldsymbol{\beta} \partial \boldsymbol{\beta}'} f(\boldsymbol{Y}|\boldsymbol{b}^k; \boldsymbol{\beta})|_{\boldsymbol{\beta}^s} \,,$$

$$\mathcal{A}_{\theta\theta}^s = \frac{1}{n}\sum_{k=1}^{n} \frac{f(\boldsymbol{Y}|\boldsymbol{b}^k, \boldsymbol{\beta}^s)}{h(\boldsymbol{b}^k; \boldsymbol{\gamma}^s)} \frac{\partial^2}{\partial \boldsymbol{\theta} \partial \boldsymbol{\theta}'} f(\boldsymbol{b}^k; \boldsymbol{\theta})|_{\boldsymbol{\theta}^s} \,,$$

$$\begin{aligned} \mathcal{A}_{\beta\theta}^s =& \frac{1}{n}\sum_{k=1}^{n} \frac{1}{h(\boldsymbol{b}^k; \boldsymbol{\gamma}^s)} \frac{\partial}{\partial \boldsymbol{\beta}} f(\boldsymbol{Y}|\boldsymbol{b}^k; \boldsymbol{\beta})|_{\boldsymbol{\beta}^s} \\ & \times \left[\frac{\partial}{\partial \boldsymbol{\theta}} f(\boldsymbol{b}^k; \boldsymbol{\theta})|_{\boldsymbol{\theta}^s}\right]' \,. \end{aligned}$$

4. Compute the updated value at the $(s+1)$th step

$$\boldsymbol{\gamma}^{s+1} = \boldsymbol{\gamma}^s - (\mathcal{A}^s)^{-1} \mathcal{B}^s \,,$$

$$\text{where } \mathcal{A}^s = \begin{pmatrix} \mathcal{A}_{\beta\beta}^s & \mathcal{A}_{\beta\theta}^s \\ \left(\mathcal{A}_{\beta\theta}^s\right)' & \mathcal{A}_{\theta\theta}^s \end{pmatrix}$$

$$\text{and } \mathcal{B}^s = \left(\mathcal{B}_\beta^{s\prime}, \mathcal{B}_\theta^{s\prime}\right)' \,.$$

5. Repeat steps 2–4 until convergent criteria are met. Upon convergence, set $\hat{\boldsymbol{\gamma}} = \boldsymbol{\gamma}^s$ and the Hessian matrix $\mathcal{A} = \mathcal{A}^s$.

The covariance of the resulting $\hat{\boldsymbol{\gamma}}$ is approximated (ignoring the Monte Carlo error) by the inverse of the observed information matrix, given by

$$-\frac{\partial^2}{\partial\boldsymbol{\gamma}\partial\boldsymbol{\gamma}'}\log L(\boldsymbol{Y};\boldsymbol{\beta},\boldsymbol{\theta})|_{\hat{\boldsymbol{\gamma}}} \doteq -\hat{L}^{-1}\mathcal{A}\,,$$

where $\hat{L}$ and $\mathcal{A}$ are the approximations of $L(\boldsymbol{Y};\boldsymbol{\beta},\boldsymbol{\theta})$ and the Hessian matrix evaluated at $\hat{\boldsymbol{\gamma}} = (\hat{\boldsymbol{\beta}},\hat{\boldsymbol{\theta}})$, respectively.

38.4.3 Monte Carlo Newton–Raphson (MCNR)/ Stochastic Approximation (SA)

Monte Carlo Newton-Raphson and stochastic approximation are two similar approaches to finding the MLEs for the GLMMs. They both approximate the score function using simulated random effects and improve the precision of the approximation at each iteration step.

We first describe a typical (MCNR) algorithm. Consider the decomposition of the joint density of the response vector and random effects vector

$$f(\boldsymbol{Y},\boldsymbol{b};\boldsymbol{\gamma}) = f(\boldsymbol{Y};\boldsymbol{\gamma})f(\boldsymbol{b}|\boldsymbol{Y};\boldsymbol{\gamma})\,.$$

Hence

$$\frac{\partial\log f(\boldsymbol{Y},\boldsymbol{b};\boldsymbol{\gamma})}{\partial\boldsymbol{\gamma}} = S(\boldsymbol{\gamma}) + \frac{\partial\log f(\boldsymbol{b}|\boldsymbol{Y};\boldsymbol{\gamma})}{\partial\boldsymbol{\gamma}}\,, \quad (38.16)$$

where $S(\boldsymbol{\gamma}) = \partial\log f(\boldsymbol{Y};\boldsymbol{\gamma})/\partial\boldsymbol{\gamma}$, the score function of main interest. In view of

$$E\left(\frac{\partial\log f(\boldsymbol{b}|\boldsymbol{Y};\boldsymbol{\gamma})}{\partial\boldsymbol{\gamma}}|\boldsymbol{Y}\right) = 0\,,$$

(38.16) can be written in the format of a regression equation

$$\frac{\partial\log f(\boldsymbol{Y},\boldsymbol{b};\boldsymbol{\gamma})}{\partial\boldsymbol{\gamma}} = S(\boldsymbol{\gamma}) + \text{error}\,,$$

where the "error" term substitutes $\partial\log f(\boldsymbol{b}|\boldsymbol{Y};\boldsymbol{\gamma})/\partial\boldsymbol{\gamma}$, a mean zero term. Thus, inserting values of $\boldsymbol{b}\sim f(\boldsymbol{b}|\boldsymbol{Y})$ into $\partial\log f(\boldsymbol{Y},\boldsymbol{b};\boldsymbol{\gamma})/\partial\boldsymbol{\gamma}$ yields "data" to perform such a regression.

The MCNR algorithm is typically implemented as follows. Denote by $\boldsymbol{\gamma}^{(s)}$ the value of the estimate of $\boldsymbol{\gamma}$ at iteration step s. Generate via the Metropolis-Hastings algorithm a sequence of realized values $\boldsymbol{b}^{(s,1)},\ldots,\boldsymbol{b}^{(s,n)}\sim f(\boldsymbol{b}|\boldsymbol{Y};\boldsymbol{\gamma}^{(s)})$. At the $(s+1)$th step, compute

$$\boldsymbol{\gamma}^{(s+1)} = \boldsymbol{\gamma}^{(s)} - a_s\hat{E}\left(\frac{\partial\log f(\boldsymbol{Y},\boldsymbol{b};\boldsymbol{\gamma})}{\partial\boldsymbol{\gamma}}|_{\boldsymbol{\gamma}=\boldsymbol{\gamma}^{(s)}}\right)\,. \quad (38.17)$$

Here a_s is a constant, incorporating information about the expectation of the derivative of $\partial\log f(\boldsymbol{Y},\boldsymbol{b};\boldsymbol{\gamma})/\partial\boldsymbol{\gamma}$ at the root, an unknown quantity. In practice, a_s is often set to be the inverse of a Monte Carlo estimate of the expectation based on the realized values of $\boldsymbol{b}^{(s,1)},\ldots,\boldsymbol{b}^{(s,n)}$.

The SA differs from the MCNR in that the SA uses a single simulated value of random effects in (38.17), that is

$$\boldsymbol{\gamma}^{(s+1)} = \boldsymbol{\gamma}^{(s)} - a_s\frac{\partial\log f(\boldsymbol{Y},\boldsymbol{b}^{(s)};\boldsymbol{\gamma})}{\partial\boldsymbol{\gamma}}|_{\boldsymbol{\gamma}=\boldsymbol{\gamma}^{(s)}}\,,$$

and a_s is chosen to gradually decrease to zero. *Ruppert* and *Gu* and *Kong* have recommended that

$$a_s = \frac{e}{(s+\kappa)^\alpha}\left[\hat{E}\left(\frac{\partial^2\log f(\boldsymbol{Y},\boldsymbol{b};\boldsymbol{\gamma})}{\partial\boldsymbol{\gamma}\partial\boldsymbol{\gamma}'}\right)\right]^{-1}\,,$$

where $e=3$, $\kappa=50$ and $\alpha=0.75$ as chosen by *McCulloch* and *Searle* [38.11]. The multiplier a_s decreases the step size as the iterations increase in the SA and eventually serves to eliminate the stochastic error involved in the Metropolis-Hastings steps. *McCulloch* and *Searle* [38.11] stated that the SA is advantageous in that it can use all of the simulated data to calculate estimates and only uses the simulated values one at a time; however, the detailed implementations of both methods are yet to be settled on in the literature.

38.4.4 S–U Algorithm

The S–U algorithm is a technique for finding the solution of an estimating equation that can be expressed as the expected value of a full data estimating equation, where the expectation is taken with respect to the missing data, given the observed data. This algorithm alternates between two steps: a simulation step wherein the missing values are simulated based on the conditional distributions given the observed data, and an updating step wherein parameters are updated without performing a numerical maximization. An attractive feature of this approach is that it is sequential – the number of Monte Carlo replicates does not have to be specified in advance, and the values of previous Monte Carlo replicates do not have to be stored or regenerated for later use. In the following, we will apply this approach in order to solve the maximum likelihood equations.

Differentiating the log-likelihood (38.26) with respect to the unknown parameters, $\boldsymbol{\gamma} = (\boldsymbol{\beta}, \boldsymbol{\theta})$, gives

$$\boldsymbol{S}_b(\boldsymbol{\beta}, \boldsymbol{\theta}) = \frac{\partial \ell}{\partial \boldsymbol{\beta}} = \frac{1}{f(\boldsymbol{Y}; \boldsymbol{\gamma})} \times \int \boldsymbol{S}_b(\boldsymbol{Y}|\boldsymbol{b}; \boldsymbol{\beta}) f(\boldsymbol{Y}|\boldsymbol{b}; \boldsymbol{\beta}) f(\boldsymbol{b}; \boldsymbol{\theta}) \mathrm{d}\boldsymbol{b} \,, \tag{38.18}$$

$$\boldsymbol{S}_t(\boldsymbol{\beta}, \boldsymbol{\theta}) = \frac{\partial \ell}{\partial \boldsymbol{\theta}} = \frac{1}{f(\boldsymbol{Y}; \boldsymbol{\gamma})} \times \int \boldsymbol{S}_t(\boldsymbol{b}; \boldsymbol{\theta}) f(\boldsymbol{Y}|\boldsymbol{b}; \boldsymbol{\beta}) f(\boldsymbol{b}; \boldsymbol{\theta}) \mathrm{d}\boldsymbol{b} \,, \tag{38.19}$$

where $f(\boldsymbol{Y}; \boldsymbol{\gamma})$ is the marginal likelihood of the observed data set, and $\boldsymbol{S}_b(\boldsymbol{Y}|\boldsymbol{b}; \boldsymbol{\beta})$, $\boldsymbol{S}_t(\boldsymbol{b}; \boldsymbol{\theta})$ are conditional scores when treating $\boldsymbol{b}$ as observed constants, that is $\boldsymbol{S}_b(\boldsymbol{Y}|\boldsymbol{b}; \boldsymbol{\beta}) = \partial \log f(\boldsymbol{Y}|\boldsymbol{b}; \boldsymbol{\beta})/\partial \boldsymbol{\beta}$, and $\boldsymbol{S}_t(\boldsymbol{b}; \boldsymbol{\theta}) = \partial \log f(\boldsymbol{b}; \boldsymbol{\theta})/\partial \boldsymbol{\theta}$.

Some algebra gives the second derivatives of the log-likelihood, which are needed in the algorithm. More specifically,

$$\boldsymbol{S}_{bb}(\boldsymbol{\beta}, \boldsymbol{\theta}) = \frac{\partial^2 \ell}{\partial \boldsymbol{\beta} \partial \boldsymbol{\beta}'} = -\boldsymbol{S}_b^{\otimes 2}(\boldsymbol{\beta}, \boldsymbol{\theta}) + \frac{1}{f(\boldsymbol{Y}; \boldsymbol{\gamma})} \times \int \{\boldsymbol{S}_{bb}(\boldsymbol{Y}|\boldsymbol{b}; \boldsymbol{\beta}) + \boldsymbol{S}_b^{\otimes 2}(\boldsymbol{Y}|\boldsymbol{b}; \boldsymbol{\beta})\} f(\boldsymbol{Y}|\boldsymbol{b}; \boldsymbol{\beta}) f(\boldsymbol{b}; \boldsymbol{\theta}) \mathrm{d}\boldsymbol{b} \,, \tag{38.20}$$

$$\boldsymbol{S}_{bt}(\boldsymbol{\beta}, \boldsymbol{\theta}) = \frac{\partial^2 \ell}{\partial \boldsymbol{\beta} \partial \boldsymbol{\theta}'} = -\boldsymbol{S}_b(\boldsymbol{\beta}, \boldsymbol{\theta}) \boldsymbol{S}_t'(\boldsymbol{\beta}, \boldsymbol{\theta}) + \frac{1}{f(\boldsymbol{Y}; \boldsymbol{\gamma})} \times \int \boldsymbol{S}_b(\boldsymbol{\beta}, \boldsymbol{\theta}) \boldsymbol{S}_t'(\boldsymbol{b}; \boldsymbol{\theta}) f(\boldsymbol{Y}|\boldsymbol{b}; \boldsymbol{\beta}) f(\boldsymbol{b}; \boldsymbol{\theta}) \mathrm{d}\boldsymbol{b} \,, \tag{38.21}$$

$$\boldsymbol{S}_{tt}(\boldsymbol{\beta}, \boldsymbol{\theta}) = \frac{\partial^2 \ell}{\partial \boldsymbol{\theta} \partial \boldsymbol{\theta}'} = -\boldsymbol{S}_t^{\otimes 2}(\boldsymbol{\beta}, \boldsymbol{\theta}) + \frac{1}{f(\boldsymbol{Y}; \boldsymbol{\gamma})} \times \int \left\{\boldsymbol{S}_{tt}(\boldsymbol{b}; \boldsymbol{\theta}) + \boldsymbol{S}_t^{\otimes 2}(\boldsymbol{b}; \boldsymbol{\theta})\right\} f(\boldsymbol{Y}|\boldsymbol{b}; \boldsymbol{\beta}) f(\boldsymbol{b}; \boldsymbol{\theta}) \mathrm{d}\boldsymbol{b} \,, \tag{38.22}$$

where $\boldsymbol{S}_{bb}(\boldsymbol{Y}|\boldsymbol{b}; \boldsymbol{\beta})$, $\boldsymbol{S}_{tt}(\boldsymbol{b}; \boldsymbol{\theta})$ are conditional information when treating $\boldsymbol{b}$ as observed constants, that is $\boldsymbol{S}_{bb}(\boldsymbol{Y}|\boldsymbol{b}; \boldsymbol{\beta}) = \partial^2 \log f(\boldsymbol{Y}|\boldsymbol{b}; \boldsymbol{\beta})/\partial \boldsymbol{\beta} \partial \boldsymbol{\beta}'$, and $\boldsymbol{S}_{tt}(\boldsymbol{b}; \boldsymbol{\theta}) = \partial^2 \log f(\boldsymbol{b}; \boldsymbol{\theta})/\partial \boldsymbol{\theta} \partial \boldsymbol{\theta}'$. Here for a column vector $\boldsymbol{a}$, $\boldsymbol{a}^{\otimes 2} = \boldsymbol{a}\boldsymbol{a}'$.

Hence, one can use the importance sampling scheme [38.23] to approximate these functions and their derivatives. We proceed as follows.

Having obtained the approximants $\hat{\boldsymbol{\gamma}}_1 = (\hat{\boldsymbol{\beta}}_1, \hat{\boldsymbol{\theta}}_1), \ldots, \hat{\boldsymbol{\gamma}}_j = (\hat{\boldsymbol{\beta}}_j, \hat{\boldsymbol{\theta}}_j)$ to $\hat{\boldsymbol{\gamma}} = (\hat{\boldsymbol{\beta}}, \hat{\boldsymbol{\theta}})$, the true MLE, at the jth S-step of the algorithm, we simulate $\boldsymbol{b}^{(j,l)}, l = 1, \ldots, n$, independently from $f(\boldsymbol{b}; \hat{\boldsymbol{\theta}}_j)$. Denote $w^{(j,l)}$ by

$$w^{(j,l)} = f\left(\boldsymbol{Y}|\boldsymbol{b}^{(j,l)}; \hat{\boldsymbol{\beta}}_j\right)$$

and let

$$\bar{w}_j = \frac{1}{j \cdot n} \sum_{j'=1}^{j} \sum_{l=1}^{n} w^{(j',l)} \,.$$

As $j \to \infty$, the law of large numbers gives that $\bar{w}_j$ is asymptotically equal to $f(\boldsymbol{Y}; \hat{\boldsymbol{\gamma}})$ provided that $\hat{\boldsymbol{\gamma}}_j \xrightarrow{p} \hat{\boldsymbol{\gamma}}$.

We write

$$\bar{\boldsymbol{S}}_{b,j} = \frac{1}{jn\bar{w}_j} \sum_{j'=1}^{j} \sum_{l=1}^{n} w^{(j',l)} \boldsymbol{S}_b\left(\boldsymbol{Y}|\boldsymbol{b}^{(j',l)}; \hat{\boldsymbol{\beta}}_j\right) \,,$$

$$\bar{\boldsymbol{S}}_{t,j} = \frac{1}{jn\bar{w}_j} \sum_{j'=1}^{j} \sum_{l=1}^{n} w^{(j',l)} \boldsymbol{S}_t\left(\boldsymbol{b}^{(j',l)}; \hat{\boldsymbol{\theta}}_j\right) \,,$$

$$\bar{\boldsymbol{S}}_{bb,j} = -\bar{\boldsymbol{S}}_{b,j}^{\otimes 2} + \frac{1}{jn\bar{w}_j} \sum_{j'=1}^{j} \sum_{l=1}^{n} w^{(j',l)} \times \left[\boldsymbol{S}_{bb}\left(\boldsymbol{Y}|\boldsymbol{b}^{(j',l)}; \hat{\boldsymbol{\beta}}_j\right) + \boldsymbol{S}_b^{\otimes 2}\left(\boldsymbol{Y}|\boldsymbol{b}^{(j',l)}; \hat{\boldsymbol{\beta}}_j\right)\right] \,,$$

$$\bar{\boldsymbol{S}}_{tt,j} = -\bar{\boldsymbol{S}}_{t,j}^{\otimes 2} + \frac{1}{jn\bar{w}_j} \sum_{j'=1}^{j} \sum_{l=1}^{n} w^{(j',l)} \times \left[\boldsymbol{S}_{tt}\left(\boldsymbol{b}^{(j',l)}; \hat{\boldsymbol{\beta}}_j\right) + \boldsymbol{S}_t^{\otimes 2}\left(\boldsymbol{b}^{(j',l)}; \hat{\boldsymbol{\beta}}_j\right)\right] \,,$$

$$\bar{\boldsymbol{S}}_{bt,j} = -\bar{\boldsymbol{S}}_{b,j} \bar{\boldsymbol{S}}_{t,j}' + \frac{1}{jn\bar{w}_j} \sum_{j'=1}^{j} \sum_{l=1}^{n} w^{(j',l)} \times \left[\boldsymbol{S}_b\left(\boldsymbol{Y}|\boldsymbol{b}^{(j',l)}; \hat{\boldsymbol{\beta}}_j\right) \boldsymbol{S}_t'\left(\boldsymbol{b}^{(j',l)}; \hat{\boldsymbol{\beta}}_j\right)\right] \,,$$

With j sufficiently large, $\bar{\boldsymbol{S}}_{b,j}, \bar{\boldsymbol{S}}_{t,j}, \bar{\boldsymbol{S}}_{bb,j}, \bar{\boldsymbol{S}}_{bt,j}, \bar{\boldsymbol{S}}_{tt,j}$ provide good estimates for (38.18, 22).

Denote $\boldsymbol{S}_j = (\boldsymbol{S}_{b,j}', \boldsymbol{S}_{t,j}')'$ and

$$\boldsymbol{H}_j = \begin{pmatrix} \bar{\boldsymbol{S}}_{bb,j} & \bar{\boldsymbol{S}}_{bt,j} \\ \bar{\boldsymbol{S}}_{bt,j}' & \bar{\boldsymbol{S}}_{tt,j} \end{pmatrix} \,.$$

Then, at the jth U-step, the updated value for $\hat{\boldsymbol{\gamma}}$ is

$$\boldsymbol{\gamma}^{(j+1)} = \boldsymbol{\gamma}^{(j)} - a_j \boldsymbol{H}_j^{-1} \boldsymbol{S}_j \,,$$

where the tuning parameter a_j can be chosen as discussed in the previous section. Note that each of the quantities required at this step, such as $\bar{\boldsymbol{S}}_j$, $\bar{\boldsymbol{S}}_{\boldsymbol{\beta},j}$, and so on, can be calculated recursively so that the past values of these intermediate variables never need to be stored.

Following *Satten* and *Datta* [38.24], as $j \to \infty$, $\hat{\boldsymbol{\gamma}}_j$ almost surely converges to $\hat{\boldsymbol{\gamma}}$. Denote the S–U estimate

by $\hat{\boldsymbol{\gamma}}_{\mathrm{SU}}$. The total sampling variance of $\hat{\boldsymbol{\gamma}}_{\mathrm{SU}}$ around $\boldsymbol{\gamma}_0$ is the sum of the variance of $\hat{\boldsymbol{\gamma}}_{\mathrm{SU}}$ around $\hat{\boldsymbol{\gamma}}$ due to the S–U algorithm and the sampling variance of $\hat{\boldsymbol{\gamma}}$ around $\boldsymbol{\gamma}_0$ [38.25]. In most cases, the S–U algorithm should be iterated until the former is negligible compared to the latter. In theory, the starting value for the S–U algorithm is arbitrary. However, a poor starting value might cause instability at the beginning of this algorithm. Hence, in the next section, we consider several approximate methods that generate a starting value sufficiently close to the true zero of the estimating equations.

38.4.5 Some Approximate Methods

In view of the cumbersome and often intractable integrations required for a full likelihood analysis, several techniques have been made available for approximate inference in the GLMMs and other nonlinear variance component models.

The penalized quasi-likelihood (PQL) method introduced by *Green* [38.26] for semiparametric models was initially exploited as an approximate Bayes procedure to estimate regression coefficients. Since then, several authors have used the PQL to draw approximate inferences based on random effects models: *Schall* [38.5] and *Breslow* and *Clayton* [38.8] developed iterative PQL algorithms, *Lee* and *Nelder* [38.27] applied the PQL directly to hierarchical models. We present the PQL from the likelihood perspective below.

Consider the GLMM (38.10). For notational simplicity, we write the integrand of the likelihood function

$$f(\boldsymbol{Y}|\boldsymbol{b};\boldsymbol{\beta})f(\boldsymbol{b};\boldsymbol{\theta}) = \exp[-K(\boldsymbol{Y},\boldsymbol{b})]\,. \tag{38.23}$$

More generally, if one only specifies the first two conditional moments of $\boldsymbol{Y}$ given $\boldsymbol{b}$ in lieu of a full likelihood specification, $f(\boldsymbol{Y}|\boldsymbol{b};\boldsymbol{\beta})$ in (38.23) can be replaced by the quasi-likehood function $\exp[ql(\boldsymbol{Y}|\boldsymbol{b};\boldsymbol{\beta})]$, where

$$ql(\boldsymbol{Y}|\boldsymbol{b};\boldsymbol{\beta}) = \sum_{i=1}^{m}\sum_{j=1}^{n_i}\int_{Y_{ij}}^{\mu_{ij}^{b}} \frac{Y_{ij}-t}{V(t)}\mathrm{d}\,t\,.$$

Here $\mu_{ij}^{\mathrm{b}} = E(Y_{ij}|\boldsymbol{b};\boldsymbol{\beta})$ and $V(\mu_{ij}^{\mathrm{b}}) = \mathrm{var}(Y_{ij}|\boldsymbol{b};\boldsymbol{\beta})$.

Next evaluate the marginal likelihood. We temporarily assume that $\boldsymbol{\theta}$ is known. For any fixed $\boldsymbol{\beta}$, expanding $K(\boldsymbol{Y},\boldsymbol{b})$ around its mode $\hat{\boldsymbol{b}}$ up to the second-order term, we have

$$\begin{aligned} L(\boldsymbol{Y};\boldsymbol{\beta},\boldsymbol{\theta}) &= \int \exp[-K(\boldsymbol{Y},\boldsymbol{b})]\mathrm{d}\,\boldsymbol{b} \\ &= \left|\left|2\pi\left[K''(\boldsymbol{Y},\tilde{\boldsymbol{b}})\right]^{-1}\right|\right|^{1/2}\exp\left[-K(\boldsymbol{Y},\hat{\boldsymbol{b}})\right], \end{aligned}$$

where $K''(\boldsymbol{Y},\boldsymbol{b})$ denotes the second derivative of $K(\boldsymbol{Y},\boldsymbol{b})$ with respect to $\boldsymbol{b}$, and $\tilde{\boldsymbol{b}}$ lies in the segment joining zero and $\hat{\boldsymbol{b}}$. If $K''(\boldsymbol{Y},\boldsymbol{b})$ does not vary too much as $\boldsymbol{b}$ changes (for instance, $K''(\boldsymbol{Y},\boldsymbol{b}) = \textit{constant}$ for normal data), maximizing the marginal likelihood (38.11) is equivalent to maximizing

$$\mathrm{e}^{-K(\boldsymbol{Y},\hat{\boldsymbol{b}})} = f(\boldsymbol{Y}|\hat{\boldsymbol{b}},\boldsymbol{\beta})f(\hat{\boldsymbol{b}};\boldsymbol{\theta})\,.$$

Or, equivalently, $\hat{\boldsymbol{\beta}}(\boldsymbol{\theta})$ and $\hat{\boldsymbol{b}}(\boldsymbol{\theta})$ are obtained by jointly maximizing $f(\boldsymbol{Y}|\boldsymbol{b};\boldsymbol{\beta})f(\boldsymbol{b};\boldsymbol{\theta})$ w.r.t. $\boldsymbol{\beta}$ and $\boldsymbol{b}$ with $\boldsymbol{\theta}$ being held constant. If $\boldsymbol{\theta}$ is unknown, it can be estimated by maximizing the approximate profile likelihood of $\boldsymbol{\theta}$,

$$\left|\left|2\pi\left\{K''[\boldsymbol{Y},\hat{\boldsymbol{b}}(\boldsymbol{\theta})]\right\}^{-1}\right|\right|^{1/2}\exp\left\{-K[\boldsymbol{Y},\hat{\boldsymbol{b}}(\boldsymbol{\theta})]\right\}.$$

A more detailed discussion can be found in *Breslow* and *Clayton* [38.8].

As no closed-form solution is available, the PQL is often performed through an iterative process. In particular, *Schall* [38.5] derived an iterative algorithm where the random effects follow normal distributions. Specifically, with the current estimated values of $\boldsymbol{\beta}$, $\boldsymbol{\theta}$ and $\boldsymbol{b}$, a working 'response' $\tilde{\boldsymbol{Y}}$ is constructed by the first-order Taylor expansion of $g(\boldsymbol{Y})$ around $\boldsymbol{\mu}^{\mathrm{b}}$, or explicitly,

$$\begin{aligned} \tilde{\boldsymbol{Y}} &= g(\boldsymbol{\mu}^{\mathrm{b}}) + g'(\boldsymbol{\mu}^{\mathrm{b}})(\boldsymbol{Y}-\boldsymbol{\mu}^{\mathrm{b}}) \\ &= \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}b + g'(\boldsymbol{\mu}^{\mathrm{b}})(\boldsymbol{Y}-\boldsymbol{\mu}^{\mathrm{b}})\,, \end{aligned} \tag{38.24}$$

where $g(\cdot)$ is defined in (38.9).

Viewing the last term in (38.24) as a random error, (38.24) suggests fitting a linear mixed model on $\tilde{\boldsymbol{Y}}$ to obtain the updated values of $\boldsymbol{\beta}, \boldsymbol{b}$ and $\boldsymbol{\theta}$, which are used to recalculate the working 'response'. The iteration continues until convergence. Computationally, the PQL is easy to implement; it only requires repeatedly calling in existing software, for example, SAS 'PROC MIXED'. The PQL procedure yields exact MLEs for normally distributed data and for some cases when the conditional distribution of $\boldsymbol{Y}$ and the distribution of $\boldsymbol{b}$ are conjugate.

Other approaches, such as the Laplace method and the Solomon-Cox approximation, have also received much attention. The Laplace method (see for example *Liu* and *Pierce* [38.28]) differs from the PQL only in that the former obtains $\hat{\boldsymbol{b}}(\boldsymbol{\beta},\boldsymbol{\theta})$ by maximizing the integrand $\mathrm{e}^{-K(\boldsymbol{Y},\boldsymbol{b})}$ with $\boldsymbol{\beta}$ and $\boldsymbol{\theta}$ being held fixed, and subsequently estimates $(\hat{\boldsymbol{\beta}},\hat{\boldsymbol{\theta}})$ by jointly maximizing

$$\left|\left|2\pi\left[K''(\boldsymbol{Y},\hat{\boldsymbol{b}})\right]^{-1}\right|\right|^{1/2}\exp\left[-K(\boldsymbol{Y},\hat{\boldsymbol{b}})\right].$$

On the other hand, with the assumption of $E(\boldsymbol{b}) = 0$, the Solomon-Cox technique approximates

the integral $\int f(\boldsymbol{Y}|\boldsymbol{b})f(\boldsymbol{b})\mathrm{d}\boldsymbol{b}$ by expanding the integrand $f(\boldsymbol{Y}|\boldsymbol{b})$ around $\boldsymbol{b}=0$; see *Solomon* and *Cox* [38.29].

In general, none of these approximate methods produce consistent estimates,h except in some special cases, for example with normal data. Moreover, these methods are essentially based on normal approximation, and they often do not perform well for sparse data, such as binary data, and when the cluster size is relatively small [38.30].

38.5 Special Topics: Testing Random Effects for Clustered Categorical Data

It is useful to test for correlation within clusters and the heterogeneity among clusters when (or prior to) fitting random effects models. Tests have been proposed that are based on score statistics for the null hypothesis that variance components are zero for clustered continuous, binary and Poisson outcomes within the random effects model framework [38.31, 32]. However, literature that deals with tests for clustered polytomous data is scarce.

A recent article by *Li* and *Lin* [38.33] investigated tests for within-cluster correlation for clustered polytomous and censored discrete time-to-event data by deriving score tests for the null hypothesis that variance components are zero in random effects models. Since the null hypothesis is on the boundary of the parameter space, unlike the Wald and likelihood ratio tests whose asymptotic distributions are mixtures of chi-squares, the score tests are advantageous because their asymptotic distributions are still chi-square. Another advantage of the score tests is that no distribution needs to be assumed for the random effects except for their first two moments. Hence they are robust to mis-specifying the distributions of the random effects. Further, the Wald tests and the LR tests involve fitting random effects models that involve numerical integration, in contrast with the score tests, which only involve fitting standard models under the null hypothesis using existing standard software, and do not require numerical integration.

A common problem in the analysis of clustered data is the presence of covariate measurement errors. For example, in flood forecasting studies, the radar measurements of precipitation are 'highly susceptible' to error due to improper electronic calibration [38.34]; in AIDS studies, CD4 counts are often measured with error [38.35]. Valid statistical inference needs to account for measurement errors in covariates. *Li* and *Lin* [38.33] have extended the score tests for variance components to the situation where covariates are measured with errors. They applied the SIMEX method [38.36] to correct for measurement errors and develop SIMEX score tests for variance components. These tests are an extension of the SIMEX score test of *Lin* and *Carroll* [38.37] to clustered polytomous data with covariate measurement error.

Random effects-generalized logistic models and cumulative probability models have been proposed to model clustered nominal and ordinal categorical data [38.38, 39]. This section focuses on the score tests for the null hypothesis that the variance components are zero in such models to test for the within-cluster correlation.

38.5.1 The Variance Component Score Test in Random Effects–Generalized Logistic Models

Suppose that, for the jth ($j=1,\ldots,n_i$) subject in the i-th ($i=1,\ldots,m$) cluster, a categorical response Y_{ij} belongs to one of N categories indexed by $1,\ldots,N$. Conditional on the cluster-level random effect b_i, the observations Y_{ij} are independent and the conditional probability $P_{ij,k}=P(Y_{ij}=k|b_i)$ depends on the $p\times 1$ covariate vector $\boldsymbol{X}_{ij}$ through a generalized logistic model

$$\log\left(\frac{P_{ij,k}}{P_{ij,N}}\right)=\alpha_k+\boldsymbol{X}'_{ij}\boldsymbol{\beta}_k+b_i=\boldsymbol{X}'_{ij,k}\boldsymbol{\beta}+b_i\,,\quad k=1,\ldots,N-1 \tag{38.25}$$

where $\boldsymbol{\beta}_k$ is a $p\times 1$ vector of fixed effects, $b_i\sim F(b_i;\theta)$ for some distribution function F that has zero mean and a variance θ, $\boldsymbol{X}'_{ij,k}=\boldsymbol{e}'_k\otimes(1,\boldsymbol{X}'_{ij})$; $\otimes$ denotes a Kronecker product, $\boldsymbol{e}_k$ is an $(N-1)\times 1$ vector with the kth component equal to 1 and the rest of the components set to zero, and $\boldsymbol{\beta}=(\alpha_1,\boldsymbol{\beta}'_1,\cdots,\alpha_{N-1},\boldsymbol{\beta}'_{N-1})'$.

The marginal log-likelihood function for $(\boldsymbol{\beta},\theta)$ is

$$\ell(\boldsymbol{\beta},\theta)=\sum_{i=1}^{m}\log\int\exp[\ell_i(\boldsymbol{\beta},b_i)]\mathrm{d}\,F(b_i;\theta)\,, \tag{38.26}$$

where $\ell_i(\boldsymbol{\beta},b_i)=\sum_{j=1}^{n_i}\sum_{k=1}^{N}y_{ij,k}\log P_{ij,k}$, $y_{ij,k}=I(Y_{ij}=k)$ and $I(\cdot)$ is an indicator function. The magnitude of θ measures the degree of the within-cluster correlation. We are interested in testing $H_0:\theta=0$

vs. $H_1 : \theta > 0$, where $H_0 : \theta = 0$ corresponds to no within-cluster correlation. Since the null hypothesis is on the boundary of the parameter space, neither the likelihood ratio test nor the Wald test follows a chi-square distribution asymptotically [38.40].

Li and *Lin* [38.33] considered a score test for H_0 and showed that it still follows a chi-square distribution asymptotically. Specifically, they showed that the score statistic of θ evaluated under $H_0 : \theta = 0$ is

$$U_\theta(\boldsymbol{\beta}) = \left.\frac{\partial \ell(\boldsymbol{\beta}, \theta)}{\partial \theta}\right|_{\theta=0} = \sum_{i=1}^{m} \frac{1}{2}\left[\frac{\partial^2 \ell_i(\boldsymbol{\beta}, b_i)}{\partial b_i^2} + \left(\frac{\partial \ell_i(\boldsymbol{\beta}, b_i)}{\partial b_i}\right)^2\right]\Bigg|_{b_i=0} \tag{38.27}$$

$$= \frac{1}{2}\sum_{i=1}^{m}\left\{\left[\sum_{j=1}^{n_i}(\widetilde{Y}_{ij} - \widetilde{P}_{ij})\right]^2 - \sum_{j=1}^{n_i}\widetilde{P}_{ij}(1-\widetilde{P}_{ij})\right\}, \tag{38.28}$$

where

$$\widetilde{Y}_{ij} = \sum_{k=1}^{N-1} y_{ij,k} = I(Y_{ij} \le N-1)$$

and

$$\widetilde{P}_{ij} = \sum_{k=1}^{N-1} \exp(X'_{ij,k}\,\boldsymbol{\beta}) \Big/ \left[1 + \sum_{k=1}^{N-1} \exp(X'_{ij,k}\boldsymbol{\beta})\right]$$

is the mean of $\widetilde{Y}_{ij}$ under H_0. It is interesting to note that the form of (38.28) resembles the variance component score statistic for clustered binary data [38.31]. It can be shown that under $H_0 : \theta = 0$, $E[U_\theta(\boldsymbol{\beta})] = 0$ and $m^{-1/2}U_\theta(\boldsymbol{\beta})$ is asymptotically normal $MVN(0, I_{\theta\theta})$, where $I_{\theta\theta}$ is given in (38.30).

To study the properties of $U_\theta(\boldsymbol{\beta})$ under $H_1 : \theta > 0$, they expanded $E(\widetilde{Y}_{ij}|b_i)$ as a quadratic function of b_i, and showed that, under $H_1 : \theta > 0$,

$$E[U_\theta(\boldsymbol{\beta})] \approx \frac{1}{2}\sum_{i=1}^{m}\left[\sum_{j=1}^{n_i}\sum_{k\neq j}^{n_i} a_{ij}a_{ik} + \frac{1}{2}\sum_{j=1}^{n_i} a_{ij}\{a'_{ij}\}^2\right]\theta\,,$$

where $a_{ij} = \widetilde{P}_{ij}(1-\widetilde{P}_{ij})$ and $a'_{ij} = 1 - 2\widetilde{P}_{ij}$. As a result, $E[U_\theta(\boldsymbol{\beta})]$ is an increasing function of θ. Hence the test is consistent and one would expect a large value of $U_\theta(\boldsymbol{\beta})$ for a large value of θ.

Since $\boldsymbol{\beta}$ is unknown under H_0 and needs to be estimated, the score statistic for testing H_0 is

$$S = U_\theta(\hat{\boldsymbol{\beta}})/\widetilde{I}_{\theta\theta}^{1/2}(\hat{\boldsymbol{\beta}})\,, \tag{38.29}$$

where $\hat{\boldsymbol{\beta}}$ is the MLE of $\boldsymbol{\beta}$ under H_0 and can be easily obtained by fitting the generalized logistic model $\log(P_{ij,k}/P_{ij,N}) = \boldsymbol{X}'_{ij,k}\boldsymbol{\beta}$, (using SAS PROC CATMOD for example), and $\widetilde{I}_{\theta\theta} = I_{\theta\theta} - I_{\theta\boldsymbol{\beta}'}I^{-1}_{\boldsymbol{\beta}\boldsymbol{\beta}'}I_{\boldsymbol{\beta}\theta}$ is the efficient information of θ evaluated under $H_0 : \theta = 0$. Using L'Hôpital's rule, some calculations show that

$$I_{\theta\theta} = E\left[\left(\frac{\partial \ell}{\partial \theta}\right)^2\right] = \frac{1}{4}\sum_{i=1}^{m}\left[\sum_{j=1}^{n_i}\widetilde{P}_{ij}\widetilde{Q}_{ij}(1 - 6\widetilde{P}_{ij}\widetilde{Q}_{ij}) + 2\left(\sum_{j=1}^{n_i}\widetilde{P}_{ij}\widetilde{Q}_{ij}\right)^2\right], \tag{38.30}$$

$$I_{\boldsymbol{\beta}\boldsymbol{\beta}'} = \sum_{i=1}^{m} E\left(\frac{\partial \ell_i}{\partial \boldsymbol{\beta}}\frac{\partial \ell_i}{\partial \boldsymbol{\beta}'}\right) = \sum_{i=1}^{m}\mathbf{X}'_i\boldsymbol{\Sigma}_i\mathbf{X}_i\,, \tag{38.31}$$

$$I_{\theta\boldsymbol{\beta}'} = \sum_{i=1}^{m} E\left(\frac{\partial \ell_i}{\partial \theta}\frac{\partial \ell_i}{\partial \boldsymbol{\beta}'}\right) = \frac{1}{2}\sum_{i=1}^{m}\mathbf{P}'_i\{\mathbf{I}_{N-1}\otimes\mathbf{G}_i\}\mathbf{X}_i\,, \tag{38.32}$$

where the expectations are taken under H_0; $\mathbf{I}_{N-1}$ denotes an $(N-1)\times(N-1)$ identity matrix, and $\boldsymbol{X}_i = (\mathbf{X}'_{i1}, \ldots, \mathbf{X}'_{in_i})'$, where $\boldsymbol{X}_{ij} = (\boldsymbol{X}_{ij,1}, \ldots, \boldsymbol{X}_{ij,N-1})'$, $\tilde{Q}_{ij} = 1 - \tilde{P}_{ij}$, and $\boldsymbol{\Sigma}_i = (\boldsymbol{\Sigma}_{i,rl})$, which is an $(N-1)\times(N-1)$ block matrix whose (r,l)-th block is

$$\boldsymbol{\Sigma}_{i,rr} = \mathrm{diag}[P_{i1,r}(1-P_{i1,r}), \ldots, P_{in_i,r}(1-P_{in_i,r})]$$
$$\boldsymbol{\Sigma}_{i,rl} = \mathrm{diag}[-P_{i1,r}P_{i1,l}, \ldots, -P_{in_i,r}P_{in_i,l}]\,,\ r \neq l\,,$$

$\mathbf{G}_i = \mathrm{diag}(2\tilde{P}_{ij}^2 - 3\tilde{P}_{ij} + 1, \ldots, 2\tilde{P}_{in_i}^2 - 3\tilde{P}_{in_i} + 1)$ and $\mathbf{P}_i = (\boldsymbol{P}'_{i,1}, \ldots, \boldsymbol{P}'_{i,N-1})'$, where $\boldsymbol{P}_{i,r} = (P_{ij,r}, \ldots, P_{in_i,r})'$. Standard asymptotic calculations show that S is asymptotically $N(0,1)$ under H_0 and one rejects H_0 if S is large and the test is one-sided.

The score test S for $H_0 : \theta = 0$ has several attractive features. First, it can be easily obtained by fitting the generalized logistic model $\log(P_{ij,k}/P_{ij,N}) = \boldsymbol{X}'_{ij,k}\boldsymbol{\beta}$, which is model (38.25) under H_0, using standard software, such as SAS PROC CATMOD. Hence calculations of S do not involve any numerical integration. Secondly, it is the most powerful test locally. Finally it is robust, as no distribution is assumed for the random effect b_i. We discuss an application of the test based on (38.25) in Sect. 38.5.4.

38.5.2 The Variance Component Score Test in Random Effects Cumulative Probability Models

A widely used model for clustered ordinal data is the cumulative probability random effects model obtained by modeling the cumulative probabilities $r_{ij,k} = P(Y_{ij} \le k)$ as

$$g(r_{ij,k}) = \alpha_k + \boldsymbol{X}'_{ij}\boldsymbol{\beta}_x + b_i = \boldsymbol{X}'_{ij,k}\boldsymbol{\beta} + b_i \,, \quad k = 1, \ldots, N-1 \,, \tag{38.33}$$

where $g(\cdot)$ is a link function, $\boldsymbol{X}_{ij,k} = (\boldsymbol{e}'_k, \boldsymbol{X}'_{ij})'$, $\boldsymbol{\beta} = (\alpha_1, \cdots, \alpha_{N-1}, \boldsymbol{\beta}'_x)$, and $b_i \sim F(., \theta)$ for some distribution function F with zero mean and variance θ. For $g(\cdot) = \text{logit}(\cdot)$ and $g(\cdot) = \log[-\log(1-\cdot)]$, we have proportional odds and complementary log-log models. Define $o_{ij,k} = I(Y_{ij} \le k)$. Denote $\boldsymbol{r}_{ij} = (r_{ij,1}, \ldots, r_{ij,N-1})'$, $\boldsymbol{R}_i = (\boldsymbol{r}'_{i1}, \ldots, \boldsymbol{r}'_{in_i})'$ and define $\boldsymbol{o}_{ij}$, $\boldsymbol{O}_i$ similarly. Some calculations show that the score statistic of θ under $H_0 : \theta = 0$ is

$$U_\theta(\boldsymbol{\beta}) = \frac{1}{2}\sum_{i=1}^{m}\Big[(\boldsymbol{O}_i - \boldsymbol{R}_i)'\boldsymbol{\Gamma}_i^{-1}\boldsymbol{H}_i b f 1_i b f 1'_i \boldsymbol{H}_i \boldsymbol{\Gamma}_i^{-1} \times (\boldsymbol{O}_i - \boldsymbol{R}_i) - b f 1'_i \tilde{\boldsymbol{W}}_i b f 1_i\Big] \,, \tag{38.34}$$

where $\boldsymbol{1}_i$ is an $n_i(N-1)\times 1$ vector of ones; the weight matrices of $\boldsymbol{H}_i$, $\boldsymbol{\Gamma}_i$ and $\tilde{\boldsymbol{W}}_i$ are given in Appendix A.2 of *Li* and *Lin* [38.33]. Though seemingly complicated, (38.34) essentially compares the empirical variance of the weighted responses to its nominal variance.

The score statistic for testing $H_0 : \theta = 0$ is $S = U_\theta(\hat{\boldsymbol{\beta}}) \,/\, \tilde{I}^{1/2}_{\theta\theta}(\hat{\boldsymbol{\beta}})$, where $\hat{\boldsymbol{\beta}}$ is the MLE of $\boldsymbol{\beta}$ under H_0, and it can be easily obtained by fitting the standard cumulative probability model $g(r_{ij,k}) = \boldsymbol{X}'_{ij,k}\boldsymbol{\beta}$, and $\tilde{I}_{\theta\theta}(\hat{\boldsymbol{\beta}})$ is the efficient information of θ. Computing the information matrices is tedious since the calculations involve the third and fourth cumulants of a multinomial distribution. The explicit expressions of the information matrices are given in *Li* and *Lin* [38.33].

Standard asymptotic calculations show that the score statistic S follows $N(0,1)$ asymptotically below H_0, and has the same optimality and robustness properties stated at the end of Sect. 38.5.1. It can be easily calculated by fitting the standard cumulative probability model $g(r_{ij,k}) = \boldsymbol{X}'_{ij,k}\boldsymbol{\beta}$ using existing software, such as SAS PROC CATMOD, and does not require any numerical integration. Again a one-sided test is used and H_0 is rejected for a large value of S. An application of score test based on (38.33) is presented in Sect. 38.5.4.

38.5.3 Variance Component Tests in the Presence of Measurement Errors in Covariates

Li and *Lin* [38.33] extended the variance component score tests to the situation when covariates are measured with error. To proceed, we denote a vector of unobserved covariates (such as the true precipitation level or the true CD4 count) by $\boldsymbol{X}_{ij}$ and $\boldsymbol{C}_{ij}$ denotes other accurately measured covariates (such as rainfall location or patients' gender).

The random effects cumulative probability model (38.33) and the random effects generalized logistic model (38.25) can be written in a unified form

$$g(p_{ij,k}) = \alpha_k + \boldsymbol{X}'_{ij}\boldsymbol{\beta}_{x,k} + \boldsymbol{C}'_{ij}\boldsymbol{\beta}_{c,k} + b_i \,, \tag{38.35}$$

where b_i follows some distribution $F(., \theta)$ with mean 0 and variance θ. For the random effects cumulative probability model (38.33), $p_{ij,k} = r_{ij,k}$ and $\boldsymbol{\beta}_{x,1} = \ldots = \boldsymbol{\beta}_{x,N-1}$ and $\boldsymbol{\beta}_{c,1} = \ldots = \boldsymbol{\beta}_{c,N-1}$. For the random effects generalized logistic model (38.25), $p_{ij,k} = P_{ij,k}/P_{ij,N}$ and $g(\cdot) = \log(\cdot)$.

Suppose the observed covariates $\mathbf{W}_{ij}$ (such as radar measurements of rainfall or observed CD4 counts) measure $\boldsymbol{X}_{ij}$ (such as the true precipitation amount or the true CD4 counts) with error. It is customary to postulate a nondifferential additive measurement error model for $\mathbf{W}_{ij}$ [38.41],

$$\mathbf{W}_{ij} = \mathbf{X}_{ij} + \mathbf{U}_{ij} \,, \tag{38.36}$$

where the $\mathbf{U}_{ij}$ are independent measurement errors following $MVN(0, \boldsymbol{\Sigma}_u)$. Suppose that the measurement error covariance $\boldsymbol{\Sigma}_u$ is known or is estimated as $\hat{\boldsymbol{\Sigma}}_u$, using replicates or validation data for example. We are interested in testing for no within-cluster correlation $H_0 : \theta = 0$ in the random effects measurement error models (38.35) and (38.36). *Li* and *Lin* [38.33] have proposed using the SIMEX method by extending the results in the previous two sections to construct score tests for H_0 to account for measurement errors.

Simulation extrapolation (SIMEX) is a simulation-based functional method for inference on model parameters in measurement error problems [38.36], where no distributional assumption is made about the unobserved covariates $\mathbf{X}_{ij}$. We first briefly describe parameter estimation in random effects measurement error models (38.35, 36) using the SIMEX method, then discuss how to use the SIMEX idea to develop SIMEX score tests for $H_0 : \theta = 0$.

The SIMEX method involves two steps: the simulation step and the extrapolation step. In the simulation step, data $\mathbf{W}_{ij}^*$ is generated by adding to $\mathbf{W}_{ij}$ a random error following $N(0, \eta\boldsymbol{\Sigma}_u)$ for some constant $\eta > 0$. Naive parameter estimates are then calculated by fitting (38.35) with $\boldsymbol{X}_{ij}$ replaced by $\mathbf{W}_{ij}^*$. This gives the naive estimates if the measurement error covariance is $(1+\eta)\boldsymbol{\Sigma}_u$. This procedure is repeated for a large number B of times (for example $B = 100$), and the mean of the resulting B naive parameter estimates is calculated. One does this for a series of values of η (such as $\eta = 0.5, 1, 1.5, 2$). In the extrapolation step, a regression (such as a quadratic) model is fitted to the means of these naive estimates as a function of η, and is extrapolated to $\eta = -1$, which corresponds to zero measurement error variance. These extrapolated estimates give the SIMEX estimates for the model parameters. For details of the SIMEX method, see *Cook* and *Stefanski* [38.36] and *Carroll* et al. [38.41]. The SIMEX idea can be utilized to construct score tests for $H_0 : \theta = 0$ in the random effects measurement error models (38.35) and (38.36) by extending the results in Sects. 38.5.1 and 38.5.2. The resulting SIMEX score tests are an extension of the work of *Lin* and *Carroll* [38.37] to random effects measurement error models for clustered polytomous data.

In the absence of measurement error, the score statistics for testing $H_0 : \theta = 0$ under (38.35) take the same form $U_\theta(\hat{\boldsymbol{\beta}}) \,/\, \widetilde{I}_{\theta\theta}^{1/2}(\hat{\boldsymbol{\beta}})$, where $U_\theta(\hat{\boldsymbol{\beta}})$ is given in (38.34) for random effects cumulative probability models and in (38.28) for random effects generalized logistic models. The denominator $\widetilde{I}_{\theta\theta}(\hat{\boldsymbol{\beta}})$ is in fact the variance of $U_\theta(\hat{\boldsymbol{\beta}}|)$. The main idea of the SIMEX variance component score test is to treat the score statistic in the numerator $U_\theta(\cdot)$ as if it were a parameter estimator and use the SIMEX variance method (*Carroll* et al. [38.41]) to calculate the variance of this 'estimator'. Specifically, in the SIMEX simulation step, one simply calculates naive score statistics using the score formulae (38.34) and (38.28) by replacing $\boldsymbol{X}_{ij}$ with the simulated data $\boldsymbol{W}_{ij}^*$. The rest of the steps parallel those in the standard SIMEX method for parameter estimation. Denoting the results by $U_{\text{simex}}(\cdot)$ and $\widetilde{I}_{\theta\theta,\text{simex}}$ respectively, the SIMEX score statistic is simply

$$S_{\text{simex}} = U_{\text{simex}} / \widetilde{I}_{\theta\theta,\text{simex}}^{1/2} , \qquad (38.37)$$

which follows $N(0, 1)$ asymptotically when the true extrapolation function is used. Since the true extrapolation function is unknown in practice, an approximation (such as a quadratic) is used. The simulation study reported by *Li* and *Lin* [38.33] shows that the SIMEX score tests perform well. The theoretical justification for the SIMEX score tests can be found in *Lin* and *Carroll* [38.37].

The SIMEX score test possesses several important advantages. First, it can be easily calculated by fitting standard cumulative probability models using available software such as SAS PROC CATMOD. Secondly, it is robust in the sense that no distribution needs to be assumed for the frailty b_i and for the unobserved covariates $\boldsymbol{X}$.

38.5.4 Data Examples

To illustrate the variance component score tests for clustered polytomous data, we examine data from a longitudinal study on the efficacy of steam inhalation for treating common cold symptoms, conducted by *Macknin* et al. [38.42]. This study included 30 patients with colds of recent onset. At the time of enrolment, each patient went through two 20 min steam inhalation treatments spaced 60–90 minutes apart. Assessment of subjective response was made on an individual daily score card by the patient from day 1 (baseline) to day 4. On each day, the severity of nasal drainage was calibrated into four ordered categories (no symptoms, mild, moderate and severe symptoms). The study examined whether the severity improved following the treatment, and tested whether the observations over time for each subject were likely to be correlated.

Li and *Lin* [38.33] considered models (38.25) and (38.33) with the time from the baseline as a covariate. They first assumed a random effects logistic model (38.25), and obtained a variance component score statistic 5.32 (p-value < 0.001), which provided strong evidence for within-subject correlation over time. Similar results were found when they fitted a random effects proportional odds model (38.33) (score statistic = 9.70, p-value < 0.001). In these two tests they assumed no distribution for the random effect b_i.

To further examine the effect of time, they fitted (38.33) by further assuming that the random effect b_i followed $N(0, \theta)$. The MLE of the coefficient of time was -0.33 (SE $= 0.21$), which suggested that the severity improved following the treatment but that improvement was not statistically significant (p-value $= 0.11$). The estimated variance component was 2.31 (SE $= 0.45$). This result was consistent with the test results.

38.6 Discussion

Central to the idea of mixed modeling is the idea of fixed and random effects. Each effect in a model must be classified as either a fixed or a random effect. Fixed effects arise when the levels of an effect constitute the entire population of interest. For example, if an industrial experiment focused on the effectiveness of three brands of a machine, *machine* would be a fixed effect only if the experimenter's interest did not go beyond the three machine brands. On the other hand, an effect is classified as a random effect when one wishes to make inferences on an entire population, and the levels in the experiment represent only a sample from that population. Consider an example of psychologists comparing test results between different groups of subjects. Depending on the psychologists' particular interest, the group effect might be either fixed or random. For example, if the groups are based on the sex of the subject, *sex* would be a fixed effect. But if the psychologists are interested in the variability in test scores due to different teachers, they might choose a random sample of teachers as being representative of the total population of teachers, and *teacher* would be a random effect. Returning to the machine example presented earlier, *machine* would also be considered to be a random effect if the scientists were interested in making inferences on the entire population of machines and randomly chose three brands of machines for testing.

In summary, what makes a random effect unique is that each level of a random effect contributes an amount that is viewed as a sample from a population of random variables. The estimate of the variance associated with the random effect is known as the variance component because it measures the part of the overall variance contributed by that effect. In mixed models, we combine inferences about means (of fixed effects) with inferences about variances (of random effects).

A few difficulties arise from setting up the likelihood function to draw inference based on a random effects model. The major obstacle lies in computation, as, for practitioners, the main issue focuses on how to handle the intractable MLE calculations. This chapter reviews some commonly used approaches to estimating the regression coefficients and the variance components in the (generalized) linear mixed models. We note that the EM algorithm can yield maximum likelihood estimates, which are consistent and most efficient under regularity conditions. However, its computational burden is substantial, and the convergence rate is often slow. Laplace approximation greatly reduces the computational load, but the resulting estimates are generally biased. The simulated maximum likelihood estimation is considerably less computationally burdensome compared to the EM. For example, the rejection sampling is avoided, saving much computing time. However, its obvious drawback is the local convergence – a 'good' initial point is required to achieve the global maximizer. The so-called SA and S–U algorithms seem to be promising, as they make full use of the simulated data and obtain the estimates recursively. However, the detailed implementation of both methods have yet to be finalized in the literature.

It is worth briefly discussing marginal models, another major tool for handling clustered data. In a marginal model, the marginal mean of the response vector is modeled as a function of explanatory variables [38.43]. Thus, in contrast to the random effect models, the coefficients in a marginal model have population average interpretations. This type of model is typically fitted via the so-called generalized estimating equation (GEE). An appealing feature is that, for the right mean structure, even when the covariance structure of the response is mis-specified, the GEE acquires consistent estimates. However, the GEE method faces several difficulties, which may easily be neglected. First, the GEE estimator's efficiency becomes problematic when the variance function is mis-specified. Secondly, the consistency of the estimator is only guaranteed under noninformative censoring; informative censoring generally leads to biased estimates. More related discussion can be found in *Diggle* et al. [38.43].

Lastly, we point out other active research areas in mixed modeling, including evaluating the model's goodness of fit, choosing the best distribution for the random effects and selecting the best collection of covariates for a model. Readers are referred to some recent articles on these topics (such as [38.44–47]).

39. Cluster Randomized Trials: Design and Analysis

The first section of this chapter gives an introduction to cluster randomized trials, and the reasons why such trials are often chosen above simple randomized trials. It also argues that more advanced statistical methods for data obtained from such trials are required, since these data are correlated due to the nesting of persons within clusters. Traditional statistical techniques, such as the regression model ignore this dependency, and thereby result in incorrect conclusions with respect to the effect of treatment. In the first section it is also argued that the design of cluster randomized trials is more complicated than that of simple randomized trials; not only the total sample size needs to be determined, but also the number of clusters and the number of persons per cluster.

The second section describes and compares the multilevel regression model and the mixed effects analysis of variance (ANOVA) model. These models explicitly take into account the nesting of persons within clusters, and thereby the dependency of outcomes of persons within the same cluster. It is shown that the traditional regression model leads to an inflated type I error rate for treatment testing.

Optimal sample sizes for cluster randomized trials are given in Sects. 39.3 and 39.4. These sample sizes can be shown to depend on the intra-class correlation coefficient, which measures the amount of variance in the outcome variable at the cluster level. A guess of the true value of this parameter must be available in the design stage in order to calculate the optimal sample sizes. Section 39.5 focuses on the robustness of the optimal sample size against incorrect guesses of this parameter. Section 39.6 focuses on optimal designs when the aim is to estimate the intra-class correlation with the greatest precision.

Cluster randomized trials are experiments in which complete clusters of persons, rather than the persons themselves, are randomized to treatment conditions. Such trials are frequently used in the agricultural, (bio-)medical, social, and behavioral sciences. Examples are school-based smoking prevention and cessation interventions with pupils nested within classes within schools, clinical trials with patients nested within clinics or general practices, and studies on interventions to reduce absences due to sick leave with employers nested within divisions within companies. Cluster randomized trials are very natural in the case of existing clusters, but can also be used when groups are created for the purpose of the trial. An example is a trial with therapy groups to reduce alcohol addiction. Alcoholics are assigned to small therapy groups, which in turn are assigned to treatment conditions. The difference is that, in trials with existing clusters, the persons also meet and interact outside the time slots during which the intervention is delivered, resulting in a larger degree of mutual influence.

39.1 Cluster Randomized Trials

Cluster randomized trials are often chosen above simple randomized trials that randomize persons to treatment conditions, although cluster randomized trials can easily be shown to be less efficient (Sect. 39.2). The reasons why cluster randomized trials are so often adopted must rest on other considerations than statistical efficiency, and these are often of an administrative, financial, political or ethical nature. As an example consider a study on the impact of vitamin A supplementation on childhood mortality [39.1]. In this study complete villages in Indonesia were randomly assigned to either the supplementation or control group because it was not considered politically feasible to randomize children. Another advantage of adopting a cluster randomized trial in this example is that the capsules containing the vitamin A supplements only have to be delivered to those villages in the supplementation group, which results in a reduction of travel costs. A trial that randomizes children would suffer from control-group contamination if the children in the control group were able to get access to the vitamin A from children in the supplementation group in the same village. In some cases there is no alternative to cluster randomized trials, such as in community-based interventions where the intervention will necessarily affect all members in the community. Another reason to adopt a cluster randomized trial is the wish to increase compliance. It may be reasonable to expect that compliance increases in a study where complete families, rather that just a few family members, are randomized to treatment conditions.

Due to the nesting of persons within clusters, the design and analysis of cluster randomized trials is more complicated than for simple randomized trials. The traditional assumption of independence is by definition violated when data have a nested structure. This is obvious, since there is mutual influence among persons within the same cluster. So a person's opinion, behavior, attitude or health is influenced by that of other persons in the same cluster. Furthermore, persons are influenced by cluster policy and cluster leaders. In school-based smoking prevention interventions, for instance, a pupil's smoking behavior is influenced by that of other pupils within the same class and (to a lesser degree) school, that of teachers, the school policy towards smoking and the availability of cigarettes and advertisements on smoking in the school and its neighborhood.

The traditional regression model, which assumes independent outcomes, cannot be used for the analysis of nested data. Naively using this model may lead to incorrect point estimates and standard errors of regression coefficients, and therefore to incorrect conclusions on the effect of treatment conditions and covariates on the outcome [39.2–5]. The appropriate model is the multilevel model [39.6], which is also referred to as the hierarchical (linear) model [39.7], or random coefficient model [39.6]. The multilevel model treats the persons as the unit of analysis, but explicitly takes into account nesting of persons within clusters and the correlation of outcomes of persons within the same cluster. It assumes that the clusters in the study represent a random sample from their population, and treats their effects as random in the regression analysis so that the results can be generalized to this population. Multilevel models are an extension of the variance components models and mixed effects ANOVA (analysis of variance) models [39.8] that have long been used in the biological and agricultural sciences. They are an extension in the sense that they do not only include categorical, but also continuous explanatory variables. They have been developed since the early 1980s, and in the first instance especially gained attention from the educational sciences, where data by nature have a multilevel structure due to the nesting of pupils within classes within schools. Nowadays, multilevel models are used in various fields of science, ranging from political sciences to nursery, and from studies on interviewer effects to studies with longitudinal data. It is to be expected that multilevel analysis will become part of the standard statistical techniques in the near future and that editors of scientific journals will no longer consider contributions that use old-fashioned methods to analyze multilevel data.

The design of cluster randomized trials is more complicated than that of simple randomized trials, since it does not only involve the calculation of the required number of persons, but also the calculation of the optimal allocation of units, that is, the optimal sample sizes at the cluster level and the person level. One may wonder if it is more efficient to sample many small clusters or to sample just a few large clusters. Of course, the number of available clusters is limited and the optimal number of clusters cannot therefore be larger than the available number of clusters. Likewise, the optimal cluster size cannot be larger than the actual cluster size, and such preconditions must be taken into account when calculating the optimal design. Furthermore, it is often less expensive to sample a person within an already sampled cluster than to sample a new cluster. So, the costs of sampling persons and clusters and the available budget

should also be taken into account, and it is worthwhile to calculate the required budget to achieve a pre-specified power level to detect a relevant treatment effect, or vice versa, the maximum power level given a fixed budget.

A concern in the design of cluster randomized trials is the fact that the optimal design depends on the true value of the intra-class correlation coefficient, a parameter which measures the amount of variance of the outcome variable at the cluster level. Of course, the true value is not known at the design stage, and an educated guess of this parameter must be used instead. Such a guess can be obtained from knowledge of the subject matter or from similar studies in the past. There is, however, no guarantee that such an educated guess is correct, and it is therefore worthwhile to study the robustness of optimal designs against an incorrect prior value of the intra-class correlation coefficient, and to development robust optimal design techniques.

The contents of this chapter are as follows. In the next section the multilevel regression model and the mixed effects ANOVA model are described and compared. Section 39.3 gives formulae for the optimal allocation of units for models without covariates. The extension to models with covariates is the topic of Sect. 39.4. In Sect. 39.5 we focus on the robustness properties of optimal designs. In Sect. 39.6 we present designs that are useful when interest lies in the degree of the intra-class correlation. Finally, conclusions and a discussion are given in Sect. 39.7. For the sake of simplicity, we focus on optimal designs for models with two levels of nesting, two treatment conditions, and a continuous outcome.

39.2 Multilevel Regression Model and Mixed Effects ANOVA Model

In the simplest version of a cluster randomized trial we wish to compare the effects of an intervention and a control on a single continuous outcome variable. The multilevel regression model relates outcome y_{ij} for person i in cluster j to treatment condition z_j

$$y_{ij} = \beta_0 + \beta_1 z_j + u_j + e_{ij} \,. \tag{39.1}$$

In this chapter, the treatment condition is coded $z_j = -0.5$ for the control condition and $z_j = +0.5$ for the intervention condition. So, β_0 is the mean outcome, and β_1 is the treatment effect, which is estimated by the difference in mean outcomes in both treatment groups. The null hypothesis of no treatment effect is tested by the statistic $t = \hat{\beta}_1 / \sqrt{\hat{\text{var}}(\hat{\beta}_1)}$, which has a t-distribution with $n_2 - 2$ degrees of freedom under the null hypothesis.

The multilevel model differs from the traditional regression model since it contains two random error terms. The term $u_j \sim N(0, \tau^2)$ at the cluster level is the deviation of cluster j from the mean outcome in its treatment condition, and the term $e_{ij} \sim N(0, \sigma^2)$ at the person level is the deviation of person i from the mean outcome in cluster j. These two error terms are assumed to be independent of each other and of possible covariates in the model. In general, the within-cluster variance σ^2 is much larger than the between-cluster variance τ^2.

The first two terms and the right-hand side of (39.1) are the fixed part of the model, whereas the second two terms are the random part. Since it contains both fixed and random effects, the multilevel model is a mixed effects model. Fixed effects are effects that are attributable to a finite set of levels of a factor, and they occur in the data because interest lies only in them, and not in any other levels of that factor. An example of a fixed effect is a treatment factor in a smoking prevention intervention with two levels: intervention and control. We are only interested in the comparison of these two treatment conditions, and not in any other. Random effects, on the other hand, are attributable to an infinite set of levels of a factor, of which only a random sample is included in the study at hand. An example of a random effect is the school effect in a school-based smoking prevention intervention. Although not all schools of the population under study are included in the study, we wish to generalize its findings to all schools in the population. Therefore, school is included as a random effect rather than a fixed effect.

The variances σ^2 and τ^2 are called the variance components since they sum up to the total variance of the outcome of person i within cluster j:

$$\text{var}(y_{ij}) = \sigma^2 + \tau^2 \,. \tag{39.2}$$

Furthermore, there is correlation between outcomes of two persons within the same cluster j:

$$\text{cov}(y_{ij}, y_{i'j}) = \tau^2 \,. \tag{39.3}$$

The intra-class correlation coefficient ρ measures the proportion of variation in the outcomes at the cluster

level, that is

$$\rho = \frac{\mathrm{var}(y_{ij})}{\mathrm{cov}(y_{ij}, y_{i'j})} = \frac{\tau^2}{\sigma^2 + \tau^2} \,. \tag{39.4}$$

This parameter may be interpreted as the standard Pearson correlation coefficient between any two outcomes in the same cluster. Intra-class correlation coefficients are often considerably larger in small clusters such as households, than in large clusters such as postcode levels. This can be explained by the fact that members in small clusters meet each other more often, which results in a higher level of mutual influence. As we will see in the next section, the intra-class correlation coefficient plays a crucial role in calculating the optimal sample sizes.

In a balanced design, randomization is done such that both treatment conditions have $\frac{1}{2}n_2$ clusters, and each cluster consists of n_1 persons. The variance of the treatment effect estimator is then given by

$$\mathrm{var}(\hat{\beta}_1) = 4\frac{\sigma^2 + n_1\tau^2}{n_1 n_2} = 4\frac{\sigma^2 + \tau^2}{n_1 n_2}\left[1 + (n_1 - 1)\rho\right] \,. \tag{39.5}$$

This variance is larger than that obtained with the traditional regression model due to the inclusion of the factor $[1 + (n_1 - 1)\rho]$. This factor is called the design effect, and it increases with the cluster size n_1 and the intra-class correlation coefficient ρ. Since it is always larger than 1, a cluster randomized trial is less efficient than a trial that randomizes persons to treatment conditions. Even for small values of ρ, the design effect may already be considerable. For example, if $\rho = 0.1$ and $n_1 = 10$ the design effect is equal to 1.9, and so the $\mathrm{var}(\hat{\beta}_1)$ as obtained with the multilevel model is about twice that obtained with ordinary regression analysis. So, incorrectly using the traditional regression model results in a value of $\mathrm{var}(\hat{\beta}_1)$ that is too low, and consequently in an inflated type I error rate [39.2]. This is especially the case when the cluster size n_1 and the intra-class correlation coefficient ρ are large.

When treatment condition is the only predictor variable we can write the multilevel model in terms of a mixed effects ANOVA model. For person $i = 1, \ldots, n_1$ in cluster $j = 1, \ldots, n_2$ in treatment $t = 1, 2$ we have

$$y_{ijt} = \mu + \alpha_t + u_{jt} + e_{ijt} \,. \tag{39.6}$$

Here, μ is the grand mean, α_t is the fixed effect of the t-th treatment, and u_{jt} and e_{ijt} are the random effects at the cluster and person level, which are assumed to be normally distributed with zero mean and variances of τ^2 and σ^2 respectively. Since clusters are nested within treatment conditions, we have a nested ANOVA model.

When $t = 1$ corresponds to the control group and $t = 2$ corresponds to the intervention group the correspondence between the parameters in the multilevel regression model in (39.1) and the mixed effects ANOVA model in (39.6) is given by

$$\mu = \beta_0, \quad \alpha_2 - \alpha_1 = \beta_1, \quad u_{jt} = u_j, \quad e_{ijt} = e_{ij} \,. \tag{39.7}$$

Table 39.1 gives the expected means squares (MS) for the mixed effect ANOVA model. The test statistic for the null hypothesis of no treatment effect is given by $F = MS_{\mathrm{treatment}}/MS_{\mathrm{cluster}}$, which, under the null hypothesis, has an F-distribution with 1 and $n_2 - 2$ degrees of freedom. The value of the F-test statistic for the mixed effects ANOVA model can be shown to be equal to the square of the value of the t-test statistic for the multilevel regression model [39.9]. The two variance components are estimated by

$$\hat{\sigma}^2 = \mathbf{MS}_{\mathrm{person}} \,, \tag{39.8}$$

and

$$\hat{\tau}^2 = \left(\mathbf{MS}_{\mathrm{cluster}} - \mathbf{MS}_{\mathrm{person}}\right)/n \,, \tag{39.9}$$

and the intra-class correlation coefficient is estimated by

$$\hat{\rho}^2 = \frac{\mathbf{MS}_{\mathrm{cluster}} - \mathbf{MS}_{\mathrm{person}}}{\mathbf{MS}_{\mathrm{cluster}} + (n-1)\mathbf{MS}_{\mathrm{person}}} \,. \tag{39.10}$$

For a long time the estimation of mixed models was a difficulty because of the lack of suitable estimation methods and computer programs. Different models

Table 39.1 Values for the mixed effects ANOVA model

Source	Degrees of freedom	Mean squares	Expected MS
Treatment	1	$MS_{\mathrm{treatment}}$	$\sigma^2 + n_1\tau^2 + n_1 n_2 \sum_t \alpha_t^2$
Clusters within treatment	$n_2 - 2$	MS_{cluster}	$\sigma^2 + n_1\tau^2$
Persons within clusters	$n_1 n_2 - n_2$	MS_{person}	σ^2
Total	$\boldsymbol{n_1 n_2 - 1}$		

were used but these can be shown to result in incorrect estimates of regression coefficients and their standard errors [39.2]. One such model is the traditional ordinary regression model, which assumes independent outcomes and thereby ignores nesting of persons within clusters and correlation of outcomes within the same cluster. Another approach is to calculate mean scores of variables at the cluster level and to use these in a regression model. With this approach, clusters are used as the unit of analysis, which results in loss of information. A third approach is to include clusters as fixed effects in the regression model, even if the results have to be generalized to the populations of clusters.

A method for estimation of mixed effects model became available with the development of full-information maximum-likelihood (ML), and restricted maximum-likelihood estimators (REML). The first calculates the regression coefficients and (co-)variance components such that the log likelihood log (L) is maximized, where

$$\log(L) = -\frac{1}{2}\sum_j n_{1j}\log 2\pi - \frac{1}{2}\log|\mathbf{V}| - \frac{1}{2}(\boldsymbol{y}-\mathbf{X}\boldsymbol{\beta})'\mathbf{V}^{-1}(\boldsymbol{y}-\mathbf{X}\boldsymbol{\beta})\,. \qquad (39.11)$$

The vector $\boldsymbol{y}$ is the vector of outcomes, $\boldsymbol{\beta}$ is the vector of regression coefficients, and $\mathbf{V}$ is the covariance matrix of the outcomes, which is a function of the variance components. The design matrix $\mathbf{X}$ contains the measures on the predictor variables. REML is an adjustment of ML since it takes into account the loss of degrees of freedom resulting from estimating the fixed effects while estimating the variance components. So, the ML estimates of the variance components are downward-biased, while those for REML are not. For a large number of clusters (say $n_2 > 30$), the difference between the two estimates is negligible.

During the 1980s much attention was paid to the development of methods for the computation of ML and REML estimates, such as iterative generalized least squares (IGLS) [39.10], and restricted iterative generalized least squares (RIGLS) [39.11], which in the normal case produce ML and REML estimates, respectively. Furthermore, attention was paid to the application of existing methods, such as the Fisher scoring algorithm [39.12], and the expectation-maximization (EM) algorithm [39.13, 14]. The introduction and widespread use of personal computers have initiated the development of specialized computer programs for multilevel analysis, such as MLwin [39.15] and HLM [39.16]. Nowadays, multilevel analysis is part of general-purpose statistical software, such as SPSS and STATA.

39.3 Optimal Allocation of Units

39.3.1 Minimizing Costs to Achieve a Fixed Power Level

The primary aim of an experiment is to gain insight into the magnitude of the treatment effect, and to test if it is different from zero. Thus, we wish to test the null hypothesis $H_0 : \beta_1 = 0$ against the alternative that its value is different from zero. This hypothesis is tested by the test statistic $t = \hat{\beta}_1/\sqrt{\hat{\text{var}}(\hat{\beta}_1)}$, which has a t-distribution with $n_2 - 2$ degrees of freedom under the null hypothesis. When the number of clusters is large, the standard normal distribution can be used as an approximation, as will be done in the remainder of this chapter. For a two-sided alternative hypothesis $H_1 : \beta_1 \neq 0$, the power $1-\gamma$, type I error rate α, and the true value of β_1 are related to the variance $\text{var}(\hat{\beta}_1)$ as follows:

$$\text{var}(\hat{\beta}_1) = \left(\frac{\beta_1}{z_{1-\alpha/2} + z_{1-\gamma}}\right)^2, \qquad (39.12)$$

where $z_{1-\alpha/2}$ and $z_{1-\gamma}$ are the $100(1-\alpha/2)\%$ and $100(1-\gamma)\%$ standard normal deviates. For a one-sided alternative hypothesis, $1-\alpha/2$ may be replaced by $1-\alpha$. In general, the true value of the treatment effect β_1 is unknown at the design stage, and it is replaced by the minimal relevant deviation of β_1 from zero. If this effect is expressed in terms of units of the standard deviation $\sqrt{\sigma^2+\tau^2}$ of the outcome y_{ij}, then it is a relative treatment effect. Relative treatment effects equal to 0.2, 0.5, and 0.8 can be considered small, medium, and large, respectively, where a medium treatment effect is visible to the naked eye of a careful researcher [39.17].

As follows from (39.12), the power increases with the true value of β_1, which is obvious since large treatment effects are easier to detect than small treatment effects. Also, the power increases with the type I error rate, since null hypotheses are easier rejected if the probability of a type I error is large. Furthermore, the power is inversely related to the $\text{var}(\hat{\beta}_1)$. So, maximizing the power corresponds to minimizing the variance

of the estimated treatment effect. For studies with non-nested data this variance is related to the total sample size, and minimal sample sizes can be found in, for instance, *Cochran* [39.18]. For studies with two levels of nesting, $\text{var}(\hat{\beta}_1)$ does not only depend on the total sample size $n_1 n_2$, but also on the cluster size n_1, as follows from (39.5). Note that we use non-varying cluster sizes since that leads to the most efficient design [39.19]. In reality, cluster sizes generally vary, so that we have to take a sample of size n_1 from each cluster, meaning that not all persons in the sampled clusters are enrolled in the experiment.

The required sample sizes n_1 and n_2 can be calculated by substituting $\text{var}(\hat{\beta}_1)$ from (39.5) into (39.12). For fixed cluster size n_1 the required number of clusters is equal to

$$n_2 = 4\frac{\sigma^2+\tau^2}{n_1}\left[1+(n_1-1)\rho\right]\left(\frac{z_{1-\alpha/2}+z_{1-\gamma}}{\beta_1}\right)^2 . \tag{39.13}$$

For a fixed number of clusters n_2, the required cluster size is equal to

$$n_1 = \frac{4\sigma^2}{\left(\frac{\beta_1}{z_{1-\alpha/2}+z_{1-\gamma}}\right)^2 n_2 - 4\tau^2} \tag{39.14}$$

Figure 39.1 shows the power to detect a small relative treatment effect in a two-sided test with a type I error rate of $\alpha = 0.05$ as a function of the cluster size n_1, number of clusters n_2, and the intra-class correlation coefficient ρ. As is obvious, more clusters, larger cluster sizes and a lower intra-class correlation lead to higher power levels. For instance, 114 clusters are needed to achieve a power of 0.8 when there are 10 persons per cluster and the intra-class correlation coefficient is equal to $\rho = 0.05$. For a cluster size of $n_1 = 30$ only 66 clusters are needed. However, the total sample size for the first scenario ($n_1 n_2 = 1140$) is smaller than that for the second ($n_1 n_2 = 1980$). So, the first scenario is favorable when the aim is to minimize the total sample size, whereas the second should be selected when the aim is to minimize the number of clusters, provided that enough clusters with 30 persons are available.

As follows from the left pane in Fig. 39.1 the power increases to one when the number of clusters increases and the cluster size is fixed. On the other hand the power increases to a value not necessarily equal to one when the cluster size increases, given a fixed number of clusters. This can be explained by the fact that the cluster size n_1 appears in both the numerator and denominator of the $\text{var}(\hat{\beta}_1)$, which is inversely related to power, whereas the number of clusters n_2 appears in both. So

$$\lim_{n_1\to\infty} \text{var}(\hat{\beta}_1) = \lim_{n_1\to\infty} 4\frac{\sigma^2+n_1\tau^2}{n_1 n_2} = 4\frac{\tau^2}{n_2} , \tag{39.15}$$

and

$$\lim_{n_2\to\infty} \text{var}(\hat{\beta}_1) = \lim_{n_2\to\infty} 4\frac{\sigma^2+n_1\tau^2}{n_1 n_2} = 0 , \tag{39.16}$$

which explains why a low number of clusters cannot be compensated by a larger cluster size in order to achieve sufficient power.

When both n_1 and n_2 are free to vary, the optimal sample sizes are calculated such that the costs C for

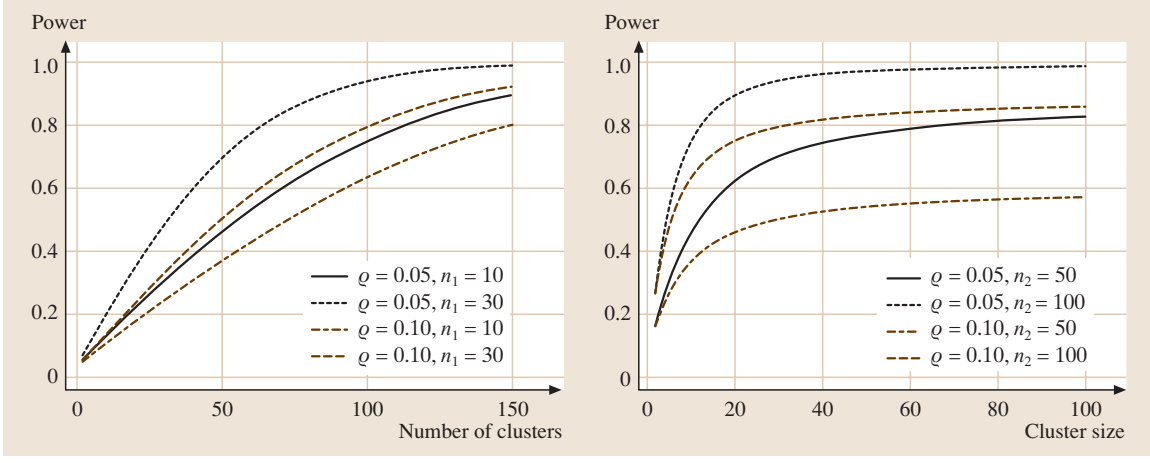

Fig. 39.1 Power as a function of cluster size, number of clusters, and intra-class correlation

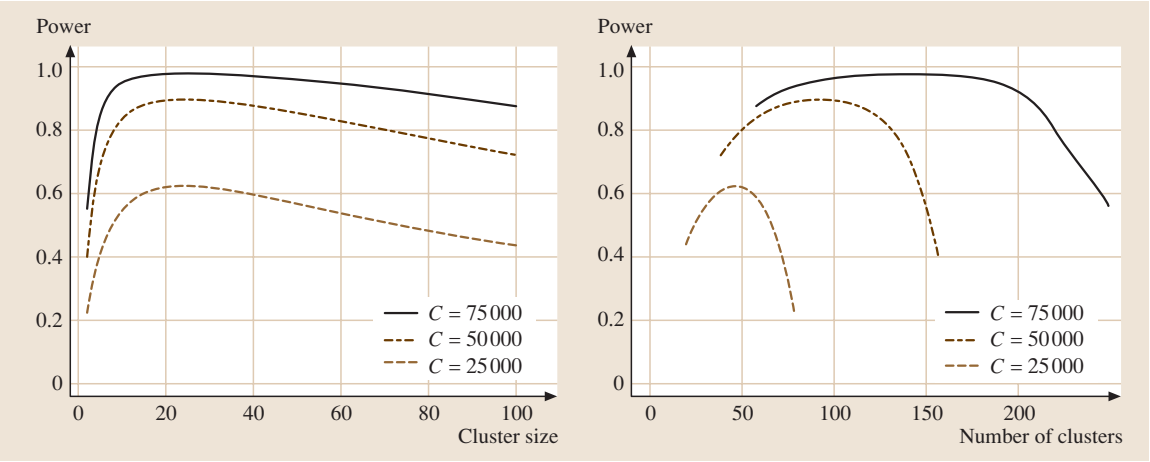

Fig. 39.2 Power as a function of cluster size and number of clusters for various budgets C and costs $c_1 = 300$ and $c_2 = 10$

recruiting and measuring persons and clusters are minimized. These costs are a function of the total number of persons $n_1 n_2$, the number of clusters n_2, the costs per person c_1, and the costs per cluster c_2:

$$C = c_1 n_1 n_2 + c_2 n_2 \,. \tag{39.17}$$

Since the design is balanced, c_1 and c_2 are the costs at the person and cluster level averaged over the two treatment conditions. In general the costs at the cluster level will be much higher than the costs at the person level. The optimal cluster size can be shown to be equal to

$$n_1 = \sqrt{\frac{c_2(1-\rho)}{c_1 \rho}} \,. \tag{39.18}$$

and n_2 follows from (39.13). Equation (39.18) was derived by expressing n_2 in terms of n_1 and C using (39.17), substituting in (39.5) for $\text{var}(\hat{\beta}_1)$, and minimizing with respect to n_1. In some cases the optimal number of persons per cluster is larger than the actual number of persons per cluster. Then, all persons have to be sampled, and additional money should be spent on sampling more clusters.

39.3.2 Maximizing Power Given a Fixed Budget

Equation (39.18) gives the optimal cluster size to achieve a pre-specified power level while minimizing costs C. On the other hand, we can also calculate the optimal cluster size for maximizing the power level when the budget is fixed to a constant C. The optimal cluster size is again equal to that given in (39.18), and the optimal number of clusters is equal to

$$n_2 = \frac{C}{\sqrt{\frac{1-\rho}{\rho} c_1 c_2} + c_2} \,. \tag{39.19}$$

The variance of the treatment effect estimator can be calculated by substituting the optimal n_1 and n_2 from (39.18) and (39.19) into (39.5), which gives

$$\text{var}(\hat{\beta}_1) = (\sigma^2 + \tau^2) \frac{\left[\sqrt{\rho c_2} + \sqrt{(1-\rho) c_1}\right]^2}{C} \,. \tag{39.20}$$

As is obvious, a larger budget C results in a smaller optimal $\text{var}(\hat{\beta}_1)$. Furthermore, a larger budget C results in sampling more clusters, but not in sampling more persons per cluster since the optimal cluster size does not depend on C. The optimal cluster size is an increasing function of the intra-class correlation coefficient ρ, so that larger cluster sizes are required when there is much variation in the outcome at the person level. Furthermore, the optimal cluster size is a function of the costs c_2 for recruiting a cluster relative to the costs c_1 for sampling a person. So, fewer clusters will be sampled in favor of sampling more persons per cluster when it is relatively expensive to sample a cluster.

Figure 39.2 shows the power to detect a small treatment effect as a function of the cluster size, number of clusters and total budget C when $c_1 = 300$ and $c_2 = 10$ and $\rho = 0.05$. The optimal cluster size is $n_1 = 24$ and this value does not depend on the budget. A budget approximately equal to $C = 75\,000$ is required to achieve a power level of 0.9 to detect a small treatment effect. The optimal number of clusters is an increasing function

of the budget C. For a large budget the power curve is rather flat around it optimum, but this is not the case for lower budgets. Of course, these power curves hold when dropout is absent, and a somewhat larger sample size is required when persons and/or clusters are expected to drop out.

39.4 The Effect of Adding Covariates

Until now we have only considered optimal designs for models without covariates. This section focuses on the effects of adding a single covariate x_{ij} that varies at the cluster and/or person level on the optimal sample sizes. The extension to multiple covariates is straightforward and not given here. The between- and within-cluster effect of the covariate on the outcome are not necessarily the same [39.20]. The covariate is therefore split up into a between-cluster component $\bar{x}_{.j}$ and a within-cluster component $(x_{ij}-\bar{x}_{.j})$, and the multilevel model is given by

$$y_{ij}=\beta_0^*+\beta_1^* z_j+\beta_2^*\bar{x}_{.j}+\beta_3^*(x_{ij}-\bar{x}_{.j})+u_j^*+e_{ij}^*\,, \tag{39.21}$$

where $\beta_2^*\neq\beta_3^*$. As in the model without covariates, the random terms $u_j^*\sim N(0,\tau^{*2})$ and $e_{ij}^*\sim N(0,\sigma^{*2})$ are assumed to be independent of each other and the covariate.

When the covariate only varies at the cluster level, the term $\beta_3^*(x_{ij}-\bar{x}_{.j})$ is equal to zero and may be removed from model. An example of a cluster-level covariate is the type of school (public versus private) in a school-based smoking prevention intervention. Likewise, when the covariate only varies at the person level, the term $\beta_2^*\bar{x}_{.j}$ is equal to zero and may be removed from the model. An example of such a covariate is gender, given that the percentage of boys per school does not vary across the schools.

Note that the regression coefficients and random terms are superscripted with an asterisk in order to stress that their values may differ from those in the model without covariates (39.1). Given a grand-mean centered covariate and treatment condition coded $z_j=-0.5$ for the control group and $z_j=+0.5$ for the intervention group, the treatment effect is estimated by

$$\hat{\beta}_1^*=\frac{\sum z_j y_{ij}\sum x_j^2-\sum z_j x_j\sum x_j y_{ij}}{n_1 n_2\sum x_j^2(1-r_{xc}^2)}\,, \tag{39.22}$$

with variance

$$\mathrm{var}(\hat{\beta}_1^*)=4\frac{\sigma^{*2}+n_1\tau^{*2}}{n_1 n_2}\frac{1}{(1-r_{zx}^2)}\,. \tag{39.23}$$

When comparing formulae (39.23) with that for the variance in a model without covariates, we see that an additional factor $1/(1-r_{zx}^2)$ is introduced. This factor is often called the variance inflation factor (VIF), and $\mathrm{var}(\hat{\beta}_1^*)$ reaches it minimum when the correlation r_{zx}^2 between the treatment condition and covariate is equal to zero. The within-cluster component $(x_{ij}-\bar{x}_{.j})$ and the treatment condition z_j are orthogonal, and therefore r_{zx}^2 is equal to the correlation between the between-cluster component $\bar{x}_{.j}$ and the treatment condition z_j. For normally and binary covariates this correlation is approximately normally distributed with variance $1/n_2$ [39.21], and thus $r_{zx}^2\in(0,4/n_2)$ with 95% probability. So, this correlation will be small when the number of clusters is large, and clusters are randomly assigned to treatment conditions. When the cluster randomized trial only has a small number of clusters, a correlation r_{zx}^2 equal to zero may be achieved by pre-stratification on the covariate, which means that for each value of $\bar{x}_{.j}$ half of the clusters are randomized to the control condition while the others are randomized to the intervention condition.

In the remainder of this section we will assume that the correlation between covariate and treatment condition is zero. Then, the estimated treatment effect is equal to that in a model without covariates, and the optimal sample sizes are equal to those in a model without covariates as given in (39.18) and (39.19) with τ^2 and σ^2 replaced by τ^{*2} and σ^{*2}, respectively [39.22]. The relations between the variance components in a model with and without covariates can be established using the method described in [39.23]. During the analysis stage the total variation in the outcome y_{ij} is given by the observed data and the estimated variance components change if covariates are added to or excluded from the model. The chance in the estimated variance components can be derived by assuming that the variance of the observed outcomes and covariance of two outcomes within the same cluster are given by the data and are therefore equal for model (39.21) and (39.1):

$$\begin{aligned}\mathrm{var}(y_{ij})&=\mathrm{var}(\beta_1 z_j+u_j+e_{ij})\\&=\mathrm{var}\left[\beta_1^* z_j+\beta_2^*(x_{ij}-\bar{x}_{.j})+\beta_3^*\bar{x}_{.j}+u_j^*+e_{ij}^*\right]\end{aligned} \tag{39.24}$$

Table 39.2 Changes in the variance components due to the inclusion of a covariate

Changes due to the inclusion of $\bar{x}_{.j}$	Changes due to the inclusion of $(x_{ij} - \bar{x}_{.j})$
$\tau^2 - \tau^{*2} = \hat{\beta}_2^{*2}\text{var}(\bar{x}_{.j}) > 0$	$\tau^2 - \tau^{*2} = \hat{\beta}_3^{*2}\text{cov}(x_{ij} - \bar{x}_{.j}, x_{i,j} - \bar{x}_{.j}) < 0$ ≈ 0 for large n_1
$\sigma^2 - \sigma^{*2} = 0$	$\sigma^2 - \sigma^{*2} = \hat{\beta}_3^{*2}\left[\text{var}(x_{ij} - \bar{x}_{.j}) - \text{cov}(x_{ij} - \bar{x}_{.j}, x_{i,j} - \bar{x}_{.j})\right] > 0$ $\approx \hat{\beta}_3^{*2}\text{var}(x_{ij} - \bar{x}_{.j}) > 0$ for large n_1
Note: It is assumed that $r_{zx}^2 = 0$	

and

$$\begin{aligned}\text{cov}(y_{ij}, y_{i'j}) &= \text{cov}(\beta_1 z_j + u_j, \beta_1 z_j + u_j)\\ &= \text{cov}\Big[\beta_1^* z_j + \beta_2^*(x_{ij} - \bar{x}_{.j}) + \beta_3^* \bar{x}_{.j}\\ &\quad + u_j^*, \beta_1^* z_j + \beta_2^*(x_{i'j} - \bar{x}_{.j})\\ &\quad + \beta_3^* \bar{x}_{.j} + u_j^*\Big]\,. \end{aligned} \tag{39.25}$$

Table 39.2 shows the changes in the estimated variance components due to the inclusion of one covariate. The variance component at the person level remains unchanged when a cluster-level covariate is added to the model, and decreases when a person-level covariate is added to the model. The variance component at the cluster level decreases when a cluster-level component is added, but *increases* when a person-level covariate is added. However, for large cluster sizes this increase is negligible, and it may be nullified by the decreasing effect of adding a cluster-level covariate. So, adding covariates will in general lead to a decrease in the variance components, and therefore in a more efficient design, given a zero correlation between the covariate and treatment condition.

Of course, costs are associated with measuring covariates and one may wonder when adding a covariate may be a more cost-efficient strategy to increase the power to detect a treatment effect than sampling more clusters. Both strategies have recently been compared, and it was concluded that adding covariates is more efficient when the costs to measure these covariates are small and the correlation between the covariate and the outcome is large [39.24]. Adding a covariate at the cluster level is recommended when clusters are large (say $n_1 = 100$) and the costs to recruit and measure a cluster are small in relation to the costs to recruit and measure a person. Vice versa, adding a covariate that only varies at the person level is recommended when clusters are small (say $n_1 = 4$) and the relative costs to recruit and measure a cluster are large.

39.5 Robustness Issues

In the Sect. 39.3 it was shown that the optimal sample sizes depend on the value of the intra-class correlation coefficient. The value of this parameter is generally unknown at the design stage and an educated guess must be obtained from subject-matter knowledge or similar studies in the past. Table 1 in [39.25] gives an overview of recent papers that report values of the intra-class correlation coefficient. There is, however, no guarantee that the values of similar studies in the past are the true values for the current study at hand, since the study may be conducted in a different year of country, or may target a different population (e.g. elementary-school children instead of high-school children).

As an example consider a cluster randomized trials that aims at detecting a small relative treatment effect at power level 0.9 in a two-sided test with $\alpha = 0.05$. The cluster size is equal to $n_1 = 30$, and the true but unknown intra-class correlation is $\rho = 0.05$. The required number of clusters at prior value $\rho = 0.05$ is equal to $n_2 = 86$, and this results in a power equal to 0.9, since the prior ρ is equal to the true ρ. However, if the prior estimate is equal to $\rho = 0.10$, then the required number of clusters can be calculated to be equal to $n_2 = 138$. Thus, the number of clusters is overestimated by 60%, and the power level at the true ρ is equal to 0.98. For a prior estimate as small as $\rho = 0.025$, the required number of clusters is equal to $n_2 = 62$, which results in a power level of 0.78 at the true ρ. Hence, cluster randomized trials are not very robust against an incorrect prior estimate of the intra-class correlation coefficient.

Since it is increasingly difficult to obtain adequate financial recourses, and since cluster randomized trials require the willingness of clusters and persons to participate, it is extremely important to design trials such

Table 39.3 Assumptions about the intra-class correlation coefficient, with associated power with 86 groups and required number of groups for a power level of 0.9

Intra-class correlation coefficient Median (95% interval)	Power with 86 groups Median (95% interval)	Number of groups for power = 0.9 Median (95% interval)
0.05–0.051	0.90–0.898	86–88
0.008–0.099	0.734–0.995	44–136

that they are not under- or overpowered. Two procedures to calculate robust optimal designs are Bayesian optimal designs, where a prior distribution on the intra-class correlation is used, and designs with sample-size re-estimation based on data obtained from a pilot.

39.5.1 Bayesian Optimal Designs

Bayesian methods allow us to implicitly take uncertainty about model parameters into account by using a prior distribution on the parameters. Consider the example given above and suppose that we assume the intra-class correlation to be around 0.05, but that there is some change that it is up to 0.10. This uncertainty may be reflected by a normal distribution with mean 0.05 and standard deviation 0.025, but truncated at zero so that we exclude negative values. We can now sample from this prior distribution and calculate the required number of clusters to achieve a power level of 0.9. In addition, we can also calculate the power level that is achieved with 86 clusters.

The results in Fig. 39.3 and Table 39.3 were obtained after 100 000 iterations, which took less that one minute on a desktop computer with a 2.8-GHz CPU and 1 Gb of RAM. The median intra-class correlation coefficient is equal to 0.051, at which there are hardly any values larger than 0.1. The median power achieved with 86 clusters is equal to 0.0898, so there is a change of about 50% that the power is less than the required level of 0.9. In some cases, it can even be as small as 0.7. The median required number of clusters is equal to 88, whereas the boundaries of the 95% interval are 44 and 136. So, on the basis of the results in Fig. 39.3 and Table 39.3 we might decide to use a number of clusters larger than 86 to be reasonably confident that the study has sufficient power.

39.5.2 Designs with Sample-Size Re-Estimation

Designs with sample-size re-estimation have been proposed by *Stein* [39.26] in the context of comparing two treatment conditions with respect to a continuous outcome. His procedure includes two stages. In the first stage (the internal pilot) the variance of the outcome is estimated using the observations collected so far, and the total sample size is re-estimated based on the variance estimate. In the second stage the remainder of the observations is collected such that re-estimated total sample size is achieved. Only the observations of the first stage are used to estimate the variance

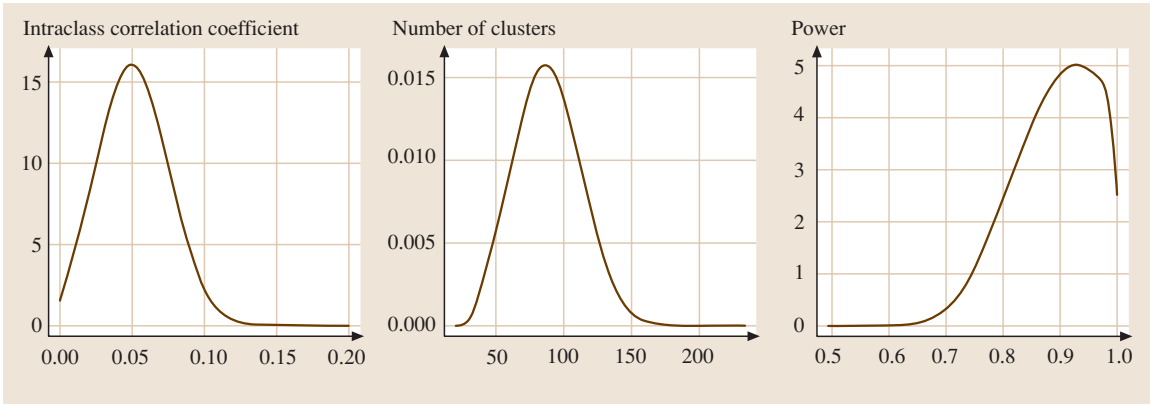

Fig. 39.3 Densities of the prior distribution of the intra-class correlation coefficient, the required number of clusters to achieve a power level 0.9, and the power at 86 clusters

Table 39.4 Empirical type I error rate α and power $1-\beta$ for the standard design and re-estimation design for three values of the prior ρ. The true $\rho = 0.05$

Prior ρ	Standard design		Re-estimation design					
			$\pi = 0.25$		$\pi = 0.5$		$\pi = 0.75$	
	α	$1-\beta$	α	$1-\beta$	α	$1-\beta$	α	$1-\beta$
0.025	0.0538	0.7812	0.0526	0.8690	0.0600	0.9072	0.0586	0.9012
0.05	0.0480	0.9004	0.0576	0.8886	0.0530	0.9094	0.0556	0.8986
0.10	0.0502	0.9832	0.0534	0.8964	0.0588	0.9114	0.0532	0.9474

of the outcomes, while all observations are used in the calculation of the group means. This procedure was modified by *Wittes* and *Britain* [39.27] such that all data are used in the final analysis. In contrast to the Stein procedure, the Wittes and Britain procedure does not preserve the type I error rate since the total sample size depends on the variance estimate in the pilot. Internal pilots have been shown to work well for cluster randomized trials by *Lake* et al. [39.28].

We consider the same example where we wish to detect a small relative treatment effect at power level 0.9. The true $\rho = 0.05$, and we have three prior values $\rho = 0.025$, 0.05, and 0.10. Table 39.4 shows the empirical type I error rates and power levels in a simulation study with 5000 runs. The power levels for the design without sample-size re-estimation (i. e. the standard design) are too small when the prior ρ is underestimated and too large when the prior ρ is overestimated. The values of the type I error rate are close to their nominal value of $\alpha = 0.05$.

For designs with sample-size re-estimation the required number of clusters is calculated on the basis of the prior ρ . Then, a predefined proportion π of this number of clusters is used in the internal pilot. The required number of clusters in the second stage is calculated on the basis of the parameter estimates obtained from data collected in the internal pilot. When the size of the internal pilot is already sufficiently large, a second stage is not needed. Table 39.4 shows that the power levels for studies with incorrect prior values ρ are much closer to the value 0.9 than they are in the standard design. For $\pi = 0.25$ and prior $\rho = 0.025$, the power is somewhat lower than 0.9, which is explained by the fact that the size of the internal pilot is somewhat too small to result in a good estimate of the true ρ. For $\pi = 0.75$ and prior $\rho = 0.10$, the power is larger than 0.9, which is explained by the fact that the size of the internal pilot is already too large. The empirical type I error rates are somewhat, but not dramatically, larger than the nominal value $\alpha = 0.05$.

39.6 Optimal Designs for the Intra-Class Correlation Coefficient

So far we have focussed on optimal designs that maximize the power to detect a treatment effect or, equivalently, minimize the variance of the treatment effect estimator. Another option is to design a study such that it minimizes the variance of the intra-class correlation coefficient estimator, which is equal to

$$\mathrm{var}(\hat{\rho}) = \frac{2(1-\rho)^2(1+(n_1-1)\rho)^2}{(n_1-1)(n_1n_2-n_1)} \,. \qquad (39.26)$$

Such optimal designs are especially useful for pilot studies that aim at an estimate of the intra-class correlation coefficient. Again, we can minimize this variance under the precondition that the costs for recruiting persons and clusters do not exceed the budget, as specified by (39.17). Closed-form equations for the optimal n_1 and n_2 do not exist. Instead, the optimal design may be found by expressing n_2 in terms of n_1, c_1, c_2 and C using (39.17): $n_2 = C/(c_1n_1 + c_2)$. This relation may then be substituted into (39.26), from which the optimal n_1 may be calculated.

For most trials the main focus lies on the treatment effect, but researchers may also be interested in the degree of variability of the outcome that is between clusters. If the amount of between-cluster variability turns out to be high, then one may wish to identify those schools for which the intervention performs worst and try to characterize these schools in terms of their school-level variables. The intervention can then be adjusted for these types of schools. For instance, a smoking prevention intervention that works well for high schools may

have to be adjusted for schools for lower vocational education.

When a researcher has multiple objectives in mind, he or she may design a multiple-objective optimal design. Suppose that we wish to design a trial that aims at estimating both the treatment effect and intra-class correlation with largest precision, that is, it aims at minimizing $\text{var}(\hat{\beta}_1)$ and $\text{var}(\hat{\rho}_1)$. These two variances are the two objectives and the first is the most important since the trial is, in the first instance, designed to gain insight into the value of the treatment effect, whereas the intra-class correlation coefficient is of secondary importance. The two-objective optimal design is the one that does best under the criterion $\text{var}(\hat{\rho}_1)$ subject to the constraint that the value $\text{var}(\hat{\beta}_1)$ is smaller than a user-specified constant c:

$$\min \text{var}(\hat{\rho}) \text{ subject to } \text{var}(\hat{\beta}_1) \leq c \,. \tag{39.27}$$

The design that satisfies this criterion is often called a constrained optimal design. For convenience, this criterion is often rewritten as

$$\min \text{var}(\hat{\rho}) \text{ subject to } \text{eff}(\hat{\beta}_1) \geq e \,, \tag{39.28}$$

where $\text{eff}(\hat{\beta}_1)$ is the efficiency in estimating the treatment effect. So, the least important optimality criterion is minimized subject to the constraint that the efficiency in estimating the treatment effect is larger than a user-selected constraint. The efficiency is calculated as the $\text{var}(\hat{\beta}_1)$ obtained with the optimal sample sizes as given by (39.18) and (39.19) divided by the $\text{var}(\hat{\beta}_1)$ obtained with any other sample sizes n_1 and n_2. The efficiency varies between zero and one. Its interpretation is that, if N observations are used in the optimal design, then $N/\text{eff}(\hat{\beta}_1)$ observations are used in the suboptimal design to obtain the same amount of information.

Constrained optimal designs are often difficult to derive, and one may wish to construct a compound optimal design to minimize

$$\lambda \, \text{var}(\hat{\rho}) + (1-\lambda) \, \text{var}(\hat{\beta}_1) \,. \tag{39.29}$$

Compound optimal designs are generally easier to solve, either numerically or analytically. Under convexity and differentiability constrained and compound optimal designs are equivalent [39.29]. So, in order to derive

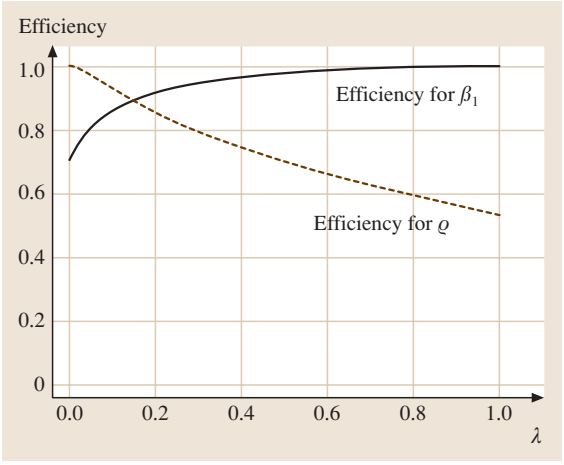

Fig. 39.4 Efficiency plot

the constrained optimal design one may first derive the compound optimal design as a function of the weight λ in (39.29). That is, for each value of λ the sample sizes n_1 and n_2 that minimize (39.29) are derived. Subsequently, an efficiency plot is drawn in which the efficiencies $\text{eff}(\hat{\beta}_1)$ and $\text{eff}(\hat{\rho})$ are plotted as a function of λ. The constrained optimal design is the design for which $\text{eff}(\hat{\beta}_1) \geq e$ and $\text{eff}(\hat{\rho})$ is maximized. In most practical situations the constant e is chosen to be 0.8 or 0.9.

Figure 39.4 shows an efficiency plot for a trial with $C = 50\,000$, $c_1 = 30$, $c_2 = 10$ and $\rho = 0.025$. The optimal design for estimating ρ with the greatest precision is $n_1 = 45.4$ and $n_2 = 103.4$ and is achieved when $\lambda = 1$. The efficiency for ρ is a decreasing function of λ. The optimal for estimating β_1 with largest precision is $n_1 = 10.8$ and $n_2 = 362.8$, and is achieved when $\lambda = 0$. The efficiency for β_1 is a increasing function of λ. Note that the two lines do not necessarily meet at the point. When we wish to estimate ρ with the greatest precision, given the condition that $\text{eff}(\hat{\beta}_1) \geq 0.9$, then we draw a horizontal line at $e = 0.9$ to intersect the graph of $\text{eff}(\hat{\beta}_1)$. Then a vertical line is drawn from this point of intersection to meet the λ-axis. This results in $\lambda = 0.17$, which corresponds to $n_1 = 23.42$ and $n_2 = 189.3$, and $\text{eff}(\hat{\rho}) = 0.876$. Of course, these sample sizes have to rounded off to integer values. Large efficiencies are possible for both criteria, which are therefore called compatible.

39.7 Conclusions and Discussion

Cluster randomized trials randomize complete groups of persons, rather than the persons themselves, to treatment conditions. They are often used in situations where the intervention is delivered to groups of persons, such as in school-based smoking prevention interventions with class teaching on smoking and health. Since the outcomes of persons in a group cannot be considered to be independent, a larger sample size is required to achieve a pre-specified power level than in a simple randomized trial, especially when the intra-class correlation coefficient and/or the cluster size are large.

Multisite trials are an alternative to cluster randomized trials. Multisite trials randomize persons within clusters to treatment conditions, such that all treatments are available within each cluster. So, for multisite trials cluster and treatment condition are crossed, whereas for cluster randomized trails clusters are nested within treatment conditions. Multisite trials have two advantages above cluster randomized trials: they are more powerful, and they allow for the estimation of the cluster by treatment interaction [39.30]. A main drawback of multisite trials is that they do not protect from control-group contamination, which occurs when information on the intervention leaks from the individuals in the intervention group to those in the control group [39.31]. In some cases blinding may be an option to prevent control-group contamination, such as in double-blind placebo-controlled multicentre clinical trial with patients nested within clinics. This is an option when the experimental treatment is a new pill, which only differs from the pills in the control group by the amount of active substance. When patients are randomly assigned to treatment conditions and neither the patient nor the researchers know who belongs to which treatment, a multisite study may be an alternative to a cluster randomized trial. Blinding is of course no option when the intervention consists of interpersonal relationships, such as in peer-pressure groups. Control-group contamination may also be due to the person delivering the intervention, such as in guideline trials with patients nested within family practices. If both a control and intervention group are available in each practice, it will be extremely difficult for the physician not to let patients in the control group benefit from the intervention. Of course, the choice for a cluster randomized trial does not guarantee the absence of control-group contamination. An example is a trial in which general practices are randomized to treatment conditions and the intervention consists of leaflets to promote healthy lifestyles. Control-group contamination can occur when staff members work between practices and distribute leaflets in the control practices. Another example is a school-based smoking prevention intervention where children from different families attend different schools, and thereby encounter different treatment conditions.

This chapter has given an introduction to the design and analysis of cluster randomized trails. It focused on models with two levels of nesting, two treatment conditions, and continuous outcomes. The extension to three or more levels of nesting is straightforward and can be found elsewhere [39.30, 32]. The optimal sample sizes were shown to depend on the value of the intra-class correlation coefficient and it was shown that an incorrect prior may lead to an under- or overpowered study. This may be overcome by using a robust optimal design, such as a Bayesian optimal design or a design using sample-size re-estimation. Such designs are also very useful for the planning of cluster randomized trials with binary outcomes, since then the optimal sample size can be shown not only to depend on the intra-class correlation coefficient, but also on the probabilities of a positive response in each treatment condition [39.33, 34].

40. A Two-Way Semilinear Model for Normalization and Analysis of Microarray Data

A proper normalization procedure ensures that the normalized intensity ratios provide meaningful measures of relative expression levels. We describe a two-way semilinear model (TW-SLM) for normalization and analysis of microarray data. This method does not make the usual assumptions underlying some of the existing methods. The TW-SLM also naturally incorporates uncertainty due to normalization into significance analysis of microarrays. We propose a semiparametric M-estimation method in the TW-SLM to estimate the normalization curves and the normalized expression values, and discuss several useful extensions of the TW-SLM. We describe a back-fitting algorithm for computation in the model. We illustrate the application of the TW-SLM by applying it to a microarray data set. We evaluate the performance of TW-SLM using simulation studies and consider theoretical results concerning the asymptotic distribution and rate of convergence of the least-squares estimators in the TW-SLM.

Microarrays are a useful tool for monitoring gene expression levels on a large scale and has been widely used in functional genomics [40.1, 2]. In a microarray experiment, cDNA segments representing the collection of genes and expression sequence tags (ESTs) to be probed are amplified by the polymerase chain reaction (PCR) and spotted in high density on glass microscope slides using a robotic system. Such slides are called microarrays. Each microarray contains thousands of reporters of the collection of genes or ESTs. The microarrays are queried in a co-hybridization assay using two fluorescently labeled biosamples prepared from the cell populations of interest. One sample is labeled with the fluorescent dye Cy5 (red), and another with the fluorescent dye Cy3 (green). Hybridization is assayed using a confocal laser scanner to measure fluorescence intensities, allowing simultaneous determination of the relative expression levels of all the genes represented on the slide [40.3]. The ability to monitor gene expressions on a large scale promises to have a profound impact on the understanding of basic cellular processes, developing better tools for disease diagnostics and treatment, cancer classification, and identifying drug targets, among others. Indeed, microarrays have already been used for detecting differentially expressed genes in different cell populations, classifying different cancer subtypes, identifying gene clusters based on co-expressions [40.4–7].

Because a microarray experiment monitors thousands of genes simultaneously, it routinely produces a massive amount of data. This and the unique nature of microarray experiments present a host of challenging statistical issues. Some of these can be dealt with using the existing statistical methods, but many are novel questions that require innovative solutions. One such question is normalization. The purpose of normalization is to remove bias in the observed expression levels and establish the baseline ratios of intensity levels from

the florescent dyes Cy3 and Cy5 across the whole dynamic range. A proper normalization procedure ensures that the intensity ratios provide meaningful measures of relative expression levels. In a microarray experiment, many factors may cause bias in the observed expression levels, such as differential efficiency of dye incorporation, differences in concentration of DNA on arrays, difference in the amount of RNA labeled between the two channels, uneven hybridizations, differences in the printing pin heads, among others.

Many researchers have considered various normalization methods; see for example [40.8–13]. For reviews of some of the existing normalization methods, see [40.14, 15]. More recently, *Fan* et al. [40.16] proposed a semilinear in-slide model (SLIM) method that makes use of replications of a subset of the genes in an array. If the number of replicated genes is small, the expression values of the replicated genes may not cover the entire dynamic range or reflect the spatial variation in an array. *Fan* et al. [40.17] generalized the SLIM method to account for across-array information, resulting in an aggregated SLIM, so that replication within an array is no longer required.

A widely used normalization method is the local regression *lowess* [40.18] normalization proposed by *Yang* et al. [40.11]. This method estimates the normalization curves using the robust *lowess* for log-intensity ratio versus log-intensity product using all the genes in the study. The underlying assumption of this normalization method is either that the number of differentially expressed genes is relatively small or that the expression levels of up- and down-regulated genes are symmetric, so that the *lowess* normalization curves are not affected significantly by the differentially expressed genes. If it is expected that many genes will have differential expressions, *Yang* et al. [40.11] suggested using dye-swap for normalization. This approach makes the assumption that the normalization curves in the two dye-swaped slides are symmetric. Because of the slide-to-slide variation, this assumption may not always be satisfied.

Strictly speaking, an unbiased normalization curve should be estimated using genes whose expression levels remain constant and cover the whole range of the intensity. Thus *Tseng* et al. [40.12] first used a rank-based procedure to select a set of invariant genes that are likely to be non-differentially expressed, and then use these genes for *lowess* normalization. However, they pointed out that the number of invariant genes may be small and not cover the whole dynamic range of the expression values, and extrapolation is needed to fill in the gaps that are not covered by the invariant genes. In addition, a threshold value is required in this rank-based procedure. The level of the sensitivy of the final result to the threshold value may need to be evaluated on a case-by-case basis.

A common practice in microarray data analysis is to consider normalization and detection of differentially expressed genes separately. That is, the normalized values of the observed expression levels are treated as data in the subsequent analysis. However, because normalization typically includes a series of statistical adjustments to the data, there are variations associated with this process. These variations will be inherited in any subsequent analysis. It is desirable to take them into account in order to assess the uncertainty of the analysis results correctly.

We have proposed a two-way semilinear model (TW-SLM) for normalization and analysis of microarray data [40.19–21]. When this model is used for normalization, it does not require some of the assumptions that are needed in the *lowess* normalization method. Below, we first give a description of this model, and then suggest an M-estimation (including the least squares estimator as a special case) and a local regression method for estimation in this model. We describe a back-fitting algorithm for computation in the model. We then consider several useful extensions of this model. We illustrate the application of the TW-SLM by applying it to the Apo A1 data set [40.7]. We evaluate the performance of TW-SLM using simulation studies. We also state theoretical results concerning the asymptotic distribution and rate of convergence of the least squares estimator of the TW-SLM.

40.1 The Two-Way Semilinear Model

Suppose there are J genes and n slides in the study. Let R_{ij} and G_{ij} be the red (Cy 5) and green (Cy 3) intensities of gene j in slide i, respectively. Let y_{ij} be the log-intensity ratio of the red over green channels of the j-th gene in the i-th slide, and let x_{ij} be the corresponding average of the log-intensities of the red and green channels. That is,

$$y_{ij} = \log_2 \frac{R_{ij}}{G_{ij}}, \quad x_{ij} = \frac{1}{2}\log_2(R_{ij}G_{ij}),$$
$$i = 1, \ldots, n, \quad j = 1, \ldots, J\,.$$

Let $z_i \in \mathbb{R}^d$ be a covariate vector associated with the i-th slide. It can be used to code various types of designs. The TW-SLM model decomposes the observed intensity ratio y_{ij} in the following way:

$$y_{ij} = f_i(x_{ij}) + z_i' \beta_j + \sigma_{ij}\varepsilon_{ij}, \quad i = 1, \ldots, n, \quad j = 1, \ldots, J, \tag{40.1}$$

where f_i is the intensity-dependent normalization curve for the i-th slide, $\beta_j \in \mathbb{R}^d$ is the effect associated with the j-th gene; σ_{ij} are the residual standard deviation, ε_{ij} have mean 0 and variance 1. We note that f_i can be considered as the log-intensity ratios in the absence of the gene effects. From a semiparametric modeling standpoint, these f_i functions are nonparametric components in the model and are to be estimated. In model (40.1), it is only made explicit that the normalization curves f_i are slide-dependent. It can also be made dependent upon regions of a slide to account for spatial effects. For example, it is straightforward to extend the model with an additional subscript in (y_{ij}, x_{ij}) and f_i and make f_i also depend on the printing-pin blocks within a slide. We describe this and two other extensions of TW-SLM in Sect. 40.4. Below, we denote the collection of the normalization curves by $\boldsymbol{f} = \{f_1, \ldots, f_n\}$ and the matrix of the gene effects by $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_J)' \in \mathbb{R}^{J\times d}$. Let $\Omega_0^{J\times d}$ be the space of all $J \times d$ matrices $\boldsymbol{\beta}$ satisfying $\sum_{j=1}^J \beta_j = 0$. From the definition of the TW-SLM model (40.1), $\boldsymbol{\beta}$ is identifiable only up to a member in $\Omega_0^{J\times d}$.

We call (40.1) TW-SLM since it contains the two-way analysis of variation (ANOVA) model as a special case with $f_i(x_{ij}) = \alpha_i$ and $z_i = 1$. Our approach naturally leads to the general TW-SLM

$$y_{ij} = f_i(x_{ij}) + z_{ij}' \beta_j + \varepsilon_{ij}, \tag{40.2}$$

which could be used to incorporate additional prior knowledge in the TW-SLM (Sect. 40.3). The identifiability condition $\sum_j \beta_j = 0$ is no longer necessary in (40.2) unless $z_{ij} = z_i$ as in (40.1).

The TW-SLM is an extension of the semiparametric regression model (SRM) proposed by *Wahba* [40.22] and *Engle* et al. [40.23]. Specifically, if $f_1 = \cdots = f_n \equiv f$ and $J = 1$, then the TW-SLM simplifies to the SRM, which has one nonparametric component and one finite-dimensional regression parameter. Much work has been done concerning the properties of the semiparametric least squares estimator (LSE) in the SRM, see for example, *Heckman* [40.24] and *Chen* [40.25]. It has been shown that, under appropriate regularity conditions, the semiparametric least squares estimator of the finite-dimensional parameter in the SRM is asymptotically normal, although the rate of convergence of the estimator of the nonparametric component is slower than $n^{1/2}$.

40.2 Semiparametric M-Estimation in TW-SLM

We describe two approaches of semiparametric M-estimation in the TW-SLM. The first one uses linear combinations of certain basis functions (e.g. B-splines) to approximate the normalization curves. The second one uses the local regression technique for estimation in the TW-SLM. Three important special cases in each approach include the least squares estimator, the least absolute deviation estimator, and Huber's robust estimator [40.26].

40.2.1 Basis-Based Method

Let $\boldsymbol{x}_i = (x_{i1}, \ldots, x_{iJ})'$, $\boldsymbol{y}_i = (y_{i1}, \ldots, y_{iJ})'$ and $f(\boldsymbol{x}_i) \equiv [f(x_{i1}), \ldots, f(x_{iJ})]'$ for a univariate function f. We write the TW-SLM (40.1) in vector notation as

$$\boldsymbol{y}_i = \boldsymbol{\beta} z_i + f_i(\boldsymbol{x}_i) + \epsilon_i, \quad i = 1, \ldots, n. \tag{40.3}$$

Let $\Omega_0^{J\times d}$ be the space of all $J \times d$ matrices $\boldsymbol{\beta} \equiv (\beta_1, \ldots, \beta_J)'$ satisfying $\sum_{j=1}^J \beta_j = 0$. It is clear from the definition of the TW-SLM model (40.3) that $\boldsymbol{\beta}$ is identifiable only up to a member in $\Omega_0^{J\times d}$, since we may simply replace β_j by $\beta_j - \sum_{k=1}^J \beta_k/J$ and $f_i(x)$ by $f_i(x) + \sum_{k=1}^J \beta_k' z_i/J$ in (40.1). In what follows, we assume

$$\boldsymbol{\beta} \in \Omega_0^{J\times d} \equiv \left\{ \boldsymbol{\beta} : \sum_{j=1}^J \beta_j = 0 \right\}. \tag{40.4}$$

Let $b_{i1}, \ldots, b_{i,K_i}$ be K_i B-spline basis functions[40.27]. Let

$$S_i \equiv \overline{\{b_{i0}(x) \equiv 1, b_{ik}(x), k = 1, \ldots, K_i\}} \tag{40.5}$$

be the spaces of all linear combinations of the basis functions. We note that wavelet, Fourier and other types of basis functions can also be used. We approximate f_i

by

$$\alpha_{i0} + \sum_{k=1}^{K_i} b_{ik}(x)\alpha_{ik} \equiv \boldsymbol{b}_i(x)'\alpha_i, \in S_i$$

where $\boldsymbol{b}_i(x) = [1, b_{i1}(x), \ldots, b_{i,K_i}(x)]'$, and $\alpha_i = (\alpha_{i0}, \alpha_{i1}, \ldots, \alpha_{iK_i})'$ are coefficients to be estimated from the data. Let $\boldsymbol{b}f = (f_1, \ldots, f_n)$ and

$$M_s(\boldsymbol{\beta}, \boldsymbol{f}) = \sum_{i=1}^{n}\sum_{j=1}^{J} m_s\left[y_{ij} - f_i(x_{ij}) - \beta_j' z_i\right], \tag{40.6}$$

where m_s is an appropriate convex function which may also depend on a scale parameter s. Three important special cases are $m_s(t) = t^2$, $m_s(t) = |t|$, and the Huber ρ function. We define the semiparametric M-estimator of $\{\boldsymbol{\beta}, \boldsymbol{f}\}$ to be the $\{\hat{\boldsymbol{\beta}}, \hat{\boldsymbol{f}}\} \in \Omega_0^{J\times d} \times \prod_{i=1}^{n} S_i$ that minimizes $M_s(\boldsymbol{\beta}, \boldsymbol{f})$. It is often necessary to consider a scale parameter s in robust estimation. This scale parameter usually needs to be estimated jointly with $(\boldsymbol{\beta}, \boldsymbol{f})$.

One question is how to determine the number of basis functions K_i. For the purpose of normalization, it is reasonable to use the same K for all the arrays, that is, let $K_1 = \cdots = K_n \equiv K$. This will make normalization consistent across the arrays. For the cDNA microarray data, the total intensity has positive density over a finite interval, typically [0, 16]. For the cubic polynomial splines, we have used the number of knots $K = 12$, and the data percentiles as the knots in the R function bs.

40.2.2 Local Regression (Lowess) Method

We can also use the lowess method [40.18] for the estimation of TW-SLM. Let W_λ be a kernel function with window width λ. Let

$$s_p(t; \boldsymbol{\alpha}, x) = \alpha_0(x) + \alpha_1(x)t + \cdots + \alpha_p(x)t^p$$

be a polynomial in t with order p, where $p = 1$ or 2 are common choices. The objective function of the *lowess* method for the TW-SLM is

$$M_s(\boldsymbol{\alpha}, \boldsymbol{\beta}) = \sum_{i=1}^{n}\sum_{j=1}^{J}\sum_{k=1}^{J} W_\lambda(x_{ik}, x_{ij}) m_s\Big[y_{ik} - s_p(x_{ik}; \boldsymbol{\alpha}, x_{ij}) - z_i'\beta_k\Big]. \tag{40.7}$$

Let $(\hat{\boldsymbol{\alpha}}, \hat{\boldsymbol{\beta}})$ be the value that minimizes M_L. The lowess M-estimator of f_i at x_{ij} is $\hat{f}_i(x_{ij}) = s_p(x_{ij}, \hat{\boldsymbol{\alpha}}, x_{ij})$.

40.2.3 Back-Fitting Algorithm in TW-SLM

In both the basis-based and local regression methods, we use a back-fitting algorithm [40.28] to compute the semiparametric M-estimators. For the M-estimator based on the basis spaces S_i defined in (40.6), set $\boldsymbol{\beta}^{(0)} = 0$. For $k = 0, 1, 2, \ldots,$

- Step 1: compute $\boldsymbol{f}^{(k)}$ by minimizing $M_s\left(\boldsymbol{f}, \boldsymbol{\beta}^{(k)}\right)$ with respect to the space $\prod_{i=1}^{n} S_i$.
- Step 2: for the $\boldsymbol{f}^{(k)}$ computed above, obtain $\boldsymbol{\beta}^{(k+1)}$ by minimizing $M_s\left(\boldsymbol{f}^{(k)}, \boldsymbol{\beta}\right)$ with respect to $\boldsymbol{\beta}$ in $\Omega_0^{J\times d}$.

Iterate between steps 1 and 2 until the desired convergence criterion is satisfied.

For strictly convex m, e.g., $m(t) = t^2$ or $m(t) = |t|$, the algorithm converges to the unique global optimal point. The back-fitting algorithm can be also applied to the lowess M-estimators. When $m(t) = t^2$, then computation consists of a series of weighted regression problems.

40.2.4 Semiparametric Least Squares Estimation in TW-SLM

An important special case of the M-estimator is the least squares (LS) estimator, which has an explicit form in the TW-SLM [40.19, 20]. The LS objective function is

$$D^2(\boldsymbol{\beta}, \boldsymbol{f}) = \sum_{i=1}^{n}\sum_{j=1}^{J}\left[y_{ij} - f_i(x_{ij}) - z_i'\beta_j\right]^2.$$

The semiparametric least squares estimator (SLSE) of $\{\boldsymbol{\beta}, \boldsymbol{f}\}$ is the $\{\hat{\boldsymbol{\beta}}, \hat{\boldsymbol{f}}\} \in \Omega_0^{J\times d} \times \prod_{i=1}^{n} S_i$ that minimizes $D^2(\boldsymbol{\beta}, \boldsymbol{f})$. That is,

$$\left(\hat{\boldsymbol{\beta}}, \hat{\boldsymbol{f}}\right) = \arg\min_{(\boldsymbol{\beta}, \boldsymbol{f}) \in \Omega_0^{J\times d} \times \prod_{i=1}^{n} S_i} D^2(\boldsymbol{\beta}, \boldsymbol{f}). \tag{40.8}$$

Denote the spline basis matrix for the i-th array by

$$B_i = \begin{pmatrix} B_{i1}' \\ \vdots \\ B_{iJ}' \end{pmatrix} = \begin{pmatrix} 1 & b_{i1}(x_{i1}) & \ldots & b_{iK_i}(x_{i1}) \\ \vdots & \vdots & \vdots & \vdots \\ 1 & b_{i1}(x_{iJ}) & \ldots & b_{iK_i}(x_{iJ}) \end{pmatrix}.$$

Define the projection matrix Q_i as

$$Q_i = B_i\left(B_i'B_i\right)^{-1}B_i', \quad i = 1, \ldots, n.$$

Let $\alpha_i = (\alpha_{i0}, \ldots, \alpha_{iK_i})'$ be the spline coefficients for the estimation of f_i and $\boldsymbol{\alpha} = (\alpha_1, \ldots, \alpha_n)'$. We can write $D^2(\boldsymbol{\beta}, \boldsymbol{\alpha}) = D^2(\boldsymbol{\beta}, \boldsymbol{f})$. Then the problem of minimizing

$D^2(\boldsymbol{\beta}, \boldsymbol{\alpha})$ with respect to $(\boldsymbol{\beta}, \boldsymbol{\alpha})$ is equivalent to solving the linear equations:

$$\hat{\boldsymbol{\beta}} \sum_{i=1}^{n} z_i z_i' + \sum_{i=1}^{n} B_i \hat{\alpha}_i z_i' = \sum_{i=1}^{n} \boldsymbol{y}_i z_i', \; B_i' B_i \hat{\alpha}_i + B_i' \hat{\boldsymbol{\beta}} z_i = B_i' \boldsymbol{y}_i \; .$$

Let $(\hat{\boldsymbol{\beta}}, \hat{\boldsymbol{\alpha}})$ be the solution. We define $\hat{f}_i(x) \equiv \boldsymbol{b}_i(x)' \hat{\alpha}_i$, $i = 1, \ldots, n$.

Using (40.3), it can be shown that the SLSE (40.8) equals

$$\hat{\boldsymbol{\beta}} = \arg\min_{\boldsymbol{\beta}} \sum_{i=1}^{n} \left\| \boldsymbol{y}_i - (I_J - Q_i)\, \boldsymbol{\beta} z_i \right\|^2 . \quad (40.9)$$

In the special case when $d = 1$ (scalar β_j) and $\boldsymbol{\beta}$ is a vector in $\mathbb{R}^J$, (40.9) is explicitly

$$\hat{\boldsymbol{\beta}} = \hat{\Lambda}^{-1} \left[\frac{1}{n} \sum_{i=1}^{n} (I_J - Q_i) \boldsymbol{y}_i z_i' \right] , \quad (40.10)$$

since $I_J - Q_i$ are projections in $\mathbb{R}^J$, where $z_i = 1$ (scalar) and, where

$$\hat{\Lambda}_{J,n} \equiv \frac{1}{n} \sum_{i=1}^{n} (I_J - Q_i) \otimes z_i z_i' \; . \quad (40.11)$$

We note that $\hat{\Lambda}$ can be considered as the observed information matrix. Here and below, $\boldsymbol{A}^{-1}$ denotes the generalized inverse of matrix $\boldsymbol{A}$, defined by $\boldsymbol{A}^{-1}\boldsymbol{x} \equiv \arg\min\left(\|\boldsymbol{b}\| : \boldsymbol{A}\boldsymbol{b} = \boldsymbol{x} \right)$. If $\boldsymbol{A}$ is a symmetric matrix with eigenvalues λ_j and eigenvectors $\boldsymbol{v}_j$, then $\boldsymbol{A} = \sum_j \lambda_j \boldsymbol{v}_j \boldsymbol{v}_j'$ and $\boldsymbol{A}^{-1} = \sum_{\lambda_j \neq 0} \lambda_j^{-1} \boldsymbol{v}_j \boldsymbol{v}_j'$.

For general z_i and $d \geq 1$, (40.9) is still given by (40.10) with

$$\hat{\Lambda}_{J,n} \equiv \frac{1}{n} \sum_{i=1}^{n} (I_J - Q_i) \otimes z_i z_i' \; . \quad (40.12)$$

The information operator (40.11) is an average of tensor products, i. e. a linear mapping from $\Omega_0^{J \times d}$ to $\Omega_0^{J \times d}$ defined by $\hat{\Lambda}\boldsymbol{\beta} \equiv n^{-1} \sum_{i=1}^{n} (I_J - Q_i) \boldsymbol{\beta} z_i z_i'$.

Although the SLSE has an explicit expression, direct computation of SLSE involves inversion of a large $J \times J$ matrix. So we use the back-fitting algorithm. In this case, computation in each step of the back-fitting algorithm becomes an easier least squares problem and has explicit expressions as follows. Set $\boldsymbol{\beta}^{(0)} = \boldsymbol{0}$. For $k = 0, 1, 2, \ldots,$

- Step 1: compute $\boldsymbol{\alpha}^{(k)}$ by minimizing $D^2(\boldsymbol{\beta}^{(k)}, \boldsymbol{\alpha})$ with respect to $\boldsymbol{\alpha}$. The explicit solution is

$$\alpha_i^{(k)} = \left(B_i' B_i \right)^{-1} B_i' \left(\boldsymbol{y}_i - \boldsymbol{\beta}^{(k)} z_i \right), \; i = 1, \ldots, n \; .$$

- Step 2: given the $\boldsymbol{\alpha}^{(k)}$ computed in step 1, let $f_i^{(k)}(x) = \boldsymbol{b}_i(x)' \alpha_i^{(k)}$, compute $\boldsymbol{\beta}^{(k+1)}$ by minimizing $D_w\left(\boldsymbol{\beta}, \boldsymbol{\alpha}^{(k)}\right)$ with respect to $\boldsymbol{\beta}$. The explicit solution is

$$\hat{\beta}_j^{(k+1)} = \left(\sum_{i=1}^{n} z_i z_i' \right)^{-1} \sum_{i=1}^{n} z_i \left[y_{ij} - f_i^{(k)}\left(x_{ij}\right) \right] , \quad j = 1, \ldots, J \; . \quad (40.13)$$

The algorithm converges to the sum of residual squares. Suppose that the algorithm meets the convergence criterion at step K. Then the estimated values of β_j are $\widehat{\beta}_j = \beta_j^{(K)}$, $j = 1, \ldots, J$, and the estimated normalization curves are

$$\hat{f}_i(x) = \boldsymbol{b}_i(x)' \alpha_i^{(K)} = \boldsymbol{b}_i(x)' (B_i' B_i)^{-1} B_i' (\boldsymbol{y}_i - \hat{\boldsymbol{\beta}} z_i) \, , \quad i = 1, \ldots, n \; . \quad (40.14)$$

The algorithm described above can be conveniently implemented in the statistical computing environment R [40.29]. Specifically, steps 1 and 2 can be solved by the function LM in R. The function BS can be used to create a basis matrix for the polynomial splines.

Let $\boldsymbol{x}_i = (x_{i1}, \ldots, x_{iJ})'$ and $f_i(\boldsymbol{x}_i) = [f_i(x_{i1}), \ldots, f_i(x_{iJ})]'$. Let $Q_i = B_i (B_i' B_i)^{-1} B_i'$. By (40.14), the estimator of $f_i(\boldsymbol{x}_i)$ is

$$\hat{f}_i(\boldsymbol{x}_i) = Q_i (\boldsymbol{y}_i - \hat{\boldsymbol{\beta}} z_i) \, .$$

Thus the normalization curve is the result of the linear smoother Q_i operating on $\boldsymbol{y}_i - \hat{\boldsymbol{\beta}} z_i$. The gene effect $\hat{\boldsymbol{\beta}} z_i$ is removed from $\boldsymbol{y}_i$. In comparison, the lowess normalization method does not remove the gene effect. An analogue of the lowess normalization, but using polynomial splines, is

$$\tilde{f}_i(\boldsymbol{x}_i) = Q_i \boldsymbol{y}_i = B_i \boldsymbol{\alpha}_i^{(0)} \, . \quad (40.15)$$

We shall call (40.15) a *spline* normalization method. Comparing $\hat{f}_i(\boldsymbol{x}_i)$ with $\tilde{f}_i(\boldsymbol{x}_i)$, we find that, if there is a relatively large percentage of differentially expressed genes, the difference between these two normalization curves can be large. The magnitude of the difference also depends on the magnitude of the gene effects.

40.3 Extensions of the TW-SLM

In this section, we describe three models that are extensions of the basic TW-SLM. These models include the multi-way SLM (MW-SLM); a model that incorporates control genes in the normalization; and a model for simultaneous location and scale normalization.

40.3.1 Multi-Way Semilinear Models

Just as TW-SLM is a semilinear extension of two-way ANOVA, for data sets with a higher-dimensional structure, multi-way ANOVA can be extended to multi-way semilinear models (MW-SLM) in the same manner by including nonparametric and linear functions of covariates as the main and interactive terms/effects in the model. This connection between ANOVA and MW-SLM is important in design of experiments and in understanding and interpretation of the contribution of different effects and identifiability conditions. The examples below are motivated by real data sets.

In model (40.1), it is only made explicit that the normalization curve f_i is array-dependent. It is straightforward to construct a 3W-SLM to normalize the data at the printing-pin block level:

$$y_{ikj} = f_{ik}(x_{ikj}) + z_i'\beta_{kj} + \epsilon_{ikj}\,, \qquad (40.16)$$

with the identifiability condition $\sum_j \beta_{kj} = 0$, where y_{ikj} and x_{ikj} are the log-intensity ratio and log-intensity product of gene j in the k-th block of array i, respectively. Model (40.16) includes nonparametric components for the block and array effects and their interaction and linear components for the gene effects and their interaction with the block effects. It was used in *Huang* et al. [40.21] to analyze the Apo A1 data [40.7], as an application of the TW-SLM (for each fixed k) at the block level. The interaction between gene and block effects is present in (40.16) since we assume that different sets of genes are printed in different blocks. If a replication of the same (or entire) set of genes is printed in each block, we may assume no interaction between gene and block effects ($\beta_{kj} = \beta_j$) in (40.16) and reduce it to the TW-SLM with (i, k) as a single index, treating a block/array in (40.16) as an array in (40.1).

As an alternative to (40.16) we may also use constants to model the interaction between array and block effects as in ANOVA, resulting in the model

$$y_{ikj} = f_i(x_{ikj}) + \gamma_{ik} + z_i'\beta_{kj} + \epsilon_{ikj}\,, \qquad (40.17)$$

with identifiability conditions $\sum_i \gamma_{ik} = \sum_k \gamma_{ik} = 0$ and $\sum_{kj} \beta_{kj} = 0$. This can be viewed as an extension of the three-way ANOVA model $Ey_{ikj} = \mu + \alpha_{i\bullet\bullet} + \gamma_{ik\bullet} + \beta_{\bullet k\bullet} + \beta_{\bullet kj} + \beta_{\bullet\bullet j}$ without $\{i, j\}$ and three-way interactions, via $\mu + \alpha_{i\bullet\bullet} \Rightarrow f_i$ and $\beta_{\bullet k\bullet} + \beta_{\bullet kj} + \beta_{\bullet\bullet j} \Rightarrow \beta_{kj}$. Note that the main block effects are represented by f_{ik} in (40.16) and by β_{kj} in (40.17).

Our approach easily accommodates designs where genes are printed multiple times in each array. Such a design is helpful for improving the precision and for assessing the quality of an array using the coefficient of variation [40.12]. Suppose there is a matrix of printing-pin blocks in each array and that a replication of the same (or entire) set of genes is printed in each column of blocks in the matrix in each array. As in (40.17), a 4W-SLM can be written as

$$y_{icrj} = f_i(x_{icrj}) + \gamma_{icr} + z_i'\beta_{rj} + \epsilon_{icrj} \qquad (40.18)$$

for observations with the j-th gene in the block at c-th column and r-th row of the matrix in the i-th array, with identifiability conditions $\sum_i \gamma_{icr} = \sum_r \gamma_{icr} = 0$ and $\sum_{rj} \beta_{rj} = 0$, with or without the three-way interaction or the interaction between the column and row effects in γ_{icr}. Note that the matrix of blocks does not have to match the physical columns and rows of printing-pin blocks. In model (40.18), the only nonparametric component is the array effects and the block effects are modeled as in ANOVA. If the block effects also depend on the log-intensity product x_{icrj}, the f_i and γ_{icr} in (40.18) can be combined into $f_{icr}(x_{icrj})$, resulting in the TW-SLM (for each fixed r) at the row level, which is equivalent to (40.16). If the replication of genes is not balanced, we may use a MW-SLM derived from an ANOVA model with incomplete/unbalanced design or the modeling methodologies described in Sect. 40.2.

From the above examples, it is clear that, in an MW-SLM, the combination of main and interactive effects represented by a term is determined by the labeling of the parameter (not that of the covariates) of the term as well as the presence or absence of associated identifiability conditions. Furthermore, since the center of a nonparametric component, e.g. $\sum_j f_i(x_{ij})$ in a TW-SLM, is harder to interpret, identifiability conditions are usually imposed on parametric components. As a result, a nonparametric component representing an interactive effect usually represents all the associated main effects as well, and many MW-SLMs are equivalent to an implementation of the TW-SLM with a suitable partition of data, as in (40.16).

40.3.2 Spiked Genes and Incorporation of Prior Knowledge in the MW-SLM

We describe three methods to incorporate prior knowledge in an MW-SLM: augmenting models, coding covariates, and imposing linear constraints. An important application of these methods is inclusion of spiked genes in normalization.

In many customized microarray experiments, it is possible to include a set of spiked genes with equal concentrations in the Cy5 and Cy3 channels. An important reason to use spiked genes is to calibrate scanning parameters, for example, intensity levels from the spiked genes can be used for tuning the laser power in each scanning channel in order to balance the Cy5 and Cy3 intensities. Spiked genes do not necessarily show an observed 1:1 ratio due to experimental variations. Because the number of spiked genes is often small, it is not adequate just to use the spiked genes as the basis for normalization.

Let y_{ik}^s and x_{ik}^s be the log-intensity ratio and product of the k-th spiked gene in the i-th array, $i = 1, \ldots, n$, $k = 1, \ldots, K$. Then we can augment the TW-SLM (40.1) as follows:

$$y_{ik}^s = f_i\left(x_{ik}^s\right) + \varepsilon_{ik}^s,\ y_{ij} = f_i\left(x_{ij}\right) + z_i'\beta_j + \varepsilon_{ij}\ . \tag{40.19}$$

The first equation is for the spiked genes, whose corresponding β_k^s are zero. Since a common f_i is used in (40.19) for each array, data from both spiked genes and genes under study contribute to the estimation of normalization curves as well as gene effects. Note that the identifiability condition $\sum_j \beta_j = 0$ in (40.1) is neither necessary nor appropriate for (40.19).

We may also use the general TW-SLM (40.2) to model spiked genes by simply setting $z_{ij} = 0$ if a spiked gene is printed at the j-th spot in the i-th array and $z_{ij} = z_i$ otherwise, where z_i are the design variable for the i-th array as in (40.1).

A more general (but not necessarily simpler) method of incorporating prior knowledge is to impose constraints in addition or as alternatives to the identifiability conditions in an MW-SLM. For example, we set $\beta_j = 0$ if j corresponds to a spiked gene, and $\beta_{j_1} = \cdots = \beta_{j_r}$ if there are r replications of a experimental gene at spots $\{j_1, \ldots, j_r\}$ in each array.

40.3.3 Location and Scale Normalization

The models we described above are for location normalization. It is often necessary to perform scale normalization to make arrays comparable in scale. The standard approach is to perform scale normalization after the location normalization, as discussed in *Yang* et al. [40.11], so that normalization is completed in two separate steps. We can extend the MW-SLM to incorporate the scale normalization by introducing a vector of array-specific scale parameters $(\tau_1, \ldots, \tau_n)$, as in

$$\frac{y_{ij} - f_i(x_{ij})}{\tau_i} = z_i'\beta_j + \varepsilon_{ij}, \quad i = 1, \ldots, n\ , \quad j = 1, \ldots, J\ , \tag{40.20}$$

for the TW-SLM, where $\tau_1 \equiv 1$ and the τ_i are restricted to be strictly positive. A more general model would allow τ_i also to depend on the total intensity levels.

40.4 Variance Estimation and Inference for β

In addition to being a standalone model for normalization, the TW-SLM can also be used for detecting differentially expressed genes. For this purpose, we need to estimate the variance of $\hat{\boldsymbol{\beta}}$. This requires the estimation of residual variances.

We have considered the model in which the residual variances depend smoothly on the total intensity values, and such dependence may vary from array to array [40.21]. The model is

$$\sigma_{ij}^2 = \sigma_i^2(x_{ij}),\ i = 1, \ldots, n,\ j = 1, \ldots, J\ ,$$

where σ_i^2 is a smooth positive function. This model takes into account the possible array-to-array variations in the variances. Because of the smoothness assumption on σ_i^2, this model says that, in each array, the genes with similar expression intensity values also have similar residual variances. This is a reasonable assumption, since for many microarray data, the variability of the log-intensity ratio depends on the total intensity. In particular, it is often the case that the variability is higher in the lower range of the total intensity than in the higher range.

We use the method proposed by *Ruppert* et al. [40.30] and *Fan* and *Yao* [40.31] in estimating the variance function in a nonparametric regression model. For each $i = 1, \ldots, n$, we fit a smooth curve through the scatter plot $(x_{ij}, \hat{\epsilon}_{ij}^2)$, where $\hat{\epsilon}_{ij}^2 = (y_{ij} - \hat{f}_i(x_{ij}) - z_i'\hat{\beta}_j)^2$. This is equivalent to fitting the nonparametric regression

model

$$\hat{\epsilon}_{ij}^2 = \sigma_i^2(x_{ij}) + \tau_{ij},\ \ j = 1, \ldots, J\ ,$$

for $i = 1, \ldots, n$, where τ_{ij} is the residual term in this model. We use the same spline bases as in the estimation of f_i (40.14). The resulting spline estimator $\hat{\sigma}_i^2$ can be expressed as

$$\hat{\sigma}_i^2(x) = \boldsymbol{b}_i'(x)(B_i'B_i)^{-1}B_i'\hat{\boldsymbol{\epsilon}}_i^2, \tag{40.21}$$

where $\hat{\boldsymbol{\epsilon}}_i^2 = (\hat{\epsilon}_{i1}^2, \ldots, \hat{\epsilon}_{iJ}^2)'$. The estimator of σ_{ij}^2 is then $\hat{\sigma}_{ij}^2 = \hat{\sigma}_i^2(x_{ij})$.

We can now approximate the variance of $\hat{\beta}_j$ as follows [40.21]. Let $Z_n = \sum_{i=1}^n z_i z_i'$. Based on (40.13), we have

$$\begin{aligned}\mathrm{var}(\hat{\beta}_j) &\approx Z_n^{-1}\left[\sum_{i=1}^n z_i z_i' \mathrm{var}(\epsilon_{ij})\right] Z_n^{-1} \\ &\quad + Z_n^{-1}\left[\sum_{i=1}^n z_i z_i' \mathrm{var}\left[\hat{f}_i(x_{ij})\right]\right] Z_n^{-1} \\ &\equiv \Sigma_{\epsilon,j} + \Sigma_{f,j}\ .\end{aligned}$$

The variance of $\hat{\beta}_j$ consists of two components. The first component represents the variation due to the residual errors in the TW-SLM, and the second component is due to the variation in the estimated normalization curves.

For the first term $\Sigma_{\epsilon,j}$, we have

$$\Sigma_{\epsilon,j} = Z_n^{-1}\left(\sum_{i=1}^n z_i z_i' \sigma_{ij}^2\right) Z_n^{-1}\ .$$

Suppose that $\hat{\sigma}_{ij}^2$ is a consistent estimator of σ_{ij}^2, which will be given below. We estimate $\Sigma_{\epsilon,j}$ by

$$\hat{\Sigma}_{\epsilon,j} = Z_n^{-1}\left(\sum_{i=1}^n z_i z_i' \hat{\sigma}_{ij}^2\right) Z_n^{-1}\ .$$

For the second term $\Sigma_{f,j}$, we approximate $\hat{\boldsymbol{f}}_i$ by the ideal normalization curve, that is,

$$\begin{aligned}\hat{f}_i(\boldsymbol{x}_i) &= Q_i\left(\boldsymbol{y}_i - \hat{\boldsymbol{\beta}} z_i\right) \approx Q_i\left(\boldsymbol{y}_i - \boldsymbol{\beta} z_i\right) \\ &= Q_i[\boldsymbol{\epsilon}_i + f_i(\boldsymbol{x}_i)]\ .\end{aligned}$$

Therefore, conditional on $\boldsymbol{x}_i$, we have,

$$\mathrm{var}\left[\hat{f}_i(\boldsymbol{x}_i)\right] \approx Q_i \mathrm{var}(\boldsymbol{\epsilon}_i) Q_i\ ,$$

and

$$\mathrm{var}\left[\hat{f}_i(x_{ij})\right] = \boldsymbol{e}_j' Q_i \mathrm{var}(\boldsymbol{\epsilon}_i) Q_i \boldsymbol{e}_j\ ,$$

where $\boldsymbol{e}_j$ is the unit vector whose j-th element is 1. Let $\hat{\Sigma}_i$ be an estimator of $\mathrm{var}(\boldsymbol{\epsilon}_i)$. We estimate $\Sigma_{f,j}$ by

$$\hat{\Sigma}_{f,j} = Z_n^{-1}\boldsymbol{e}_j'\left(\sum_{i=1}^n Q_i \hat{\Sigma}_i Q_i\right)\boldsymbol{e}_j Z_n^{-1}\ .$$

Finally, we estimate $\mathrm{var}\left(\hat{\beta}_j\right)$ by

$$\hat{\Sigma}_{\beta,j} = \hat{\Sigma}_{\epsilon,j} + \hat{\Sigma}_{f,j}\ . \tag{40.22}$$

Then a test for the contrast $c'\beta_j$, where c is a known contrast vector, is based on the statistic

$$t_j = \frac{c'\hat{\beta}_j}{\sqrt{c'\hat{\Sigma}_{\beta,j}c}}\ .$$

As is shown in Sect. 40.6, for large J, the distribution of t_j can be approximated by the standard normal distribution under the null $c'\beta_j = 0$. However, to be conservative, we use a t distribution with an appropriate number of degrees of freedom to approximate the null distribution of t_j when $c'\beta_j = 0$. For example, for a direct comparison design, the number of degrees of freedom is $n-1$. For a reference design in a two sample comparison, the variances for the two groups can be estimated separately, and then Welch's correction for the degrees of freedom can be used. Resampling methods such as permutation or bootstrap can also be used to evaluate the distribution of t_j.

Another approach is to estimate σ_{ij}^2 jointly with $(\boldsymbol{f}, \boldsymbol{\beta})$. This approach is computationally more intensive but may yield more efficient estimates of $(\boldsymbol{\beta}, \boldsymbol{f})$ and σ_{ij}^2. Consider an approximation to σ_{ij}^2 using the spline basis functions:

$$\sigma_{ij}^2 = \sigma_i^2(x_{ij}) = \sum_{k=1}^{K_i} \gamma_{ik} b_k(x_{ij})\ . \tag{40.23}$$

Let $\boldsymbol{\gamma}$ be the collection of the γ_{ik}. Assuming normality for ε_{ij}, the negative likelihood function is

$$\ell(\boldsymbol{\beta}, \boldsymbol{f}, \boldsymbol{\gamma}) = -\prod_{i=1}^n \prod_{j=1}^J \frac{1}{\sigma_{ij}}\phi\left(\frac{y_{ij} - f_i(x_{ij}) - \beta_j' z_i}{\sigma_{ij}}\right)\ , \tag{40.24}$$

where ϕ is the density of $N(0,1)$. For robust M-estimation, we define the M-estimation objective function as

$$M_s(\boldsymbol{\beta}, \boldsymbol{f}, \boldsymbol{\gamma}) = \sum_{i=1}^n \sum_{j=1}^J \sigma_{ij} m_s\left(\frac{y_{ij} - f_i(x_{ij}) - \beta_j' z_i}{\sigma_{ij}}\right)\ . \tag{40.25}$$

Again, we can use a back-fitting algorithm for computing the M-estimators, but with an extra step in each iteration for $\boldsymbol{\gamma}$.

40.5 An Example and Simulation Studies

40.5.1 Apo A1 Data

We now illustrate the TW-SLM for microarray data by the Apo A1 data set of *Callow* et al. [40.7]. The analysis described here is from *Huang* et al. [40.21]. The purpose of this experiment is to identify differentially expressed genes in the livers of mice with very low high-density lipoprotein (HDL) cholesterol levels compared to inbred mice. The treatment group consists of eight mice with the apo A1 gene knocked out and the control group consists of eight C57BL/6 mice. For each of these mice, target cDNA is obtained from mRNA by reverse transcription and labeled using a red fluorescent dye (Cy5). The reference sample (green fluorescent dye Cy3) used in all hybridizations was obtained by pooling cDNA from the eight control mice. The target cDNA is hybridized to microarrays containing 5548 cDNA probes. This data set was analyzed by *Callow* et al. [40.7] and *Dudoit* et al. [40.32]. Their analysis uses lowess normalization and the two-sample t-statistic. Eight genes with multiple comparison adjusted permutation p-value ≤ 0.01 are identified.

We apply the proposed normalization and analysis method to this data set. As in *Dudoit* et al. [40.32], we use printing-tip-dependent normalization. The TW-SLM model used here is

$$y_{ikj} = f_{ik}(x_{ikj}) + z_i' \beta_{kj} + \varepsilon_{ikj} \,,$$

where $i = 1, \ldots, 16$, $k = 1, \ldots, 16$, and $j = 1, \ldots, 399$. Here i indexes arrays, k indexes printing-tip blocks, and j index genes in a block. ε_{ikj} are residuals with mean 0 and variance σ^2_{ikj}. We use the model

$$\sigma^2_{ikj} = \sigma^2_{ik}(x_{ikj}) \,,$$

where σ^2_{ik} are unknown smooth functions. We apply the printing-pin-dependent normalization and estimation approach described in Sect. 40.3.2. The covariate $z_i = (1, 0)'$ for the treatment group (apo A1 knock-out mice) and $z_i = (0, 1)'$ for the control group (C57BL/6 mice). The coefficient $\beta_{kj} = (\beta_{kj1}, \beta_{kj2})$. The contrast $\beta_{kj1} - \beta_{kj2}$ measures the expression difference for the j-th gene in the k-th block between the two groups.

To compare the proposed method with the existing ones, we also analyzed the data using the lowess normalization method as in *Dudoit* et al. [40.32], and a lowess-like method where, instead of using local regression, splines are used in estimating the normalization curves described in (40.15) at the end of Sect. 40.2. We refer to this method as the spline (normalization) method below.

As examples of the normalization results, Fig. 40.1 displays the M–A plots and printing-tip-dependent normalization curves in the 16 printing-pin blocks of the array from one knock-out mouse. The solid line is the normalization curve based on the TW-SLM model, and the dashed line is the lowess normalization curve. The degrees of freedom used in the spline basis function in the TW-SLM normalization is 12, and following *Dudoit* et al. [40.32], the span used in the lowess normalization is 0.40. We see that there are differences between the normalization curves based on the two methods. The lowess normalization curve attempts to fit each individual M–A scatter plot, without taking into account the gene effects. In comparison, the TW-SLM normalization curves do not follow the plot as closely as the lowess normalization. The normalization curves estimated using the spline method with exactly the same basis functions used in the TW-SLM closely resemble those estimated using the lowess method. Because they are indistinguishable by eye, these curves are not included in the plots.

Figure 40.2 displays the volcano plots of $-\log_{10}$ p-values versus the mean differences of log-expression values between the knock-out and control groups. In the first (left panel) volcano plot, both the normalization and estimation of $\boldsymbol{\beta}$ are based on the TW-SLM. We estimated the variances for $\hat{\beta}_{kj1}$ and $\hat{\beta}_{kj2}$ separately. These variances are estimated based on (40.21), which assumes that the residual variances depend smoothly on the total log-intensities. We then used Welch's correction for the degrees of freedom in calculating the p-values. The second (middle panel) plot is based on the lowess normalization method and use the two-sample t-statistics as in *Dudoit* et al. [40.32], but the p-values are obtained based on Welch's correction for the degrees of freedom. The third (right panel) plot is based on the spline normalization method and uses the same two-sample t-statistics as in the lowess method. The eight solid circles in the lowess volcano plot are the significant genes that were identified by *Dudoit* et al. [40.32]. These eight genes are also plotted as solid circles in the TW-SLM and spline volcano plots, and are significant based on the TW-SLM and spline methods, as can be seen from the volcano plots. Comparing the three volcano plots, we see that: (i) the $-\log_{10}$ p-values based on the TW-SLM method tend to be higher than those based on the lowess and

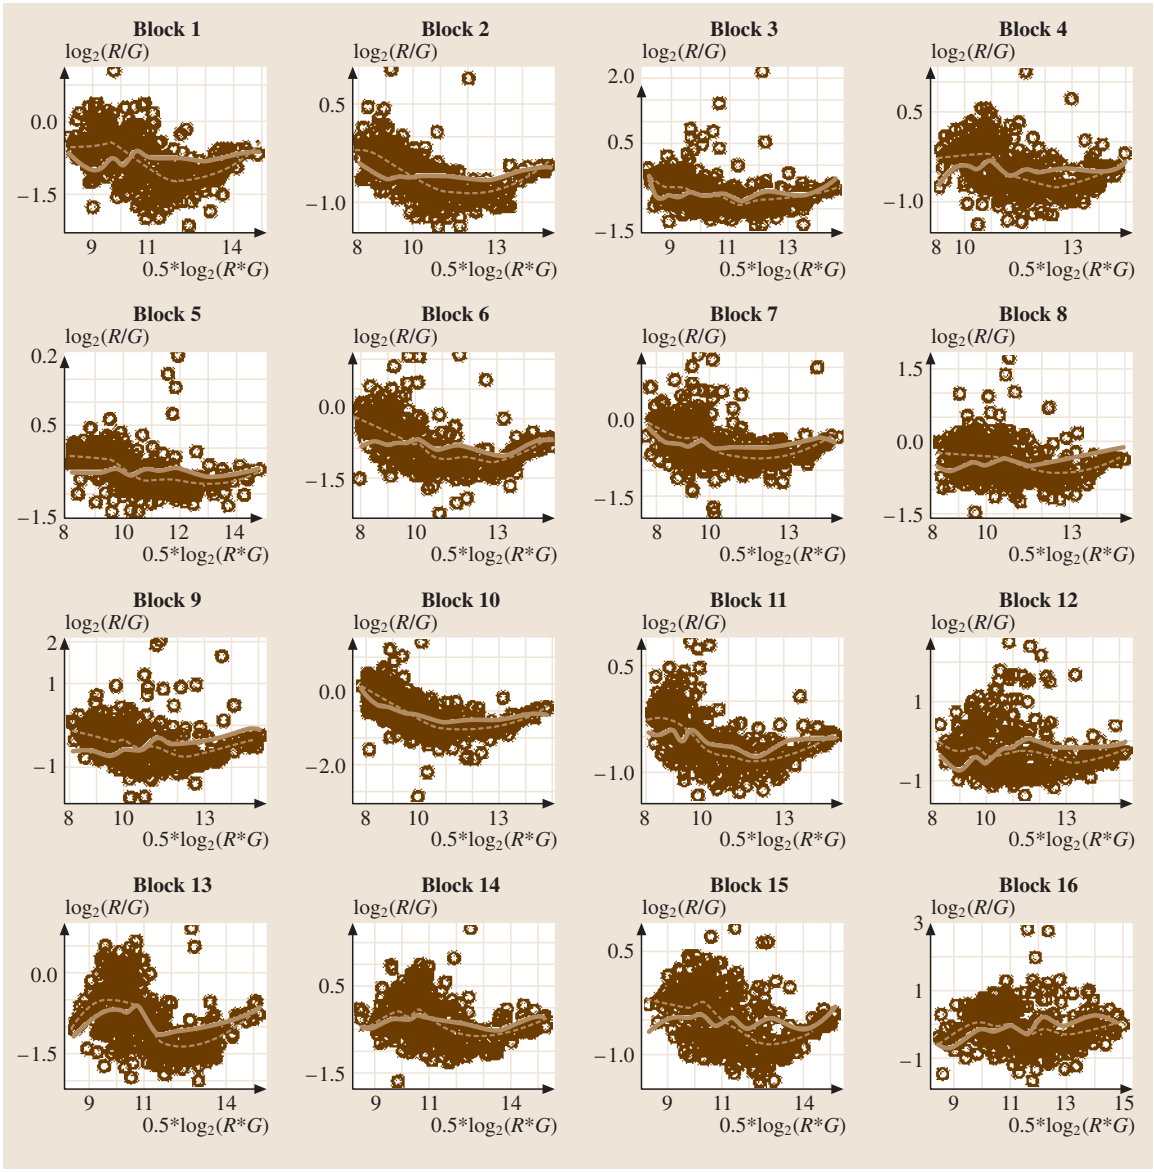

Fig. 40.1 Apo AI data: comparison of normalization curves in the 16 blocks of the array from one knock-out mouse in the treatment group. *Solid line*: normalization curve based on TW-SLM; *dashed line*: normalization curve based on lowess

spline methods; (ii) the p-values based on the lowess and spline methods are comparable.

Because we use exactly the same smoothing procedure in the TW-SLM and spline methods, and because the results between the lowess and spline methods are very similar, we conclude that the differences between the TW-SLM and lowess volcano plots are mostly due to the different normalization methods and two difference approaches for estimating the variances. We first examine the differences between the TW-SLM normalization values and the lowess as well as the spline normalization values. We plot the three pairwise scatter plots of estimated mean expression differences based on the TW-SLM, lowess, and spline normalization methods, see

Fig. 40.3. In each scatter plot, the solid line is the fitted linear regression line. For the TW-SLM versus lowess comparison (left panel), the fitted regression line is

$$y = 0.00029 + 1.090x\,. \tag{40.26}$$

The standard error of the intercept is 0.0018, so the intercept is negligible. The standard error of the slope is 0.01. Therefore, on average, the mean expression differences based on the TW-SLM normalization method are about 10% higher than those based on the lowess normalization method. For the TW-SLM versus spline comparison (middle panel), the fitted regression line and the standard errors are virtually identical to (40.26) and its associated standard errors. For the spline versus lowess comparison (right panel), the fitted regression line is

$$y = 0.00027 + 1.00257x\,. \tag{40.27}$$

The standard error of the intercept is 0.000 25, and the standard of the slope is 0.0015. Therefore, the mean expression differences based on the lowess and spline normalization methods are essentially the same, as can also be seen from the scatter plot in the right panel in Fig. 40.3.

Figure 40.4 shows the histograms of the standard errors obtained based on intensity-dependent smoothing defined in (40.21) using the residuals from the TW-SLM normalization (top panel), and the standard errors calculated for individual genes using the lowess and spline methods (middle and bottom panels). The standard errors (SE) based on the individual genes have a relatively large range of variation, but the range of standard errors based on intensity-dependent smoothing shrinks towards the middle. The SEs based on the smoothing method are more tightly centered around the median value of about 0.13. Thus, the analysis based on the smooth estimate of the error variances is less susceptible to the problem of artificially small p-values resulting from random small standard errors calculated from individual genes.

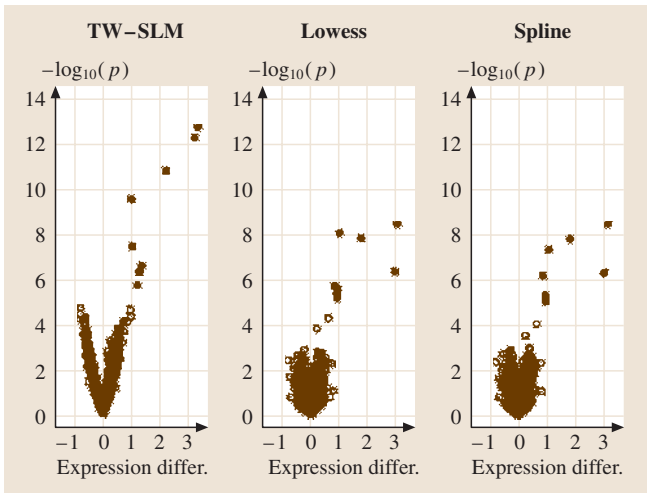

Fig. 40.2 Volcano plots: scatter plot of $-\log_{10}(p-\text{value})$ versus estimated mean expression value. The left panel shows the volcano plot based on the TW-SLM; the middle panel shows the plot based on the lowess method; the right panel shows the result based on the spline method

40.5.2 Simulation Studies

We use simulation to compare the TW-SLM, lowess, and spline normalization methods with regard to the mean square errors (MSE) in estimating expression levels β_j. The simulation models and results are from *Huang* et al. [40.21]. Let α_1 and α_2 be the percentages of up- and down-regulated genes, respectively, and let $\alpha = \alpha_1 + \alpha_2$. We consider four models in our simulation.

- Model 1: there is no dye bias. So the true normalization curve is set at the horizontal line at 0. That is $f_i(x) \equiv 0, 1 \le i \le n$. In addition, the expression levels of up- and down-regulated genes are symmetric and $\alpha_1 = \alpha_2$.
- Model 2: as in model 1, the true normalization curves $f_i(x) \equiv 0, 1 \le i \le n$, but the percentages of up- and down-regulated genes are different. We set $\alpha_1 = 3\alpha_2$.
- Model 3: there are nonlinear and intensity-dependent dye biases. The expression levels of up- and down-regulated genes are symmetric and $\alpha_1 = \alpha_2$.
- Model 4: there is nonlinear and intensity-dependent dye bias. The percentages of up- and down-regulated genes are different. We set $\alpha_1 = 3\alpha_2$.

Models 1 and 2 can be considered as the baseline ideal case in which there is no channel bias. The data-generating process is as follows:

- Generate β_j. For most of the genes, we simulate $\beta_j \sim N(0, \tau_j^2)$. The percentage of such genes is $1-\alpha$. For up-regulated genes, we simulate $\beta_j \sim N(\mu, \tau_{\mathrm{U}j}^2)$ where $\mu > 0$. For down-regulated genes, we simulate $\beta_j \sim N(-\mu, \tau_{\mathrm{D}j}^2)$. We use $\tau_j = 0.6$, $\mu = 2$, $\tau_{\mathrm{U}j} = \tau_{\mathrm{D}j} = 1$.
- Generate x_{ij}. We simulate $x_{ij} \sim 16 \times Beta(a, b)$, where $a = 1$, $b = 2.5$.
- Generate ϵ_{ij}. We simulate $\epsilon_{ij} \sim N(0, \sigma_{ij}^2)$, where $\sigma_{ij} = \sigma(x_{ij})$. Here $\sigma(x) = 0.3 * x^{-1/3}$. So the error variance is higher at lower intensity range than at higher intensity range.
- In models 1 and 2, the log-intensity ratios are computed as $y_{ij} = f_i(x_{ij}) + \beta_j + \epsilon_{ij}$.

In models 3 and 4, the log-intensity ratios are computed according to a printing-tip-dependent model with $y_{ij} = \beta_j + f_{ik(j)}(x_{ij}) + \varepsilon_{ij}$, where the function $k(j)$ indicates the printing-pin block. This is equivalent to the model used in the analysis of the Apo A1 data in Sect. 40.5.1, with $z_i = 1$ there. We use

$$f_{ik} = \frac{a_{ik1} x^2 \sin(x/\pi)}{1 + a_{ik2} x^2} ,$$

where a_{i1} and a_{i2} are generated independently from the uniform distribution U(0.6, 1.4). Thus the normalization curves vary from block to block within an array and between arrays.

The number of printing-pin blocks is 16, and in each block there are 400 spots. The number of arrays in each data set is 10. The number of replications for each simulation is 10. Based on these 10 replications, we calculate the bias, variance, and mean square error of estimated expression values relative to the generating values. In each of the four cases, we consider two levels of the percentage of differentially expressed genes: $\alpha = 0.01$ and 0.06.

Tables 40.1–40.4 present the summary statistics of the MSEs for estimating the relative expression levels β_j in the four models described above. In Table 40.1

Table 40.1 Simulation results for model 1. 10 000 × Summary of MSE. The true normalization curve is the horizontal line at 0. The expression levels of up- and down-regulated genes are symmetric: $\alpha_1 = \alpha_2$, where $\alpha_1 + \alpha_2 = \alpha$

		Min.	1st quartile	Median	Mean	3rd quartile	Max.
$\alpha = 0.01$	TW-SRM	3.74	51.59	75.08	88.88	106.20	4980.00
	Lowess	3.38	50.72	72.77	87.89	105.10	7546.00

	Lowess	7.39	57.19	85.47	107.70	128.10	2570.00
	Splines	9.37	69.26	102.80	122.80	148.50	2230.00

Table 40.4 Simulation results for model 4. 10 000 × Summary of MSE. There are nonlinear and intensity-dependent dye biases. The percentages of up- and down-regulated genes are different: $\alpha_1 = 3\alpha_2$, where $\alpha_1 + \alpha_2 = \alpha$

		Min.	1st quartile	Median	Mean	3rd quartile	Max.
$\alpha = 0.01$	TW-SRM	5.89	51.26	74.53	85.89	107.20	2810.00
	Lowess	9.29	68.30	101.60	118.60	140.00	4088.00
	Splines	9.68	67.85	98.82	119.80	141.00	2465.00
$\alpha = 0.06$	TW-SRM	4.96	54.12	79.92	98.79	122.70	2130.00
	Lowess	6.49	71.54	113.90	130.90	169.50	2474.00
	Splines	5.77	65.46	107.57	128.40	171.60	1898.00

for simulation model 1, in which the true normalization curve is the horizontal line at 0 and the expression levels of up- and down-regulated genes are symmetric, the TW-SLM normalization tends to have slightly higher MSEs than the lowess method. The spline method has higher MSEs than both the TW-SLM and lowess methods. In Table 40.2, when there is no longer symmetry in the expression levels of up- and down-regulated genes, the TW-SLM method has smaller MSEs than both the lowess and spline methods. In Table 40.3 for simulation model 3, there is nonlinear intensity-dependent dye bias, but there is symmetry between the up- and down-regulated genes. The TW-SLM has comparable but slightly smaller MSEs than the lowess method. The spline method has higher MSEs than both the TW-SLM and lowess methods. In Table 40.4

for simulation model 4, there is nonlinear intensity-dependent dye bias, and the percentages of up- and down-regulated genes are different, the TW-SLM has considerably smaller MSEs. We have also examined biases and variances. There are only small differences in variances among the TW-SLM, lowess, and spline methods. However, the TW-SLM method generally has smaller biases.

40.6 Theoretical Results

In this section, we provide theoretical results concerning the distribution of $\hat{\boldsymbol{\beta}}$ and the rate of convergence for the normalization of f_i. The proofs can be found in *Huang* et al. [40.21]. Our results are derived under subsets of the following four conditions. We assume that the data from different arrays are independent, and impose conditions on the n individual arrays. Our conditions depend on n only through the uniformity requirements across the n arrays, so that all the theorems in this section hold in the case of fixed $n \geq 2$ as the number of genes $J \to \infty$ as well as the case of $(n, J) \to (\infty, \infty)$ with no constraint on the order of n in terms of J. In contrast, *Huang* and *Zhang* [40.20] focused on applications with large number of arrays. The results in this section hold for any basis functions b_{ik} in (40.5), e.g. spline, Fourier, or wavelet bases, as long as Q_i in (40.9) are projections from $\mathbb{R}^J$ to $\{f(\boldsymbol{x}_i) : f \in S_i\}$ with $Q_i \boldsymbol{e} = \boldsymbol{e}$, where $\boldsymbol{e} = (1, \ldots, 1)'$. Furthermore, with minor modifications in the proof, the results hold when Q_i are replaced by nonnegative definite smoothing matrices A_i with their largest eigenvalues bounded by a fixed constant, see [40.20, 21].

Condition I: *In (40.3), $\boldsymbol{x}_i$, $i = 1, \ldots, n$, are independent random vectors, and for each i $\left(x_{ij}, j \leq J\right)$ are exchangeable random variables. Furthermore, for each $i \leq n$, the space S_i in (40.5) depends on design variables $\left(\boldsymbol{x}_k, z_k, k \leq n\right)$ only through the values of $\boldsymbol{x}_i$ and $(z_k, k \leq n)$.*

The independence assumption follows from the independence of different arrays, which is satisfied in a typical microarray experiment. The exchangeability condition within individual arrays is reasonable if there is no prior knowledge about the total intensity of expression values of the genes under study. It holds when $\left(x_{ij}, j \leq J\right)$ are conditionally independent identically distributed (iid) variables given certain (unobservable random) parameters, including within-array iid $x_{ij} \sim G_i$ as a special case. The exchangeability condition also holds if $\left(x_{ij}, j \leq J\right)$ are sampled without replacement from a larger collection of variables.

Condition II: *The matrix $Z_n \equiv \sum_{i=1}^n z_i z_i'$ is of full rank with $\max_{i \leq n} z_i' Z_n^{-1} z_i \leq \kappa^* < 1$.*

Condition II is satisfied by common designs such as the reference and direct comparison designs. Since $\sum_{i=1}^n Z_n^{-1} z_i z_i' = I_d$, $\sum_{i=1}^n z_i' Z_n^{-1} z_i = d$. In balanced designs or orthogonal designs with replications, $Z_n \propto I_d$, n is a multiplier of d, and $z_i' Z_n^{-1} z_i = \kappa^* = d/n < 1$ for all $i \leq n$. In particular, (40.6) describes a balanced design with $d = 1$, so that condition II holds as long as $n \geq 2$.

Condition III: *For the projections Q_i in (40.9), $K_{J,n}^* \equiv \max_{i \leq n} E\left[\mathrm{tr}(Q_i) - 1\right] = O\left(J^{1/2}\right)$.*

An assumption on the maximum dimensions of the approximation spaces is usually required in nonparametric smoothing. Condition III assumes that the ranks of the projections Q_i are uniformly of the order $O\left(J^{1/2}\right)$ to avoid overfitting, and more important, to avoid colinearity between the approximation spaces for the estimation of $(f_i(\boldsymbol{x}_i), i \leq n)$ and the design variables for the estimation of $\boldsymbol{\beta}$. Clearly, $E\left[\mathrm{tr}(Q_i) - 1\right] \leq K_i$ for the K_i in (40.5).

Condition IV: $\rho_{J,n}^* \equiv \max_{i \leq n} E\left\| f_i(\boldsymbol{x}_i) - Q_i f_i(\boldsymbol{x}_i)\right\|^2 / (J-1) \to 0$.

Condition IV demands that the ranges of the projections Q_i be sufficiently large that the approximation errors for $f_i(\boldsymbol{x}_i)$ are uniformly $O(1)$ in an average sense. Although this is the weakest possible condition on Q_i for the consistent estimation of $f_i(\boldsymbol{x}_i)$, the combination of conditions III and IV does require careful selection of spaces S_i in (40.5) and certain condition on the tail probability of x_{ij}. See the two examples in *Huang* et al. [40.21] that illustrate this point.

40.6.1 Distribution of $\hat{\beta}$

We now describe the distribution of $\hat{\boldsymbol{\beta}}$ in (40.9) conditionally on all the covariates and provide an upper bound for the conditional bias of $\hat{\boldsymbol{\beta}}$.

Let $\hat{\Lambda}$ be the information operator in (40.12). Define

$$\tilde{\beta}_{J,n} = -\Pi_{J,n}\boldsymbol{\beta} + \hat{\Lambda}_{J,n}^{-1}\left[\frac{1}{n}\sum_{i=1}^{n}(I_J - Q_i) f_i(\boldsymbol{x}_i) z_i'\right], \tag{40.28}$$

where $\Pi_{J,n}$ is the projection to $\{\boldsymbol{b} \in \Omega_0^{J\times d} : \hat{\Lambda}_{J,n}\boldsymbol{b} = 0\}$. Define

$$V_{J,n} = \frac{1}{n}\sum_{i=1}^{n} V_i \otimes z_i z_i' ,$$
$$V_i = (I_J - Q_i)\mathrm{var}(\boldsymbol{\epsilon}_i)(I_J - Q_i) . \qquad (40.29)$$

Here $\hat{\Lambda}_{J,n}^{-1}$, the generalized inverse of $\hat{\Lambda}_{J,n}$, is uniquely defined as a one-to-one mapping from the range of $\hat{\Lambda}_{J,n}$ to the space $(I_J \otimes I_d - \Pi_{J,n})\Omega_0^{J\times d} = \{\boldsymbol{b} \in \Omega_0^{J\times d} : \Pi_{J,n}\boldsymbol{b} = 0\}$. For any $J\times b$ matrix $\boldsymbol{b}$, the matrix $B = \hat{\Lambda}_{J,n}^{-1}\boldsymbol{b}$ can be computed by the following recursion:

$$B^{(k+1)} \leftarrow n(\boldsymbol{b} - \Pi_{J,n}\boldsymbol{b})Z_n^{-1} + \sum_{i=1}^{n} Q_i B^{(k)} z_i z_i' Z_n^{-1} \qquad (40.30)$$

with the initialization $B^{(1)} = n(\boldsymbol{b} - \Pi_{J,n}\boldsymbol{b})Z_n^{-1}$ and $Z_n = \sum_{i=1}^{n} z_i z_i'$.

Theorem 40.1
Let $\hat{\boldsymbol{\beta}}_{J,n}$, $\hat{\Lambda}$ and $V_{J,n}$ be as in (40.9), (40.12) and (40.29) respectively. Suppose that given $\{\boldsymbol{x}_i, i \le n\}$, $\boldsymbol{\epsilon}_i$ are independent normal vectors. Then, conditionally on $\{\boldsymbol{x}_i, i \le n\}$,

$$\hat{\boldsymbol{\beta}} - \boldsymbol{\beta} \sim N\left(\tilde{\boldsymbol{b}}_{J,n}, \frac{1}{n}\hat{\Lambda}_{J,n}^{-1} V_{J,n} \hat{\Lambda}_{J,n}^{-1}\right) . \qquad (40.31)$$

In particular, for all $\boldsymbol{b} \in \Omega_0^{J\times d}$, $\lim_{k\to\infty} B^{(k)} = \hat{\Lambda}^{-1}\boldsymbol{b}$ with the $B^{(k)}$ in (40.30), and

$$\sigma_{J,n}^2(\boldsymbol{b}) \equiv \mathrm{var}\left[\mathrm{tr}\left(\boldsymbol{b}'\hat{\boldsymbol{\beta}}\right)\middle|\{\boldsymbol{x}_i, i \le n\}\right]$$
$$= \frac{1}{n^2}\sum_{i=1}^{n} z_i'\left(\hat{\Lambda}^{-1}\boldsymbol{b}\right)' V_i \left(\hat{\Lambda}^{-1}\boldsymbol{b}\right) z_i . \qquad (40.32)$$

Our next theorem provides sufficient conditions under which the bias of $\hat{\boldsymbol{\beta}}$ is of smaller order than its standard error.

Theorem 40.2
Suppose conditions I to IV hold. If $c_{J,n}/\rho_{J,n}^* \to \infty$, then

$$\sup\left\{E\min\left(1, \frac{\mathrm{tr}^2\left(\boldsymbol{b}'\tilde{\boldsymbol{b}}_{J,n}\right)}{\mathrm{tr}\left(\boldsymbol{b}Z_n^{-1}\boldsymbol{b}'\right)c_{J,n}}\right) : \boldsymbol{b} \in \Omega_0^{J\times d}, \boldsymbol{b} \neq 0\right\} = O(1). \qquad (40.33)$$

In particular, if given $\{\boldsymbol{x}_i, i \le n\}$, $\boldsymbol{\epsilon}_i$ are independent normal vectors with $\mathrm{var}(\boldsymbol{\epsilon}_i) \ge \sigma_*^2 I_J$ for certain $\sigma_* > 0$, then

$$\sup_{\boldsymbol{b}\in\Omega_0^{J\times d}, \boldsymbol{b}\neq 0}\left\{\sup_{x\in\mathbb{R}}\left|P\left(\frac{\mathrm{tr}\left(\boldsymbol{b}'\left(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}\right)\right)}{\sigma_{J,n}(\boldsymbol{b})} \le x\right) - \Phi(x)\right|\right\} = O(1) , \qquad (40.34)$$

where Φ is the cumulative distribution function for $N(0, 1)$.

This result states that, under conditions I to IV, appropriate linear combinations of $\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}$, such as contrasts, have an approximate normal distribution with mean zero and the approximation is uniform over all linear combinations. Therefore, this result provides theoretical justification for inference procedures based on $\hat{\boldsymbol{\beta}}$, such as those described in Sect. 40.3. Without the normality condition, (40.29) is expected to hold under the Lindeberg condition as $(n, J) \to (\infty, \infty)$, even in the case $n = O(J)$ [for example $n = O(\log J)$]. We assume the normality here so that (40.29) holds for fixed n as well as large n.

40.6.2 Convergence Rates of Estimated Normalization Curves $\hat{f}_i$

Normalization is not only important in detecting differentially expressed genes, it is also a basic first step for other high-level analysis, including classification and cluster analysis. Thus, it is of interest in itself to study the behavior of the estimated normalization curves. Here we study the convergence rates of $\hat{f}_i$.

Since $\hat{f}_i(\boldsymbol{x}_i) = Q_i(\boldsymbol{y}_i - \hat{\boldsymbol{\beta}}z_i)$, it follows from (40.3) that

$$\hat{f}_i(\boldsymbol{x}_i) = Q_i\left[f_i(\boldsymbol{x}_i) + \boldsymbol{\epsilon}_i\right] - Q_i\left(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}\right)z_i . \qquad (40.35)$$

Therefore, the convergence rates of $\|\hat{f}_i(\boldsymbol{x}_i) - f_i(\boldsymbol{x}_i)\|$ are bounded by the sums of the rates of $\|Q_i\left[f_i(\boldsymbol{x}_i) + \boldsymbol{\epsilon}_i\right] - f_i(\boldsymbol{x}_i)\|$ for the ideal fits $Q_i(\boldsymbol{y}_i - \boldsymbol{\beta}z_i)$ and the rates of $\|Q_i\left(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}\right)z_i\|$.

Theorem 40.3
Suppose conditions I to IV hold and $\mathrm{var}(\boldsymbol{\epsilon}_i) \le (\sigma^*)^2 I_J$ for certain $0 < \sigma^* < \infty$. Then, for certain $\epsilon_{J,M}$ with $\lim_{M\to\infty}\lim_{J\to\infty}\epsilon_{J,M} \to 0$,

$$\max_{i\le n} P\left\{\|\hat{f}_i(\boldsymbol{x}_i) - f_i(\boldsymbol{x}_i)\|^2/J > M\left[\rho_{J,n}^* + (\sigma^*)^2 K_{J,n}^*/J\right]\right\} \le \epsilon_{J,M} .$$

In particular, if $K^*_{J,n} = O(1)J^{1/(2\alpha+1)}$ and $\rho^*_{J,n} = O(1)J^{2\gamma/(2\alpha+1)}$ for certain $0 < \gamma \le \alpha$, then $\|\hat{f}_i(\boldsymbol{x}_i) - f_i(\boldsymbol{x}_i)\|^2/J = O_P\left(J^{-2\gamma/(2\alpha+1)}\right)$, where the O_P is uniform in $i \le n$.

In the case of $\mathrm{var}(\boldsymbol{\epsilon}_i) = \sigma^2 I_J$, $\max_{i\le n} E\|Q_i(\boldsymbol{y}_i - \boldsymbol{\beta}z_i) - f_i(\boldsymbol{x}_i)\|^2/J \ge \max\left(\rho^*_{J,n}, \sigma^2 K^*_{J,n}/J\right)$ is the convergence rate for the ideal fits $Q_i(\boldsymbol{y}_i - \boldsymbol{\beta}z_i)$ for $f_i(\boldsymbol{x}_i)$. Theorem 3 asserts that $\hat{f}_i(\boldsymbol{x}_i)$ have the same convergence rates as the ideal fits. Thus, $\hat{f}_i(\boldsymbol{x}_i)$ achieve or nearly achieve the optimal rate of convergence for normalization under standard conditions. See the two examples in *Huang* et al. [40.21].

40.7 Concluding Remarks

The basic idea of TW-SLM normalization is to estimate the normalization curves and the relative gene effects simultaneously. The TW-SLM normalization does not assume that the normalization is constant as in the global normalization method, nor does it make the assumptions that the percentage of differentially expressed genes is small or that the up- and down-regulated genes are distributed symmetrically, as are required in the lowess normalization method [40.11]. This model puts normalization and significant analysis of gene expression in the framework of a high dimensional semiparametric regression model. We used a back-fitting algorithm to compute the semiparametric M-estimators in the TW-SLM. For identification of differentially expressed genes, we used an intensity-dependent variance model. This variance model is a compromise between the constant residual variance assumption used in the ANOVA method and the approach in which the variances of all the genes are treated as being different. We described two nonparametric methods for variance estimation. The first method is to smooth the scatter plot of the squared residuals versus the total intensity. The second one is to estimate the variance function jointly with the normalization curves and gene effects. For the example we considered in Sect. 40.6, the proposed method yields reasonable results when compared with the published results. Our simulation studies show that the TW-SLM normalization has better performance in terms of the mean squared errors than the lowess and spline normalization methods. Thus the proposed TW-SRM for microarray data is a powerful alternative to the existing normalization and analysis methods.

The TW-SLM is qualitatively different from the SRM. For microarray data, the number of genes J is always much greater than the number of arrays n. This fits the description of the well-known small-n large-p difficulty (we use p instead of J to be consistent with the phrase used in the literature). Furthermore, in the TW-SLM, both n and J play the dual role of sample size and number of parameters. That is, for estimating $\boldsymbol{\beta}$, J is the number of parameters, n is the sample size. But for estimating $\boldsymbol{f}$, n is the number of (infinite dimensional) parameters, J is the sample size for each f_i. On one hand, sufficiently large n is needed for the inference of $\boldsymbol{\beta}$. But a large n makes normalization more difficult, because then more nonparametric curves need to be estimated. On the other hand, sufficiently large J is needed for accurate normalization, but then estimation of $\boldsymbol{\beta}$ becomes more difficult. We are not aware of any other semiparametric models [40.33] in which both n and J play such dual roles of sample size and number of parameters. Indeed, here the difference between the sample size and the number of parameters is no longer as clear as in a conventional statistical model. This reflects a basic feature of microarray data in which self-calibration in the data is required when making statistical inference.

41. Latent Variable Models for Longitudinal Data with Flexible Measurement Schedule

This chapter provides a survey of the development of latent variable models that are suitable for analyzing unbalanced longitudinal data. This chapter begins with an introduction, in which the marginal modeling approach (without the use of latent variable) for correlated responses such as repeatedly measured longitudinal data is described. The concepts of random effects and latent variables are introduced at the beginning of Sect. 41.1. Section 41.1.1 describes the linear mixed models of Laird and Ware for continuous longitudinal response; Sect. 41.1.2 discusses generalized linear mixed models (with latent variables) for categorical response; and Sect. 41.1.3 covers models with multilevel latent variables. Section 41.2.1 presents an extended linear mixed model of Laird and Ware for multidimensional longitudinal responses of different types. Section 41.2.2 covers measurement error models for multiple longitudinal responses. Section 41.3 describes linear mixed models with latent class variables—the latent class mixed model that can be useful for either a single or multiple longitudinal responses. Section 41.4 studies the relationships between multiple longitudinal responses through structural equation models. Section 41.5 unifies all the above varieties of latent variable models under a single multilevel latent variable model formulation.

Longitudinal data consists of variables that are measured repeatedly over time. Longitudinal data can be collected either prospectively or retrospectively. The defining feature of longitudinal data is that the set of observations on one subject are likely to be correlated, and this within-subject correlation must be taken into account in order to make valid scientific inferences from the data. A frequently encountered problem in longitudinal studies is data that are missing due to missed visits or dropouts. As a result subjects often do not have a common set of visit times or they visit at nonscheduled times, thus longitudinal data may be highly unbalanced.

Except in the Introduction, the remaining sections are devoted to the study of the models along the lines of the Laird and Ware-style mixed model [41.1] and models with latent variables since they naturally handle unbalanced longitudinal data and of course these models are also useful for regularly spaced, balanced, repeatedly measured responses. Models suitable only for balanced longitudinal data as well as missing data models are not discussed in this chapter. All the models discussed in this chapter have been proved successful in practice. However, the models covered in this chapter only reflect the choice of illustration by the author and are by no means inclusive of all the variants and extensions of latent variable models.

Before moving onto the next section, let us first look at the marginal models that do not involve latent variables. Let Y_{ij} denote the longitudinal response for subject i $(i = 1, \ldots, N)$ at the j-th time point

$(j = 1, \ldots, n_i)$. For example, in the study of the evolution of the CD4+ lymphocyte in human immunodeficiency virus (HIV) positive subjects, longitudinal CD4+ cell counts can be modeled with the following *general linear model* for continuous response as:

$$Y_{ij} = \boldsymbol{x}_{ij}^{\mathrm{T}}\boldsymbol{\beta} + \boldsymbol{\epsilon}_{ij} \,, \tag{41.1}$$

where $\boldsymbol{x}_{ij} = (x_{ij1}, \ldots, x_{ijp})^{\mathrm{T}}$ is a vector of fixed p covariates at j-th time point that includes the intercept of one, the linear term of time in months, the indicator of AZT (an anti-retrovirus drug) usage, the Karnovsky score, anemia, etc., $\boldsymbol{\beta} = (\beta_0, \beta_1, \ldots, \beta_{p-1})^{\mathrm{T}}$ are the coefficients for the intercept and the partial slopes, and ϵ_{ij} is an error term that has a zero mean and variance of σ^2. The correlation between ϵ_{ij} and $\epsilon_{ij'}$ is $\rho_{jj'}$ for $j \neq j'$. Let $\boldsymbol{Y}_i = (Y_{i1}, \ldots, Y_{in_i})^{\mathrm{T}}$ and $\mathbf{X}_i = (\boldsymbol{x}_{i1}^{\mathrm{T}}, \ldots, \boldsymbol{x}_{in_i}^{\mathrm{T}})^{\mathrm{T}}$, then the above model can be written in matrix notation as

$$\boldsymbol{Y}_i = \mathbf{X}_i\boldsymbol{\beta} + \boldsymbol{\epsilon}_i \,.$$

So $\boldsymbol{Y}_i$ has mean vector $\mathbf{X}_i\boldsymbol{\beta}$ and variance matrix $\sigma^2\mathbf{R}_i$, where $\mathbf{R}_i$ is the correlation matrix for $\boldsymbol{\epsilon}_i = (\epsilon_{i1}, \ldots, \epsilon_{i,n_i})^{\mathrm{T}}$.

For discrete responses, marginal models that extend the *generalized* linear models GLMs can be applied [41.2]. Marginal models model a *link* function of the population-average response, $E(Y_{ij})$, as a function of a common set of explanatory variables $\boldsymbol{x}$. The mean of the longitudinal response is modeled separately from the within-subject correlation that is usually assumed to be a function of the modeled marginal means and possibly additional parameters $\boldsymbol{\nu}$. The marginal model is specified as:

$$g(\mu_{ij}) = \boldsymbol{x}_{ij}^{\mathrm{T}}\boldsymbol{\beta} \,, \tag{41.2}$$

where g is the monotone *link* function, $\mu_{ij} = E(Y_{ij})$. For example, g is an identity link for continuous Gaussian response, g can be a *logit* link for binary response. An attractive feature of the marginal model is that within-subject correlation does not have to be modeled explicitly, rather a class of generalized estimating equations (GEE) that gives consistent estimates of the $\boldsymbol{\beta}$ and their variance is used under some assumed working correlation matrices for within-subject dependence without specifying a multivariate distribution for $\boldsymbol{Y}_i$ [41.3].

The regression coefficients $\boldsymbol{\beta}$ in marginal models have population-average interpretation but any heterogeneity beyond the recorded covariates cannot be accounted for in marginal models. In models with latent variables, that are studied in following sections, heterogeneity among subjects in a subset of the regression coefficients, e.g., the intercept, are taken into account via subject-specific regression coefficients and/or covariates. In latent variable models, the covariate effects and within-subject association are modeled simultaneously. The concept of latent variables is a convenient way to represent statistical variation in terms of measurement error, random coefficients and variance components. Modeling the heterogeneity of a subset of regression coefficients not only reduces the extent of unexplained variation beyond the recorded explanatory variables but may be of interest in its own right. Estimates of the parameters in the latent variable models studied in this chapter can be obtained via the likelihood method with either the EM (expectation-maximization) algorithm or (adaptive) Gaussian quadrature.

41.1 Hierarchical Latent Variable Models for Longitudinal Data

One may consider longitudinal data as having a two-level structure, with repeated measurements (level 1) of a response variable being nested within subjects (level 2). Traditional fixed-effect analytical methods (e.g., analysis of variance) are limited in their treatment of the technical difficulties presented by nested designs, and in the questions they are able to address. Models that include random regression coefficients are more suited to the hierarchical data structure generally found in longitudinal data.

Latent variables are unobservable individual regression coefficients, predictors/covariates or response variables in regression models. Latent variables here are thus divided into the following three types, and sometimes a latent variable qualifies for more than one of the three types. The first type is called *random effects*, which model heterogeneity among subjects in a subset of the regression coefficients that vary from one subject to the next. A defining feature of random effects is that the individual regression coefficients are assumed to be a random sample from a common distribution so that a few parameters for the distribution characterize the behavior of the entire random coefficients. The second type is called *latent covariates*; these unobservable latent covariates have their own fixed regression coefficients that are called *factor loadings*. The third type is

called *latent responses*, which are further modeled on other fixed covariates and/or latent covariates.

Softwares for fitting latent variable models are abundant, although they may only handle a limited number of the models discussed in this chapter. Many researcher-written computer codes and softwares are also available for fitting complicated latent variable models. One omnipass software for fitting the latent variable models studied in this chapter is the STATA module generalized linear latent and mixed models (GLLAMM) developed over years by *Rabe-Hesketh* et al. [41.4]. For some models, it may take quite some computer and real time to fit. The computing time usually depends on the size of data, the number of structural levels in the data, and more critically on the number of latent variables involved. Software development will not be further discussed in this chapter.

41.1.1 Linear Mixed Model with a Single-Level Latent Variable

Since repeated measurements are obtained from each individual at different times, there may be considerable variation among individuals in the number and timing of observations. The resulting unbalanced data are typically not amenable to analysis using a general multivariate model such as (41.1) above, mainly due to the difficulty in specifying the covariance for $\boldsymbol{\epsilon}_i$ without the aid of latent variables. Although marginal models like (41.2) can handle unbalanced longitudinal data they do not model the heterogeneity across individual subjects beyond the recorded covariates. The model with random effects originally proposed by *Laird* and *Ware* [41.1] readily accommodates both the unbalanced nature of the data and the heterogeneity across subjects.

For continuous responses, their model is specified as:

$$\boldsymbol{Y}_i = \mathbf{X}_i\boldsymbol{\beta} + \mathbf{Z}_i\boldsymbol{b}_i + \boldsymbol{\epsilon}_i \ . \tag{41.3}$$

Here, $\boldsymbol{Y}_i = (Y_{i1}, \cdots, Y_{in_i})^{\mathrm{T}}$, is the n_i-vector of longitudinal readings for subject i. Fixed covariates including the intercept and possibly deterministic functions of time (such as a linear term of time) from subject i are represented by the $n_i \times p$ matrix $\mathbf{X}_i = (\boldsymbol{x}_{i1}^{\mathrm{T}}, \cdots, \boldsymbol{x}_{in_i}^{\mathrm{T}})^{\mathrm{T}}$, with associated p-vector of coefficients $\boldsymbol{\beta} = (\beta_0, \beta_1, \ldots, \beta_{p-1})^{\mathrm{T}}$. The j-th row of $\mathbf{X}_i$, denoted $\boldsymbol{x}_{ij}^{\mathrm{T}}$, is thus a p-vector of covariate values measured at the j-th occasion. Covariates for random effects are denoted by the $n_i \times q$ matrix $\mathbf{Z}_i$, which is often a subset of $\mathbf{X}_i$ although does not have to be. The q-vector of individual regression coefficients, the random effects $\boldsymbol{b}_i = (b_{i1}, \ldots, b_{iq})^{\mathrm{T}}$, are taken to be independent, multi-normally distributed with mean $\mathbf{0}$ or non-zero (see the example of random intercept only that follows) and variance–covariance $\mathbf{D}$. The error $\boldsymbol{\epsilon}_i = (\epsilon_{i1}, \ldots, \epsilon_{in_i})^{\mathrm{T}}$ is an n_i-vector that is uncorrelated with $\boldsymbol{b}_i$, independent normals with mean $\mathbf{0}$ and covariance matrix $\mathbf{R}_i$, which is often assumed to be a n_i-diagonal matrix of $\sigma^2\mathbf{I}_{n_i}$. Given the random effects, the timings of covariates and $\boldsymbol{Y}$ are assumed to be non-informative.

Marginally, the $\boldsymbol{Y}_i$ are independent normals with mean $\mathbf{X}_i\boldsymbol{\beta}$ and covariance matrix $\mathbf{R}_i + \mathbf{Z}_i\mathbf{D}\mathbf{Z}_i^{\mathrm{T}}$. For a single time point response Y_{ij}, the above model can be rewritten as:

$$Y_{ij} = \boldsymbol{x}_{ij}^{\mathrm{T}}\boldsymbol{\beta} + \boldsymbol{z}_{ij}^{\mathrm{T}}\boldsymbol{b}_i + \epsilon_i \ . \tag{41.4}$$

It can be seen that the covariance between two responses measured at different times points j and j' within a subject is $z_{ij}\mathbf{D}\boldsymbol{z}_{ij'}^{\mathrm{T}} = \mathrm{cov}(Y_{ij}, Y_{ij'})$.

The covariates that have random effects in this model have the means of their effects absorbed into the fixed effects so that the mean of $\boldsymbol{b}_i$ can be conveniently assumed to be zero. For a linear growth model with random intercept only, the above model becomes

$$Y_{ij} = \beta_0 + \beta_1 t_{ij} + b_{i0} + \epsilon_{ij} \ ,$$

where t_{ij} is the time of j-th repeated measure for subject i, the random intercept b_{i0} is assumed to have independent normal distribution with mean zero and variance σ_b^2, and the error term ϵ_{ij} is assumed to be independent of b_{i0} and to be normally distributed with mean zero and variance σ^2. The same model can also be written as:

$$Y_{ij} = b_0^* + \beta_1 t_{ij} + \epsilon_{ij}$$

in which the random intercept b_0^* is assumed to have a non-zero mean of β_0 and variance σ_b^2. Notice that a random effect can either be represented as having a mean or as being deviations from the mean.

For this random intercept model, the within-subject correlation coefficient is $\sigma_b/\sqrt{\sigma^2 + \sigma_b^2}$. It should be pointed out that, for the linear mixed model (41.4), the population-average inference can be made readily from the fixed-effects part, that is, $E\boldsymbol{Y}_{\overline{X}} = \overline{\mathbf{X}}\boldsymbol{\beta}$, where $\overline{\mathbf{X}}$ is the population-average covariate values. Although the number of individual random regression coefficients is large, the additional parameters that need to be estimated beyond the fixed regression coefficients are only those involved in the variance of the individual regression coefficients, which are called *variance components*. The use of random effects not only allows individualized

growth trajectories, but also conveniently accommodates within-subject correlation. The model (41.4) can be fit with the readily available software such as the SAS proc MIXED, as well as many other commercial softwares through the (restricted) maximum-likelihood method.

41.1.2 Generalized Linear Model with Latent Variables

Harville and *Mee* [41.5] extended the aforementioned linear mixed model for continuous response to clustered ordinal data using a threshold probit model, which also turned out to be suitable for longitudinal ordinal response. Their model was motivated by a study in which cattle breeders were interested in comparing sire with respect to the difficulty experienced in the birth of their offspring. There are five ordinal difficulty levels for the response variable: no problem, slight difficulty, needed assistance, considerable force needed and extreme difficulty. Let Y_{ij} be the ordinal response for the j-th birth by sire i ($i = 1, \ldots, N$; $j = 1, \ldots, n_i$) that take a value from one of the ordered difficulty categories $1, \ldots, M$, where here $M = 5$. For the threshold probit model, it is often assumed that there is an unobserved latent variable η relating to the actual observed ordinal response Y. Here, a response occurs in category m ($Y_{ij} = m$) if the latent variable η_{ij} exceeds the threshold value θ_{m-1} but does not exceed the threshold value θ_m. The ordinal response is related to the latent variable via the following probit model:

$$P(Y_{ij} = m|\eta_{ij}) = \Phi\left(\frac{\theta_m - \eta_{ij}}{\sigma}\right) - \Phi\left(\frac{\theta_{m-1} - \eta_{ij}}{\sigma}\right) , \tag{41.5}$$

where Φ is the cumulative distribution of a standard normal and σ is the standard error of the residual ϵ_{ij} from the following linear mixed model for the latent response η:

$$\eta_{ij} = \boldsymbol{x}_{ij}^{\mathrm{T}}\boldsymbol{\beta} + \boldsymbol{z}_{ij}^{\mathrm{T}}\boldsymbol{b}_i + \epsilon_{ij} .$$

This model is similar to the model (41.4) except Y_{ij} is now replaced by η_{ij}. It can be seen that η serves both as a latent covariate and a latent response.

The ordinal response can also be specified by a threshold cumulative probit model [41.6] as:

$$P(Y_{ij} \le m|\eta_{ij}) = \Phi\left(\frac{\theta_m - \eta_{ij}}{\sigma}\right) . \tag{41.6}$$

For binary, nominal or count data, Y_{ij}, can be modeled using the generalized linear mixed model (GLMM) [41.7], which is a direct generalization of the linear mixed model (41.4):

$$g(\mu_{ij}|\boldsymbol{b}_i) = \boldsymbol{x}_{ij}^{\mathrm{T}}\boldsymbol{\beta} + \boldsymbol{z}_{ij}^{\mathrm{T}}\boldsymbol{b}_i , \tag{41.7}$$

where g is the *link* function of μ. g can be probit or logit binary Y_{ij}; g can be log for count Y_{ij}; g can be logit and $\mu_{ij} = \{P(Y_{ij} = m), m \in [1, \ldots, M]\}$ for nominal Y_{ij}. It should be noted that the marginal means of Y_{ij} are no longer $\boldsymbol{x}_{ij}^{\mathrm{T}}\boldsymbol{\beta}$, but a more complicated function depending on the form of the link function g and on the mean of the response itself. Both SAS proc NLMIXED and the STATA add-on function GLLAMM [41.4] can fit the nonlinear mixed model with logit and probit links for binomial data, logit link for polychotomous data, probit and cumulative probit for ordinal data, and log link for Poisson data.

41.1.3 Model with Hierarchical Latent Variables

Consider, the example of the National Youth Survey data analyzed by *Duncan* et al. [41.8], where repeated measures were taken from individuals nested within households nested within geographical areas. The resulting data structure, therefore, consists of four levels: repeated observations within a subject (level 1), subjects (level 2), households (level 3), and geographical areas (level 4). The response variable of interest is recorded as a scale of substance use. A question that naturally arises is whether each level in the data structure has its own submodel representing the structural relations and variability occurring at that level.

Since there was no evidence of variation among the geographical areas, a three-level model without the fourth level is presented here. Let $j = 1, \ldots, n_i$, $i = 1, \ldots, N$ and $k = 1, \ldots, K$ index respectively the repeated observations within a subject, subjects within a household, and households. Let t_{kij} denote the j-th time point when the measurements for subject i in household k are taken. The level-1 within-individual growth model can be expressed as:

$$Y_{kij} = \boldsymbol{x}_{kij}^{\mathrm{T}}\boldsymbol{\beta} + \boldsymbol{z}_{kij}^{\mathrm{T}}\boldsymbol{\eta}_{ki} + \boldsymbol{\epsilon}_{kij} , \tag{41.8}$$

where Y_{kij} is the response for subject i in household k at the j-th time point, $\boldsymbol{x}_{kij} = \boldsymbol{z}_{kij} = (1, t_{kij})^{\mathrm{T}}$ is a vector of covariates including the intercept and the time. The fixed coefficients vector $\boldsymbol{\beta} = (\beta_0, \beta_1)^{\mathrm{T}}$ includes the intercept and the slope of time for Y_{kij}. The errors $\boldsymbol{\epsilon}_{ki} = (\epsilon_{ki1}, \ldots, \epsilon_{kin_i})^{\mathrm{T}}$ are assumed to be normally distributed with mean zerp and covariance matrix $\mathbf{R}_i$,which is a diagonal matrix with diagonal elements σ^2.

The individual random effects vector $\boldsymbol{\eta}_{ki} = (\eta_{ki0}, \eta_{ki1})^{\mathrm{T}}$ including the intercept and the slope is modeled in the following level-2 model for individuals within the same household as:

$$\boldsymbol{\eta}_{ki} = \boldsymbol{b}_k + \boldsymbol{\xi}_{ki} \,, \tag{41.9}$$

where the entries in the household-level random effects vector $\boldsymbol{b}_k = (\boldsymbol{b}_{0k}, \boldsymbol{b}_{1k})^{\mathrm{T}}$ at level 3are assumed to be bivariate normal distributions with mean zero and covariance matrix $\mathbf{D}$, and where $\boldsymbol{\xi}_{ki}$ is the residual vector, which is independent across different subjects, uncorrelated with $\boldsymbol{b}_k$, and bivariate normal distributed with mean $\mathbf{0}$ and covariance matrix $\boldsymbol{\Sigma}$.

Models (41.8) and (41.9) can be combined into the following single model:

$$Y_{kij} = \boldsymbol{x}_{kij}^{\mathrm{T}}\boldsymbol{\beta} + z_{kij}^{\mathrm{T}}\boldsymbol{b}_k + z_{kij}^{\mathrm{T}}\boldsymbol{\xi}_{ki} + \boldsymbol{\epsilon}_{ki}, \tag{41.10}$$

in which, there are coefficients of fixed effects $\boldsymbol{\beta}$, random individual effects $\boldsymbol{\xi}_{ki}$ nested within a household and random household effects $\boldsymbol{b}_k$. The covariance between two repeated measures at different time points j and j' for a subject i is $z_{kij}\mathbf{D}z_{kij'}^{\mathrm{T}} + z_{kij}\boldsymbol{\Sigma}z_{kij'}^{\mathrm{T}}$ and the covariance between measurements from two different subjects i and i' within a household is $z_{kij}\mathbf{D}z_{kij'}^{\mathrm{T}}$. This example showed that the multilevel model can be formulated and estimated within the linear mixed model framework [41.9].

41.2 Latent Variable Models for Multidimensional Longitudinal Data

Longitudinal studies offer us an opportunity to develop detailed descriptions of the process of growth and development or of the course of progression of chronic diseases. Most longitudinal analyses focus on characterizing change over time in a single outcome variable and identifying predictors of growth or decline. Both growth and degenerative diseases, however, are complex processes with multiple markers of change, so that it may be important to model more than one outcome measure and to understand their relationship over time.

41.2.1 Extended Linear Mixed Model for Multivariate Longitudinal Responses

Lin et al. modeled multiple continuous longitudinal responses by using a mixed effects model for each of the longitudinal responses; the correlations among the different longitudinal responses were modeled through intercorrelated random effects across the mixed effects models; and the model naturally allows different measurement schedules for different types of longitudinal responses even within a same subject [41.10]. The model was illustrated with the data example from a trial of chemoprevention of cancer with β-carotene [41.11]. The trial was a randomized double-blind placebo-controlled trial with 264 patients whose primary objective was to determine whether supplemental β-carotene (50 mg/d) reduced recurrence of the primary tumors in patients cured from a recent early-stage head and neck cancer. The trial concluded that the β-carotene supplementation had no significant effect on second head and neck cancers. During the trial, blood samples of the patients were collected at about 0, 3 months, 12 months and yearly thereafter until 60 months. Several plasma nutrient concentrations were determined from the available blood samples. Analysis was focused on plasma concentrations of lycopene and lutein +zeaxanthin.

Let $i = 1, \ldots, N$ index the i-th subject, $k = 1, \ldots, K$ index the k-th type of the longitudinal response variables and $j = 1, \ldots, n_{ki}$ index the j-th time point when type k-th response is measured in subject i. For the above example $K = 2$ with $k = 1$ and 2 indexing lycopene and lutein+zeaxanthin, respectively. Let $\boldsymbol{x}_{kij}$ denote a p_k-vector of fixed effects covariates for the type k longitudinal response measured at the j-th time in subject i, which includes the intercept, the baseline plasma cholesterol concentration, the treatment assignment indicator of β-carotene, site (0 for Connecticut and 1 for Florida), age, sex, smoking status ($\{0, 0\}$ for nonsmoker, $\{1, 0\}$ for transient smoker and $\{0, 1\}$ for steady smoker), and linear and quadratic terms of time. The vector of random effects z_{kij} is a q_k-subvector of $\boldsymbol{x}_{kij}$ that includes the intercept and linear and quadratic terms of time. The model for the multiple longitudinal responses is specified as:

$$Y_{kij} = \boldsymbol{x}_{kij}^{\mathrm{T}}\boldsymbol{\beta}_k + z_{kij}^{\mathrm{T}}\boldsymbol{b}_{ki} + \epsilon_{kij} \,. \tag{41.11}$$

In the above specification, $\boldsymbol{x}_{kij}$ and z_{kij} are associated with fixed regression coefficients $\boldsymbol{\beta}_k$ and random coefficients $\boldsymbol{b}_{ki}$, respectively. The q_k-vector of random effects $\boldsymbol{b}_{ki}$ is assumed to be independent across the i and multinormally distributed with mean $\mathbf{0}$ and covariance $\mathbf{D}_{kk}$. The n_{ki}-vector of error term $\boldsymbol{\epsilon}_{ki} = (\epsilon_{ki1}, \ldots, \epsilon_{kin_{ki}})^{\mathrm{T}}$ is uncorrelated with $\boldsymbol{b}_{ki}$, independent normal with mean $\mathbf{0}$ and variance–covariance matrix $\mathbf{R}_{ki}$. The correlations

between different types of longitudinal responses within a same subject are built through the covariance of the random effects by assuming $\mathrm{cov}(\boldsymbol{b}_{ki}, \boldsymbol{b}_{k'i}) = \mathbf{D}_{kk'}$ for $k \neq k'$ and therefore $\mathrm{cov}(Y_{kij}, Y_{k'ij'}) = z_{kij}\mathbf{D}_{kk'}z_{k'ij'}^{\mathrm{T}}$. The covariance between the repeated measures of same type at two different time points j and j' is $z_{kij}\mathbf{D}_{kk}z_{kij'}^{\mathrm{T}}$

Let $\mathbf{X}_{Ki}$ and $\mathbf{Z}_{Ki}$ denote the covariate matrices for fixed and random effects, respectively.The model (41.11) can be re-expressed exactly as (41.3) if the covariates matrices and the variance–covariance matrices are rearranged in the following way:

$$\mathbf{X_i} = \begin{pmatrix} \mathbf{X}_{1i} & \dots & \mathbf{0} \\ \vdots & \ddots & \vdots \\ \mathbf{0} & \dots & \mathbf{X}_{Ki} \end{pmatrix}, \quad \mathbf{Z_i} = \begin{pmatrix} \mathbf{Z}_{1i} & \dots & \mathbf{0} \\ \vdots & \ddots & \vdots \\ \mathbf{0} & \dots & \mathbf{Z}_{Ki} \end{pmatrix},$$

$$\mathbf{D} = \begin{pmatrix} \mathbf{D}_{11} & \dots & \mathbf{D}_{1K} \\ \vdots & \ddots & \vdots \\ \mathbf{D}_{K1} & \dots & \mathbf{D}_{KK} \end{pmatrix}, \quad \mathbf{R_i} = \begin{pmatrix} \mathbf{R}_{1i} & \dots & \mathbf{0} \\ \vdots & \ddots & \vdots \\ \mathbf{0} & \dots & \mathbf{R}_{Ki} \end{pmatrix}.$$

Using these expressions, the model (41.11) becomes

$$\boldsymbol{Y_i} = \mathbf{X_i}\boldsymbol{\beta} + \mathbf{Z_i}\boldsymbol{b_i} + \boldsymbol{\epsilon_i}\,,$$

where $\boldsymbol{Y_i} = (\boldsymbol{Y}_{1i}^{\mathrm{T}}, \dots, \boldsymbol{Y}_{Ki}^{\mathrm{T}})^{\mathrm{T}}$ with $\boldsymbol{Y}_{ki} = (Y_{ki1}, \cdots, Y_{kin_{ki}})^{\mathrm{T}}$ being a long vector of all K longitudinal response for subject i, $\boldsymbol{\epsilon_i} = (\boldsymbol{\epsilon}_{1i}^{\mathrm{T}}, \dots, \boldsymbol{\epsilon}_{Ki}^{\mathrm{T}})^{\mathrm{T}}$ is a long vector of error terms, $\boldsymbol{\beta} = (\boldsymbol{\beta}_1^{\mathrm{T}}, \dots, \boldsymbol{\beta}_K^{\mathrm{T}})^{\mathrm{T}}$ is a long vector of fixed coefficients and $\boldsymbol{b_i} = (\boldsymbol{b}_{1i}^{\mathrm{T}}, \dots, \boldsymbol{b}_{KiJ}^{\mathrm{T}})^{\mathrm{T}}$ is a long vector of random coefficients. This model has an identical expression and meaning as (41.3).

It is straightforward to see that by using proper link functions the model (41.11) can be further extended for mixed continuous and categorical longitudinal responses.

41.2.2 Measurement Error Model

Multiple outcomes are sometimes needed to jointly characterize an effect of interest properly. *Roy* considered the situation where multiple longitudinal outcomes are assumed to measure an underlying quantity of main interest from different perspectives [41.12]. Although separate linear mixed models can be fitted for each outcome, this approach is limited by the fact that it fails to borrow strength across the outcome variables. By exploiting the correlation structure with a multivariate longitudinal model, efficiency and power could be greatly increased. Since different outcomes are often measured on different scales and different units, it is of substantial interest to develop a statistical model to account for this special feature of the data. Correlation within each outcome over time and between outcomes on the same unit must be taken into account.

Roy analyzed the methadone treatment practices data in which methadone treatment is important in reducing illicit drug use and preventing HIV transmission and is effective when certain critical treatment practices are followed. The sampling unit is the treatment practice unit. The three longitudinal outcomes measuring the effectiveness of methadone treatment, including the maximum dose level [$\boldsymbol{Y}_1 = \log(\text{maximum dose})$], unit-average length of treatment ($\boldsymbol{Y}_2$), and percentage of clients receiving decreasing doses [$\boldsymbol{Y}_3 = \log(\text{percentage})$], were collected at three follow-up times. Analysis of this data set is challenging due to the fact that the outcome of major interest, the effective treatment practices level, is not observable, although several surrogates are available. In the following illustration, the same notation as for model (41.11) are used.

Suppose that the K longitudinal outcomes attempt to characterize a latent outcome of major interest, η_{ij}, e.g., the treatment practices level in unit i at the j-th follow-up time in the methadone example. One way to view this problem is that each type of observed outcome (Y_{kij}, $k = 1, \dots, K$) measures the latent variable η_{ij} with error. It is likely that the measurement error for each outcome from the same unit is correlated over time. A linear mixed model is assumed to relate Y_{kij} to η_{ij}:

$$Y_{kij} = \beta_{k0} + \beta_{k1}\eta_{ij} + b_{ki0} + \epsilon_{kij}\,, \tag{41.12}$$

where the measurement error term ϵ_{kij} is independent normal with mean zero and variance σ_k^2 and the type-specific random intercept b_{ki0} is independent between different units and assumed to have a normal distribution with mean zero and variance σ_{kb}^2. Correlation between the different types of the outcomes in an unit is due to the shared latent variable η_{ij}. The observed outcome Y_{kij} then measures the underlying true treatment practice evolution with error. The factor loading β_{k1} and the type-specific intercept β_{k0} are used to accommodate the fact that different types of outcomes have different scales. Each unit has its random intercept b_{ki0} for the type-k outcome, which is a random deviation from the type-specific intercept β_{k0}. For the sake of identifiability, β_{11} is set to one.

A linear mixed model is assumed to describe the effects of covariates on the latent variable η_{ij} of the underlying treatment practice:

$$\eta_{ij} = \boldsymbol{x}_{ij}^{\mathrm{T}}\boldsymbol{\alpha} + \boldsymbol{z}_{ij}^{\mathrm{T}}\boldsymbol{a}_i + \xi_{ij}\,, \tag{41.13}$$

where $\boldsymbol{\alpha}$ and $\boldsymbol{a}_i$ are defined similarly to $\boldsymbol{\beta}$ and $\boldsymbol{b}_i$ in the linear model (41.4), $\boldsymbol{a}_i$ is a $q-$vector with normal($\mathbf{0}$, $\mathbf{D}$) and the residual ξ_{ij} is distributed with independent normal$(0, \sigma^2)$. $\boldsymbol{x}_{ij}$ and $\boldsymbol{z}_{ij}$ are vectors of fixed and random covariates at the j-th time point for unit i that are defined similarly to those in the linear model (41.4) except that $\boldsymbol{x}_{ij}$ does do not contain the intercept.

It is often of substantial interest to estimate the unit-specific latent variables η_{ij}. The estimates of the latent effective practices score via the posterior mean $E(\boldsymbol{\eta}_i|\boldsymbol{Y}_i)$ can be used to identify the units whose treatment practices effectiveness are well below those of a typical unit. The model also provides a straightforward way to estimate and test for global covariate effects since the parameters $\boldsymbol{\alpha}$ represent the effects of the covariates on the overall effective treatment practices level in the methadone data. Estimates of the parameters in (41.12) and (41.13) can be obtained via the EM algorithm as described by Roy or using the STATA add-on function GLLAMM of *Rabe-Hesketh* et al. [41.4].

Extension of the model to allow mixed discrete and continuous outcomes is straightforward, e.g. the model (41.12), can be modified to allow discrete outcomes through the GLM formulation:

$$g_k(\mu_{kij}) = \beta_{k0} + \beta_{k1}\eta_{ij} + b_{ki0} \,,$$

where g_k is a link function specific to the type-k outcome and $\mu_{kij} = E(Y_{kij})$.

41.3 Latent Class Mixed Model for Longitudinal Data

The linear mixed model is a well-known method for incorporating heterogeneity (for example, subject-to-subject variation) into a statistical analysis for continuous responses. However heterogeneity cannot always be fully captured by the usual assumptions of normally distributed random effects. Latent class mixed models offer a way of incorporating additional heterogeneity which can be used to uncover distinct subpopulations, to incorporate correlated non-normally distributed outcomes and to classify individuals into *risk* classes. *Lin* et al. and *McCulloch* et al. used a latent class mixed model [41.13, 14] to model the trajectory of longitudinal prostate specific antigens (PSAs) before diagnosis of prostate cancer from a retrospective study of nutritional prevention of cancer (NPC) trials in which subjects were randomized to either selenium-supplement groups or the control group [41.15, 16]. Serial PSA levels were determined retrospectively from frozen blood samples that had been collected from all patients at successive clinic visits. The PSA data set that was analyzed consists of 1182 subjects with a highly variable number of readings (range 120, median 4) per subject at irregularly spaced intervals.

These latent class mixed models assume that there are K latent classes, with each class representing a subpopulation that has its own trajectories of longitudinal responses. Suppose we have N subjects indexed by $i = 1, \ldots, N$, and K latent classes labeled by $k = 1, \ldots, K$. We define $C_{ik} = 1$ if subject i is member of class k and 0 otherwise. The probability that subject i belongs to latent class k is described through the multinomial distribution of the class membership vector for subject i, $\boldsymbol{C}_i = (C_{i1}, \cdots, C_{iK})^{\mathrm{T}}$, modeled via a logit model with covariate vector $\boldsymbol{v}_i = (v_{i1}, \cdots, v_{im})^{\mathrm{T}}$ and associated class-specific coefficient vector $\boldsymbol{\phi}_k$:

$$\pi_{ik} = P(C_{ik} = 1) = \frac{\exp\left(\boldsymbol{v}_i^{\mathrm{T}}\boldsymbol{\phi}_k\right)}{\sum_{s=1}^{K}\exp\left(\boldsymbol{v}_i^{\mathrm{T}}\boldsymbol{\phi}_s\right)}, \qquad (41.14)$$

where π_{ik} denotes the probability that subject i belongs to latent class k and $\boldsymbol{\phi}_k$ is the coefficient vector for class k with $\boldsymbol{\phi}_1 = 0$.

Each subpopulation has its own model for the longitudinal response with subpopulation differences entering the mean:

$$\boldsymbol{Y}_i = \mathbf{X}_i\boldsymbol{\beta} + \mathbf{Z}_i\boldsymbol{b}_i + \mathbf{W}_i(\boldsymbol{\Gamma}\,\boldsymbol{C}_i) + \boldsymbol{\epsilon}_i \,. \qquad (41.15)$$

Here, $\boldsymbol{Y}_i, \mathbf{X}_i, \mathbf{Z}_i, \boldsymbol{\beta}, \boldsymbol{b}_i$ and $\boldsymbol{\epsilon}_i$ are defined in the same way as those in model (41.3). Covariates for class-specific effects are denoted by the $n_i \times p_w$ matrix $\mathbf{W}_i$, which has a similar structure to $\mathbf{X}_i$. There may be overlap of the covariate effects in $\mathbf{X}_i$, $\mathbf{Z}_i$ and $\mathbf{W}_i$. The class-specific regression parameters are in the $p_w \times K$ matrix $\boldsymbol{\Gamma}$, where $\boldsymbol{\Gamma} = (\boldsymbol{\gamma}_1, \cdots, \boldsymbol{\gamma}_K)$, with $\boldsymbol{\gamma}_k$ being a p_w-dimensional column vector containing the parameters specific to class k. Given $C_{ik} = 1$, we have $\boldsymbol{\Gamma}\,\boldsymbol{C}_i = \boldsymbol{\gamma}_k$ for $k = 2, \ldots, K$ and we take $\boldsymbol{\gamma}_1 = 0$ to assure identifiability.

The model (41.15) captures common characteristics of the longitudinal trajectories within a subpopulation through latent classes while accommodating the variability among subjects in the same class through random effects. The use of a mixture of multivariate normal distributions for the longitudinal response $\boldsymbol{Y}$ provides flexibility that allows non-normal distributions for random effects.

The variables included in the model are as follows. The covariate vector $\boldsymbol{v}$ used to predict class membership

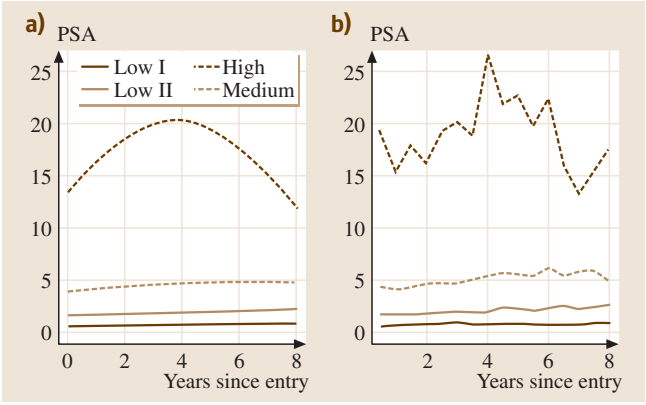

Fig. 41.1a,b Longitudinal trajectories of PSA for the four-class models. PSA values were fitted to the log-transformed data and then back-transformed to the original scale for plotting. The observed trajectories in the *right panel* are calculated by first dividing the time period into six-month intervals. For each subject, for each interval, the available PSA readings are averaged. The observed PSA trajectory for class k are calculated as averages weighted by each individual's estimated probability of class-k membership: **(a)** fitted trajectories for the four-class model; **(b)** observed trajectories for the four-class model

in (41.14) contains the treatment assignment indicator of selenium (Se) supplementation group, age at randomization, baseline PSA and Se level at randomization. The longitudinal biomarker value $\boldsymbol{Y}$ in (41.15) is the vector of log(PSA+1). The fixed effect covariate vector $\boldsymbol{X}$ contains the treatment assignment indicator, age at randomization and Se level at randomization, and linear and quadratic terms of visit time expressed in years since entry into the trial. The covariates for the random effects and class-specific effects, $\boldsymbol{Z}$ and $\boldsymbol{W}$, also contain an intercept and linear and quadratic terms of years since entry.

The four-class solution from the above latent class mixed model identifies fitted PSA trajectory classes that are labeled as "Low I","Low II", "Medium" and "High" Fig. 41.1. The majority classes "Low I" and "Low II" are characterized by a consistently low PSA level throughout the trial period. The "Medium" class has a higher PSA level than the two "Low" classes throughout the trial; the PSA level increases over time for this class. The minority class "High" has the highest PSA level at the beginning of the trial, and the predicted level of PSA increases over time until the fourth year after randomization and then decreases. In comparison the usual linear mixed model (41.4) would only be able to give one PSA trajectory that is rather flat.

Extension of the latent class mixed model to simultaneously modeling of multiple longitudinal responses is straightforward.

41.4 Structural Equation Model with Latent Variables for Longitudinal Data

Structural equation models (SEM) refer to the models that additionally specify the regression relationships among latent variables themselves. Models (41.9) and (41.13) can be regarded as SEMs.

Modeling growth within the SEM framework is a more recent approach for studying developmental trends. Because the SEM approach offers more flexibility in testing different research hypotheses about the developmental trend, many researchers have argued in favor of its superiority over some other analytic approaches [41.17, 18]. These models have provided researchers with an array of tools to interpret longitudinal data, understand developmental processes, and formulate new research questions.

Frosch et al. studied the relationship between tobacco and illicit drug use of cocaine and heroin among 166 methadone-maintained persons participating in a smoking-cessation intervention [41.19]. After completing a two-week screening period, participants were randomly assigned to one of four conditions: (a) contingency management (CM; a behavioral treatment in which participants receive increasingly valuable incentives for providing successive breath samples documenting smoking abstinence; $n = 44$); (b) relapse prevention (RP; a cognitive–behavioral group treatment providing educational and skills training information for smoking cessation; $n = 42$); (c) CM and RP combined ($n = 46$); and (d) a control condition in which participants received neither CM nor RP ($n = 43$). During the 12-week treatment period, participants provided urine and breath samples for heroin and cocaine toxicology and measurement of expired CO three times weekly (Monday, Wednesday, and Friday). The impact of use of heroin and cocaine on levels and changes in cigarette use was assessed with latent growth models in structural equations framework. The time axis is divided into two-week periods for the 12 weeks of treatment. Scales for the use of heroin, cocaine, and

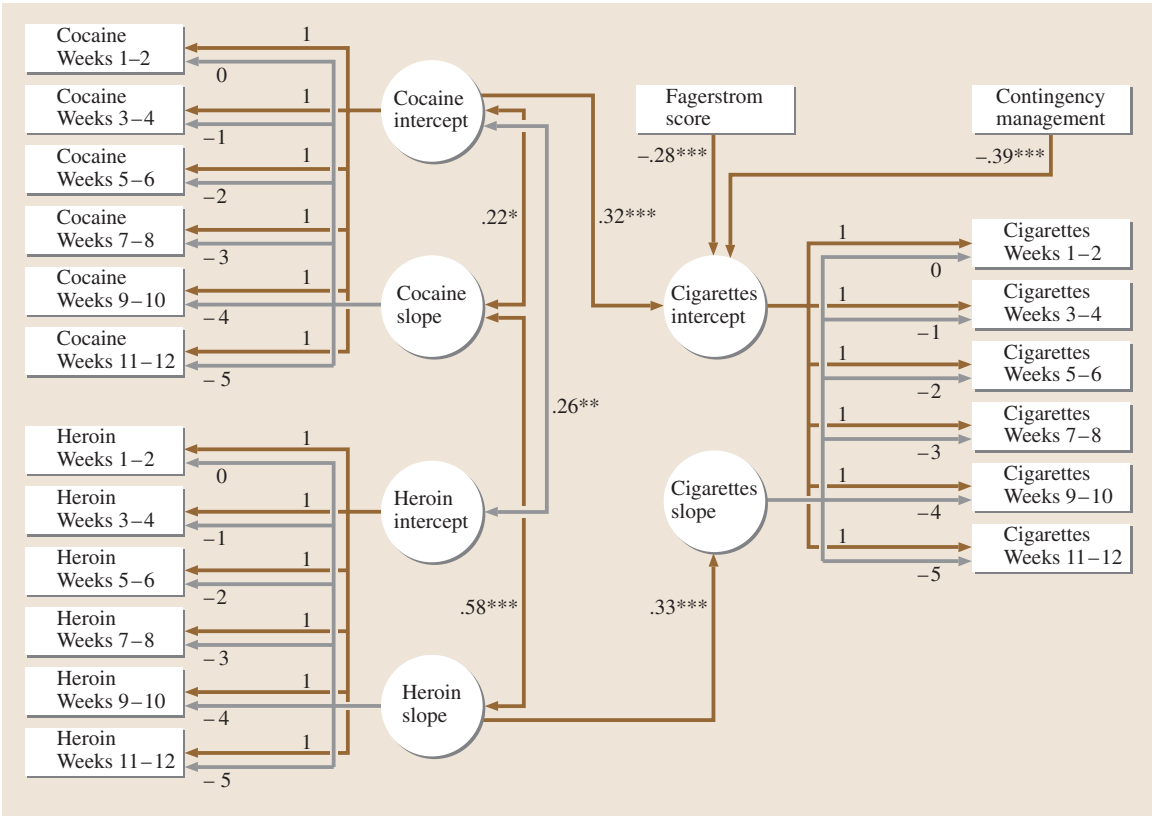

Fig. 41.2 Final latent-growth model presenting significant predictors of levels and trajectory of change in cigarette use over time. Intercepts were fixed to unity; slopes were hypothesized to be equal-interval linear trend coefficients. Double-headed arrows represent correlations; single-headed arrows represent regressions. Higher levels of cocaine use predicted higher levels of cigarette use; accelerated use of heroin predicted acceleration in use of cigarettes. *Circles* indicate latent variables; *rectangles* indicate measured variables. Parameter estimates are standardized. *Fagerstrom* = Fagerstrom test for nicotine dependence (after *Frosch* et al. [41.19])

cigarette were constructed for each of the two-week periods, and these scales were used as the longitudinal response variables.

Let $k = 1, 2, 3$ index the responses of cigarette, heroin and cocaine. For $k = 2$ or 3, an extended linear mixed model such as (41.11) is specified for heroin or cocaine response:

$$Y_{kij} = \boldsymbol{x}_{kij}^{\mathrm{T}}\boldsymbol{\beta}_k + \boldsymbol{z}_{kij}^{\mathrm{T}}\boldsymbol{\eta}_{ki} + \epsilon_{kij} \,,$$

where the fixed covariates $\boldsymbol{x}_{kij}$ include the intercept, the linear term in time in weeks and the treatment dummy variables, and where $\boldsymbol{z}_{kij}$ is a q_k-vector that includes only the intercept and the linear term in time; the model has exactly the same definitions as those of (41.11) except that the coefficients of the random effects $\boldsymbol{b}_{ki}$ in (41.11) are replaced by $\boldsymbol{\eta}_{ki}$ here. The model describes the possible improvement in heroin or cocaine use over the course of treatment and accounts for the repeated measures of the same type within the same subject with the random effects of intercept and slope included in $\boldsymbol{\eta}_{ki}$. The correlation between the responses of the two different types of heroin and cocaine use is modeled with the covariance of $\boldsymbol{\eta}_{2i}$ and $\boldsymbol{\eta}_{3i}$. The intercept represents the individual baseline level of use of cocaine or heroin. The slope represents the trend of the growth curve.

With the additional $p_{w,1}$-vector of fixed covariates of $\boldsymbol{w}_{1i}$ including the Fagerstrom score and contingency management measure, the slopes and intercepts of cocaine use and heroin use are used as the latent predictors in the following model to ascertain the impact of their initial levels and their own dynamic changes (slopes) on

predicting the slope and intercept of cigarette use:

$$\boldsymbol{\eta}_{1i} = \boldsymbol{\Lambda}_2\boldsymbol{\eta}_{2i} + \boldsymbol{\Lambda}_3\boldsymbol{\eta}_{3i} + \boldsymbol{\Gamma}_1\boldsymbol{w}_{1i} + \boldsymbol{\xi}_{1i}\,, \tag{41.16}$$

where $\boldsymbol{\Lambda}_k$ $(k = 2, 3)$ is a $q_k \times q_k$ ($q_k = 2$ here) diagonal matrix of factor loadings for $\boldsymbol{\eta}_{ki}$ with the s-th diagonal element being $\lambda_{k,s}$, $\boldsymbol{\Gamma}_1$ is a $q_1 \times p_{w,1}$ ($q_1 = p_{w,1} = 2$ here) matrix of regression coefficients associated with fixed covariates $\boldsymbol{w}_{1i}$ and ξ_{1i} is a q_1-vector of residuals.

The model (41.16) can be written as the following structural equation for the relationships among the latent variables:

$$\boldsymbol{\eta}_{\mathbf{i}} = \boldsymbol{\Lambda}\boldsymbol{\eta}_{\mathbf{i}} + \boldsymbol{\Gamma}\boldsymbol{w}_i + \boldsymbol{\xi}_i\,, \tag{41.17}$$

where $\boldsymbol{\eta}_{\mathbf{i}} = (\boldsymbol{\eta}_{1i}^{\mathrm{T}}, \ldots, \boldsymbol{\eta}_{Ki}^{\mathrm{T}})^{\mathrm{T}}$, $\boldsymbol{\Lambda}$ is a $\sum_{k=1}^{K} q_k \times \sum_{k=1}^{K} q_k$ upper-diagonal matrix of coefficients, $\boldsymbol{w}_i$ is a vector of $\sum_{k=1}^{K} p_{w,k}$ covariates, $\boldsymbol{\Gamma}$ is a $\sum_{k=1}^{K} q_k \times \sum_{k=1}^{K} p_{w,k}$ matrix of regression coefficients and $\boldsymbol{\xi}_i$ is a $\left(\sum_{k=1}^{K} q_k\right)$-vector of residuals. $\boldsymbol{\Lambda}$ is upper-diagonal, which implies that there are no simultaneous effects with latent variable 1 regressed on latent variable 2 and vice versa. The lower-level latent variables (e.g., the $\boldsymbol{\eta}_{1i}$ for cigarette use) come before the higher-level ones (e.g., the $\boldsymbol{\eta}_{2i}$ and $\boldsymbol{\eta}_{3i}$ for heroin and cocaine use) in the $\boldsymbol{\eta}$ vector, an the upper-diagonal $\boldsymbol{\Lambda}$ matrix ensures that lower-level latent variables can be regressed on higher ones but not the reverse since it would not make sense to regress a higher-level latent variable on a lower-level one. Some elements of the upper-diagonal matrix $\boldsymbol{\Lambda}$ can be additionally set to zero, which indicates that a latent variable does not depend on a corresponding higher-level one.

Using this structural equation model for the methadone-maintenance data, a significant relationship during the treatment period between rate of change in heroin and rate of change in tobacco use was revealed, with increased heroin use corresponding to increased tobacco use. Although levels of cocaine use were related to levels of tobacco use, there was no significant relationship between the rates of change of the two substances. *Frosch* et al.'s findings demonstrate the utility of latent growth models with the structural equation approach for analyzing short-term clinical trial data and strongly suggest that successful smoking cessation in this population requires a concurrent focus on reducing heroin use. The final model that *Frosch* et al. used is represented by a path diagram, as shown in Fig. 41.2.

41.5 Concluding Remark: A Unified Multilevel Latent Variable Model

In the case of hierarchical data including longitudinal data, the term *level* is often used to describe the position of a unit of observation within a hierarchy of units, typically reflecting the sampling design. Here level-1 units are nested in level-2 units, which are nested in level-3 units, a typical example being patients in clinics in regions. In this context, a random effect is said to vary at a given level, e.g. at the region level, if it varies between regions but, for a given region, is constant for all clinics and patients belonging to that region. If a repeated measure is taken on the patients and the regions are ignored, then time points are the level-1 units, patients are the level-2 units and clinics are the level-3 units. The multilevel models assume that lower-level units are conditionally independent given the higher-level latent variables and the explanatory variables. The latent variables at the same level are usually assumed to be mutually correlated whereas latent variables at different levels are independent. The aim of multilevel modeling is to analyze data simultaneously from different levels of the hierarchy. All the models discussed in this chapter can be regarded as special cases of a multilevel model with latent variables for longitudinal data.

The expression for the s-th element of $\boldsymbol{\eta}$ $(s = 1, \ldots, \sum_{k=1}^{K} q_k)$ in an SEM such as (41.16) can be substituted into the expression for $(s-1)$-th element, which can be substituted into the expression for $(s-2)$-th element, and so forth. (i. e., recursive substitution). Then, using similar notational definitions to those documented by *Rabe–Hesketh* et al. [41.4], we obtain an equation of the following form for longitudinal data with constraints among the parameters:

$$g(\mu_{kij}) = \boldsymbol{x}_{kij}^{\mathrm{T}}\boldsymbol{\beta} + \sum_{l=2}^{L}\sum_{s=1}^{q_l} \boldsymbol{z}_{kij,s}^{(l),\mathrm{T}}\boldsymbol{\lambda}_s^{(l)}\eta_{ki,s}^{(l)}\,, \tag{41.18}$$

where $l = 1, \ldots, L$ indexes the L levels, there are q_l latent variables at level l, $\eta_{ki,s}^{(l)}$ is the s-th latent variable for subject i in the type-k response at level l, $\boldsymbol{x}_{kij}$ and $\boldsymbol{z}_{kij,s}^{(l)}$ are two vectors of explanatory variables associated with fixed and latent variables and $\boldsymbol{\lambda}_s^{(l)}$ is the vector of factor loadings for the s-th latent variable $\eta_{ki,s}^{(l)}$ in level l. In the general form of equation (41.18), the latent

variables η can be continuous or discrete (e.g., latent classes).

Multilevel modeling techniques offer researchers the opportunity not only to analyze their data in a more technically appropriate manner than traditional single-level methods allow, but also to extend the range of research questions to a level with more contextual richness and complexity.

42. Genetic Algorithms and Their Applications

The first part of this chapter describes the foundation of genetic algorithms. It includes hybrid genetic algorithms, adaptive genetic algorithms and fuzzy logic controllers. After a short introduction to genetic algorithms, the second part describes combinatorial optimization problems including the knapsack problem, the minimum spanning tree problem, the set-covering problem, the bin-packing problem and the traveling-salesman problem; these are combinatorial optimization studies problems which are characterized by a finite number of feasible solutions. The third part describes network design problems. Network design and routing are important issues in the building and expansion of computer networks. In this part, the shortest-path problem, maximum-flow problem, minimum-cost-flow problem, centralized network design and multistage process-planning problem are introduced. These problems are typical network problems and have been studied for a long time. The fourth section describes scheduling problems. Many scheduling problems from manufacturing industries are quite complex in nature and very difficult to solve by conventional optimization techniques. In this part the flow-shop sequencing problem, job-shop scheduling, the resource-constrained projected scheduling problem and multiprocessor scheduling are introduced. The fifth part introduces the reliability design problem, including simple genetic algorithms for reliability optimization, reliability design with redundant units and alternatives, network reliability design and tree-based network topology design. The sixth part describes logistic problems including the linear transportation problem, the multiobjective transportation problem, the bicriteria transportation problem with fuzzy coefficients and supply-chain management network design. Finally, the last part describes location and allocation problems including the location–allocation problem, capacitated plant-location problem and the obstacle location–allocation problem.

42.1 Foundations of Genetic Algorithms

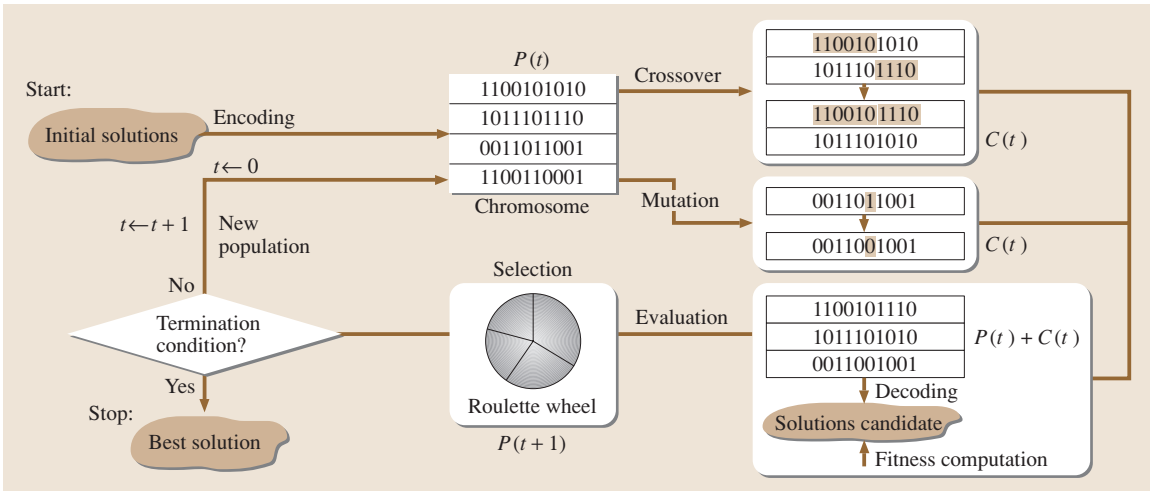

Fig. 42.1 The general structure of genetic algorithms

Recently, genetic algorithms have received considerable attention regarding their potential as an optimization technique for complex problems and have been successfully applied in the area of industrial engineering. The well-known applications include scheduling and sequencing, reliability design, vehicle routing location, transportation and many others.

42.1.1 General Structure of Genetic Algorithms

Genetic algorithms are stochastic search algorithms based on the mechanism of natural selection and natural genetics. Genetic algorithms, in contrast to conventional search techniques, start with an initial set of random solutions called the population. Each individual in the population is called a chromosome, encoding a solution to the problem at hand. A chromosome is a string of symbols, usually but not necessarily, a binary bit string. The chromosomes *evolve* through successive iterations, called generations. During each generation, the chromosomes are *evaluated*, using some measures of fitness [42.1]. To create the next generation, new chromosomes, called offspring, are formed by either merging two chromosomes from the current generation using a *crossover* operator or modifying a chromosome using a mutation operator. A new generation is formed by selecting, according to the fitness values, some of the parents and offspring, and rejecting others so as to keep the population size constant.

Fitter chromosomes have higher probabilities of being selected. After several generations, the algorithms converge to the best chromosome, which we hope represents the optimum or suboptimal solution to the problem

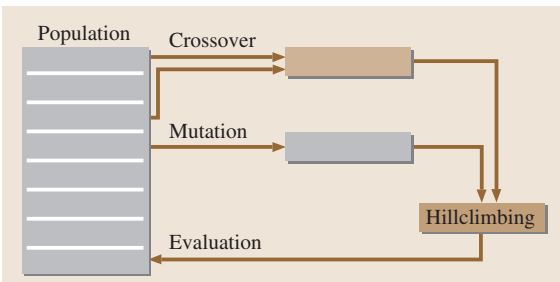

Fig. 42.2 General structure of hybrid genetic algorithms

when decoded. Let $P(t)$ and $C(t)$ be parents and offspring in the current generation t; the general structure of genetic algorithms Fig. 42.1 is described as follows:

```
procedure: genetic algorithms
begin
  t ← 0;              // t: generation number
  initialize P(t);    // P(t): population of individuals
  evaluate P(t);
  while (not termination condition) do
        crossover P(t) to yield C(t) ; // C(t): offspring
        mutation P(t) to yield C(t);
        evaluate C(t) ;
        select P(t+1) from P(t) and C(t) ;
        t ← t+1;
  end
end
```

Crossover is the main genetic operator. It operates on two chromosomes at a time and generates offspring by combining both chromosomes' features. A simple way to achieve crossover would be to choose a random cut-point and generate the offspring by combining the segment of one parent to the left of the cut-point with the segment of the other parent to the right of the cut-point.

Mutation is a background operator, which produces spontaneous random changes in various chromosomes. A simple way to achieve mutation would be to alter one or more genes.

42.1.2 Hybrid Genetic Algorithms

Genetic algorithms (GAs) have proved to be a versatile and effective approach for solving optimization problems. Nevertheless, there are many situations in which the simple GA does not perform particularly well, and various methods of have been proposed [42.2].

One of the most common forms of hybrid genetic algorithms is to incorporate local optimization as an add-on extra to the canonical GA loop of recombination and selection [42.3, 4]. With the hybrid approach, local optimization such as hill-climbing is applied to each newly generated offspring to move it to a local optimum before injecting it into the population. Genetic algorithms are used to perform global exploration among the population while heuristic methods are used to perform local exploitation around chromosomes. Because of the complementary properties of genetic algorithms and conventional heuristics, the hybrid approach often outperforms either method operating alone. Some work has been done to reveal the natural mechanism behind such a hybrid approach, among which is Lamarckian evolution. Let $P(t)$ and $C(t)$ be parents and offspring in the current generation t. The general structure of hybrid genetic algorithms is described as follows; see Fig. 42.2.

```
procedure: hybrid genetic algorithms
begin
  t ← 0 ;             // t: generation number
  initialize P(t);    // P(t): population of individuals
  evaluate P(t);
  while (not termination condition) do
        crossover P(t) to yield C(t);
                    // C(t): offspring
        mutation P(t) to yield C(t);
        locally search C(t);
        evaluate C(t);
        selection P(t+1) from P(t) and C(t);
        t  ←  t+1 ;
  end
end
```

42.1.3 Adaptive Genetic Algorithms

There are two basic approaches to applying the genetic algorithms to a given problem: 1) to adapt a problem to the genetic algorithms, 2) to adapt the genetic algorithms to a problem.

Genetic algorithms were first created as a kind of generic and weak method featuring binary encoding and binary genetic operators. This approach requires a modification of the original problem into an appropriate from suitable for the genetic algorithms, as shown in Fig. 42.3.

To overcome such problems, various nonstandard implementations of the genetic algorithm have been created for particular problems, which leave the problem unchanged and adapt the genetic algorithms by modifying a chromosome representation of a potential solution and applying appropriate genetic operators, as shown in Fig. 42.4. This approach has been successfully applied in the area of industrial engineering and is becoming the main approach in recent applications of genetic algorithms [42.5].

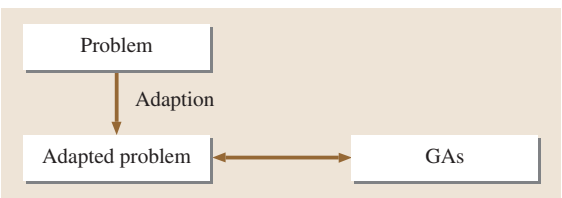

Fig. 42.3 Adapt a problem to the genetic algorithms

42.1.4 Fuzzy Logic Controller

Fuzzy logic is much closer in spirit to human thinking and natural language than the traditional logical systems. In essence, the fuzzy logic controller provides an algorithm which can convert a linguistic control strategy based on expert knowledge into an automatic control strategy. In particular, this methodology appears very useful when the processes are too complex for analysis by conventional techniques or when the available sources of information are interpreted qualitatively, inexactly, or with uncertainty [42.3].

The pioneering work to extend the fuzzy logic technique to adjust the strategy parameters of genetic algorithms dynamically was carried out by *Xu* and *Vukovich* [42.5]. The main idea is to use a fuzzy logic controller to compute new strategy parameter values that will be used by the genetic algorithms. A fuzzy logic controller is comprised of four principal components:

1. a knowledge base,
2. a fuzzification interface,
3. an inference system,
4. a defuzzification interface.

The experts' knowledge is stored in the knowledge base in the form of linguistic control rules. The inference system is the kernel of the controller, which provides an approximate reasoning based on the knowledge base. The generic structure of a fuzzy logic controller is shown in Fig. 42.5.

42.1.5 Multiobjective Optimization Problems

During the last two decades, genetic algorithms have received considerable attention regarding their potential as a novel approach to multiobjective optimization problems, known as evolutionary multiobjective optimization or genetic multiobjective optimization.

Multiobjective optimization problem with q objectives and m constraints will be formulated as follows:

$$\max \left[z_1 = f_1(\boldsymbol{x}), z_2 = f_2(\boldsymbol{x}), \ldots, z_q = f_q(\boldsymbol{x})\right] , \tag{42.1}$$

$$\text{s.t.} \quad g_i(\boldsymbol{x}) \le 0, \quad i = 1, 2, \ldots, m . \tag{42.2}$$

A. The Concept of a Pareto Solution

In most existing methods, Pareto solutions are identified at each generation and are only used to calculate fitness values or ranks for each chromosome. No mechanism is provided to guarantee that the Pareto solutions generated during the evolutionary process enter the next generation. A special pool for preserving the Pareto solutions is added onto the basic structure of genetic algorithms. At each generation, the set of Pareto solutions $E(t)$ is updated by deleting all dominated solutions and adding all newly generated Pareto solutions [42.5]. The overall structure of the approach is given as follows:

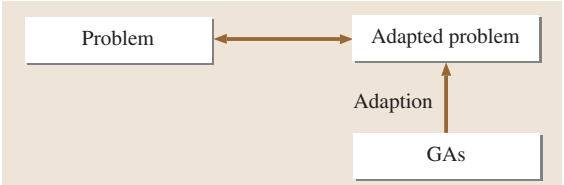

Fig. 42.4 Adapt the genetic algorithms to a problem

procedure: Pareto genetic algorithms
begin
  $t \leftarrow 0$; // t: generation number
  initialize $P(t)$; // $P(t)$: population of individuals
  objective $P(t)$;
  create Pareto $E(t)$;
  fitness $eval(P)$;
  while (not termination condition) **do**
    crossover $P(t)$ to yield $C(t)$;
      //$P(t)$: population of individuals
    mutation $P(t)$ to yield $C(t)$;
    objective $C(t)$;
    update Pareto $E(P, C)$;
    fitness $eval(P, C)$;
    selection $P(t+1)$ from $P(t)$ and $C(t)$;
    $t \leftarrow t+1$;
  end
end

B. Adaptive Weight Approach

Gen and *Cheng* proposed an adaptive weights approach which utilizes some useful information from the current population to readjust weights to obtain a search pressure towards a positive ideal point [42.6, 7].

For the examined solutions at each generation, we define two extreme points: the maximum extreme point z^+ and the minimum extreme pint z^- in criteria space as follows:

$$z^+ = \left(z_1^{\max}, z_2^{\max}, \ldots, z_q^{\max}\right) , \tag{42.3}$$

$$z^- = \left(z_1^{\min}, z_2^{\min}, \ldots, z_q^{\min}\right) , \tag{42.4}$$

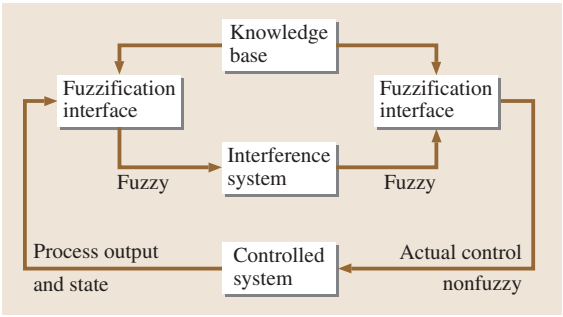

Fig. 42.5 Generic structure of a fuzzy logic controller

where $z_k^{\min}$ and $z_k^{\max}$ are the maximal value and minimal value for objective k in the current population. Let P denote the set of the current population. For a given individual $\boldsymbol{x}$, the maximal value and minimal value for each objective are defined as

$$z_k^{\max} = \max\{f_k(\boldsymbol{x}) | \boldsymbol{x} \in P\}, \quad k = 1, 2, \ldots, q\,, \tag{42.5}$$

$$z_k^{\min} = \min x\{f_k(\boldsymbol{x}) | \boldsymbol{x} \in P\}, \quad k = 1, 2, \ldots, q\,. \tag{42.6}$$

The hyperparallelogram defined by the two extreme points is a minimal hyperparallelogram containing all current solutions. The two extreme points are renewed at each generation. The maximum extreme point will gradually approximate the positive ideal point. The adaptive weight for objective k is calculated by

$$w_k = \frac{1}{z_k^{\max} - z_k^{\min}}, \quad k = 1, 2, \ldots, q\,. \tag{42.7}$$

For a given individual $\boldsymbol{x}$, the weighted-sum objective function is given by

$$z(\boldsymbol{x}) = \sum_{k=1}^{q} w_k \left(z_k - z_k^{\min}\right) \tag{42.8}$$

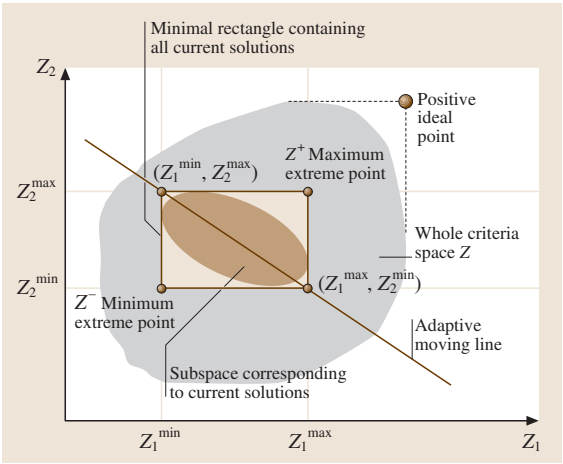

Fig. 42.6 Adaptive weights and adaptive hyperplane

$$= \sum_{k=1}^{q} \frac{z_k - z_k^{\min}}{z_k^{\max} - z_k^{\min}} \tag{42.9}$$

$$= \sum_{k=1}^{q} \frac{f_k(\boldsymbol{x}) - z_k^{\min}}{z_k^{\max} - z_k^{\min}}\,. \tag{42.10}$$

As the extreme points are renewed at each generation, the weights are renewed accordingly. Figure 42.6 is a hyperplane defined by the following extreme points in the current solutions

$$(z_1^{\max}, z_2^{\min}, \ldots, z_k^{\min}, \ldots, z_q^{\min})\,, \tag{42.11}$$

$$\ldots$$

$$(z_1^{\min}, z_2^{\min}, \ldots, z_k^{\max}, \ldots, z_q^{\min})\,, \tag{42.12}$$

$$\ldots$$

$$(z_1^{\min}, z_2^{\min}, \ldots, z_k^{\min}, \ldots, z_q^{\max})\,. \tag{42.13}$$

It is an adaptive moving line defined by the extreme points $(z_1^{\max}, z_2^{\min})$ and $(z_1^{\min}, z_2^{\max})$, as shown Fig. 42.6. The rectangle defined by the extreme points $(z_1^{\max}, z_2^{\min})$ and $(z_1^{\min}, z_2^{\max})$ is the minimal rectangle containing all current solutions.

42.2 Combinatorial Optimization Problems

Combinatorial optimization studies problems which are characterized by a finite number of feasible solutions. An important and widespread area of application concerns the efficient use of scarce resources to increase productivity. Typical problems include set covering, bin packing, knapsack, quadratic assignment, minimum spanning tree, machine scheduling, sequencing and balancing, cellular manufacturing design, vehicle routing, facility location and layout, traveling-salesman problem, and so on.

42.2.1 Knapsack Problem

Suppose that we want to fill up a knapsack by selecting some objects among various objects (generally called *items*). There are n different items available and each item j has a *weight* of w_j and a *profit* of p_j. The knapsack can hold a weight of at most W. The problem is to find an optimal subset of items so as to maximize the total profit subject to the knapsack's weight capacity. The profits, weights and capacity are positive integers [42.8].

Let x_j be binary variables given by

$$x_j = \begin{cases} 1 & \text{if item } j \text{ is selected}, \\ 0 & \text{otherwise}. \end{cases} \tag{42.14}$$

The knapsack problem can be mathematically formulated as

$$\max \sum_{j=1}^{n} p_j x_j \,, \tag{42.15}$$

$$\text{s.t.} \sum_{j=1}^{n} w_j x_j \le W \,, \tag{42.16}$$

$$x_j = 0 \quad \text{or } 1 \; j = 1, 2, \ldots, n \,. \tag{42.17}$$

Binary Representation Approach

The binary string is a natural representation for the knapsack problem, where one means the inclusion and zero the exclusion of one of the n items from the knapsack. For example, a solution for the 10-item problem can be represented as the following bit string:

$$x = (x_1 x_2 \cdots x_{10}) \\ (0\,1\,0\,1\,0\,0\,0\,0\,1\,0) \,,$$

meaning that items 2, 4 and 9 are selected for inclusion in the knapsack.

42.2.2 Minimum Spanning Tree Problem

Consider a connected undirected graph $G = (V, E)$, where $V = \{v_1, v_2, \cdots, v_n\}$ is a finite set of *vertices* representing terminals or telecommunication stations etc., $E = \{e_{ij} | e_{ij} = (v_i, v_j), v_i, v_j \in V\}$ is a finite set of *edges* representing connections between these terminals or stations. Each edge has an associated positive real number denoted by $W = \{w_{ij} | w_{ij} = w(v_i, v_j), w_{ij} > 0, v_i, v_j \in V\}$ representing distance, cost and so on. The vertices and edges are sometimes referred to as *nodes* and *links* respectively [42.9].

Based on their different backgrounds, many researchers have proposed varieties of spanning tree problems with some constraints on them, such as the spanning tree problem with a degree constraint, the stochastic spanning tree problem, the quadratic spanning tree problem, the multi-criteria spanning tree problem and the spanning tree problem with a constraint on the number of leaves or leaf-constrained spanning tree problem [42.10, 11].

A spanning tree is a minimal set of edges from E that connects all the vertices in V and therefore at least one spanning tree can be found in graph G. The minimum spanning tree is just one of the spanning trees whose total weight of all edges is minimal. It can be formulated as

$$\min z(x) = \sum_{i=1}^{n-1} \sum_{j=2}^{n} w_{ij} x_{ij} \,, \tag{42.18}$$

$$\text{s.t.} \sum_{i=1}^{n-1} \sum_{j=2}^{n} x_{ij} = n - 1 \,; \tag{42.19}$$

$$\sum_{i \in S} \sum_{\substack{j \in S \\ j > 1}} x_{ij} \le |S| - 1, \; S \subseteq V \backslash \{1\}, \; |S| \ge 2 \,, \tag{42.20}$$

$$x_{ij} = 0 \text{ or } 1 \,, \; i = 1, 2, \ldots, n-1, \\ = 2, 3, \ldots, n \,, \tag{42.21}$$

where

$$x_{ij} = \begin{cases} 1, & \text{if edge } (i, j) \text{ is selected in a spanning tree} \\ 0, & \text{otherwise} \end{cases} \tag{42.22}$$

and T is a set of the spanning trees of graph G.

A. Tree Encodings

For the minimum spanning tree (MST) problem, the method of encoding a tree is critical for the genetic algorithm approach because the solution should be a tree.

If we associate an index k with each edge, i. e., $E = \{e_k\}$, $k = 1, 2, \ldots, K$, where K is the number of edges in a graph, a bit string can represent a candidate solution by indicating which edges are used in a spanning tree, as illustrated in Fig. 42.7.

B. Genetic Approach

Representation. The chromosome representation for a spanning tree should contain, implicitly or explicitly, the degree on each vertex. Among the several tree encodings, only the Prüfer number encoding explicitly

contains the information of vertex degree, i.e. that any vertex with degree d will appear exactly $d-1$ times in the encoding. Thus the Prüfer number encoding is adopted.

Crossover and Mutation. Prüfer number encoding can still represent a tree after any crossover or mutation operations. Simply, the one-point crossover operator is used, as illustrated in Fig. 42.8. Mutation is performed as random perturbation within the permissive integer from 1 to n (n is the number of vertices in graph). An example is given in Fig. 42.9

42.2.3 Set-Covering Problem

The problem is to cover the rows of an m-row/n-column zero–one matrix by a subset of columns at minimal cost. Considering a vector $\boldsymbol{n}$ that x_j is $0-1$ variable that takes on the 3 value 1, if item j is selected (with a cost $c_j > 0$). The set-covering the problem is then formulated as

$$\min z(x) = \sum_{j=1}^{n} c_j x_j \,, \tag{42.23}$$

$$s.t. \sum_{j=1}^{n} a_{ij} x_j \geq 1 \quad i = 1, 2, \ldots, m \,, \tag{42.24}$$

$$x_j \in \{0, 1\}, \quad j = 1, 2, \ldots, n \,. \tag{42.25}$$

Genetic Approach

Representation. The fitness of an individual $f(x)$ is calculated simply by

$$f(x) = \sum_{j=1}^{n} c_j x_j \,. \tag{42.26}$$

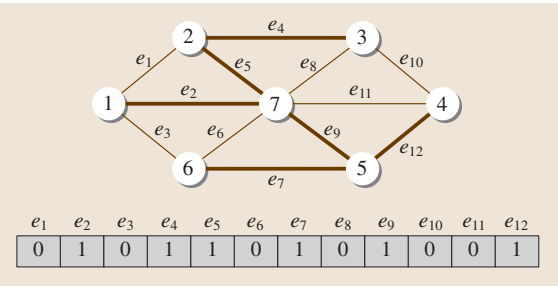

Fig. 42.7 A graph with its edge encoding for a spanning tree

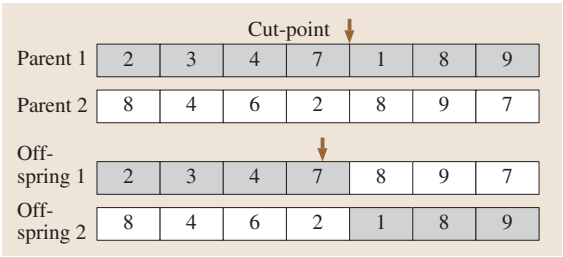

Fig. 42.8 Illustration of the crossover operation

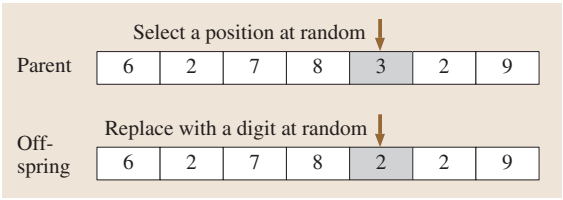

Fig. 42.9 Illustration of the mutation operation

The initial population can be generated randomly.

Genetic Operators. *Beasley* and *Chu* proposed a generalized fitness-based crossover operator called the fusion operator [42.9].

Let P_1 and P_2 be the parent strings. Let f_{P_1} and f_{P_2} be the fitness values of the parent strings P_1 and P_2, respectively. Let C be the child string. The fusion operator works as follows:

Procedure: Fusion Operator.

Step 1. $i = 1$.
Step 2. If $P_1[i] = P_2[i]$, then $C[i] \leftarrow P_1[i] = P_2[i]$.
Step 3. If $P_1[i] \neq P_2[i]$, then
(a) $C[i] \leftarrow P_1[i]$
with probability $p = f_{P_2}/(f_{P_1} + f_{P_2})$.
(b) $C[i] \leftarrow P_2[i]$ with probability $1 - p$.
Step 4. If $i = n$, stop; otherwise, set $i \leftarrow i + 1$ and go to step 1.

42.2.4 Bin-Packing Problem

The bin-packing problem consists of placing n objects into a number of bins (at most n bins). Each object has a weight ($w_i > 0$) and each bin has a limited bin capacity ($c_i > 0$). The problem is to find the best assignment of objects to bins such that the total weight of the objects in each bin does not exceed its capacity and the number of bins used is minimized.

A mathematical formulation for the bin-packing problem is given as follows [42.8]:

$$\min z(\boldsymbol{y}) = \sum_{i=1}^{n} y_i \,, \tag{42.27}$$

$$\text{s.t.} \sum_{j=1}^{n} w_j x_{ij} \le c_i y_i \,, \quad i \in N = \{1, 2, \ldots, n\} \,, \tag{42.28}$$

$$\sum_{i=1}^{n} x_{ij} = 1 \,, \quad j \in N \,, \tag{42.29}$$

$$y_i = 0 \text{ or } 1, \quad i \in N \,, \tag{42.30}$$

$$x_{ij} = 0 \text{ or } 1, \quad i,\ j \in N \,, \tag{42.31}$$

where

$$y_i = \begin{cases} 1, & \text{if bin } i \text{ is used} \\ 0, & \text{otherwise} \,, \end{cases} \tag{42.32}$$

$$x_{ij} = \begin{cases} 1, & \text{if object } j \text{ is assigned to bin } i \\ 0, & \text{otherwise} \,. \end{cases} \tag{42.33}$$

Genetic Approach

Representation. The most straightforward approach is to encode the membership of objects in the solution. For instance, the chromosome 1 4 2 3 5 2 would encode a solution where the first object is in bin 1, the second in bin 4, the third in bin 2, the fourth in bin 3, the fifth in bin 5 and the sixth in bin 2. This representation for the bin-packing problem is illustrated in Fig. 42.10.

Genetic Operators

Procedure: Crossover [42.12].

Step 1. Select at random two crossing sites, delimiting the crossing section, in each of the two parents.

Step 2. Inject the contents of the crossing section of the first parent at the first crossing site of the second parent.

Step 3. Eliminate all objects now occurring twice from the bins they were members of in the second parent, so that the *old* membership of these objects gives way to the membership specified by the *new* injected bins. Consequently, some of the *old* groups coming from the second parent are altered.

Step 4. If necessary, adapt the resulting bins, according to the hard constraints and the cost function to optimize.

Step 5. Apply steps 2–4 to the two parents with their roles permuted to generate the second child.

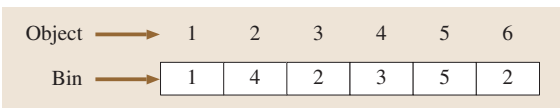

Fig. 42.10 Representation of membership of objects

42.2.5 Traveling-Salesman Problem

The traveling-salesman problem (TSP) is one of the most widely studied combinatorial optimization problems. Its statement is deceptively simple: a salesman seeks the shortest tour through n cities.

For example, a tour of a nine-city TSP

$$3-2-5-4-7-1-6-9-8$$

is simply represented as follows:

$$[3-2-5-4-7-1-6-9-8] \,.$$

This representation is also called a path representation or order representation. This representation may lead to illegal tours if the traditional one-point crossover operator is used, therefore many crossover operators have been investigated for it. Another method is the random keys representation. This representation encodes a solution with random numbers from (0,1). These values are used as sort keys to decode the solution.

For example, a chromosome for a nine-city problem may be

$$[0.23 \;\; 0.82 \;\; 0.45 \;\; 0.74 \;\; 0.87 \;\; 0.11 \;\; 0.56 \;\; 0.69 \;\; 0.78]$$

Where position i in the list represents city i. The random number in position i determines the visiting order of city i in a TSP tour. We sort the random keys in ascending order to get the following tour:

$$6-1-3-7-8-4-9-2-5$$

Genetic Approach

Representation. Permutation representation is perhaps the most natural representation of a TSP tour, where cities are listed in the order in which they are visited [42.13, 14].

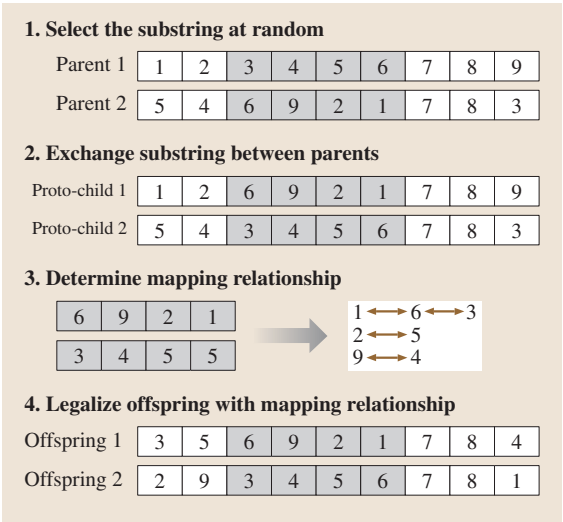

Fig. 42.11 Illustration of the PMX operator

Crossover Operators

Procedure: partial-mapped crossover (PMX) [42.14].

Step 1. Select two positions along the string uniformly at random.
Step 2. Exchange two substrings between parents to produce proto-children.
Step 3. Determine the mapping relationship between two mapping sections.

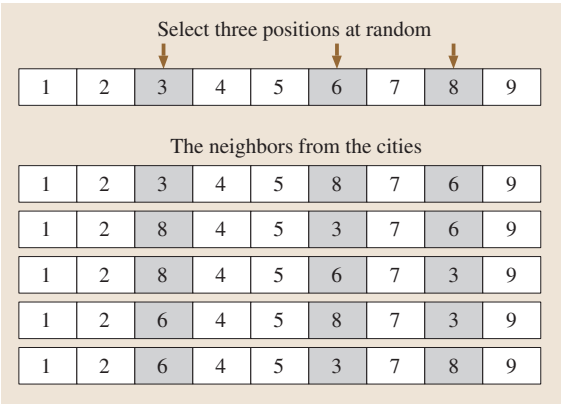

Fig. 42.12 Illustration of the heuristic mutation operator

Step 4. Legalize offspring with the *mapping relationship*.

The procedure is illustrated in Fig. 42.11.

Mutation Operators

Procedure: heuristic mutation [42.15, 16].

Step 1. Pick n genes at random.
Step 2. Generate neighbors according to all possible permutation of the selected genes.
Step 3. Evaluate all neighbors and select the best one as offspring.

The procedure is illustrated in Fig. 42.12.

42.3 Network Design Problems

Network design and routing are one of important issues in the building and expansion of computer networks. Many ideas and methods have been proposed and tested in the past two decades. Recently, there is an increasing interest in applying genetic algorithms to problems related to computer network [42.17].

42.3.1 Shortest-Path Problem

An undirected graph $G = (V, E)$ comprises a set of nodes $V = \{1, 2, \cdots, n\}$ and a set of edges $E \in V \times V$ connecting nodes in V. Corresponding to each edge, there are two nonnegative numbers c_{ij}^1 and c_{ij}^2 representing the cost and distance, or other items of interest, from node i to node j. A path from node i to node j is a sequence of edges (i, l), (l, m), $\cdots$, (k, j) from E in which no node appears more than once. A path can also be equivalently represented as a sequence of nodes $(i, l, m, \cdots, k, j)$. For the example given in Fig. 42.13, $(1, 4)$, $(4, 3)$, $(3, 5)$, $(5, 6)$ is a path from node 1 to node 6. The node representation is $(1, 4, 3, 5, 6)$.

Let 1 denote the initial node and n denote the end node of the path. Let x_{ij} be an indicator variable defined

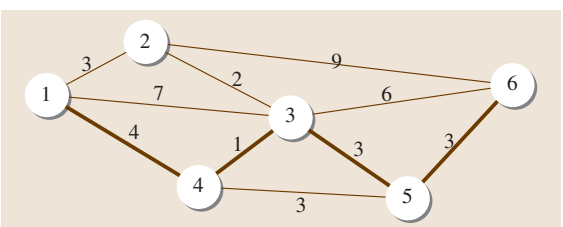

Fig. 42.13 Simple undirected graph with six nodes and 10 edges

as follows:

$$x_{ij} = \begin{cases} 1\,, & \text{if edge } (i,\,j) \text{ is included in the path} \\ 0\,, & \text{otherwise}\,. \end{cases} \tag{42.34}$$

The bicriteria shortest-path problem can be formulated as follows:

$$\min z^1(x) = \sum_i \sum_j c_{ij}^1 x_{ij}\,, \tag{42.35}$$

$$\min z^2(x) = \sum_i \sum_j c_{ij}^2 x_{ij}\,, \tag{42.36}$$

$$\text{s.t.} \sum_j x_{ij} \le 2\,, \quad \forall i \in V\,, \tag{42.37}$$

$$\sum_{j \ne k} x_{ij} \ge x_{ik}\,, \quad \forall (i,k) \in E, \quad \forall i \in V \backslash \{1, n\}\,, \tag{42.38}$$

$$\sum_j x_{1j} = \sum_j x_{jn} = 1\,, \quad \forall i,\ j \in V\,, \tag{42.39}$$

$$x_{ij} = x_{ji}\,, \quad \forall (i,j) \in E\,, \tag{42.40}$$

$$0 \le x_{ij} \le 1\,, \quad \forall (i,j) \in E\,. \tag{42.41}$$

Genetic Approach

Priority-Based Encoding [42.18–20]. The position of a gene is used to represent a node and the value is used to represent the priority of the node for constructing a path among the candidates. The encoding method is denoted by priority-based encoding. The path corresponding to a given chromosome is generated by a sequential node-appending procedure, beginning from the specified node 1 and terminating at the specified node n.

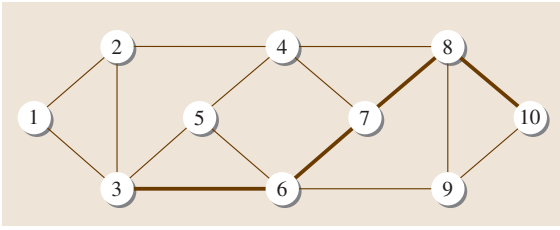

Fig. 42.14 Simple undirected graph with 10 nodes and 16 edges

Position: node ID	1	2	3	4	5	6	7	8	9	10
Value: priority	7	3	4	6	2	5	8	10	1	9

Fig. 42.15 Example of priority-based encoding

Consider the undirected graph shown in Fig. 42.14. Suppose we are going to find a path from node 1 to node 10. An encoding of the instance is given in Fig. 42.15. At the beginning, we try to find a node for the position next to node 1. Nodes 2 and 3 are eligible for the position, which can be easily fixed according to the adjacency relation among nodes. The priorities of them are 3 and 4, respectively. Node 3 has the highest priority and is put into the path. The possible nodes next to node 3 are nodes 2, 5 and 6. Because node 6 has the largest priority value, it is put into the path. Then we form the set of nodes available for the next position and select the one with the highest priority among them. These steps are repeated until we obtain a complete path (1, 3, 6, 7, 8, 10).

For an n-node problem, let Ω be a set containing integers from 1 up to n, that is, $\Omega = \{1, 2, \ldots, n\}$, let p_i denote the priority for node i, which is a random integer exclusively from the set Ω. Priorities p_i of all nodes satisfy the following conditions:

$$p_i \ne p_j, \quad p_i,\ p_j \in \Omega, \quad i \ne j,\ i, j = 1, 2, \ldots, n \tag{42.42}$$

Then the priority-based encoding can be formally defined as

$$[p_1 \ \ p_2 \ \ \cdots \ \ p_n]\,.$$

Genetic Operators

Here the position-based crossover operator proposed by *Syswerda* is adopted [42.21]. It can be viewed as a kind of uniform crossover operator for integer permutation representation together with a pairing procedure, as shown in Fig. 42.16. Essentially, it takes some genes from one parent at random and fills the vacuum position with genes from the other parent using a left-to-right scan. The swap mutation operator is used here, which simply selects two positions at random and swaps their contents as shown in Fig. 42.17.

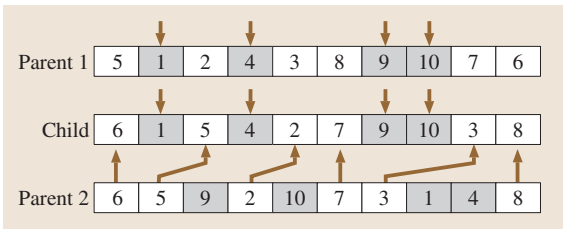

Fig. 42.16 Position-based crossover operator

42.3.2 Maximum-Flow Problem

There have been many applications of this problem in the real world. One of them is to determine the maximum flow through a pipeline network. Assume that oil should be shipped from the refinery (the source) to a storage facility (the sink) along arcs of the network. Each arc has a capacity which limits the amount of flow along that arc. Here, we want to determine the largest possible flow that can be sent from the refinery to the storage facility with the restriction that no arc (pipe) capacity can be exceeded. MXF has also been applied to some other applications such as: the problem of selecting sites for an electronic message-transmission system and dynamic flows in material-handling systems [42.22–24].

A mathematical formulation for the bin-packing problem is given by:

$$\max f \,, \tag{42.43}$$

$$\text{s.t.} \sum_{j=1}^{m} x_{ij} - \sum_{k=1}^{m} x_{ki} = \begin{cases} f, & \text{if} \quad i = 1 \\ 0, & \text{if} \quad i = 2, 3, \\ & \quad \ldots, m-1 \\ -f, & \text{if} \quad i = m \end{cases} , \tag{42.44}$$

$$0 \le x_{ij} \le u_{ij}, \quad i,\ j = 1, 2, \ldots, m \,, \tag{42.45}$$

where f is the amount of flow in the network from node 1 to node m and u_{ij} is arc capacities.

Genetic Approach

The priority-based encoding method is used to represent the chromosome. The chromosome here is represented by m-digit numbers that are generated randomly. Each number represents the priority of the node.

Crossover. As the first step in the crossover operation, we generate random numbers γ_k in the range [0, 1] ($k = 1, 2, \ldots, popSize$). Next, we select the chromosomes v_k to which the crossover operation will be applied. If $\gamma_k < p_C$ then the crossover operation will be applied to chromosome v_k.

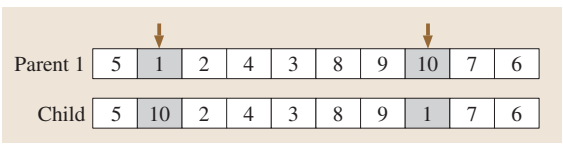

Fig. 42.17 Swap mutation operator

Mutation. Similarly, the first step in the mutation operation is to generate a random γ_r in the range [0, 1], ($r = 1, 2, \ldots, popSize$).

If $\gamma_r < p_M$ then the chromosome $v_k \quad (l = (r/m + 1))$ is chosen for the mutation operation.

42.3.3 Minimum-Cost-Flow Problem

The minimum-cost-flow problem (MCF) is known as a useful type of network optimization problem. It consists of finding the minimum-cost flows in the networks. For this problem, we are given a directed network $G = (X,\ A)$ in which each arc connecting node i and j in the network is associated with a cost c_{ij} and a capacity u_{ij}. A feasible solution to the MCF problem should satisfy two constraints. First, the flow through each arc should satisfy the capacity constraint. Second, the conservation of flow in all nodes should also be preserved. The conservation of flows here means that the flow into a node must equal the flow out of the node. The common objective is to determine the feasible network flow that minimizes the total cost.

A mathematical formulation for the bin-packing problem is given by:

$$\min z = \sum_{i=1}^{m} \sum_{j=1}^{m} c_{ij} x_{ij} \,, \tag{42.46}$$

$$\text{s.t.} \sum_{j=1}^{m} x_{ij} - \sum_{k=1}^{m} x_{ki} = b_i, i = 1, \ldots, m \tag{42.47}$$

$$x_{ij} \ge 0, i, j = 1, \ldots, m \,, \tag{42.48}$$

where x_{ij} is the flow through an arc and c_{ij} is the unit shipping cost along the arc. Equation (42.46) is called the flow-conservation or Kirchhoff equation and indicates that flow may be neither created nor destroyed in the network.

Genetic Approach

Representation. The chromosome here is represented by m-digit numbers generated randomly. Each number represents the priority of the node respectively.

Crossover. The crossover is done by selecting two chromosome randomly. We use the partially matched crossover (PMX) method for the crossover operation.

Mutation. Mutation here is done by selecting a chromosome at random. Two bit positions of the chromosome are exchanged.

42.3.4 Centralized Network Design

Consider a complete, undirected graph $G = (V,\ E)$, let $V = \{1, 2, \cdots, n\}$ be the set of nodes representing terminals. Denote the central site or *root* node as node 1, and let $E = \{(i, j)|i, j \in V\}$ be the set of edges representing all possible telecommunication wiring. For a subset of nodes $S(\subseteq V)$, define $E(S) = \{(i, j)|i, j \in S\}$ as the edges whose endpoints are both in S. Define the following binary decision variables for all edges $(i, j) \in E$:

$$x_{ij} = \begin{cases} 1\,, & \text{if edge } (i, j) \text{ is selected} \\ 0\,, & \text{otherwise}\,. \end{cases} \tag{42.49}$$

Let c_{ij} be the fixed cost with respect to edge (i, j) in the solution, and suppose that d_i represents the demand at each node $i \in V$, where by convention the demand of the root node is $d_1 = 0$. Let $d(S)$, $S \subseteq V$ denote the sum of the demands of nodes of S. The subtree capacity is denoted with κ. The centralized network design problem can be formulated as follows [42.10]:

$$\min z = \sum_{i=1}^{n-1}\sum_{j=2}^{n} c_{ij}x_{ij}\,, \tag{42.50}$$

$$s.t. \sum_{i=1}^{n-1}\sum_{j=2}^{n} x_{ij} = 2(n-1)\,, \tag{42.51}$$

$$\sum_{i\in S}\sum_{j\in S} x_{ij} \le 2[|S| - \lambda(S)]\,,$$

$$S \subseteq V\backslash\{1\}\,, |S| \ge 2\,, \tag{42.52}$$

$$\sum_{i\in U}\sum_{j\in U} x_{ij} \le 2(|U| - 1)\,,\quad U \subset V\,,$$

$$|U| \ge 2\,,\quad \{1\} \in U\,, \tag{42.53}$$

$$x_{ij} = 0 \text{ or } 1\,,\quad i = 1, 2, \ldots, n-1,$$

$$j = 2, 3, \ldots, n\,. \tag{42.54}$$

Equality (42.51) is true of all spanning trees: a tree with n nodes must have $n-1$ edges. Inequality (42.53) is a standard inequality for spanning trees: if more than $|U|-1$ edges connect the nodes of a subset U, then the set U must contain a cycle. The parameter $\lambda(S)$ refers to the *bin-packing number* of set S, namely, the number of bins of size κ needed to pack the nodes of items of size d_i for all $i \in S$. These constraints are similar to those for inequality (42.53), except that they reflect the capacity constraint: if the set S does not contain the root node, then the nodes of S must be contained in at least $\lambda(S)$ different subtrees of the root.

Up to now, all heuristic algorithms for this problem are only focused on how to deal with the constraints to make the problem simpler to solve. In the cutting plane algorithms or branch-bound algorithm, the network topology of the problem are usually neglected. As a result, it leads in an exponential explosion of constraints.

In Fig. 42.18, node ID is the node number based on the depth-first search (DFS) and the degree at node ID is the number of connecting nodes.

Genetic Approach

To solve the centralized network design problem by using a genetic algorithm, a tree-based permutation encoding method is adopted to encode the candidate solutions, as illustrated in Fig. 42.18.

42.3.5 Multistage Process Planning

The multistage process planning (MPP) system usually consists of a series of machining operations, such as turning, drilling, grinding, finishing, and so on, to transform a part into its final shape or product. The whole process can be divided into several stages. At each stage, there are a set of similar manufacturing operations. The MPP problem is to find the optimal process planning among all possible alternatives given certain criteria such as minimum cost, minimum time, maximum quality, or under several of these criteria.

For an n-stage MPP problem, let s_k be some state at stage k, $D_k(s_k)$ be the set of possible states to be chosen at stage k, $k = 1, 2, \ldots, n$, x_k be the decision variable to determine which state to choose at stage k; obviously $x_k \in D_k(s_k)$, $k = 1, 2, \ldots, n$. Then the MPP problem can be formulated as follows:

$$\min_{\substack{x_k\in D_k(s_k)\\ k=1,2,\ldots,n}} V(x_1,\ x_2, \cdots,\ x_n) = \sum_{k=1}^{n} v_k(s_k,\ x_k)\,, \tag{42.55}$$

where $v_k(s_k,\ x_k)$ represents the criterion to determine x_k under state s_k at stage k, usually defined as a real number such as cost, time, or distance.

Genetic Approach

Representation. The MPP solution can be concisely encoded in a state permutation format by concatenating all the set states of stages. This state permutation encoding has a one-to-one mapping for the MPP problem. The probability of randomly producing a process

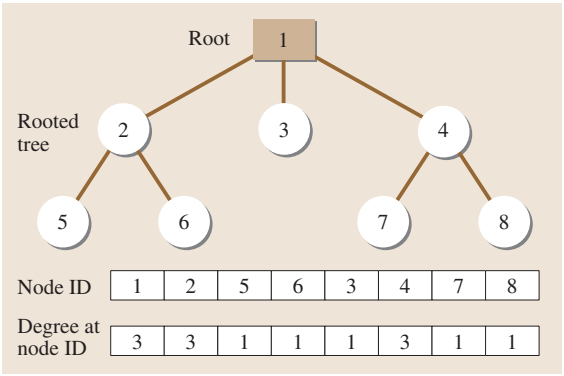

Fig. 42.18 Rooted tree and its tree-based permutation

planning is definitely 1. It is also easy to decode and evaluate. As to the initial population for an n-stage MPP problem, each individual is a permutation with $n-1$ integers whereas the integers are generated randomly with the number of all possible states in the corresponding stage.

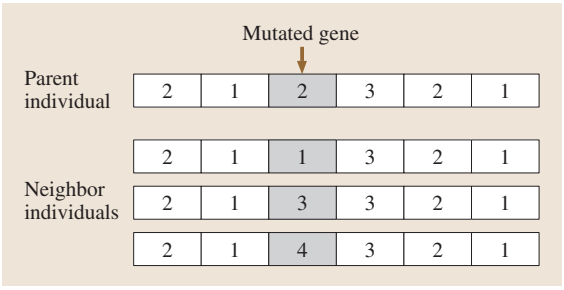

Fig. 42.19 Mutation with neighborhood search

Genetic Operation. In Zhou and Gen's method, only the mutation operation was adopted because it is easy to hybrid the neighborhood search technique to produce more adapted offspring. This hybrid mutation operation provides a great chance to evolve to the optimal solution. Figure 42.19 shows an example for this mutation operation with a neighborhood search technique supposing that the gene is at stage 3 and the number of possible states to be chosen is 4.

42.4 Scheduling Problems

Scheduling problems exist almost everywhere in real-world situations, especially in the industrial engineering world. Many scheduling problems from manufacturing industries are quite complex in nature and very difficult to solve by conventional optimization techniques.

42.4.1 Flow-Shop Sequencing Problem

The flow-shop sequencing problem is generally described as follows: there are m machines and n jobs, each job consists of m operations, and each operation requires a different machine. n jobs have to be processed in the same sequence on m machines. The processing time of job i on machine j is given by t_{ij} $(i = 1, \ldots, n;\ j = 1, \ldots, m)$. The objective is to find the sequence of jobs minimizing the maximum flow time, which is called makespan.

Heuristics for General m-Machine Problems

Genetic algorithms have been successfully applied to solve flow-shop problems. We describe Gen, Tsujimura, and Kubota's approach.

Representation. Because the flow-shop problem is essentially a permutation schedule problem [42.25–27], we can use the permutation of jobs as the representation scheme of chromosome, which is the natural representation for a sequencing problem. For example, let the k-th chromosome be

$$v_k = [3\ \ 2\ 4\ \ 1]\,,$$

meaning that the jobs sequence is $j_3,\ j_2,\ j_4,\ j_1$.

Crossover and Mutation. Here, Goldberg's PMX is used. Mutation is designed to perform random exchange; that is, it selects two genes randomly in a chromosome and exchanges their positions. An example is given in Fig. 42.20.

42.4.2 Job-Shop Scheduling

In the job-shop scheduling problem, we are given a set of jobs and a set of machines. Each machine can handle at most one job at a time. Each job consists of a chain

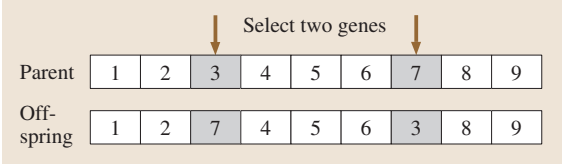

Fig. 42.20 Swap mutation

of operations, each of which needs to be processed during an uninterrupted time period of a given length on a given machine. The purpose is to find a schedule, that is, an allocation of the operations to time intervals on the machines, which has a minimum duration required to complete all jobs [42.25].

Adapted Genetic Operators

During the past two decade, various crossover operators have been proposed for literal permutation encodings, such as partial-mapped crossover (PMX), order crossover (OX), cycle crossover (CX), etc.

Partial-Mapped Crossover (PMX). PMX is explained in the previous section.

Order Crossover (OX). Order crossover was proposed by Davis. OX has the following major steps [42.14]:

Step 1. Select a substring from one parent at random.
Step 2. Produce a proto-child by copying the substring into the corresponding positions as they are in the parent.
Step 3. Delete all the symbols from the second parent that are already in the substring. The resulted sequence contains the symbols the proto-child needs.
Step 4. Place the symbols into the unfixed positions of the proto-child from left to right according to the order of the sequence to produce an offspring.

Cycle Crossover (CX). Cycle crossover was proposed by *Oliver* et al.. CX works as follows [42.25]:

Step 1. Find the cycle which is defined by the corresponding positions of symbols between parents.
Step 2. Copy the symbols in the cycle to a child with the corresponding positions of one parent.
Step 3. Determine the remaining symbols for the child by deleting those symbols which are already in the cycle from the other parent.
Step 4. Fill the child with the remaining symbols.

Mutation. It is relatively easy to make some mutation operators for the permutation representation. During the last decade, several mutation operators have been proposed for permutation representation, such as inversion, insertion, displacement, reciprocal exchange mutation, and shift mutation [42.9]. *Inversion mutation* selects two positions within a chromosome at random and then inverts the substring between these two positions. *Insertion mutation* selects a gene at random and inserts it in a random position.

42.4.3 Resource-Constrained Projected Scheduling Problem

The problem of scheduling activities under resource and precedence restrictions with the objective of minimizing the project duration is referred to as the resource-constrained project scheduling problem in the literature [42.25, 28].

The problem can be stated mathematically as follows:

$$\min\ t_n\ , \tag{42.56}$$

$$s.t.,\ t_j - t_i \geq d_i\ , \quad \forall j \in S_i\ , \tag{42.57}$$

$$\sum_{t_i \in A_{t_i}} r_{ik} \leq b_k, \quad k = 1, 2, \ldots, m\ , \tag{42.58}$$

$$t_i \geq 0, \quad i = 1, 2, \ldots, n\ , \tag{42.59}$$

where t_i is the starting time of activity i, d_i the duration (processing time) of activity i, S_i the set of successors of activity i, r_{ik} the amount of resource k required by activity i, b_k the total availability of resource k, A_{ti} the set of activities in process at time t_i, and m the number of different resource types. Activities 1 and n are dummy activities which mark the beginning and end of the project. The objective is to minimize the total project duration.

A. Priority-Based Encoding

For this problem, priority-based encoding is used; it is explained in the previous section.

B. Genetic Operators

Position-Based Crossover. The position-based crossover operator is used. This crossover is explained in the previous section.

Swap Mutation. The swap mutation operator was used here, which simply selects two positions at random and swaps their contents, as shown in Fig. 42.21.

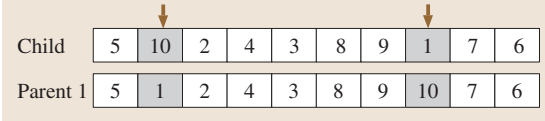

Fig. 42.21 Swap mutation operator

42.4.4 Multiprocessor Scheduling

The multiprocessor scheduling is to assign n tasks to m processors in such a way that precedence constraints are maintained, and to determine the start and finish times of each task with the objective of minimizing the completion time. There is a paper which deals with real-time tasks [42.29]. However, here we introduce an algorithm concerned with general tasks. The mathematical formulation of the problem is given as

$$\min[\max_j(x_j y_{ij})]\,, \tag{42.60}$$

$$\text{s.t.} x_k - x_j \geq p_k\,, \quad T_j \prec T_k\,, \tag{42.61}$$

$$\sum_{j=1}^{n} p_j y_{ij} \leq t_{\max}\,, \quad i = 1, \ldots, n\,, \tag{42.62}$$

$$\sum_{i=1}^{m} y_{ij} = 1\,, \quad j = 1, \ldots, m\,, \tag{42.63}$$

$$y_{ij} = 0 \;\; or \;\; 1\,, \quad i = 1, \ldots, m, \quad j = 1, \ldots, n\,, \tag{42.64}$$

where

$$y_{ij} = \begin{cases} 1\,, & \text{if task } T_j \text{ is assigned to processor } P_i \\ 0\,, & \text{otherwise}\,, \end{cases} \tag{42.65}$$

and where $t_{\max} = \max_i(t_i)$, x_j is the completion time of task T_j, p_j is the processing time of task T_j, t_i is the time required to process all tasks assigned to process P_i, and $\prec$ represents a precedence relation; a precedence relation between tasks, $T_j \prec T_k$, means that T_k precedes T_j.

Genetic Algorithm for MSP

For the chromosome representation scheme and genetic operations, we adopt the concept of the height function [42.10], which considers precedence relations among the tasks in the implementation of a genetic algorithm.

Height Function. To facilitate the generation of the schedule and the construction of the genetic operators, we define the *height* of each task in the task graph as

$$\text{height}(T_i) = \begin{cases} 0 & \text{if pre}(T_i) = \phi \\ 1 + \max\limits_{T_j \in \text{pre}(T_i)} [\text{height}(T_j)]\,, & \text{otherwise} \end{cases} \tag{42.66}$$

$$\begin{aligned} \text{height}'(T_j) = {} & \text{rand} \in \{\max[\text{height}(T_i)] + 1, \\ & \min[\text{height}'(T_k)] - 1\} \text{ over all } T_i \in \text{pre } T_j \\ & \text{and } T_k \in \text{suc}\,(T_j)\,, \end{aligned} \tag{42.67}$$

where $\text{pre}(T_j)$ is the set of predecessors of T_j and $\text{suc}(T_j)$ is the set of successors of T_j.

Representation. The chromosome representation used here is based on the schedule of the tasks in each processor. The representation of the schedule for genetic algorithms must accommodate the precedence relations between the computational tasks.

Genetic Operators. The function of the genetic operators is to create new search nodes based on the current population of search nodes. New search nodes are typically constructed by combining or rearranging parts of the old search nodes.

Operation 1. Operation 1 is performed in the following steps

Step 1. Generate a random number c from the range $[1, \max(\text{height}')]$.
Step 2. Place the cut-point at each processor in such a way that the tasks' height$'$ before the cut-point is less than c and more than or equal to c after the cut-point.
Step 3. Exchange the second partial schedules.

Operation 2. Operation 2 is performed in the following steps

Step 1. Generate a random number c from the range $[1, \max(\text{height}')]$.
Step 2. At each processor, pick all tasks whose height$'$ is c.
Step 3. Replace the position of all tasks randomly.

42.5 Reliability Design Problem

Reliability optimization appeared in the late 1940s and was first applied to communication and transportation systems. Much of the early work was confined to the analysis of certain performance aspects of systems. One

goal of the reliability engineer is to find the best way to increase system reliability. The reliability of a system can be defined as the probability that the system has operated successfully over a specified interval of time under stated conditions.

42.5.1 Simple Genetic Algorithm for Reliability Optimization

The problem is to maximize the system reliability subject to three nonlinear constraints with parallel redundant units in subsystems that are subject to A failures, which occur when the entire subsystem is subjected to the failure condition. It can be mathematically stated as follows:

$$\max R(m) = \prod_{i=1}^{3} \left\{ 1 - [1 - (1 - q_{i1})^{m_i+1}] - \sum_{u=2}^{4} (q_{iu})^{m_i+1} \right\} , \quad (42.68)$$

$$\text{s.t.} \quad G_1(m) = (m_1+3)^2 + (m_2)^2 + (m_3)^2 \le 51 , \quad (42.69)$$

$$G_2(m) = 20 \sum_{i=1}^{3} \left[m_i + \exp(-m_i) \right] \ge 120 , \quad (42.70)$$

$$G_3(m) = 20 \sum_{i=1}^{3} \left[m_i \exp(-m_i/4) \right] \ge 65 , \quad (42.71)$$

$$1 \le m_1 \le 4, \quad 1 \le m_2, \quad m_3 \le 7 , \quad (42.72)$$

$$m_i \ge 0 : \text{integer}, \quad i = 1, 2, 3 , \quad (42.73)$$

Table 42.1 Failure modes and probabilities in each subsystem

Subsystem i	Failure modes $s_i = 4,\ h_i = 1$	Failure probability q_{iu}
1	O	0.01
	A	0.05
	A	0.10
	A	0.18
2	O	0.08
	A	0.02
	A	0.15
	A	0.12
3	O	0.04
	A	0.05
	A	0.20
	A	0.10

where $m = (m_1\, m_2\, m_3)$. The subsystems are subject to four failure modes ($s_i = 4$) with one O failure ($h_i = 1$) and three A failures, for $i = 1, 2, 3$. For each subsystem the failure probability is shown in Table 42.1.

Genetic Approach

Representation. The integer value of each variable m_i is represented as a binary string. The length of the string depends on the upper bound u_i of the redundant units. For instance, when the upper bound u_i equals 4, we need three binary bits to represent m_i. In this example, the upper bounds of the redundant units in each subsystem are $u_1 = 4$, $u_2 = 7$, $u_3 = 7$, so each decision variable m_i needs three binary bits. This means that a total of nine bits are required. If $m_1 = 2$, $m_2 = 3$, and $m_3 = 3$, we have the following chromosome:

$$\begin{aligned} \mathrm{v} &= [x_{33}\ \ x_{32}\ \ x_{31}\ \ x_{23}\ \ x_{22}\ \ x_{21}\ \ x_{13}\ \ x_{12}\ \ x_{11}] \\ &= [0\ \ 1\ \ 1\ \ 0\ \ 1\ \ 1\ \ 0\ \ 1\ \ 0\ ] \end{aligned}$$

where x_{ij} is the symbol for the j-th binary bit of variable m_i.

Crossover. One-cut-point crossover is used here.

Mutation. Mutation is performed on a bit-by-bit basis.

42.5.2 Reliability Design with Redundant Unit and Alternatives

Gen, *Yokota*, *Ida* and *Taguchi* further extended their work to the reliability optimization problem by considering both redundant units and alternative design [42.19, 30, 31].

The example used here was firstly given by *Fyffe* et al.as follows:

$$\max R(\boldsymbol{m}, \boldsymbol{\alpha}) = \prod_{i=1}^{14} \left\{ 1 - \left[1 - R_i(\alpha_i) \right]^{m_i} \right\} , \quad (42.74)$$

$$\text{s.t.} \quad G_1(\boldsymbol{m}, \boldsymbol{\alpha}) = \sum_{i=1}^{14} c_i(\alpha_i) m_i \le 130 , \quad (42.75)$$

$$G_2(\boldsymbol{m}, \boldsymbol{\alpha}) = \sum_{i=1}^{14} w_i(\alpha_i) m_i \le 170 , \quad (42.76)$$

$$1 \le m_i \le u_i , \quad \forall i , \quad (42.77)$$

$$1 \le \alpha_i \le \beta_i , \quad \forall i , \quad (42.78)$$

$$m_i , \ \alpha_i \ge 0 : \ \text{integer } \forall i , \quad (42.79)$$

where α_i represents the design alternative available for the i-th subsystem, m_i represents the identical units used

in redundancy for the ith subsystem, u_i is the upper bound of the redundant units for the i-th subsystem, and β_i is the upper bound of alternative design for the i-th subsystem.

Genetic Approach

Representation. The representation can be written as follows:

$$\boldsymbol{v}_k = [\ (\alpha_{k1}\ ,\ m_{k1})\ (\alpha_{k2}\ ,\ m_{k2})\ \cdots\ (\alpha_{k14}\ ,\ m_{k14})\ ]\ ,$$

where α_{ki} is a design alternative, m_{ki} is a redundant unit, the subscript k is the index of chromosome.

Crossover. The uniform crossover operator given by Syswerda is used here, which has been shown to be superior to traditional crossover strategies for combinatorial problem. Uniform crossover firstly generates a random crossover mask and then exchanges relative genes between parents according to the mask. A crossover mask is simply a binary string with the same size of chromosome.

42.5.3 Network Reliability Design

A communication network can be represented by an undirected graph $G = (V, E)$, in which the nodes V and edges E represent computer sites and communication cables, respectively. A graph G is connected if there is at least one path between ever pair of nodes i and j, which minimally requires a spanning tree with $(n-1)$ edges. The following notations are defined to describe the optimal design problem of all-terminal reliable networks: n is the number of nodes, $x_{ij} \in (0, 1)$ is the decision variable representing the edge between node i and node j, $\boldsymbol{x}(= \{x_{12}, x_{13}, \cdots, x_{n-1,n}\})$ is a topology architecture for the network design, x^* is the best solution found so far, p is the edge reliability for all edges, q is the edge unreliability for all edges (i. e., $p+q=1$), $R(x)$ is the all-terminal reliability of the network design x, $R_{\min}$ is the network reliability requirement, $R_U(x)$ is the upper bound on the reliability of the candidate network, c_{ij} is the cost of the edge between node i and node j, $c_{\max}$ is the maximum value of c_{ij}, δ has the value of 1 if $R(x) < R_{\min}$ and is 0 otherwise, E' is a set of operational edges ($E' \subseteq E$), Ω is all operational states (E'). The optimal design of network can be represented as follows [42.10, 32]:

$$\min Z(\boldsymbol{x}) = \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} c_{ij} x_{ij}\ , \tag{42.80}$$

$$\text{s. t.} \quad R(\boldsymbol{x}) \geq R_{\min}\ . \tag{42.81}$$

Genetic Approach

Representation. A genetic algorithm lends itself to this problem because each network design $\boldsymbol{x}$ is easily formed into a binary string which can be used as a chromosome for genetic algorithms. Each element of the chromosome represents a possible edge in the network design problem, so there are $n \times (n-1)/2$ string components in each candidate architecture Z.

Crossover. The one-cut-point crossover operation is used.

Mutation. The bit-flip mutation operation is employed, performed on a bit-by-bit basis.

42.5.4 Tree-Based Network Topology Design

Consider a local-area network (LAN) that connects m users (stations). Also, we assume the $n \times n$ service center topology matrix X_1, which represents the connection between service centers. An element $\boldsymbol{x}_{1ij}$ is represented as

$$\boldsymbol{x}_{1ij} = \begin{cases} 1\ , & \text{if the centers } i \text{ and } j \text{ are connected} \\ 0\ , & \text{otherwise}\ . \end{cases} \tag{42.82}$$

Assume that the LAN is partitioned into n segments (service centers or clusters). The users are distributed over those n service centers. The $n \times m$ clustering matrix $\boldsymbol{X}_2$ specifies which user belongs to which center. Thus

$$\boldsymbol{x}_{2ij} = \begin{cases} 1\ , & \text{if user } j \text{ belongs to center } i \\ 0\ , & \text{otherwise}\ . \end{cases} \tag{42.83}$$

A user can only belong to one center; thus, $\forall j = 1, 2, \ldots, m$, $\sum_{i=1}^{n} x_{2ij} = 1$. We define an $n \times (n+m)$ matrix $\boldsymbol{X}$ called the spanning tree matrix ($[\boldsymbol{X}_1\ \ \boldsymbol{X}_2]$). The bicriteria LAN topology design problem can be formulated as the following nonlinear 0–1 programming model [42.10, 33, 34]:

$$\max R(\boldsymbol{X})\ , \tag{42.84}$$

$$\min \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} w_{1ij} x_{1ij} + \sum_{i=1}^{n} \sum_{j=1}^{m} w_{2ij} x_{2ij}\ , \tag{42.85}$$

$$\text{s. t.} \sum_{j=1}^{m} x_{1ij} \leq g_i\ , \quad i = 1, 2, \ldots, n\ , \tag{42.86}$$

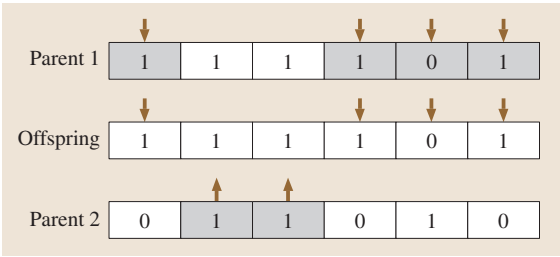

Fig. 42.22 Uniform crossover operator

$$\sum_{i=1}^{n} x_{2ij} = 1\,, \quad j = 1, 2, \ldots, m\,, \tag{42.87}$$

where $R(\boldsymbol{X})$ is the network reliability, w_{1ij} is the weight of the link between the centers i and j, w_{2ij} is the weight of the link between the center i and the user j, g_i is the maximum number that can connect to the center i.

Genetic Approach

Representation. We can easily construct an encoding as follows:

procedure: Encoding of Prüfer number

Step 1. Let node i be the smallest labeled leaf node in a labeled tree T.
Step 2. Let j be the first digit in the encoding as the node j incident to node i is uniquely determined. The encoding is built by appending digits from left to right.
Step 3. Remove node i and the link from i to j; thus we have a tree with $k-1$ nodes.
Step 4. Repeat the above steps until one link is left. We produce a Prüfer number or an encoding with $k-2$ digits between 1 and k inclusive.

Crossover. Uniform crossover is used. This type of crossover is accomplished by selecting two parent solutions and randomly taking a component from one parent to form the corresponding component of the offspring Fig. 42.22.

Mutation. Swap mutation is used, as explained in the previous section.

42.6 Logistic Network Problems

The transportation problem is a basic model in the logistic networks. Many scholars have since refined and extended the basic transportation model to include not only the determination of optimum transportation patterns but also the analysis of production scheduling problems, transshipment problems, and assignment problems.

42.6.1 Linear Transportation Problem

The linear transportation problem (LTP) involves the shipment of some homogeneous commodity from various origins or sources of supply to a set of destinations, each demanding specified levels of the commodity. The usual objective function is to minimize the total transportation cost or total weighted distance or to maximize the total profit contribution from the allocation [42.35].

Given m origins and n destinations, the transportation problem can be formulated as a linear programming model:

$$\min z = \sum_{i=1}^{m}\sum_{j=1}^{n} c_{ij}x_{ij}\,, \tag{42.88}$$

$$\text{s.t.} \quad \sum_{j=1}^{n} x_{ij} \le a_i, \quad i = 1, 2, \ldots, m\,, \tag{42.89}$$

$$\sum_{i=1}^{m} x_{ij} \ge b_j, \quad j = 1, 2, \ldots, n\,, \tag{42.90}$$

$$x_{ij} \ge 0, \quad \text{for all } i \text{ and } j\,, \tag{42.91}$$

where x_{ij} is the amount of units shipped from origin i to destination j; c_{ij} is the cost of shipping one unit from source i to destination j; a_i is the number of units available at origin i; and b_j is the number of units demanded at destination j.

Genetic Approach

Representation. Perhaps the matrix is the most natural representation of a solution for the transportation problem. The allocation matrix for the transportation problem can be written as follows:

$$\boldsymbol{X}_p = \begin{pmatrix} x_{11} & x_{12} & \cdots & x_{1n} \\ x_{21} & x_{22} & \cdots & x_{2n} \\ \cdots & \cdots & \cdots & \cdots \\ x_{m1} & x_{m2} & \cdots & x_{mn} \end{pmatrix} \tag{42.92}$$

where $\boldsymbol{X}_p$ denotes the p-th chromosome and x_{ij} is the corresponding decision variable.

Crossover. Assume that two matrices $\boldsymbol{X}_1 = (x_{ij}^1)$ and $\boldsymbol{X}_2 = (x_{ij}^2)$ are selected as parents for the crossover operation. The crossover is performed in the following three main steps:

Step 1. Create two temporary matrices $\boldsymbol{D} = (d_{ij})$ and $\boldsymbol{R} = (r_{ij})$ as follows: $d_{ij} = \left[\left(x_{ij}^1 + x_{ij}^2\right)/2\right]$ and $r_{ij} = \left(x_{ij}^1 + x_{ij}^2\right) \mod 2$.

Step 2. Divide matrix $\boldsymbol{R}$ into two matrices $\boldsymbol{R}^1 = \left(r_{ij}^1\right)$ and $\boldsymbol{R}^2 = \left(r_{ij}^2\right)$ such that: $\boldsymbol{R} = \boldsymbol{R}^1 + \boldsymbol{R}^2$

Step 3. Then we produce two offspring of $\boldsymbol{X}_1'$ and $\boldsymbol{X}_2'$ as follows: $\boldsymbol{X}_1' = \boldsymbol{D} + \boldsymbol{R}^1$ and $\boldsymbol{X}_2' = \boldsymbol{D} + \boldsymbol{R}^2$

Mutation. The mutation is performed in following three main steps:

Step 1. Make a submatrix from the parent matrix. Randomly select $\{i_1, \cdots, i_p\}$ rows and $\{j_1, \cdots, j_q\}$ columns to create a $(p * q)$ submatrix $\boldsymbol{Y} = (y_{ij})$, where $\{i_1, \cdots, i_p\}$ is a proper subset of $\{1, 2, \ldots, m\}$ and $2 \le p \le m$, $\{j_1, \cdots, j_q\}$ is a proper subset of $\{1, 2, \ldots, n\}$ and $2 \le q \le n$, and y_{ij} takes the value of the element in the crossing position of selected row i and column j in the parent matrix.

Step 2. Reallocate commodity for the submatrix. The available amount of commodity a_i^y and the demands b_j^y for the submatrix are determined as follows:

$$a_i^y = \sum_{j \in \{j_1, \cdots, j_q\}} y_{ij}\,, \quad i = i_1, i_2, \cdots, i_p\,, \tag{42.93}$$

$$b_j^y = \sum_{i \in \{i_1, \cdots, i_p\}}^{y_{ij}}\,, \quad j = j_1, j_2, \cdots, j_q\,. \tag{42.94}$$

Step 3. Replace appropriate elements of the parent matrix by new elements from the reallocated submatrix $\boldsymbol{Y}$.

Spanning Tree-Based Approach. Transportation problems (TP) as a special type of network problem have a special data structure characterized as a transportation graph in their solutions. The spanning tree-based GA incorporating this data structure of TP was proposed by Gen and Li. This GA utilized the Prüfer number encoding based on a spanning tree, which is adopted because it is capable of representing all possible trees. Using the Prüfer number representation the memory only requires $m + n - 2$ entries for a chromosome in the TP. Transportation problems have separable sets of nodes for plants and warehouses. From this point, *Gen* and *Cheng* designed the criterion for feasibility of the chromosome. The proposed spanning tree-based GA can find the optimal or near-optimal solution for transportation problems in the solution space [42.10].

42.6.2 Multiobjective Transportation Problem

In the transportation problem, multiple objectives are required in practical situations, such as minimizing transportation cost, minimizing the average shipping time to priority customers, maximizing production using a given process, minimizing fuel consumption, and so on. The traditional multiobjective transportation problem (mTP) with m plants and n warehouses can be formulated as

$$\min z_q = \sum_{i=1}^{m} \sum_{j=1}^{n} c_{ij}^q x_{ij} \quad q = 1, 2, \ldots, Q\,, \tag{42.95}$$

$$\text{s. t.} \sum_{j=1}^{n} x_{ij} \le a_i\,, \quad i = 1, 2, \ldots, m\,, \tag{42.96}$$

$$\sum_{i=1}^{m} x_{ij} \ge b_j, \quad j = 1, 2, \ldots, n\,, \tag{42.97}$$

$$x_{ij} \ge 0\,, \quad \forall i,\ j\,, \tag{42.98}$$

where q means the q-th objective function.

Spanning Tree-based GA for Multi-objective TP

The Pareto optimal solutions are usually characterized as the solutions of the multiobjective programming problem [42.36, 37].

42.6.3 Bicriteria Transportation Problem with Fuzzy Coefficients

Consider the following two objectives: minimizing total transportation cost and minimizing total delivery time. Let $\tilde{c}_{ij}^1$ be the fuzzy data representing the transportation cost of shipping one unit from plant i to warehouse j, let $\tilde{c}_{ij}^2$ be the fuzzy data representing the delivery time of shipping one unit of the product from plant i to warehouse j, a_i be the number of units available at plant i,

and b_j be the number of units demanded at warehouse j. This problem with m plants and n warehouses can be formulated as [42.10]:

$$\min \tilde{z}_1 = \sum_{i=1}^{m} \sum_{j=1}^{n} \tilde{c}_{ij}^1 x_{ij} \,, \tag{42.99}$$

$$\min \tilde{z}_2 = \sum_{i=1}^{m} \sum_{j=1}^{n} \tilde{c}_{ij}^2 x_{ij} \,, \tag{42.100}$$

$$\text{s.t.} \sum_{j=1}^{n} x_{ij} \le a_i \,, \quad i = 1, 2, \ldots, m \,, \tag{42.101}$$

$$\sum_{i=1}^{m} x_{ij} \ge b_j \,, \quad j = 1, 2, \ldots, n \,, \tag{42.102}$$

$$x_{ij} \ge 0 \,, \quad \forall i \,, \; j \,, \tag{42.103}$$

where x_{ij} is the unknown quantity to be transported from plant i to warehouse j.

Genetic Approach

The proposed genetic algorithm approach is based on spanning tree. In multicriteria optimization, we are interested in finding Pareto solutions. When the coefficients of objectives are represented with fuzzy numbers, the objective values become fuzzy numbers. Since a fuzzy number represents many possible real numbers, it is not easy to compare solutions to determine which is the Pareto solution. Fuzzy ranking techniques can help us to compare fuzzy numbers. In this approach, Pareto solutions are determined based on the ranked values of fuzzy objective functions, and genetic algorithms are used to search for Pareto solutions.

Representation. The spanning-tree encoding, the Prüfer number, is used to represent the candidate solution. The criterion for the solution's feasibility designed in the proposed spanning-tree-based GA is also employed.

Crossover. For simplicity one-point crossover is used.

Mutation. Inversion mutation and displacement mutation are used.

42.6.4 Supply-Chain Management (SCM) Network Design

Supply-chain management (SCM) aims to choose the subset of plants and distribution centers to be opened and to design the distribution network strategy that can satisfy all capacities and demand requirements imposed by customers with minimum cost. We formulate the problem by using the following mixed integer linear programming model (MILP) [42.28, 38–41]:

$$\min \sum_i \sum_j s_{ij} x_{ij} + \sum_j \sum_k t_{jk} y_{jk} + \sum_k \sum_l u_{kl} z_{kl} + \sum_j f_j w_j + \sum_k g_k z_k \tag{42.104}$$

$$\text{s.t.} \sum_j x_{ij} \le a_i, \; \forall i \,, \tag{42.105}$$

$$\sum_k y_{jk} \le b_j w_j \,, \; \forall j \,, \tag{42.106}$$

$$\sum_j w_j \le P \,, \tag{42.107}$$

$$\sum_l z_{kl} \le c_k z_k, \; \forall k \,, \tag{42.108}$$

$$\sum_k z_k \le W \,, \tag{42.109}$$

$$\sum_k z_{kl} \ge d_l, \; \forall l \,, \tag{42.110}$$

$$w_j, z_k = (0, 1) \,, \; \forall j, \; k \,, \tag{42.111}$$

$$x_{ij}, y_{jk}, z_{kl} \ge 0, \; \forall i, \; j, \; k, \; l \,, \tag{42.112}$$

where i is the number of suppliers, j is the number of plants, K is the number of distribution centers, L is the number of customers, a_i is the capacity of supplier i, b_i is the capacity of plant j, c_k is the capacity of distribution center k, d_l is the demand of customer l, s_{ij} is the unit cost of production in plant j using material from supplier i, t_{jk} is the unit cost of transportation from plant j to the distribution center k, u_{kl} is the unit cost of transportation from distribution k to customer l, f_j is the fixed cost for operating plant j, g_k is the fixed cost for operating distribution center k, W is an upper limit on the total number of distribution centers that can be opened and P is an upper limit on the total number of plants that can be opened.

Here, x_{ij} is the quantity produced at plant j using raw material from supplier i, y_{jk} is the amount shipped from plant j to distribution center k and z_{kl} is the amount shipped from distribution center k to customer l. w_j and z_k are defined as

$$w_j = \begin{cases} 1, & \text{if production takes place at plant } j \\ 0, & \text{otherwise} \,, \end{cases} \tag{42.113}$$

$$z_k = \begin{cases} 1, & \text{if distribution center } k \text{ is opened} \\ 0, & \text{otherwise} . \end{cases} \tag{42.114}$$

Genetic Approach

Crossover. The crossover is done by exchanging the information of two parents to provide a powerful exploration capability. We employ a one-cut-point crossover operation, which randomly selects one cut-point and exchanges the right parts of the two parents to generate offspring.

Mutation. Modifying one or more of the gene values of an existing individual, mutation creates a new individual to increase the variability of the population. We use inversion and displacement mutation operations.

42.7 Location and Allocation Problems

Location–allocation problems arise in many practical settings. The classical single location–allocation problem is to find the single location which minimizes the summed distance from some number of fixed points, representing customers with known locations.

42.7.1 Location–Allocation Problem

There are m facilities to be located, and n customers with known locations are to be allocated to the variable facilities. Each customer has the requirement q_j, $j = 1, 2, \ldots, n$, and each facility has the capacity b_i, $i = 1, 2, \ldots, m$. We need to find the locations of facilities and allocations of customers to facilities so that the total summed distance among the customers and their serving facilities is minimized Fig. 42.23. This problem is formulated mathematically as [42.9]:

$$\min \sum_{i=1}^{m} \sum_{j=1}^{n} \sqrt{(x_i - u_j)^2 + (y_i - v_j)^2}\ z_{ij} \tag{42.115}$$

$$\text{s.t.} \sum_{j=1}^{n} q_j \cdot z_{ij} \le b_i , \quad i = 1, 2, \ldots, m , \tag{42.116}$$

$$\sum_{i=1}^{m} z_{ij} = 1 , \quad j = 1, 2, \ldots, n , \tag{42.117}$$

$$z_{ij} = 0 \text{ or } 1 , \ i = 1, 2, \ldots, m, \ j = 1, 2, \ldots, n , \tag{42.118}$$

where

$$(u_j, v_j) = \text{location of customer } j, \ j = 1, 2, \ldots, n , \tag{42.119}$$

$$(x_j, y_j) = \text{location of facility } i, \tag{42.120}$$

$$\text{decision variables } i = 1, 2, \ldots, m , \tag{42.121}$$

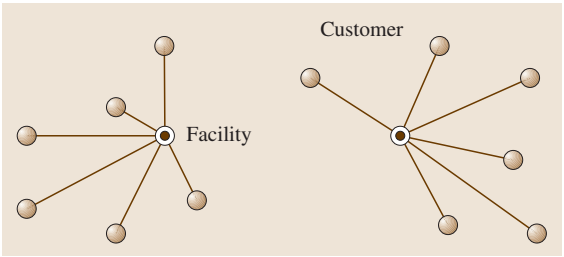

Fig. 42.23 Location–allocation problem

$$z_{ij} = 0 - 1 \text{ decision variable} ,$$

$$z_{ij} = \begin{cases} 1, & \text{customer } j \text{ is served by facility } i \\ 0, & \text{otherwise} \end{cases} . \tag{42.122}$$

A. Genetic Approach

Representation. Since location variables are continuous, the float-value chromosome representation is used. A chromosome is given as follows:

$$\boldsymbol{c}^k = \left[\left(x_1^k, y_1^k\right) \left(x_2^k, y_2^k\right) \cdots \left(x_m^k, y_m^k\right) \right]$$

where $\left(x_i^k, y_i^k\right)$ is the location of the i-th facility in the k-th chromosome, $i = 1, 2, \ldots, m$.

Crossover. Two mating strategies are used: one is free mating, which selects two parents at random; another is dominating mating, which uses the fittest individual as a fixed parent and randomly selects another parent from the population pool. These two strategies are used alternatively in the evolutionary process.

Suppose two parents with the following chromosomes are selected to produce a child

$$\boldsymbol{c}^{k_1} = \left[\left(x_1^{k_1}, y_1^{k_1}\right) \left(x_2^{k_1}, y_2^{k_1}\right) \cdots \left(x_m^{k_1}, y_m^{k_1}\right) \right] ,$$

$$\boldsymbol{c}^{k_2} = \left[\left(x_1^{k_2}, y_1^{k_2}\right)\left(x_2^{k_2}, y_2^{k_2}\right) \cdots \left(x_m^{k_2}, y_m^{k_2}\right) \right] .$$

Only one child is allowed to be produced:

$$\begin{aligned} \boldsymbol{c} &= [(x_1, y_1)(x_2, y_2) \cdots (x_m, y_m)] , \\ x_i &= r_i \cdot x_i^{k_1} + (1 - r_i) \cdot x_i^{k_2} , \\ y_i &= r_i \cdot y_i^{k_1} + (1 - r_i) \cdot y_i^{k_2} . \end{aligned} \tag{42.123}$$

Mutation. Suppose the candidate chromosome to be mutated is as follows:

$$\boldsymbol{c}^k = \left[\left(x_1^k, y_1^k\right)\left(x_2^k, y_2^k\right) \cdots \left(x_m^k, y_m^k\right) \right]$$

then the chromosome of the child produced by subtle mutation $\boldsymbol{c} = [x_1, y_1, x_2, y_2, \cdots, x_m, y_m]$ is as follows:

$$\begin{aligned} x_i &= x_i^k + \text{random value in } [-\varepsilon, \varepsilon] , \\ y_i &= y_i^k + \text{random value in } [-\varepsilon, \varepsilon] . \end{aligned} \tag{42.124}$$

B. Numerical Example

Cooper and *Rosing*'s examples are used to test the effectiveness of this method [42.42]. Cooper carefully constructed the front half data which contains three natural groups and Rosing increased the number of customers with random points. These examples provide a good benchmark to test the effectiveness of the proposed method because their global optimal solutions have already been found.

These examples include 30 customers whose location coordinates are shown in Table 42.2. Theirs is a common location–allocation problem where the requirements of the customers are treated as equal and the capacities of the facilities are assumed to be unlimited.

Both the alternative location-allocation (ALA) method and the hybrid evolutionary method (HEM) were applied to solve these examples. When using the ALA method, it was run to solve the same problem 40 times from randomly generated initial locations. The computed results are given in Table 42.3 [42.10]. In the table, the percent error was calculated by (actual value−optimal value)/optimal value ×100%.

Table 42.2 Coordinates of Cooper and Rosing's example

Order number	X	Y	Order number	X	Y

14	41	30	29	16	40
15	49	31	30	22	45

42.7.2 Capacitated Plant Location Problem

The capacitated plant location problem (cPLP) is referred to as a fixed-charge problem to determine the locations of plants with minimal total cost, including production, shipping costs, and fixed costs where

Table 42.3 Comparison results of Cooper and Rosing's example

Problem n/m	Rosing's method optimal objective	ALA Best	ALA Percent error	HEM Best	HEM Percent error
15/2	214.281	219.2595	2.32	214.2843	0.0015

30/6	–	208.4301	3.4940	201.4031	0.0

the plants are located. In this case, m sources (or facility locations) produce a single commodity for n customers, each with demand of b_j ($j = 1, \ldots, n$) units. If a particular source i is opened (or facility is built), it has a fixed cost $d_i \geq 0$ and a production capacity $a_i \geq 0$ associated with it. There is also a positive cost c_{ij} for shipping a unit from source i to customer j. The problem is to determine the locations of the plants so that capacities are not exceeded and demands are met, all at a minimal total cost. The cPLP is a mixed integer program, as shown in the following [42.10]

$$\min z(x) = \sum_{i=1}^{m}\sum_{j=1}^{n} c_{ij}x_{ij} + \sum_{i=1}^{m} d_i y_i \qquad (42.125)$$

$$\text{s.t.} \sum_{i=1}^{m} x_{ij} = b_j, \quad j = 1, 2, \ldots, n, \qquad (42.126)$$

$$\sum_{j=1}^{n} x_{ij} \leq a_i y_i, \quad i = 1, 2, \ldots, m, \qquad (42.127)$$

$$x_{ij} \geq 0, \quad \forall i, j, \qquad (42.128)$$

$$y_i = 0 \text{ or } 1, \quad i = 1, 2, \ldots, m. \qquad (42.129)$$

The variables are x_{ij} and y_i, which represent the amount shipped from plant i to warehouse j and whether a plant is open (or located) ($y_i = 1$) or closed ($y_i = 0$), respectively.

Spanning Tree-Based GA for Plant Location Problems

The spanning tree-based GA for the capacitated plant location problem is the same as that of the fixed-charge transportation problem except there is a different evaluation function in the evolutionary process.

42.7.3 Obstacle Location–Allocation Problem

There are n customers with known locations and m facilities to be built to supply some kind of services to all customers, for example, supplying materials or energy. There are also p obstacles representing some forbidden areas. The formulation of the mathematical model is based on the following assumptions:

- customer j has service demand q_j, $j = 1, 2, \ldots, n$,
- facility i has service capacity b_i, $i = 1, 2, \ldots, m$,
- each customer should be served by only one facility,
- new facilities should not be built within any obstacle,
- connecting paths between facilities and customers should not be allowed to pass through any of the obstacles.

The problem is to choose the best locations for facilities so that the sum of distances between customers and their serving facilities is minimal, as illustrated in Fig. 42.24. The obstacle location–allocation problem can be formulated as follows [42.9]:

$$\min f(\mathrm{D}, z) = \sum_{i=1}^{m}\sum_{j=1}^{n} t(\mathrm{D}_i, \mathrm{C}_j)\cdot z_{ij} \qquad (42.130)$$

$$\text{s.t.} \sum_{j=1}^{n} d_j z_{ij} \leq q_i, \quad i = 1, 2, \cdots, m, \qquad (42.131)$$

$$\sum_{i=1}^{m} z_{ij} = 1, \quad j = 1, 2, \cdots, n, \qquad (42.132)$$

$$\mathrm{D}_i = (x_i, y_i) \notin \mathrm{Q}_k, \quad i = 1, 2, \cdots, m, k = 1, 2, \cdots, q, \qquad (42.133)$$

$$(x_i, y_i) \in \mathrm{R}_\mathrm{T}, \quad i = 1, 2, \cdots, m, \qquad (42.134)$$

$$x_i, y_j \in R \quad i = 1, 2, \cdots, m \qquad (42.135)$$

$$z_{ij} = 1 \text{ or } 0, \quad i = 1, 2, \cdots, m, j = 1, 2, \cdots, n, \qquad (42.136)$$

where $\mathrm{C}_j = (u_j, v_j)$ is the location of the j-th customer, $\mathrm{D}_i = (x_i, y_i)$ is the decision variable, the location of the j-th distribution center DC_i should not fall within any of the obstacles, $t(\mathrm{D}_i,\mathrm{C}_j)$ is the shortest connecting path from the set of possible paths between the distribution center DC_i and the customer C_j which avoids all obstacles, R_T is the total area considered for the location and allocation problem and z_{ij} is a 0–1 decision variable; $z_{ij} = 1$ indicates that the j-th customer is served by DC_i, $z_{ij} = 0$ otherwise.

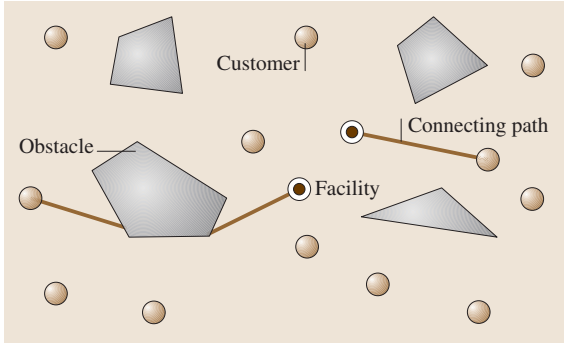

Fig. 42.24 Obstacle location–allocation problem

Hybrid Evolutionary Method

Since there are obstacles, the locations of the chromosome produced by initialization, crossover and mutation procedure may become infeasible. Generally, there are three kinds of methods to treat infeasible chromosomes. The first is to discard it, but according to the experience of other researchers this method may lead to very low efficiency. The second is to add a penalty to infeasible chromosomes. The third is to repair the infeasible chromosome according to the characteristics of the specified problem.

43. Scan Statistics

Section 43.1 introduces the concept of scan statistics and overviews types used to localize unusual clusters in continuous time or space, in sequences of trials or on a lattice. Section 43.2 focuses on scan statistics in one dimension. Sections 43.2.2 and 43.2.3 deal with clusters of events in continuous time. Sections 43.2.4 and 43.2.5 deal with success clusters in a sequence of discrete binary (s-f) trials. Sections 43.2.6 and 43.2.7 deal with the case where events occur in continuous time, but where we can only scan a discrete set of positions. Different approaches are used to review data when looking for clusters (the retrospective case in Sects. 43.2.2, 43.2.5, 43.2.6), and for ongoing surveillance that monitors unusual clusters (the prospective case in Sects. 43.2.2, 43.2.3, 43.2.7). Section 43.2.7 describes statistics used to scan for clustering on a circle (are certain times of the day or year more likely to have accidents?). Section 43.3 describes statistics used to scan continuous space or a two-dimensional lattice for unusual clusters. Sections 43.2 and 43.3 focus on how unusual the largest number of events within a scanning window is. Section 43.4.1 deals with scanning for unusually sparse regions. In some cases the researcher is more interested in the number of clusters, rather than the size of the largest or smallest, and Sect. 43.4.2 describes results useful for this case. The double-scan statistic of Sect. 43.4.3 allows the researcher to test for unusual simultaneous or lagged clustering of two different types of events. Section 43.4.4 describes scan statistics that can be used on data with a complex structure.

43.1 Overview

During design, monitoring, or analysis work, engineers and other scientists often need to take into account unusually large *clusters* of events in time or space. Mechanical engineers design system capacity to provide reliability to pipeline systems. Telecommunication experts seek to avoid outage caused by too many mobiles transmitting within the same area served by a single base station. Quality control experts monitor for clusters of defectives. Epidemiologists investigate *hotspots* of cancer cases, and carry out syndrome surveillance to monitor for bioterrorism attacks. Computer scientists base an information flow control mechanism on a large enough number of information packets within a temporal *sliding window*. Astronomers scan for muon clusters. Electrical engineers build in multiple redundancies to improve reliability, and use clusters of successes

as a criteria for start-up reliability. Molecular biologists search for clusters of specific types of patterns in protein or DNA sequences to focus on regions with important biologic functions. These scientists seek to determine which clusters are unlikely to occur by chance. The distributions given by various cluster statistics are tools that answer this question.

Scan statistics measure an unusually large cluster of events in time and or space. Given events distributed over a time period $(0, T)$, S_w is the largest number of events in any subinterval of length w. S_w is called the (temporal) *scan statistic*, from the viewpoint that one scans the time period $(0, T)$ with a window of size w, and finds the maximum cluster of points. A simple example illustrates this.

Example 1: A public health officer reviewing the records for a nursing home observed 60 deaths over the five-year period from January 1, 2000 through December 31, 2004. This was about average for such facilities. However, the officer observed that in the one-year period between April 1, 2003 to March 31, 2004 there were 23 deaths. Given that the 60 dates of death were independent, and occurred at random over the five-year period, how likely is it that there would be any one year period with 23 or more deaths? That is, if we scan the $T = 5$ year period with a $w = 1$ year period, how likely is it that the scan statistic $S_w \geq 23$? Note that the officer did not just divide the five-year period up into five calendar years and look at the calendar year with the largest number of deaths. In fact, the cluster observed did not occur in a calendar year. The scan statistic takes into account that the officer looked at a very large number of overlapping one-year periods. We see below that, even taking into account these multiple comparisons, the cluster of 23 deaths in a one-year period is fairly unusual. $P(S_w \geq 23, \text{ given } N = 60, w/T = 0.2) < 0.03$.

There is a large volume of literature and much current research being done on scan statistics. Three recent books [43.1–3] summarize and reference many results. Chapters 9 through 12 of [43.1] deals with scan statistics in a sequence of trials. There are useful engineering applications to reliability in consecutive systems, quality control, matching in genetic sequences, sooner and later waiting time problems and 556 references on runs and scans. Recent advances from articles by researchers are detailed in [43.2] together with applications. In [43.3], the first six chapters systematically show many applications with useful simple formulae for scan statistics, and are aimed at practitioners; the remaining 12 chapters develop the theory and methodology of scan statistics, and this is followed by a bibliography of over 600 references. In this review we draw heavily on these references, particularly [43.3], and subsequent research to give an overview of scan statistics, and highlight many results that have proved useful in many scientific applications. Scan statistics have been developed and applied for a variety of temporal and spatial scenarios. Time can be viewed as continuous or a discrete sequence of trials or time periods. Space can be viewed as continuous, or as a discrete grid of points at which events can occur. In two dimensions, results have been derived for square, rectangular, circular, triangular, and other shapes of scanning windows. The scan statistic S_w is the largest number of points in any window (for a fixed window size, shape, and orientation; or for a range of window sizes). The two-dimensional regions scanned include rectangles, the surface of a sphere, and more irregularly shaped geographical areas. In certain applications the events can only occur naturally at a discrete set of points in space. In other applications the underlying events can occur anywhere in space, but the method of observation limits events to a grid or lattice of points. Scan distributions have been derived for uniform, Poisson, and other distributed points in continuous space, and binomial, hypergeometric, and other distributions on two-dimensional grids. In the next section we discuss temporal scenarios.

43.2 Temporal Scenarios

One aspect of the scenario is whether its view is retrospective or prospective. A researcher might be reviewing events over some past time period of length T. The events might be a call for service, a reported cancer case, or an unacceptable item from an assembly line. In the *retrospective* case, the total number of events in the review period is a known number, N. The retrospective scan statistic analysis will typically be conditioned on N, a fixed known number, and in this case is referred to as either the *retrospective* or *conditional* case.

In other applications, the scientist uses scan statistics *prospectively* either to design a system's capacity to handle clustered demands, or to set up a monitoring system that will sound an alarm when an unusual cluster occurs. System capacity can be designed to give a specified small probability of overload within some future

period of operations of length T. Scan monitoring systems can be similarly designed so that (provided the process is "in control") there is, for example, only a 1% chance of a false alarm within a year; this is equivalent to saying that there is a 99% chance that the waiting time until a false alarm is greater than a year. Note that the total number of events, N, in time T is not known at either the system design time, or at the time an alarm is to be sounded. In the prospective case, the distribution of scan statistics cannot be conditioned on N. However, we often have information on the expected number of events in $(0, T)$. The prospective case is referred to as either the *prospective* or the *unconditional* case.

For each of the retrospective and prospective views, scan statistic distributions have been developed for continuous and for several discrete time scenarios. For example, the starting time of a hospital emergency room admission might be recorded to the nearest minute, and whether the patient had a particular syndrome may be recorded for each admission. For the event "admission of patient with syndrome," the scan statistic might be based on reported admission times, where time is viewed as a continuum. The *continuous scan statistic* is the maximum number of events in a window of length w that scans the time period $(0, T)$. In the continuous scenario, the times of occurrence of events are reported and for each time t in the review period, $(w \le t \le T)$, one knows the observed number of events $Y_w(t)$ and the expected number of events $E_w(t)$ in the subinterval $[t-w, t)$.

Alternatively, the analyst may only have a sequential list of patients available, and may only know whether or not each has the syndrome. In this case, the data is in the form of a discrete sequence of binary trials, and a *discrete* case scan statistic will be used. The data is viewed as a sequence of T trials, where for each trial whether or not an event has occurred is recorded; the discrete scan statistic is the maximum number of events in any w consecutive trials. For $t = w, w+1, \ldots, T$, $Y_w(t)$ and $E_w(t)$ are the observed and expected number of events within the w consecutive trials, $t-w+1, t-w+2, \ldots, t$.

In other cases, the reported data may only give hourly summary counts of patients with the syndrome, and the researcher may be keeping a moving sum of the number of such patients in the past six hours. In this discrete case we might use the *ratchet scan statistic*. In the ratchet scenario, time is divided into T disjoint intervals (hours, days, or weeks) and the reported data consists of the number of events in each interval. For $t = w, w+1, \ldots, T$, $Y_w(t)$ and $E_w(t)$ are the observed and expected number of events within the w consecutive intervals, $t-w+1, t-w+2, \ldots, t$.

Let S_w denote the scan statistic, $\max_t[Y_w(t)]$. For several important models for the above scenarios, exact formulae, approximations, and bounds are available for the distribution of S_w and related statistics. The following sections detail some of the most useful formula for the case where $E_w(t) = E_w$, a constant.

43.2.1 The Continuous Retrospective Case

The completely at random (constant background) model for this case is where N points (number of events) are independent uniform random variables over $(0, T)$.

$P(S_w \ge k | E_w, T)$ only depends on k, $N = (T/w)E_w$, and the ratio w/T. Choosing the units of measurement to make $T = 1$ simplifies the notation. A related scan statistic is the *minimum $(k-1)$th order gap*, W_k, the length of the smallest subinterval that contains k points. W_{k+1} is also referred to as the smallest *k-th-nearest neighbor distance* among the N points. The statistics are related by

$$P(S_w \ge k) = P(W_k \le w) \tag{43.1}$$

Now denote the common probability $P(k; N, w)$. W_N is the sample range, and W_2 is the smallest gap between any pair of points.

$$\begin{aligned} P(2; N, w) &= 1 - [1-(N-1)w]^N \,; \\ &\quad \text{for} \quad 0 \le w \le 1/(N-1) \\ &= 1 \,; \\ &\quad \text{for} \quad 1/(N-1) \le w \le 1 \,. \end{aligned} \tag{43.2}$$

$$\begin{aligned} P(N; N, w) &= Nw^{N-1} - (N-1)w^N \,. \\ &\quad \text{for} \quad 0 \le w \le 1 \,. \end{aligned} \tag{43.3}$$

For a given k and N, the expressions for $P(k; N, w)$ are piecewise polynomials in w with different polynomials for different ranges of w. A direct integration approach can be used to derive the piecewise polynomials for a few simple cases, but it becomes overly complex in general. An alternative combinatorial approach is used by [43.4] to derive the piecewise polynomials for $k > N/2$, with one polynomial for $w \le 0.5$, and another polynomial for $w > 0.5$. For $k > N/2$, $0 \le w \le 0.5$, the formula is particularly simple,

$$\begin{aligned} P(k; N, w) &= [(k - E_w)(1/w) + 1] \\ &\quad \times P(Y_t = k) + 2P(Y_t > k) \,, \\ &= \left[\left(kw^{-1} - \mathrm{N} + 1\right)\right. \\ &\quad \left. \times P(Y_t = k)\right] + 2P(Y_t \ge k) \,, \end{aligned} \tag{43.4}$$

where E_w is $N(w/T)$ and $P(Y_t = k)$ is the binomial probability $b(k; N, w)$

$$b(k; N, w) = \binom{N}{k} w^k (1-w)^{N-k} . \quad (43.5)$$

For $w > 0.5, k > (N+1)/2$, there are some additional terms involving binomials and cumulative binomial terms. This leaves the case $k \le N/2$ when $w \le 0.5$. Below we discuss exact results, tabled values, approximations and bounds that can be used to compute values for some cases. However, for hypothesis testing, [43.5] uses (43.4) as an accurate approximation for small to moderate (< 0.10, and even larger) $P(k; N, w)$ when $k \le N/2, w \le 0.5$.

In Example 1, there were 60 dates of death over a five-year period, and a one-year period with 23 or more deaths. Assuming that the 60 deaths were randomly distributed over the five-year period, $P(S_1 \ge 23 | T = 5) = P(23; 60, 0.2) = 0.029$, obtained by approximating using (43.4).

For certain applications one may seek to evaluate large values of $P(k; N, w)$, where the Wallenstein–Neff approximation may not be sufficiently accurate. In [43.3], Chapt. 8 discusses exact formulae, Chapt. 9 bounds, Chapt. 10 approximations, and Chapt. 2 details of the application of $P(k; N, w)$ to the continuous conditional (retrospective) case. We now give an overview of the types of exact results, other more accurate approximations, and bounds for $P(k; N, w)$.

Exact Results for $P(k; N, w)$

A general expression for $P(k; N, 1/L)$ (where L is an integer), in terms of sums of $L \times L$ determinants, is derived in [43.6]; This is generalized in [43.7] for $P(k; N, r/L)$ in terms of sums of products of several determinants, and simplified further by [43.8] in terms of sums of products of two determinants. These general formulae are computationally intense for small w small as they involve summing determinants of large matrices; however, these formulae can be used to generate the piecewise polynomials that can be used to compute the probabilities for any w. A procedure to do this is given and implemented by [43.9], for $N/3 < k, N/2$. A systematic approach to generating the polynomials is described in [43.10], Table 3, which lists the piecewise polynomials for $N \le 20$. The polynomials are then used to generate (in their Table 1a), $P(k; N, w)$ for $w \le 0.5, k \le N/2$, for $N \le 25$, with w to three decimal places. (Table 1 in [43.10] gives values for all k, for $N \le 25$, with w to two places.)

A powerful general *spacings* approach is derived in [43.11], and is used to find the distribution of W_k, the minimum of the sum of $k-1$ adjacent spacings between times of events. Huffer and Lin also find the maximum sum of $k-1$ adjacent spacings, which is related to the minimum number of events in a scanning window. They use their method to increase the range of values of N and k for which polynomials can be computed, with N as large as 61 for k close to $N/2$.

Approximations

A variety of approximations for $P(k; N, w)$ have been developed based on various combinations of approaches: methods with moments based on spacings, Poisson-type approximations with and without declumping, averaging bounds, using product limit approximations ([43.3], Chapt. 10). To emphasize the connection between higher order spacings and the scan statistic, we describe approximations based on using the method of moments applied to k-th order spacings or gaps. If $X_1 X_2 \ldots X_N$ are the ordered values of the N points in $(0, T)$, then $X_2 - X_1, X_3 - X_2, \ldots$ are the first-order spacings; $X_3 - X_1, X_4 - X_2, \ldots$ are the second-order spacings; and $X_k - X_1, X_{k+1} - X_2, \ldots, X_N - X_{N-k+1}$ are the $(k-1)$-order spacings. (Instead of spacings they are sometimes referred to as gaps, or quasi-ranges). Let $Z_k(w)$ denote the number of $(k-1)$-order spacings that are $\le w$.

$$P(S_w \ge k) = P(Z_k(w) \ge 1) = 1 - P(Z_k(w) = 0) . \quad (43.6)$$

The distribution of $Z_k(w)$ is complex, but it is straightforward to compute the expectation of $Z_k(w)$, and with more effort its variance.

$$\begin{aligned} E[Z_k(w)] &= (N-k+1) P(X_k - X_1 \le w) \\ &= (N-k+1) P(Y_t \ge k-1) . \end{aligned} \quad (43.7)$$

Here Y_t has the binomial distribution described in (43.5). In the method of moments we approximate the distribution of $Z_k(w)$ by a simpler distribution with some of the same moments. For example, choosing the approximating distribution to be Poissonian, with the same first moment, gives the approximation

$$P(S_w \ge k) \approx 1 - \exp[-(N-k+1) P(Y_t \ge k-1)] . \quad (43.8)$$

Note that the same Poisson model could be used to find $P(Z_k(w) \ge n)$, which could be used to approximate the distribution of the number of k-within-w clusters. Approximation (43.8) is not very good in general, because the $(N-k+1)$ overlapping $(k-1)^{st}$-order spacings are not independent. If $X_k - X_1$ is very small, this implies that $X_k - X_2$ is even smaller, which makes for

a greater chance that $X_{k+1} - X_2$ will also be small. A local declumping technique is used [43.12] to adjust for this type of association, and find an approximation of the form $1 - e^{-\mu}$. Approximations of this form, but with different μ values, have been used by [43.13] and others, and [43.14] proves limiting results of this form which suggest their use as approximations; however, care must be taken because the limiting results converge very slowly. *Glaz* in [43.15, 16] and other papers develops better approximations and a variety of bounds.

Moments for Continuous Retrospective Case

To compute the expectation, variance and other moments of S_w or W_k, one could average over the distribution of the statistic, where the cumulative distribution function of W_k is given by $P(k; N, w)$, and of S_w by $1 - P*(k+1; g, w)$. Using this method, [43.6] proves for $(N+1)/2 < k \le N$ that

$$\begin{aligned} E(W_k) &= [k - 2(N-k+1)b]/(N+1)\,, \\ \text{var}\,(W_k) &= (N-k+1)\big[(N+k+1) \\ &\quad + 2(2k-N-1)b \\ &\quad - 4(N+2)(N-k+1)b^2\big] \\ &\quad /(N+1)^2(N+2)\,, \end{aligned} \tag{43.9}$$

where b denotes the binomial term $b[N-k+1; 2(N-k+1), .5]$. Tables for the expectation and variance of W_k, for $\{k = 3, 4, 5; N = k(1)19\}$, $\{k = 6; N = 6(1)17\}$, $\{k = 7; N = 7(1)20\}$, $\{k = 8; N = 8(1)23\}$, and $\{k = 9; N = 9(1)25\}$ are generated in [43.10].

Averaging over exact and simulated values, [43.6] gives means and variances of S_w for $N \le 10$, $w = .1(.1).9$, and [43.17] tabulate means and variances of S_w for $N = 2(1)40, 40(5)70, 85, 100, 125, 150, 200(100)500, 1000$; and $w = 1/T$, $T = 3(1)6, 8, 12$.

43.2.2 Prospective Continuous Case

In certain applications, the researcher is interested in the distribution of the scan statistic given that the total number of events in $(0, T)$ is a random variable. Events are viewed as occurring at random times according to some process. The Poisson process is one completely-at-random chance model. In this process, the number of events $Y_w(t)$ in any interval $[t-w, t)$ is Poisson-distributed with mean E_w. $P[Y_w(t) = k] = p(k; E_w)$ for $k = 0, 1, 2, \ldots$, where $p(k; \lambda)$ denotes the Poisson probability $\exp(-\lambda)\lambda^k/k!$. For the Poisson process, $E_w = wE_1$ where E_1 is sometimes denoted λ; the numbers of events in any disjoint (not overlapping) intervals are independently distributed. There are various other ways to characterize the Poisson process. For the Poisson process, the arrival times between points are independent exponential random variables. Conditional on there being a total of N points from the Poisson process in $[0, T)$, these N points are uniformly distributed over $[0, T)$.

Given that events occur at random over time, let $T_{k,w}$ denote the waiting time until we first observe at least k events in an interval of length w. Formally, $T_{k,w}$ equals $X_{(i+k-1)}$ for the smallest i such that $X_{(i+k-1)} - X_{(i)} \le w$. The three scan statistics S_w, W_k, and $T_{k,w}$ are related by $P(S_w \ge k) = P(W_k \le w) = P(T_{k,w} \le T)$. These probabilities only depend on k, E_1 (the expected number of points in a window of length 1), and the ratio w/T. Denote the common probabilities for the Poisson model case by $P*(k; E_T, w/T)$, where $E_T = TE_1$. In computing $P(S_w \ge k)$ or $P(W_k \le w)$, the formula is sometimes simplified by choosing the scale of measurement to make $T = 1$ and by denoting E_1 by λ; when applying the simplified formula or using tabled values, care must be taken to interpret a λ consistent with the scale of measurement. To avoid confusion in what follows, we use the notation $P^*(k; E_T, w/T)$.

Exact and Approximate Formulae for Cluster Probabilities

In [43.18], asymptotic formulae are derived for $P^*(k; E_T, w/T)$, but these converge very slowly. The exact formulae in [43.8] for $P^*(k; E_T, w/T)$ are computationally intensive.

Table 2 in [43.10] gives $P^*(k; E_T, w/T)$ for $k = 3(1)9$, and a range of values for E_T and w/T. In Table 2, λ denotes E_T. Table 2a in [43.10] gives $P^*(k; 2E_w, 1/2)$, $P^*(k; 3E_w, 1/3)$, $P^*(k; 4E_w, 1/4)$ for $k = 3(1)9$, and a range of values for λ which denote $2E_w, 3E_w and 4E_w$ respectively in that table. Application (d) in [43.10, p. 4] illustrates how to use these values to accurately approximate $P^*(k; 2LE_w, 1/2L)$.

Reference [43.19] derives readily computable formulae for $P^*(k; 2E_w, 1/2)$ and $P^*(k; 3E_w, 1/3)$ and uses them to give the following highly accurate approximation for $P^*(k; E_T, w/T)$. Denote $1 - P^*(k; E_T, w/T)$, by $Q^*(k; E_T, w/T)$; $\exp(-\psi)\psi^j/j!$ by $p(j; \psi)$, and $\Sigma_{i \le k} p(j; \psi)$ by $F_p(k; \psi)$.

$$\begin{aligned} Q^*(k; E_T, w/T) \approx\; & Q^*(k; 2E_w, 1/2) \\ & \times [Q^*(k; 3E_w, 1/3) \\ & / Q^*(k; 2E_w, 1/2)]^{(T/w)-2}\,. \end{aligned}$$

$$
\begin{aligned}
Q^*(k;2\psi,1/2) &= [F_p(k-1;\psi)]^2 - (k-1) \\
&\quad \times p(k;\psi)p(k-2;\psi) \\
&\quad -(k-1-\psi)p(k;\psi) \\
&\quad \times F_p(k-3;\psi)\,, \\
Q^*(k;3\psi,1/3) &= (F_p(k-1;\psi))^3 \\
&\quad - A_1 + A_2 + A_3 - A_4\,, \qquad (43.10)
\end{aligned}
$$

where

$$
\begin{aligned}
A_1 &= 2p(k;\psi)F_p(k-1;\psi)[(k-1)F_p(k-2;\psi) \\
&\quad -\psi F_p(k-3;\psi)]\,; \\
A_2 &= 0.5[p(k;\psi)]^2\Big[(k-1)(k-2)F_p(k-3;\psi) \\
&\quad -2(k-2)\psi F_p(k-4;\psi)+\psi^2 F_p(k-5;\psi)\Big]\,, \\
A_3 &= \sum_{r=1}^{k-1} p(2k-r;\psi)[F_p(r-1;\psi)]^2\,, \\
A_4 &= \sum_{r=2}^{k-1} p(2k-r;\psi)p(r;\psi)[(r-1) \\
&\quad \times F_p(r-2;\psi)-\psi F_p(r-3;\psi)]\,.
\end{aligned}
$$

Subsequent researchers [43.20] note the remarkable accuracy of this approximation. Tight bounds for $Q^*(k;E_T,w/T)$ are derived by [43.21], who proves that approximation (43.10) falls within the bounds. Our experience is that it gives great accuracy over the entire range of the distribution. For example, $P^*(4,10;0.1) = 0.374$, $P^*(5;12,0.25) = 0.765$; $P^*(5;8,1/6) = 0.896$ by both the approximation and the exact tabled values in [43.10]. One can readily compute $Q^*(k;2E_w,1/2)$ and $Q^*(k;3E_w,1/3)$ for any k or E_w, or use tabled values. An even better approximation can be obtained by taking

$$
\begin{aligned}
Q^*(k;\lambda T,w/T) &\approx Q^*(k;\lambda,1/3) \\
&\quad \times [Q^*(k;4\lambda,1/4) \\
&\quad /Q^*(k;\lambda,1/3)]^{(T/w)-3}\,. \qquad (43.11)
\end{aligned}
$$

One can use values from Table 2a in *Neff* and *Naus* for $Q^*(k;\lambda,1/3)$ and $Q^*(k;4\lambda,1/4)$; or alternatively compute $Q^*(k;4\lambda,1/4)$ using the results of [43.8]. This generalizes naturally to even more accurate approximations. Recently [43.22] other highly accurate approximations for $Q^*(k;L\lambda,1/L) = Q_L$ have been developed, together with error bounds. Using terms of the form $Q^*(k;\lambda,1/r) = Q_r$, for $r = 2,3,4,\ldots$; for example, approximation (1.18) from that work uses Q_2 and Q_3, and has a relative error $< 3.3(L-1)(1-Q_2)^2$, for $L > 4$, if the error bound is small relative to 1. Approximation (1.17) uses Q_r for $r = 2,3,4,5$, and has a smaller error bound, under certain conditions.

A simpler approximation is derived by [43.23], which is computable on a calculator, and is reasonably accurate for small to moderate values of $P^*(k;\lambda T,w/T)$ that might be used when testing hypotheses for unusual clusters.

$$
\begin{aligned}
P^*(k;E_T,w/T) &\approx 1 - F_p(k-1;E_w) \\
&\quad \times \exp[-[(k-E_w)/k)] \\
&\quad \times \lambda(T-w)p(k-1;E_w)]\,. \qquad (43.12)
\end{aligned}
$$

For larger values of $P^*(k;E_T,w/T)$, (43.12) may not be accurate. For example, (43.12) gives $P^*(5,12,25) \approx 0.555$, as compared to the exact value of 0.765. In certain applications one seeks the distribution or moments of distribution of S_w, or the related statistics W_k, or $T_{k,w}$. If formulae for the moments are not available, one could average over the approximate distribution of the statistic, but in this case one would want to use an approximation that is accurate over the range of the distribution.

Example 2: A telecommunications engineer seeks to develop a system with the capacity to handle the possibility of multiple calls being dialed simultaneously. Dialing times start at random according to a Poisson process, with a 10 s dialing time. During an average 8 h busy period, 57 600 calls are dialed. The engineer asks how likely it is that at some point in the 8 h busy period there will be 50 or more phone calls being dialed simultaneously. There are an infinite number of overlapping intervals, each of 10 s duration, in an 8 h period. The maximum number of calls in any of the infinite number of overlapping windows is the scan statistic S_w. Here we are scanning a $T = 28\,800$ s period that has an expected number of calls $E_{28800} = 57600$, with a scanning window of $w = 10$ s, and asking how likely it is that $S_{10} \geq 50$. The answer needs to take into account the multiple comparisons involved in scanning the infinite number of overlapping 10 s periods within an 8 h period, and is given by $P^*(50;57600,10/28800)$, computed by (43.10) or (43.12).

Moments of Scan Statistic Distributions: Continuous Prospective Case

To compute the expectation, variance and other moments of S_w, W_k or $T_{k,w}$, one could average over the distribution of the statistic, where the cumulative distribution functions of W_k or $T_{k,w}$ are given by $P^*(k;E_T,w/T)$, and of S_w by $1 - P^*(k+1;E_T,w/T)$. To derive formula or compute the moments, one could use either the

exact formula or approximation (43.10), which is highly accurate over the range of the distribution.

Example 3: A window information flow control scheme is described in [43.24] where a sender of information packets stops sending when there is evidence of overload. An open-loop control mechanism avoids feedback delays by basing the control mechanism on the maximum number of information packets in a sliding time window of fixed prespecified length, the scan statistic. Strong approximations are used in [43.24] to derive asymptotic (for $T \gg w > \log T$) results for $P(S_w \geq k)$. For $w = 20$, $T = 1\,000\,000$ and a Poisson process with an average of one observation per unit of time, their asymptotic approximation gives $\mathrm{AVE}(S_w) = 42$, compared to their simulated value of 44.5. Reference [43.3] (pp. 33–34) uses approximation (43.10) to compute $Q^*(k; 1\,000\,000, 20/1\,000\,000)$ for $k = 41(1)52$), which gives all of the distribution needed to compute $AVE(S_w) = \Sigma_{k>1}[1 - Q^*(k)] \approx 44.84$. This is because for $k < 41$, $Q^*(k) < Q^*(41) \approx 6.6E-7$; and for $k > 52$, $Q^*(k) > Q^*(52) \approx 0.9999$.

Various approximations are given by [43.25] and [43.26] for moments of $T_{k,w}$. For the Poisson process, [43.26] gives approximations and bounds for the expectation and variance of $T_{k,w}$, and bounds for the expectation for general point processes with i.i.d. interarrival times between the points. Details are given for the Poisson, Bernoulli, and compound Poisson processes. We now discuss Samuel–Cahn's results for the Poisson case. Let $\delta_{k,w}$ denote the total number of points observed until the first cluster of k points within an interval of length w occurs. Note that $\delta_{k,w}$, $T_{k,w}$, S_w, and W_k are different but interrelated statistics associated with the scanning process. For a Poisson process with mean λ per unit time, the expected waiting times between points is $1/\lambda$. She applies Wald's lemma, to find for the Poisson case,

$$E(T_{k,w}) = E(\delta_{k,w})/\lambda \,, \tag{43.13}$$

and derives a series of approximations for $E(\delta_{k,w})$. The simplest of these is

$$E(\delta_{k,w}) \approx k + \left\{ [F_p(k-2; \lambda w)]^2 / P(\delta_{k,w} = k+1) \right\} , \tag{43.14}$$

where

$$P(\delta_{k,w} = k+1) = \sum_{i=0}^{k-2} (-1)^{k-2-i} p(i; \lambda w) + (-1)^{k-1} \exp(-2\lambda w) \,, \tag{43.15}$$

and where $p(i; \lambda w)$ and $F_p(k-2; \lambda w)$ are Poisson terms defined before (43.10).

43.2.3 Discrete Binary Trials: The Prospective Case

In start-up tests for a piece of equipment, the equipment might perform successfully on the first test trial, then fail on the second. Consecutive points in a QC chart may be in or out of a warning zone. In a stream of items sampled from an assembly line, some are defective while some are acceptable. Here the data is viewed as a sequence of T binary outcome trials. Each trial t results in a "success" or "failure." For $t = w, w+1, \ldots, T$, $Y_t(w)$ and $E_t(w)$ are the observed and expected number of "successes" within the w consecutive trials, $t-w+1, t-w+2, \ldots, t$.

The scan statistic S_w is the maximum number of successes within any w contiguous trials within the T trials. For the special case where $S_w = w$, a *success-run* of length w has occurred within the T trials. When $S_w = k$, a *quota* of k successes within m consecutive trials has occurred. Related statistics include W_k, the smallest number of consecutive trials that contain k ones; $T_{k,w}$, the number of trials until we first observe at least k ones in an interval of length w; and V_r, the length of the longest number of consecutive trials that have at most r failures. V_0 is the length of the longest success run. The statistics are related by $P(S_w \geq k) = P(W_k \leq w) = P(T_{k,w} \leq T)$, and $P(V_r \geq k+r) = P(S_{k+r} \geq k)$. We illustrate these statistics in the following example.

Example 4: The DNA molecule most often consists of two complementary strands of nucleotides each consisting of a deoxyribose residue, a phosphate group, and a nucleotide base. The four nucleotide bases are denoted A, C, G, T, where an A on one strand links with a T on the other strand, and similarly C with G. Molecular biologists sometimes compare DNA from two different sources by taking one strand from each, viewing each as a linear sequence of the letters A, C, G, T, aligning the two sequences by a global criterion, and then looking for long perfectly or almost perfectly matching "words" (subsequences). For illustration, consider the following two aligned sequences from two different plant proteins. If letters in the same position in the two sequences match, we put an "s" at that position; if not an "f"

Source 1: A A A C C G G G C A C T A C G G T G A G A C G T G A

Source 2: A A T C C C C C G T G C C C T T A G A G G C G T G G
Match: s s f s s f f f f f f f f s s s f s s s f s s s s f
The longest perfectly *matching word* is CGTG, corresponding to a success run of length 4. For the s/f sequence, $V_o = 4$. We note that the longest word with at most one mismatch is of length eight letters (underlined). Here $V_1 = 8$. If we had scanned the sequence of $T = 26$ aligned pairs of letters, looking for the largest number of matches within $w = 8$ letters, we would find $S_8 = 7$. If we had looked for the smallest number of consecutive letters containing seven matches, we would find $W_7 = 8$. The waiting time until we first observe seven matches within eight consecutive letters is $T_{7,8} = 25$.

Exact Results

There are a variety of algorithms to compute the distribution of the prospective discrete scan statistic exactly. Recursion relations and generating functions for the special cases of $k = w - 1$ and $k = w$ are given in [43.27]. The Markov chain imbedding approach was applied in [43.28] and [43.29] to derive an exact formula for the expected waiting time until a k-in-w quota, and is refined and unified in [43.30] to be efficient for computing the distributions of runs and scans. Useful recurrence relations and other formulae are given in [43.31–33]. Recently, a martingale approach has been used to find generating functions and moments of scan statistics [43.34].

Recent studies [43.35] and [43.36] into the computational complexity of the Markov chain approach to find exact results for the discrete scan statistic shows that it is computationally feasible. Many of the results are motivated by quality control and acceptance sampling applications [43.27, 33, 37]. Other recent results are motivated by the reliability of linear systems, where the system fails if any k within w consecutive components fail [43.1, 30, 38–40].

Approximate Results

There are asymptotic results for $P(S_w \geq k)$ for a variety of probability models that are called *Erdös–Rényi laws*, or Erdös–Rényi–Shepp theorems. DNA and protein sequence matching has stimulated further generalizations (see [43.41–44]). A simple random model is the Bernoulli trials model, where the T trials are independent binary trials, with a probability of "success" on trial t equal to a constant value p. Reference [43.45] reviews and proves some important general limit law results (as T tends to infinity), and shows how they apply in the special case of a Bernoulli process. The asymptotic results converge quite slowly, and for certain applications give only rough approximations ([43.3], pp. 233-235). Various approximations to $P(S_w k)$ are derived using the method of moments, a Poisson approximation using declumping, and other methods [43.46].

For the Bernoulli process, denote $P(S_w \geq k)$ by $P'(k|w; T; p) = 1 - Q'(k|w; T; p)$.

In [43.19], the following highly accurate approximation is given for $Q'(k|w; T; p)$. Let $b(k; w, p)$ be the binomial probability defined in (43.5), and let

$$
\begin{aligned}
F_b(r; w, p) &= \Sigma_{i<r} b(i; w, p)\,, \\
Q'(k|w; T; p) &\approx Q'(k|w; 2w; p)\left[Q'(k|w; 3w; p)\right. \\
&\quad \left./\,Q'(k|w; 2w; p)\right]^{(T/w)-2}\,, \\
Q'(k|w; 2w; p) &= [F_b(k-1; w, p)]^2 \\
&\quad -(k-1)b(k; w, p) \\
&\quad \times F_b(k-2; w, p) \\
&\quad + wpb(k; w, p) \\
&\quad \times F_b(k-3; w-1, p)\,, \\
Q'(k|w; 3w; p) &= (F_b(k-1; w, p))^3 \\
&\quad - A_1 + A_2 + A_3 - A_4\,, \qquad (43.16)
\end{aligned}
$$

where

$$
\begin{aligned}
A_1 &= 2b(k; w, p)F_b(k-1; w, p)\,[(k-1) \\
&\quad \times F_b(k-2; w, p) - wpF_b(k-3; w-1, p)]\,; \\
A_2 &= 0.5[b(k; w, p)]^2\left[(k-1)(k-2)\right. \\
&\quad \times F_b(k-3; w, p) \\
&\quad -2(k-2)wpF_b(k-4; w-1, p) \\
&\quad \left.+(w-1)p^2F_b(k-5; w-2, p)\right]\,; \\
A_3 &= \sum_{r=1}^{k-1} b(2k-r; w, p)[F_b(r-1; w, p)]^2\,; \\
A_4 &= \sum_{r=2}^{k-1} b(2k-r; w, p)b(r; w, p)\,[(r-1) \\
&\quad \times F_b(r-2; w, p) - wpF_b(r-3; w-1, p)]\,.
\end{aligned}
$$

The following simpler, and fairly accurate, approximation is suggested in [43.47].

$$
P'(k|w; T; p) \approx 1 - \left[C(D/C)^{(T/w)-2}\right]\,, \qquad (43.17)
$$

where

$$
\begin{aligned}
C &= 2\Sigma_{i<k} b(i; w, p) - 1 - (k-1-wp)b(k; w, p)\,, \\
D &= 2\Sigma_{i<k} b(i; w, p) - 1 - (2k-1-2wp) \\
&\quad \times b(k; w, p)\,.
\end{aligned}
$$

Example: $k = 8$, $w = 10$, $p = 0.3$, $T = 50$. Applying (43.16), $Q'(8|10; 20; 0.3) = 0.991032$; $Q'(8|10; 30; 0.3) = 0.983827$; $P'(8|10; 50; 0.3) \approx 0.03$.

Applying (43.17) gives $C = 0.991032$; $D = 0.9837985$; $P'(8|10; 50; 0.3) \approx 0.03$. Both of these results agree with the exact result from the Markov Chain imbedding approach.

In some applications the researcher is interested in scanning for unusual clusters of successes or clusters of failures. One can use the above results to bound the probability of either type, or can use the Markov Chain imbedding or another approach to compute the probability directly [43.39]. In other applications, individual trials can result in an integer number of points and [43.48] derives accurate approximations and tight bounds for this case.

Moments of Discrete Trial Scan Statistics

An accurate approximation for the expected waiting time until a k in w cluster in a Bernoulli trials, with a probability p of *success* on an individual trial, is given in [43.19]

$$E(T_{k,w}) \approx 2w + Q'(k|w; 2w; p) \Big/ \left\{1 - [Q'(k|w; 3w; p) \Big/ Q'(k|w; 2w; p)]^{1/w}\right\} . \quad (43.18)$$

More complicated formulae for the exact expectation, and methods to find it, are given in [43.28, 29], and other approximations in [43.26] for the expectation and variance of the waiting time for the Bernoulli and more general processes.

An important generalization is to the case of independent binary trials with unequal probabilities. For many results see [43.1]. Reliability engineers have been studying the reliability of a linearly ordered set of N independent components with different probabilities of being defective. In the *k-within-consecutive-m-out-of-N systems*, the system fails if there is a quota of k defectives within any m consecutive components in the system (see [43.40, 49]).

43.2.4 Discrete Binary Trials: The Retrospective Case

In this discrete scenario, the data is viewed as a sequence of T binary outcome trials. Each trial t results in a "success" or "failure." S_w is the largest number of successes in any w consecutive trials. A simple random model is where there are N successes distributed at random over the T trials. Denote $P(S_w \geq k)$ by $P(k|w; N, T)$.

The exact distribution of $P(k|w; N, T)$ for the case $k > N/2$ is given in [43.31]. This formula can also be used to approximate small values of $P(k|w; N, T)$ for $k < N/2$, and the approximation is given below in (43.19). Reference [43.50] derives the exact distribution for all N and k, for $m/N = 1/L$, L an integer, and more generally for $m = cR$, $N = cL$, where c, R, and L are integers, and $c > 1$. These general formulae are computationally complex, but can be used to derive simpler formulae for special cases. These formulae can also be used to approximate other cases.

Approximations and bounds for $P(k|w; N, T)$ are given in [43.3] (pp. 56–58, 212–216) and in [43.1] (pp. 319–323). These can then be used to approximate the moments of the distributions of S_w and W_k. A simple approximation is given by

$$P(k|w; N, T) = [(k - E_w)(1/w) + 1]P(Y_t = k) + 2P(Y_t > k) , \quad (43.19)$$

where

$$E_w = N(w/T) ;$$

$$P(Y_t = k) = H(k, N, w, T) = \binom{w}{k}\binom{T-w}{N-k} \Big/ \binom{T}{N} .$$

For the case where w and T are large, the discrete retrospective scan probability $P(k|w; N, T)$, can be approximated by the continuous retrospective scan probability $P(k; N, w/T)$.

43.2.5 Ratchet-Scan: The Retrospective Case

In the ratchet scenario, time is divided into T disjoint intervals (hours, days, or weeks) and the reported data consists of the number of events in each interval. For $t = w, w+1, \ldots, T$, $Y_t(w)$ and $E_t(w)$ are the observed and expected number of events within the w consecutive intervals, $t - w + 1, t - w + 2, \ldots, t$. For the constant background retrospective case there are N events spread at random over the T intervals. (The model is multinomial where each of the N balls is equally likely to fall in any of the T cells, independently of the other balls.) Here $\lambda = wN/T$. Approximations and bounds for $P(k; \lambda, w, T)$ are described in [43.3] (pp. 327–328), [43.2] (p. 81–91), and [43.51]. The simple Bonferroni upper bound is

$$P(k; \lambda, w, T) < (T - w + 1)\Sigma_{i \geq k} b(i; N, p) , \quad (43.20)$$

where $N = T\lambda/w$; $p = 1/T$. Note also that $P(k; \lambda, w, T)$ for the ratchet scan must be less than that for the continuous scan. Thus, $P(k; \lambda, w, T)$ for the retrospective ratchet scan must be less than the right-hand side of (43.5)

43.2.6 Ratchet-Scan: The Prospective Case

In the ratchet scenario, time is divided into T disjoint intervals (hours, days, or weeks) and the reported data consists of the number of events in each interval. For $t = w, w+1, \ldots, T$, $Y_t(w)$ and $E_t(w)$ are the observed and expected number of events within the w consecutive intervals, $t-w+1, t-w+2, \ldots, t$. For the constant background prospective case the number of events (counts) in the T intervals are T independently and identically distributed Poisson random variables, each with expectation λ/w. For the prospective ratchet scan constant background case, the approach in [43.5] gives the following approximation:

$$P(k; \lambda, w, T) \approx (T-w+1)G(k, \lambda) - (T-w) \times \Sigma_{j=0} p(j, \lambda)[G(k-j, \lambda/w)]^2 , \quad (43.21)$$

Here $p(j, \lambda)$ is the Poisson probability defined in (43.20), and

$$G(k, \lambda) = \Sigma_{j \geq k} p(j, \lambda) .$$

For the case where the number of events in the T intervals are independently and identically distributed random variables, [43.48] derives accurate approximations and tight bounds for $P(k; \lambda, w, T)$.

43.2.7 Events Distributed on the Circle

When studying seasonality effects of disease patterns over time, one might be interested in unusual clustering during certain periods of the year. The researcher may view the time period as a circle, with January following December. In studying the directions of flights of birds or insects, the directions may be viewed as points on a circle. Many of the distributional results described above for the line have also been derived for scan statistics on the circle. The circular ratchet scan was introduced in [43.52] and further developed in [43.51]; accurate approximations for the continuous scan on the circle and line are given in [43.19]; and for the discrete scan on the circle in [43.53].

43.3 Higher Dimensional Scans

Scan statistic have been applied extensively to study the clustering of diseases over space. In two dimensions, circular, rectangular, elliptical and other shaped scanning windows are used. Regions scanned can have arbitrary shapes (typical in epidemiology), or the surface of a sphere (astronomy or ships at sea), or approximately rectangular (blood cells on a slide). In three dimensions, two of which may be spatial and one temporal, cylindrical scanning windows may be used. In the case where all three dimensions are spatial, a scanning sphere or cube may be used. Scan distributions have been approximated or simulated for events from homogeneous or heterogeneous Poisson processes, uniform, or more generally distributed points in continuous space, and for various models for two-dimensional grids. Simulation is the most widely applied approach, but can be computationally intensive for a large number of points. Not only must the points be generated, but one must check all possible positions of the scanning window, and in variable-size window applications [43.54–57] each of the window sizes must be checked too. A variety of algorithms have been developed to simulate scan probabilities in two dimensions. Efficient Monte Carlo algorithms for one and two dimensions are developed in [43.55, 58, 59]; (see [43.3], Chapt. 16). Importance sampling can be used to reduce the computational effort of the simulation [43.60]. A web-based program, SatScan [43.56], is available that scans generally distributed points over an arbitrarily shaped region with circular scanning windows (with a variety of diameters).

In two dimensions, the points are randomly distributed over a two-dimensional region. A circular (or rectangular or other shaped) window scans the region. The scan statistic S_w is the largest number of points in any window of diameter w; the scan statistic W_k generalizes to the diameter of the smallest scanning window that contains k points. The distributions of the statistics S_w and W_k are still related, $P(S_w \geq k) = P(W_k \leq w)$. However, in more than one dimension, W_{k+1} is not equivalent to the smallest k-th-nearest neighbor distance among the N points. Section 43.3.1 discusses the retrospective case of a fixed number of points in the unit square; Sect. 43.3.2 discusses the prospective case where the number of points is Poisson distributed.

43.3.1 Retrospective Continuous Two-Dimensional Scan

We first focus on the problem of scanning a rectangular region with a rectangular window with sides of length u and v that are oriented parallel to the sides of the square. There are a fixed number, N, of points distributed over the rectangular region, The units of measurement are chosen to make the rectangular region the unit square. The results for the unit square give the results for an $a \times b$ scanning window within an $S \times T$ rectangular region, by choosing the units of measurement for the $x-$ and $y-$axes to make $S = 1$ unit on the x-axis, and $T = 1$ unit on the y-axis, and by setting $u = a/S$ and $v = b/T$.

Given N points distributed at random over the unit square, let $S_{u,v}$ denote the maximum number of points in any subrectangle with sides of length u and height v parallel to the sides of the unit square. Let $P(k; N, u, v)$ denote $P(S_{u,v} \geq k)$. Bounds for $P(k; N, u, v)$, that converge for small u, v are given in [43.61], and the approximation for this case is

$$P(k; N, u, v) \cong k^2 \binom{N}{k} (uv)^{k-1} . \tag{43.22}$$

An exact formula is available for $P(N-1; N; u, v)$, (see [43.3], Chapt. 16). The following approximation by [43.62] is based on large deviation theory

$$\begin{aligned} P(k; N, u, v) \cong & \left\{ \left[N^2 w(1-u)(1-v)E^3 \right. \right. \\ & \left. \left. /(1-w)^3(1+E) \right] + C \right\} \\ & \times b(k; N, w) , \end{aligned} \tag{43.23}$$

where

$$\begin{aligned} w &= uv,\ E = (k/Nw) - 1 ; \\ b(k; N, w) &= \binom{N}{k} w^k (1-w)^{N-k} , \\ C &= [Nv(1-u)E/(1-w)] \\ &\quad + \left[Nu(1-v)E^2/(1+E)(1-w)^2 \right] \\ &\quad + [(1+E)(1-w)/E] . \end{aligned}$$

The approximation is refined further in [43.62], but (43.23) appears to give good accuracy for small $P(k; N, u, v)$. Simulation is used to evaluate larger values of $P(k; N, u, v)$. Order the points by the X coordinates, with $X_1 < X_2 \leq ... \leq X_N$. For each $i = 1, ..., N - k + 1$, check whether $(X_{k+i-1} - X_i \leq u)$, and if so, whether the corresponding Y's fall within a distance v.

For the case of a circular scanning window of radius r, the algorithm looks at pairs of points within a distance $2r$, finds the two circles of radius r on which the two points fall on the circumference, and counts the number of points in each of the circles.

The above generalizes to higher dimensions. Scan the r-dimensional unit cube with a rectangular block with sides of length $u_1, ..., u_r$, oriented parallel to the sides of the unit cube. Let $w = \prod u_i$ denote the volume of the scanning rectangle. Let $P(k; N, u_1, u_2, ..., u_r)$ denote the probability that at least one scanning rectangular block with sides $(u_1, u_2, ..., u_r)$ parallel to those of the unit cube contains at least k points. In corollary 2.3, [43.63] gives the approximation for $r = 1, 2, 3$

$$\begin{aligned} P(k; N, u_1, u_2, ..., u_r) \cong & \{1 - [Nw/k(1-w)]\}^{2r-1} \\ & \times (k^r/w) b(k : N, w) , \end{aligned} \tag{43.24}$$

where $w = \prod u_i$, and $b(k; N, w)$ is the binomial probability in (43.23). For the case $r = 2$, (43.24) does not reduce exactly to (43.23), but gives similar values for small probabilities.

43.3.2 Prospective Continuous Two-Dimensional Scan

Let the number of points in the unit square be a Poisson-distributed random variable with mean λ. Scan the unit square with a subrectangle with sides of length u and v that are parallel to the sides of the square. Let $P^*(k; \lambda, u, v)$ denote the probability that at least one uxv-scanning subrectangle contains at least k points. Several approximations from [43.64] and [43.65] are given for $P^*(k; \lambda, u, v)$, with the best approximation being (from [43.65]):

$$\begin{aligned} P^*(k; \lambda, u, v) \cong & 1 - F_p(k-1; \lambda uv) \\ & \exp\{-\zeta(1 - (\lambda uv/k))\lambda v(1-u) \\ & \times p(k-1; \lambda uv)\} , \\ \zeta = & [1 - (\lambda uv/k)]\lambda u(1-v) \\ & \times [P^*(k-1; \lambda v, u) \\ & - P^*(k; \lambda v, u)] ; \\ F_p(k-1; \lambda uv) = & \sum_{i=0}^{k-1} p(i; \lambda uv) , \end{aligned} \tag{43.25}$$

where $P^*(k; \lambda v, u)$ is the one-dimensional scan statistic. A simpler but rougher approximation is

$$\begin{aligned} P^*(k; \lambda, u, v) \cong & 1 - [1 - P^*(k-1; \lambda v, u)] \\ & \exp(-\zeta) . \end{aligned} \tag{43.26}$$

For the case of scanning an $S \times T$ rectangular region with a circular window of radius r, let $r\pi^{0.5}/S = u$, $r\pi^{0.5}/T = v$, and choose the X- and Y-scales so that $S = 1$ and $T = 1$. Let $P_c^*(k; \lambda, u, v)$ denote the probability that the maximum number of points in the scanning window is at least k, where λuv denotes the expected number of points in a circle of radius r. The following approximation is given in [43.64]:

$$P_c^* \cong 1 - \exp[-k\lambda(1-2u)(1-2v)p(k-1; \lambda uv)] . \quad (43.27)$$

The simulations in [43.65, 66] show that for small u, v, $P_c^* \cong P^*(k; \lambda, u, v)$. For small u, v, we approximate the circular window by a square window of the same area.

Researchers continue to develop more accurate approximations for the distribution of the two-dimensional scan statistic for the Poisson process; see [43.67] and [43.25]. Other researchers seek to generalize the asymptotic results and some approximations to higher dimensions or more general scanning regions. The approach of [43.65] is generalized in [43.66] to give approximations for more than two dimensions. Recent research [43.68] derives approximate results with error bounds for one and higher dimensions for general distributions, and general bounded scanning sets, and uses these results to prove various asymptotic results. Poisson approximation and large deviation theory has been used in [43.69] to derive very general results for scanning spatial regions of two and more dimensions.

43.3.3 Clustering on the Lattice

In some applications, events can only occur on a grid of points; a recent example [43.70] deals with the reliability of a two-dimensional system. Another example involves clustering of diseased plants in a field of evenly spaced plants. In other applications, the method of measurement limits the observed events to occurring on a rectangular R by T lattice of points. The researcher scans the grid looking for unusual clusters. Results have been developed for several models; The researcher scans the lattice with a rectangular m_1 by m_2 sublattice with sides parallel to those of the lattice; events are independent and equally likely to occur at any point of the lattice. This case is the discrete analog of the continuous prospective case with an oriented rectangular scanning window, as discussed in Sect. 43.3.2.

Let X_{ij} for $i = 1, .., R$; $j = 1, ..., T$ denote a rectangular lattice of independent and identically distributed Bernoulli random variables, where $P(X_{ij} = 1) = p = 1 - P(X_{ij} = 0)$. View the lattice with position (1,1) in the lower left corner. Let $Y_{r,s}(m_1, m_2)$ denote the number of events (ones) in an m_1 by m_2 subrectangle whose lower left corner is at (r, s) in the lattice. Denote the *two-dimensional discrete scan statistic* $S'_{m1,m2}$, the maximum number of events in the scanning subrectangle when we scan the R by T lattice with an m_1 by m_2 rectangle of points (with sides oriented with the sides of the lattice).

Algorithms are given in [43.71] to find the largest rectangle with all 1's in the lattice, and [43.71] generalizes the limit law to higher dimensions, and to allow for some 0's in the subrectangle. Approximations for $P\left(S'_{m1,m2} \geq k\right)$ are given in [43.72]. For the special case of a square lattice, $R = T$, and a square scanning subrectangle $m_1 = m_2 = m$, let B_s denote the event $[Y_{1,s}(m, m) < k]$. Then,

$$P\left(S'_{m,m} \geq k\right) \cong 1 - q(2m-1) \times [q(2m) / q(2m-1)]^{(T-2m+1)(T-m+1)} , \quad (43.28)$$

where

$$q(2m-1) = P(B_1 B_2 ... B_m) ,$$
$$q(2m) = P(B_1 B_2 ... B_{m+1}) .$$

The terms $q(2m-1)$ and $q(2m)$ can be evaluated using an algorithm in [43.73].

For m_1, m_2, R, and T all large, the discrete scan probability can be approximated by the continuous case probability in Sect. 43.3.2.

$$P^*(k; \lambda, u = m_1/R; v = m_2/T) \cong P\left(S'_{m,m} \geq k\right) . \quad (43.29)$$

43.4 Other Scan Statistics

43.4.1 Unusually Small Scans

Scan statistics have been developed to test for unusually sparse intervals of time, or regions of space. Given N points independently drawn from the uniform distribution on [0, 1), let D_w denote the smallest number of points in an interval of length w; let V_k denote the size of the largest subinterval of [0, 1) that contains k points.

The statistics are related:

$$P(D_w \le k) = P(V_k \ge w)\,. \tag{43.30}$$

The scan statistic V_{k+1} can be viewed as the maximum of the sum of k consecutive spacings. The interval V_{r+1} is called the "maximum r-th-order gap".

A variety of results have been derived for the related statistics D_w and V_k. In [43.14] asymptotic results are derived for the distributions of order statistics of r-th order gaps, for i.i.d. distributed spacings (gaps between consecutive points) and some more general uniform mixing stationary processes. For the special case of a minimum r-scans of $n(= N+1)$ i.i.d. uniform [0, 1) spacings, they give

$$\lim_{n->\infty} P\{V_{r+1} \le [\log_e n + (r-1) \times \log_e \log_e n + y]/n\} = \exp[\,e^{-y}/(r-1)!]\,. \tag{43.31}$$

The asymptotic convergence of (43.31) is very slow, and care must be taken in using it as an approximation. For the case of N uniformly distributed points on the line, the exact distribution of D_w and V_k are derived in [43.74]. The formulae are computationally intensive, but can be applied to derive special cases that can be used to find highly accurate approximations similar in form to (43.16). A general approach to finding the distribution of V_k is described in [43.11].

For a sequence of Bernoulli trials, the distribution of the minimum scan can be computed using the formula for the maximum scan. Let D_w^* denote the minimum number of successes in any w consecutive trials. Then $D_w^* \ge k$ if the maximum number of failures in any w trials is less than or equal to $w-k$.

The distribution of the minimum scan for the line and circle is related to a multiple coverage problem. The multiple coverage problem is as follows: Given N subarcs each of length w dropped at random on the circumference of the unit circle, what is the probability that the arcs completely cover the circumference of the circle at least m times? To relate the coverage to the scan problem, let the N points in the scan problem correspond to the midpoints of the subarcs in the coverage problem. If the N subarcs do not cover the circle m times, there must be some point on the circumference not covered enough. This implies that the subinterval of length w centered at that point contains fewer than m of the N midpoints of the N subarcs; in this case, the minimum number of the N (mid)points in a scanning window of length w must be less than m.

43.4.2 The Number of Scan Clusters

There are several ways to count clusters depending on the overlap allowed between two clusters. For example, suppose we scan (0,1) with a window of width $w = 0.20$, looking for clusters of at least $k = 3$ points. Assume that we observe the six points: 0.10, 0.15, 0.28, 0.34, 0.41, 0.62. One approach to counting the number of 3-within-0.20 clusters is to see how many of the 2-spacings are $< w$. Here, $0.28 - 0.10 = 0.18 < w$, $0.34 - 0.15 = 0.19 < w$, $0.41 - 0.28 = 0.13 \le w$, and $0.62 - 0.34 > w$. We would count three clusters. Note that two clusters share some (but not all) points, and this case is sometimes referred to as a nonoverlapping case. For the conditional case, expressions are available for the expectation and variance of the number of clusters. See [43.75] and [43.11] for this method of counting. Results are derived in [43.14] for the distribution of the number of clusters that do not overlap with a previously counted cluster A Markovian declumping is used in [43.76] and [43.77], where an r-spacing$< w$ is counted so long as the immediately previous r-spacing is not counted. A compound Poisson approach to counting the number of clumps is applied in [43.11, 76, 78] and [43.12]. This is generalized in [43.79] to two and higher dimensions. See ([43.3], Chapt. 17) for a summary of many of the results for the continuous scan.

For a sequence of trials, ([43.1], Chapt. 10) describes in detail the Markov chain approach to finding the distribution of the waiting time until the k-th discrete scan cluster, for different ways of counting clusters. In Chapt. 4, [43.1] discusses the discrete counting approach for the case of runs, and there is a great deal of literature on the number of overlapping and nonoverlapping runs; see also [43.80]. In [43.81], a compound Poisson approximation is used for the multiple cluster problem, and the motivating example is the clustering of individual claims exceeding threshold risks.

43.4.3 The Double-Scan Statistic

In [43.82], a scan-type statistic called the *double-scan statistic* is defined based on the number of "declumped" (a type of nonoverlapping) clusters that contain at least one of each of two types of event. The expectation and approximate distribution of the number of declumped clusters is derived for this test statistic for two chance models. Define the event $E(i)$ to have occurred if there are at least one of each of the two types of events anywhere within the w consecutive days $i, i+1, \ldots, i+w-1$. The event $E(i)$ indicates the occurrence

of a two-type w-day cluster. Let $Z(i) = 1$ if $E(i)$ occurs and none of $E(i-1)$, $E(i-2)$, ..., $E(i-w+1)$ occur; $Z(i) = 0$ otherwise. Let $S_{w(2)} = \Sigma_{1<i<N-w+1} Z_i . S_{w(2)}$ is the *double scan statistic*. This method counts the number of times that an $E(i)$ occurs with no previously overlapping $E(i)$'s. When the events are relatively rare and distributed according to certain chance models, the number of these declumped clusters is approximately Poisson-distributed [43.64]. This model fits well when the two types of events do not occur too frequently. As the density of the number of events increases, there comes a point where more events lead to fewer clusters. In [43.83], the distributions of a family of double-scan statistics are derived using a different approach to count clusters. This method treats clusters as recurrent events, and counts the number of times that an $E(i)$ occurs with no previously overlapping $E(i)$'s that were counted in a cluster.

The double-scan statistic can be generalized, for the case of two types of events, to clusters where there are at least r type one and s type two events within a w-day period. For other applications, the statistics can be generalized to more than two types of events, and the distribution of the number of declumped clusters can be derived.

43.4.4 Scanning Trees and Upper Level Scan Statistics

The scanning approach has been extended to a variety of data structures. In two-dimensional geographic scanning, the SatScan [43.56] simulation approach uses a range of circular window sizes to detect unusual clusters. When studying patterns of disease, a researcher may be looking for connected regions (such as counties) with above-average concentrations of disease. These regions may not all fall within a compact circular, elliptical or other simple shape. One can still scan for these linked high-density regions, and [43.84] develops a "higher-level scan" approach for assessing the unusualness of clusters that arise.

In other situations, the researcher may not be looking for clusters of disease in space, but instead for some other variable such as occupation. One might try to scan a data set combining occupations that have above-average incidence. However, scanning all possible combinations involves so many multiple comparisons that the test statistic adjusted for this would not be powerful, and the results would be difficult to interpret. In the case of occupations (and many other variables) the data can be placed in the form of a tree structure (for example, a carpenter, electrician, plumber are all under building trades). In [43.85] an approach is given to scanning data in a tree structure, looking for unusual clusters, and adjusting for the multiple comparisons made.

In some applications one seeks to scan with a range of window sizes. Simulation is typically used to test unusual clusters [43.54,56]. Asymptotic results [43.62,63, 68,69] and approximations [43.57] are also available for a variety of models.

44. Condition-Based Failure Prediction

Machine reliability is improved if failures are prevented. Preventive maintenance (PM) can be performed in order to promote reliability, but only if failures can be predicted early enough. Although PM can be approached in different ways, according to time or condition, whichever one of these approaches is adopted, the key issue is whether a failure can be detected early enough or even predicted. This chapter discusses a way to predict failure, for use with PM, in which the state of a DC motor is estimated using the Kalman filter. The prediction consists of a simulation on a computer and an experiment performed on the DC motor. In the simulation, an exponential attenuator is placed at the output end of the motor model in order to simulate aging failure. Failure is ascertained by monitoring a state variables, the rotation speed of the motor. Failure times were generated by Monte Carlo simulation and predicted by the Kalman filter. One-step-ahead and two-steps-ahead predictions are performed. The resulting prediction errors are sufficiently small in both predictions. In the experiment, the rotating speed of the motor was measured every 5 min for 80 days. The measurements were used to perform Kalman prediction and to verify the prediction accuracy. The resulting prediction errors were acceptable. Decreasing the increment time between measurements was found to increase the accuracy of Kalman prediction uses. Consequently, it is shown that failure can be prevented (promoting reliability) by performing predictive maintenance depending on the results of state estimation using the Kalman filter.

Nomenclature

$(\cdot)_k$ = The value of $(\cdot)$ at time kT
$\widehat{(\cdot)}_{a/b}$ = The estimate of $(\cdot)$ at time aT based on all information known about the process up to time bT
$\boldsymbol{A}$ = A matrix
$\boldsymbol{A}_\mathrm{c}$ = Coefficient matrix of the state equation for a continuous system
$\boldsymbol{A}_\mathrm{d}$ = Coefficient matrix of the state equation for a discrete system
$\boldsymbol{A}^\mathrm{T}$ = Transpose matrix of $\boldsymbol{A}$
$\boldsymbol{A}^{-1}$ = Inverse matrix of $\boldsymbol{A}$
B = Damping coefficient
$\boldsymbol{B}_\mathrm{c}$ = Coefficient matrix of the state equation for a continuous system
$\boldsymbol{B}_\mathrm{d}$ = Coefficient matrix of the state equation for a discrete system
$\boldsymbol{B}_\mathrm{k}$ = Coefficient matrix for the input term of a discrete state equation
$\boldsymbol{C}$ = A matrix
$\boldsymbol{C}_\mathrm{c}$ = Coefficient matrix of the state equation for a continuous system
$\boldsymbol{C}_\mathrm{d}$ = Coefficient matrix of the state equation for a discrete system

$\boldsymbol{D}_c$ = Coefficient matrix of the state equation for a continuous system
$\boldsymbol{D}_d$ = Coefficient matrix of the state equation for a discrete system
E = Applied voltage
E_r = Estimation error
$\boldsymbol{H}_k$ = Matrix giving the ideal (noiseless) connection between the measurement and the state vector
i_a = Armature winding current
J = Moment of inertia of rotor and load
k_b = Back emf constant
K_k = Kalman gain
k_T = Motor torque constant
L_a = Armature winding inductance
L^{-1} = The inverse Laplace transform
$\boldsymbol{P}_{k/k-1}$ = Estimation error covariance matrix
$\boldsymbol{Q}_k$ = Covariance matrices for disturbance
R = Armature winding resistance
$\boldsymbol{R}_k$ = Covariance matrices for noise
t = Time variable
T = Motor output torque
T = Increment time for every step in Kalman prediction
$\boldsymbol{U}_k$ = Control input of a discrete state equation at state k
V = Variation in the estimated rotating speed
$\boldsymbol{V}_k$ = Noise (measurement error vector), assumed to be a white sequence with known covariance
$\boldsymbol{W}_k$ = Disturbance (system stochastic input vector), assumed to be a white sequence with known covariance and zero cross-correlation with V_k sequence
x, X = Variable of a distribution function
$\boldsymbol{X}_{D0}$ = Initial states resulting from deterministic input
$\boldsymbol{X}_k$ = System state vector at state k
$\boldsymbol{X}_{S0}$ = Initial states resulting from stochastic input
$\boldsymbol{Y}_k$ = System output vector at state k
Z_k = Output measurement vector
θ = Motor angle displacement
$\dot{\theta}$ = Motor rotating speed
μ = Mean value of a distribution function
σ = Standard deviation of a distribution function
Φ_k = Matrix relating $\boldsymbol{X}_k$ to $\boldsymbol{X}_{k+1}$ in the absence of a forcing function, which is the state transition matrix if $\boldsymbol{X}_k$ is sampled from a continuous process

44.1 Overview

High quality and excellent performance of a system are always goals that engineers strive to achieve. Reliability engineering encourages system quality and performance from the beginning to the end of the system's lifecycle [44.1]. Therefore, reliability can be thought of as the time-dimensional quality of the system. Reliability is affected by every stage of the system's lifecycle, including its development, design, production, quality control, shipping, installation, operation, and maintenance. Consequently, paying attention to each of the stages promotes reliability. Specifically, in the onsite operation phase, failures are the main causes of worsened performance and degraded reliability. This is a very important consideration for any equipment that may cause severe damage to public safety or financial benefit upon failure, such as nuclear power plants, passenger vehicles, or semiconductor production lines. Accordingly, failure avoidance is the main approach to ensuring reliability. Effective maintenance is the best way to reduce failure [44.1]. There are three main types of maintenance: improvement maintenance (IM), corrective maintenance (CM), and preventive maintenance (PM) [44.2]. The purpose of IM is to reduce the need for maintenance or eliminate the need for it entirely . Therefore IM should be performed at the design phase of a system in order to emphasize the elimination of failure. There are many restrictions on a designer, however, such as space, budget, and market requirements. Usually the reliability of a product is related to its price.

On the other hand, CM is the repair performed after failure occurs, while PM refers to all of the actions intended to maintain equipment in good operating condition and to avoid failure [44.2]. The most common strategy for maintenance is scheduled maintenance, where maintenance occurs at set times, at set operational times, after set amounts of material have been processed, or by some other prescribed criteria. Nevertheless, there are at least two drawbacks to this type of maintenance:

1. The criteria on which the scheduled maintenance is based are statistical averages, such as mean time to failure (MTTF). This leads to an unavoidable risk that a system can fail before the criteria are exceeded; in other words a failure may occur unexpectedly.
2. The real duty cycles for certain parts or modules may be longer than those averages, but they are still replaced during a scheduled maintenance, which is wasteful.

In contrast, condition monitoring is a more reasonable type of maintenance than scheduled maintenance. However, a failure really needs to be detected prior to its occurrence.

The relationship between error, failure, and fault is illustrated in Fig. 44.1, and the three terms are defined as follows [44.3]:

1. An error is a discrepancy between a computed, observed or measured value or condition and the true, specified or theoretically correct value or condition.
2. Failure is an event where a required function is terminated (exceeding the acceptable limits).
3. Fault is the state characterized by an inability to perform a required function, excluding the inability encountered during preventive maintenance or other planned actions, or due to lack of external resources.

Based on the above statements, an error is not a failure and a fault is hence a state resulting from a failure. An error is sometimes referred to as an incipient failure [44.4]. Therefore, PM action is taken when the system is still at an error condition – within acceptable deviation and before failure occurs. Hence, PM is an effective approach to promoting reliability [44.5]. As mentioned before, time-based and condition-based maintenance are two major approaches to PM. Irrespective of the approach adopted for PM, the key issue is whether a failure can be detected early or even predicted.

Many methods have been proposed for failure prediction, such as statistical knowledge of the reliability parameters [44.6, 7], neural network studies [44.8], and understanding the failure mechanism of damaged products [44.9]. Fault detection based on modeling and estimation is one of these methods [44.10]. The Kalman filter is useful not only for state estimation but also for state prediction. It has been widely used in different fields over the past few decades, such as in on-line failure detection [44.11], real-time prediction of vehicle motion [44.12], and prediction of maneuvering target trajectories [44.13]. The Kalman filter is a linear, discrete-time, and finite-dimensional system [44.14]. Its appearance is a copy of the system that is estimated. Inputs to the filter include the control signal and the difference value between measured and estimated state variables. Actual values of the event acquired by the monitor sensor are fed into the corresponding Kalman filter to execute state estimation. By minimizing mean-square estimation errors, an optimal estimate can be derived. Using the current state, the Kalman filter provides a predicted value of the next state for the corresponding event at every time interval T. As a result, the output of the filter becomes optimal estimates of the state variables for the next time step. Each event has a prescribed failure threshold, and the predicted value is compared with the prescribed failure threshold in order to judge whether the monitored event has failed after T or is still within the established threshold. Once the estimated value reaches the threshold, failure is predicted. Therefore, the current state is a warning state and PM needs to be performed. If predicted state variables indicate that a device is going to fail, then the failure can be prevented in time using PM. However, future state variables need to be accurately predicted a reasonable time before failure occurrence [44.10, 15].

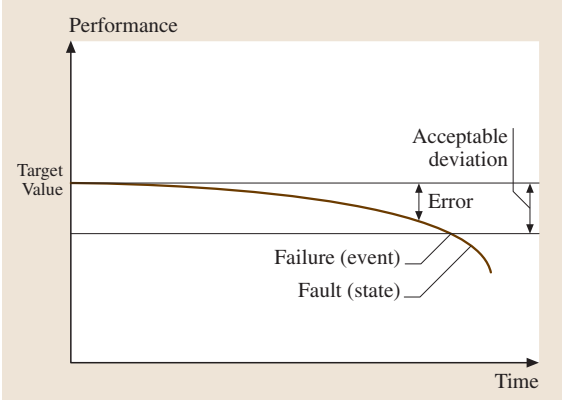

Fig. 44.1 Error, failure and fault

This chapter is about state estimation and how to predict the need for PM using a Kalman filter. A DC motor is the object on which we perform condition-based failure predictions. The prediction consists of two parts. The first part is a simulation on a computer, and the second part is an experiment on the DC motor. In the simulation, failure times were generated by Monte Carlo simulation (MCS) and predicted by the Kalman filter. One-step-ahead and two-steps-ahead predictions were conducted. The resulting prediction errors are sufficiently small in both predictions. Even so, the failure prediction was still simulated on a computer. In the second part of the prediction, a DC motor and a data acquisition system are used to implement the simulation. The rotation speed of the motor is chosen as the major state variable to judge whether the motor is going to fail, by estimating state using the Kalman filter. The rotation speed of the motor was measured and recorded every 5 min for 80 d. Instead of simulated data, the measured data are used to perform Kalman prediction and to verify the prediction accuracy.

In Sect. 44.2, we study a discrete system model with deterministic control input, white noise disturbance

and noisy output measurement. We then formulate an equation for state estimation of the Kalman filter. Deterministic inputs are considered in this formulation. Moreover, equations for N-step-ahead prediction are derived. Section 44.3 presents the transfer function, the continuous state model, and the discrete state model of the DC motor that is employed as an example in this chapter. Section 44.4 presents a simulated system with prescribed parameters, a Monte Carlo simulation and an ARMA model used to generate necessary data for a failure prediction simulation, and the exponential attenuator used to simulate the aging failure mode. Simulation results are also given and discussed. Section 44.5 presents the experimental set-up with related parameters, experimental results and discussion. Section 44.6 concludes this work.

44.2 Kalman Filtering

This section introduces the Kalman filtering that is used in this chapter to perform the failure prediction.

44.2.1 System Model

The block diagram of a discrete system is shown in Fig. 44.2. The state equations [44.14] are:

$$\boldsymbol{X}_{k+1} = \boldsymbol{\Phi}_k \boldsymbol{X}_k + \mathbf{B}_k \boldsymbol{U}_k + \boldsymbol{W}_k \,, \tag{44.1}$$

$$\boldsymbol{Y}_k = \mathbf{H}_k \boldsymbol{X}_k \,, \tag{44.2}$$

$$\boldsymbol{Z}_k = \boldsymbol{Y}_k + \boldsymbol{V}_k \,. \tag{44.3}$$

Substituting (44.2) into (44.3) yields

$$\boldsymbol{Z}_k = \mathbf{H}_k \boldsymbol{X}_k + \boldsymbol{V}_k \,. \tag{44.4}$$

Let $E[\boldsymbol{X}]$ be the expected value of $\boldsymbol{X}$; therefore, the covariance matrices for $\boldsymbol{W}_k$ and $\boldsymbol{V}_k$ are given by:

$$E\left[\boldsymbol{W}_k \boldsymbol{W}_i^{\mathrm{T}}\right] = \begin{cases} \mathbf{Q}_k \,, & i = k \\ 0 \,, & i \neq k \end{cases} \tag{44.5}$$

$$E\left[\boldsymbol{V}_k \boldsymbol{V}_i^{\mathrm{T}}\right] = \begin{cases} \mathbf{R}_k \,, & i = k \\ 0, & i \neq k \end{cases} \tag{44.6}$$

$$E\left[\boldsymbol{W}_k \boldsymbol{V}_i^{\mathrm{T}}\right] = 0 \,, \quad \text{for all } k \text{ and } i \,. \tag{44.7}$$

It follows that both $\mathbf{Q}_k$ and $\mathbf{R}_k$ are symmetric and positive definite [44.16].

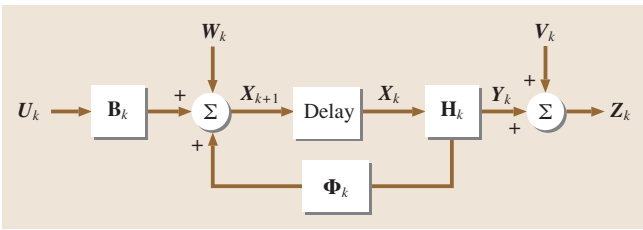

Fig. 44.2 Block diagram of a discrete system

44.2.2 State Estimation

State estimation involves guessing the value of $\boldsymbol{X}_k$ by using measured data, i. e. Z_0, Z_1, ... Z_{k-1}. Accordingly, $\hat{\boldsymbol{X}}_{k/k-1}$ is called the prior estimate of $\boldsymbol{X}$, and $\hat{\boldsymbol{X}}_{k/k}$ is called the posterior estimate of $\boldsymbol{X}$ [44.16]. The prior estimation error is defined as

$$\mathbf{e}_{k/k-1} = \boldsymbol{X}_k - \hat{\boldsymbol{X}}_{k/k-1} \,. \tag{44.8}$$

Since $\boldsymbol{W}_k$ and $\boldsymbol{V}_k$ are assumed to be white sequences, the prior estimation error has a mean of zero. Consequently, the associated error covariance matrix is written as

$$\begin{aligned} \boldsymbol{P}_{k/k-1} &= E\left[(\mathbf{e}_{k/k-1})(\mathbf{e}_{k/k-1})^{\mathrm{T}}\right] \\ &= E\left[(\boldsymbol{X}_k - \hat{\boldsymbol{X}}_{k/k-1})(\boldsymbol{X}_k - \hat{\boldsymbol{X}}_{k/k-1})^{\mathrm{T}}\right] . \end{aligned} \tag{44.9}$$

The estimation problem begins with no prior measurements. Thus, the stochastic portion of the initial estimate is zero if the stochastic process mean is zero; i. e. $\hat{\boldsymbol{X}}_{0/-1}$ is only driven by deterministic input X_{D0}. It follows from (44.8) that

$$e_{0/-1} = X_0 - \hat{\boldsymbol{X}}_{0/-1} = X_0 - X_{D0} = X_{S0} \,. \tag{44.10}$$

Employing (44.9) and (44.10) yields

$$P_{0/-1} = E\left[\boldsymbol{X}_{S0} \boldsymbol{X}_{S0}^{\mathrm{T}}\right] \,. \tag{44.11}$$

The Kalman filter is a copy of the original system and is driven by the estimation error and the deterministic input. The block diagram of the filter structure is shown in Fig. 44.3. The filter is used to improve the prior estimate to make it the posterior estimate via the measurement $\boldsymbol{Z}_k$. A linear blending of the noisy measurement and the prior estimate is written as [44.16]

$$\hat{\boldsymbol{X}}_{k/k} = \hat{\boldsymbol{X}}_{k/k-1} + \boldsymbol{K}_{\mathrm{k}}(\boldsymbol{Z}_k - \boldsymbol{H}_k \hat{\boldsymbol{X}}_{k/k-1}) \,, \tag{44.12}$$

where K_{k} is the blending factor for this structure. Once the posterior estimate is determined, the posterior estimation error and associated error covariance matrix can

be derived as

$$\mathbf{e}_{k/k} = \boldsymbol{X}_k - \hat{\boldsymbol{X}}_{k/k} \,, \tag{44.13}$$

$$\begin{aligned}\boldsymbol{P}_{k/k} &= E[(\mathbf{e}_{k/k})(\mathbf{e}_{k/k})^T] \,, \\ &= E[(\boldsymbol{X}_k - \hat{\boldsymbol{X}}_{k/k})(\boldsymbol{X}_k - \hat{\boldsymbol{X}}_{k/k})^T] \,. \end{aligned} \tag{44.14}$$

The optimal blending factor is written as [44.16]

$$K_{\mathrm{k}} = \boldsymbol{P}_{k/k-1}\mathbf{H}_{\mathrm{k}}^{\mathrm{T}}(\mathbf{H}_k\boldsymbol{P}_{k/k-1}\mathbf{H}_{\mathrm{k}}^{\mathrm{T}} + \mathbf{R}_k)^{-1} \,. \tag{44.15}$$

This specific K_{k}, namely the one that minimizes the mean-square estimation error, is called the Kalman gain.

Substituting (44.15) into (44.12), the posterior error covariance matrix can be derived as follows:

$$\begin{aligned}\boldsymbol{P}_{k/k} &= \boldsymbol{P}_{k/k-1} - \boldsymbol{P}_{k/k-1}\mathbf{H}_k^{\mathrm{T}}\left(\mathbf{H}_k\boldsymbol{P}_{k/k-1}\mathbf{H}_k^{\mathrm{T}} + \mathbf{R}_k\right)^{-1} \\ &\quad \times \mathbf{H}_k\boldsymbol{P}_{k/k-1} \\ &= \boldsymbol{P}_{k/k-1} - \boldsymbol{K}_{\mathrm{k}}\left(\mathbf{H}_k\boldsymbol{P}_{k/k-1}\mathbf{H}_k^{\mathrm{T}} + \mathbf{R}_k\right)\boldsymbol{K}_{\mathrm{k}}^{\mathrm{T}} \\ &= (I - \boldsymbol{K}_{\mathrm{k}}\mathbf{H}_k)\boldsymbol{P}_{k/k-1} \,. \end{aligned} \tag{44.16}$$

As depicted in Fig. 44.3, the one-step-ahead estimate is formulated as

$$\begin{aligned}\hat{\boldsymbol{X}}_{k+1/k} &= \boldsymbol{\Phi}_k\hat{\boldsymbol{X}}_{k/k-1} + \boldsymbol{\Phi}_k\boldsymbol{K}_{\mathrm{k}}(Z_k - \boldsymbol{H}_k\hat{\boldsymbol{X}}_{k/k-1}) \\ &\quad + \boldsymbol{B}_k\boldsymbol{U}_k \\ &= \boldsymbol{\Phi}_k[\hat{\boldsymbol{X}}_{k/k-1} + \boldsymbol{K}_{\mathrm{k}}(\boldsymbol{Z}_k - \boldsymbol{H}_k\hat{\boldsymbol{X}}_{k/k-1})] \\ &\quad + \boldsymbol{B}_k\boldsymbol{U}_k \\ &= \boldsymbol{\Phi}_k\hat{\boldsymbol{X}}_{k/k} + \boldsymbol{B}_k\boldsymbol{U}_k \,. \end{aligned} \tag{44.17}$$

Consequently, the one-step-ahead estimation error is derived as

$$\begin{aligned}\mathbf{e}_{k+1/k} &= (\boldsymbol{\Phi}_k\boldsymbol{X}_k + \mathbf{B}_k\boldsymbol{U}_k + \mathbf{W}_k) - (\boldsymbol{\Phi}_k\hat{\boldsymbol{X}}_{k/k} + \mathbf{B}_k\boldsymbol{U}_k) \\ &= \boldsymbol{\Phi}_k(\boldsymbol{X}_k - \hat{\boldsymbol{X}}_{k/k}) + \mathbf{W}_k \\ &= \boldsymbol{\Phi}_k\mathbf{e}_{k/k} + \mathbf{W}_k \,. \end{aligned} \tag{44.18}$$

In a manner similar to (44.14), the one-step-ahead error covariance matrix is derived as

$$\begin{aligned}\boldsymbol{P}_{k+1/k} &= E\left[(\boldsymbol{\Phi}_k\mathbf{e}_{k/k} + \mathbf{W}_k)(\boldsymbol{\Phi}_k\mathbf{e}_{k/k} + \mathbf{W}_k)^{\mathrm{T}}\right] \\ &= \Phi_k\boldsymbol{P}_{k/k}\Phi_k^{\mathrm{T}} + \boldsymbol{Q}_k \,. \end{aligned} \tag{44.19}$$

According to the above statements, we can make several remarks about Kalman estimation:

1. Since $\boldsymbol{K}_{\mathrm{k}}$ is optimal, the posterior estimate $\hat{\boldsymbol{X}}_{k/k}$ is an optimal estimate.
2. Based on (44.12), (44.15), (44.16), (44.17) and (44.19), recursive steps for constructing a one-step estimator are summarized in Fig. 44.4.
3. The recursive loop involves two different kinds of updating. Equations (44.12) and (44.16) yielding $\hat{\boldsymbol{X}}_{k/k}$ and $\boldsymbol{P}_{k/k}$ from $\hat{\boldsymbol{X}}_{k/k-1}$ and $\boldsymbol{P}_{k/k-1}$ are measurement updates; Equations (44.17) and (44.19) projecting $\hat{\boldsymbol{X}}_{k/k}$ and $\boldsymbol{P}_{k/k}$ to $\hat{\boldsymbol{X}}_{k+1/k}$ and $P_{k+1/k}$ are time updates.
4. The initial conditions, i. e. $\hat{\boldsymbol{X}}_{0/-1}$, $P_{0/-1}$, Φ_0, H_0, Q_0, and R_0 have to be known before we can start the recursive steps.

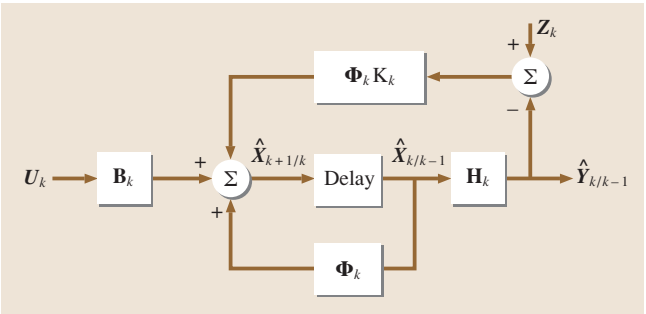

Fig. 44.3 Block diagram of a Kalman filter

44.2.3 Prediction

The estimate resulting from the recursive steps in Fig. 44.4 is a one-step-ahead prediction. Based on the posterior estimate (44.12), the state that is N steps ahead of the measurement $\boldsymbol{Z}_k$ can be predicted by using the ARMA (autoregressive and moving average) model [44.16]. From (44.17) and (44.19), the equations for N-step-ahead prediction are derived as

$$\begin{aligned}\hat{\boldsymbol{X}}_{k+N/k} &= \left(\prod_{i=k+N-1}^{k} \Phi_i\right)\hat{\boldsymbol{X}}_{k/k} \\ &\quad + \sum_{m=k}^{k+N-2}\left[\left(\prod_{i=k+N-1}^{m+1}\Phi_i\right)\boldsymbol{B}_m\boldsymbol{U}_m\right] \\ &\quad + \boldsymbol{B}_{k+N-1}\boldsymbol{U}_{k+N-1} \,, \end{aligned} \tag{44.20}$$

$$\begin{aligned}P_{k+N/k} &= \left(\prod_{i=k+N-1}^{k}\Phi_i\right)\boldsymbol{P}_{k/k}\left(\prod_{j=k}^{k+N-1}\Phi_j^{\mathrm{T}}\right) \\ &\quad + \sum_{m=k}^{k+N-2}\left[\left(\prod_{i=k+N-1}^{m+1}\Phi_i\right)Q_m \right. \\ &\quad \left. \times \left(\prod_{j=m+1}^{k+N-1}\Phi_j^{T}\right)\right] + Q_{k+N-1} \,. \end{aligned} \tag{44.21}$$

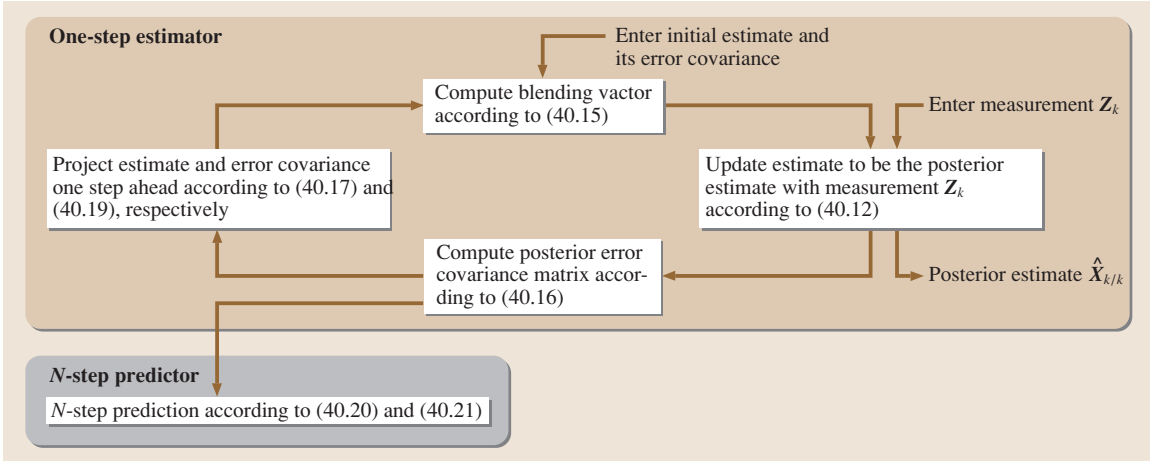

Fig. 44.4 One-step estimator and N-step predictor

The N-step predictor is an appendage of the one-step estimation loop [44.16]. It is also shown in Fig. 44.4. Since the current predicted value is assumed to be the initial value for the next prediction, the more steps the predictor predicts, the larger the error.

44.3 Armature-Controlled DC Motor

An armature-controlled DC motor is employed in this section as the physical model on which to perform failure prediction. The motor circuit representation is shown in Fig. 44.5.

44.3.1 Transfer Function

Using the properties of a DC motor, the following equations can be formulated [44.17]:

$$\phi = k_f i_f \,, \tag{44.22}$$

$$\begin{aligned} T &= \frac{ZP}{2\pi a}\phi i_a \\ &= k_1 \left(k_f i_f\right) i_a \\ &= k_T i_a \end{aligned} \tag{44.23}$$

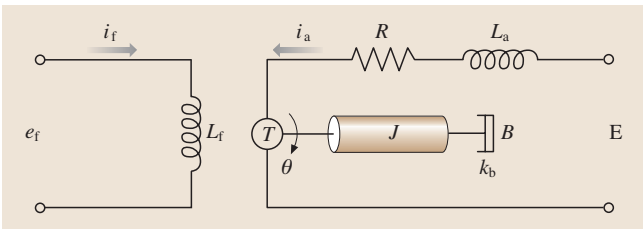

Fig. 44.5 Circuit representation of DC motor

$$e_b = k_b \frac{d\theta}{dt} \,, \tag{44.24}$$

$$L_a \frac{d}{dt} i_a + R i_a + e_b = E \,, \tag{44.25}$$

$$J\ddot{\theta} + B\dot{\theta} = T \,, \tag{44.26}$$

where $k_1 = \frac{ZP}{2\pi a}$ is called the motor constant, and $k_T = k_1 \left(k_f i_f\right)$ is the motor torque constant.

Taking the Laplace transform for (44.24), (44.25) and (44.26) results in

$$E_b(s) = k_b s\theta(s) \,, \tag{44.27}$$

$$\left(L_a s + R\right) I_a(s) = E(s) - E_b(s) \,, \tag{44.28}$$

$$\left(Js^2 + Bs\right)\theta(s) = T(s) = k_T I_a(s) \,. \tag{44.29}$$

Combining (44.27), (44.28) and (44.29), the transfer function of a DC motor is derived as

$$\frac{\theta(s)}{E(s)} = \frac{k_T}{s\left[\left(sL_a + R\right)\left(sJ + B\right) + k_T k_b\right]} \,. \tag{44.30}$$

Accordingly, the block diagram of a DC motor is as shown in Fig. 44.6. If $L_a \approx 0$, (44.30) can be rewritten as

$$\frac{\theta(s)}{E(s)} = \frac{k_m}{s\left(s\tau_m + 1\right)} \,, \tag{44.31}$$

where $k_m = \frac{k_T}{RB+k_T k_b}$ and $\tau_m = \frac{RJ}{RB+k_T k_b}$ are called the motor gain constant and the motor time constant, respectively.

44.3.2 Continuous State Space Model

Define θ, $\dot{\theta}$, and i_a as state variables, so that the state vector is $\boldsymbol{X} = [\theta\, \dot{\theta}\, i_a]^T$.

Since

$$\frac{d}{dt}\theta = \dot{\theta}\,, \tag{44.32}$$

substituting (44.23) and (44.32) into (44.26) yields

$$\frac{d}{dt}\dot{\theta} = \frac{1}{J}\left(k_T i_a - B\dot{\theta}\right) = \frac{k_T}{J} i_a - \frac{B}{J}\dot{\theta}\,. \tag{44.33}$$

Moreover, substituting (44.24) into (44.25) yields

$$\frac{d}{dt} i_a = \frac{1}{L_a}\left(E - R i_a - e_b\right) = \frac{E}{L_a} - \frac{k_b}{L_a}\dot{\theta} - \frac{R}{L_a} i_a\,. \tag{44.34}$$

During measurement, the rotation speed $\dot{\theta}$ is the motor output. According to (44.32), (44.33) and (44.34), the continuous state equations of the DC motor are

$$\frac{d}{dt}\begin{pmatrix}\theta\\ \dot{\theta}\\ i_a\end{pmatrix} = \begin{pmatrix}0 & 1 & 0\\ 0 & -\frac{B}{J} & \frac{k_T}{J}\\ 0 & -\frac{k_b}{L_a} & -\frac{R}{L_a}\end{pmatrix}\begin{pmatrix}\theta\\ \dot{\theta}\\ i_a\end{pmatrix} + \begin{pmatrix}0\\ 0\\ \frac{1}{L_a}\end{pmatrix} E, \tag{44.35}$$

$$Y = \begin{pmatrix}0 & 1 & 0\end{pmatrix}\begin{pmatrix}\theta\\ \dot{\theta}\\ i_a\end{pmatrix}\,. \tag{44.36}$$

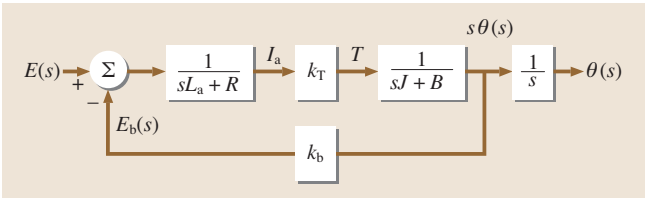

Fig. 44.6 Block diagram of DC motor

44.3.3 Discrete State Space Model

The state equations for a continuous system take the form of [44.18]:

$$\begin{aligned}\dot{X}(t) &= A_c X(t) + B_c U(t)\\ Y(t) &= C_c X(t) + D_c U(t)\end{aligned} \tag{44.37}$$

Let $\Phi_c(t) = L^{-1}[(s\mathbf{I} - \mathbf{A}_c)^{-1}]$ be the state transition matrix for (44.37). The discrete state equations sampled from (44.37) by a sample-and-hold with a time interval of T seconds are as follows [44.19]:

$$\begin{aligned}\boldsymbol{X}_{k+1} &= \mathbf{A}\boldsymbol{X}_k + \mathbf{B}\boldsymbol{U}_k\,,\\ \boldsymbol{Y}_k &= \mathbf{C}\boldsymbol{X}_k + \mathbf{D}\boldsymbol{U}_k\,,\end{aligned}$$

where

$$\mathbf{A} = \Phi_c(T)\,, \tag{44.38}$$

$$\mathbf{B} = \left[\int_0^T \Phi_c(\tau)\,d\tau\right] B_c\,, \tag{44.39}$$

$$\boldsymbol{C} = \boldsymbol{C}_c\,, \tag{44.40}$$

$$\boldsymbol{D} = \boldsymbol{D}_c\,. \tag{44.41}$$

44.4 Simulation System

This section describes a computer simulation of failure prediction for PM on a DC motor.

44.4.1 Parameters

The parameters used for the DC motor in this simulation are: follows [44.20]:

$E = 10\,\mathrm{V}$,
$B = 0.001\,\mathrm{N\,m\,s}$,
$J = 0.01\,\mathrm{kg\,m^2}$,
$K_T = 1\,\mathrm{N\,m\,/\,A}$,
$K_b = 0.02\,\mathrm{V\,s}$,
$R = 10\,\Omega$,
$L_a = 0.01\,\mathrm{H}$.

Substituting them into (44.35) and (44.36), the continuous state equations of the motor become

$$\frac{d}{dt}\begin{pmatrix}\theta\\ \dot{\theta}\\ i_a\end{pmatrix} = \begin{pmatrix}0 & 1 & 0\\ 0 & -0.1 & 100\\ 0 & -2 & -1000\end{pmatrix}\begin{pmatrix}\theta\\ \dot{\theta}\\ i_a\end{pmatrix} + \begin{pmatrix}0\\ 0\\ 100\end{pmatrix} 10\,, \tag{44.42}$$

$$Y = \begin{pmatrix}0 & 1 & 0\end{pmatrix}\begin{pmatrix}\theta\\ \dot{\theta}\\ i_a\end{pmatrix}\,. \tag{44.43}$$

The following parameters are also used to predict failure:

1. The failure threshold of the motor is defined as 5% less than the normal value, which is set to be the

initial estimate in the Kalman prediction procedure. That is, the motor is judged to fail if the rotation speed drops to 95% of the normal value.
2. Mean time between failure (MTBF) for the motor is 100 000 h [44.21].
3. Sampling interval T is 1 h (this is the increment time for every step in Kalman prediction).
4. Disturbance $\boldsymbol{W}_k$ has mean 0 and variance 0.01 V [44.22].
5. Measurement error $\boldsymbol{V}_k$ for $\dot{\theta}$ has a zero mean and a standard deviation of 3.333 rad/s, which is 1% of the full-scale accuracy [44.23] of the measurement.
6. PM lead-time is set to $n \times 60$ min, where n is the number of steps ahead in the prediction. Accordingly, the alarm signal is activated (to indicate that PM should be executed) whenever the Kalman filter predicts that the motor speed will be lower than the prescribed threshold $n \times 60$ min later.

44.4.2 Monte Carlo Simulation and ARMA Model

Assuming that motor failures occur randomly, a Monte Carlo simulation (MCS) can be used to generate the failure times of the motor. The relationship between the failure rate $h(t)$ and the distribution function of the lifetime $f(t)$ is [44.5]

$$f(t) = h(t) \exp\left[-\int_0^t h(\tau)\,\mathrm{d}\tau\right] . \qquad (44.44)$$

Failures occur randomly during the useful lifetime, statistically conforming to a bathtub curve [44.5]. The failure rate is constant during this period. Let the failure rate in (44.44) be a constant λ, and so (44.44) becomes

$$f(t) = \lambda \exp\left(-\int_0^t \lambda\,\mathrm{d}\tau\right) = \lambda\,\mathrm{e}^{-\lambda t} , \qquad (44.45)$$

which is an exponential distribution function. Let u_i, $i = 1, 2, 3, \ldots, m$, represent a set of standard uniformly distributed random numbers. The corresponding numbers t_i of the random variable t in (44.45) (in other words the simulated failure times), are written as [44.5]

$$t_i = -\frac{1}{\lambda} \ln u_i , \qquad (44.46)$$

with exponential distributions.

The measurements needed for the recursive estimation loop of the Kalman filter, as depicted in Fig. 44.4, are generated by the ARMA model ((44.1) to (44.3)). Simulations in this section are performed using MATLAB [44.24]. All random numbers and white sequences with prescribed variances needed are obtained using the random number generator in MATLAB.

44.4.3 Exponential Attenuator

To account for the aging failure modes and the exponentially distributed failure times t_i, an exponential attenuator, represented by $\mathrm{e}^{-t/\tau}$, is placed at the output ends of both the motor system and the Kalman filter. The block diagram of the simulation system is shown in Fig. 44.7. The symbol τ of the attenuator in Fig. 44.7 denotes the failure time constant of the motor, which varies with the failure times that are generated by the MCS.

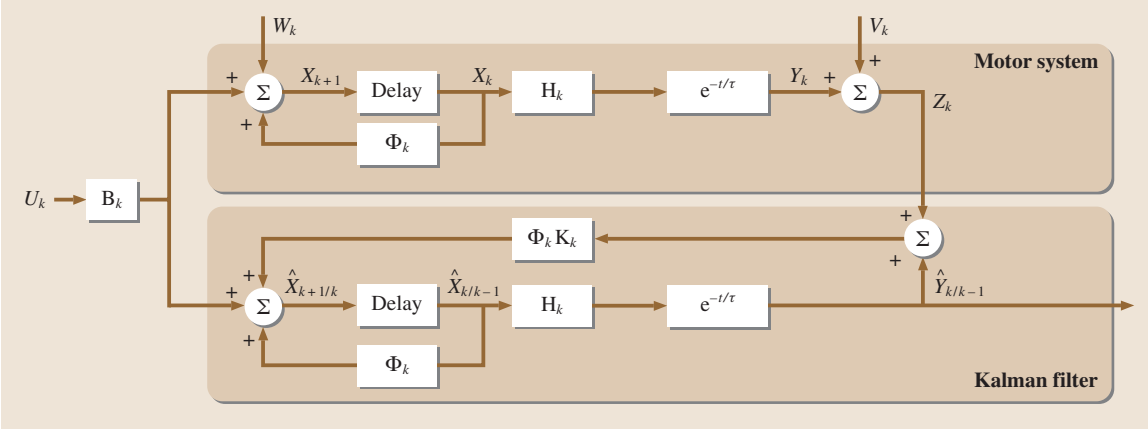

Fig. 44.7 Block diagram of the simulation system

44.4.4 Simulation Results

Two categories of simulation are conducted in this section, namely one-step-ahead prediction and two-steps-ahead prediction. According to the central limit theorem (CLT), estimators follow the normal distribution if the sample size is sufficiently large. A sample size of 30 is a reasonable number to use [44.25]. The larger the sample size, the smaller the estimated error, which tends to zero when the sample size approaches infinity. Hence, each simulation is executed 100 times. Simulation results for a lead-time of 60 min – one-step-ahead prediction – is shown in Fig. 44.8. Figure 44.8a shows the results for the 100 simulations of failure times generated by the MCS, the failure times predicted by the Kalman filter, and the associated alarm times. Figure 44.8b shows the results from one of the 100 simulations with properly scaled coordinates. The failure time differences between MCS and Kalman prediction are shown in Fig. 44.9. The mean value and the standard deviation of the differences in the 100 simulations are −34.71 min and 65.90 min, respectively. The negative sign of the mean value indicates that the failure time predicted by the Kalman filter occurs earlier than the time generated by MCS. According to the Z formula [44.25], the error in estimating the mean value of the sample population can be calculated by

$$E_r^2 = \frac{Z_{\alpha/2}^2 \sigma^2}{n} .$$

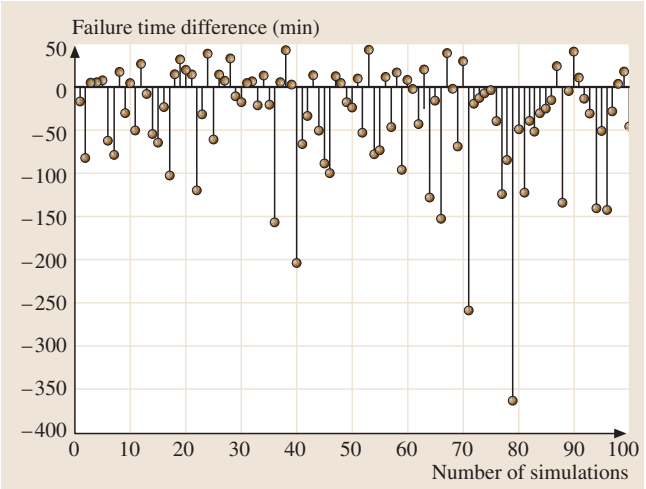

Fig. 44.9 Differences between the failure times given by Monte Carlo simulation results and Kalman filter predictions when the lead-time = 60 min

The Z value for a 99% confidence level is 2.575 [44.25]. Solving for E_r gives

$$E_r = \frac{(2.575)(65.8954)}{\sqrt{100}} = 16.97(\text{min}) .$$

According to the above data, we can say with 99% confidence that the mean value of the time difference between the MCS and the Kalman prediction is -34.71 ± 16.97 min, in other words from −17.74 min to −51.68 min. Taking the time difference into account,

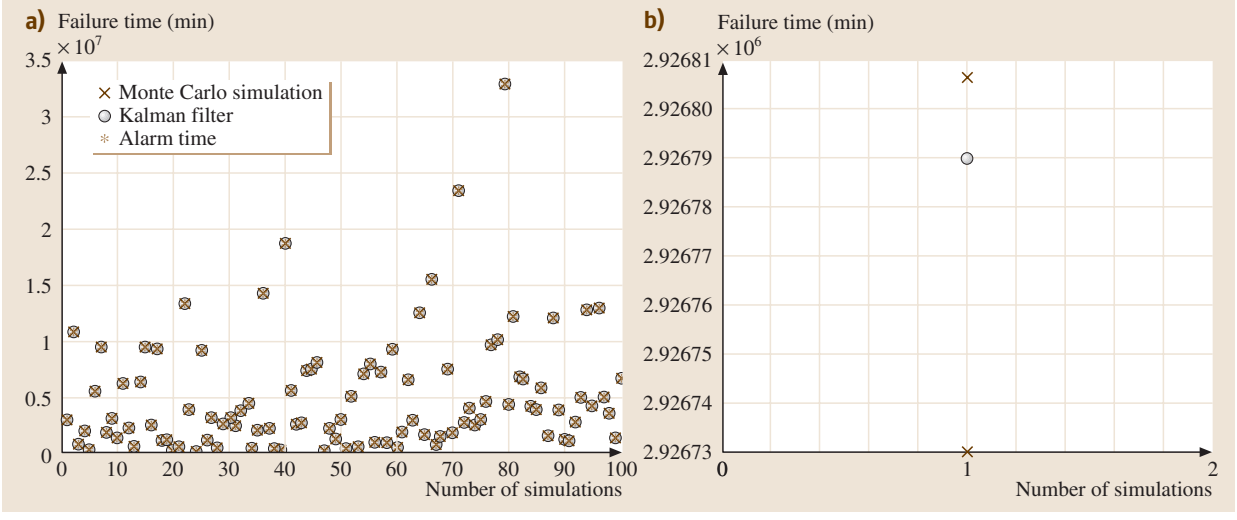

Fig. 44.8 Failure times generated by Monte Carlo simulation and predicted by Kalman filter when lead-time = 60 min

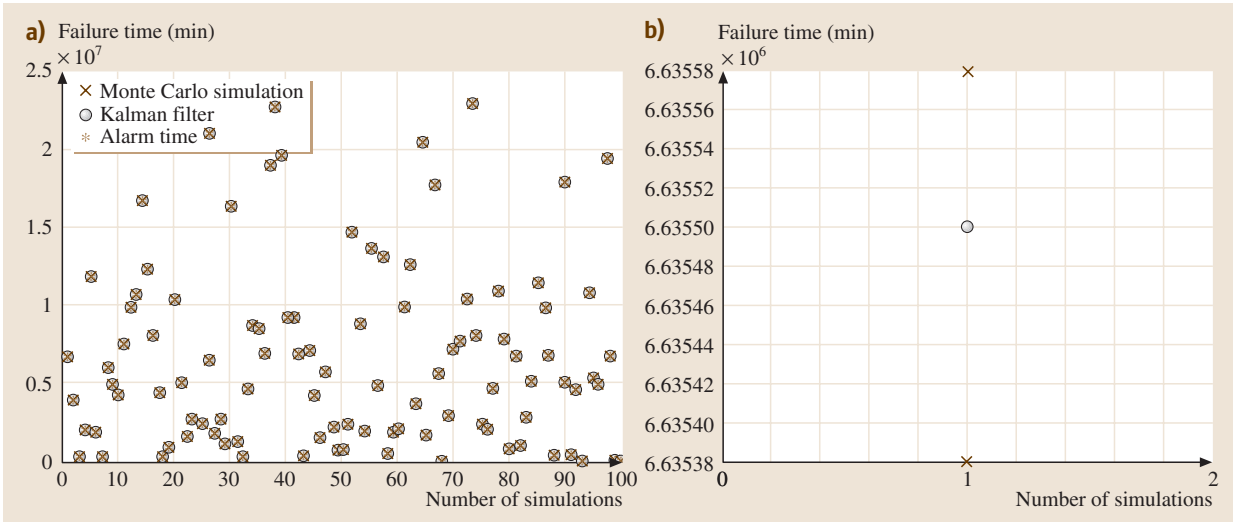

Fig. 44.10 Failure times generated by Monte Carlo simulation and predicted by Kalman filter when the lead-time = 120 min

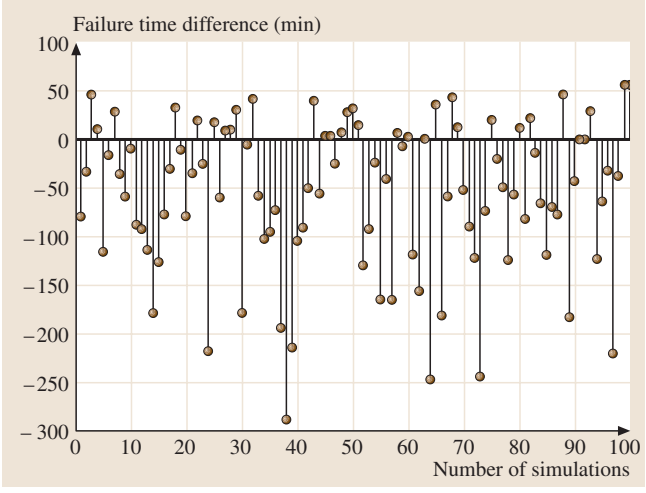

Fig. 44.11 Differences between the failure times given by Monte Carlo simulation results and Kalman filter predictions when the lead-time = 120 min

the alarm signal will appear at least 77.74 min prior to failure occurrence.

The results for the second category of simulation, – two-steps-ahead prediction, with a PM lead-time of 120 min – are shown in Figs. 44.10 and 44.11. The mean value of the difference in failure times from the MCS and the Kalman prediction is −56.34 min, and the 99% confidence interval for this mean is 20.06 min. The maximum prediction error for this case is 76.40 min, which is 1.48 times greater than the error from the one-step-ahead prediction.

44.4.5 Notes About the Simulation

1. In order to avoid false alarms, the failure threshold should not be set too close to the normal value. Otherwise, a decision-making algorithm is needed to identify that a failure has actually been predicted.
2. The disturbance amplitude should comprise all possible uncertainties about the motor and the environment.
3. The proposed method cannot deal with abrupt changes during a sampling interval. Thus, the sampling interval should not be too long.
4. Since the prediction is made for purposes of PM, the prediction time should be long enough that PM can be performed before the failure occurs.
5. In contrast to the deterministic portion, the variance that is driven by the disturbance of the system is small. The difference in state variables between prediction steps fades very rapidly. Thus, using the N-step predictor ((44.20)), only the prediction for the first few steps is of significance.
6. The proposed method in this section is exemplified by a motor system, which is treated as a component. The procedure can be executed on a multicomponent system if state equations can be constructed for the components as a whole. The procedure can be performed on either the multicomponent system or each of the components.

For a complicated or large system, the proposed method can be only performed on those elements that are present in minimum cut sets as constructed by fault tree analysis or a Petri net model for failure [44.26].

7. Multiple failure modes can be modeled as modules, such as an attenuator for simulating an aging failure mode for the electrical motor exemplified in this paper, and placed at the system model output end to extend the proposed method. As described previously, the system model may be single-component or multicomponent. System failure analysis can determine whether the failure modules occur in series, parallel or in other arrangements [44.26]. As for a multicomponent system with multiple failure modes, the system can be split into several components and the related failure module(s) placed at the output end of each component in order to perform state estimation using the Kalman filter for each component.

44.5 Armature-Controlled DC Motor Experiment

This section presents a PM failure-prediction experiment for a DC motor.

44.5.1 Experiment Design

The experiment design, shown in Fig. 44.12, comprises a DC motor with a driver unit and a data acquisition system.

DC Motor

The DC motor used in this experiment is made by TECO, Taiwan. The model number of the motor is GSDT-1/2 hp. Parameters for the DC motor used in this study are as follows [44.27]:

$E = 150\,\mathrm{V}$, $B = 0.001\,135\,\mathrm{N\,m\,s}$, $J = 0.0102\,\mathrm{kg\,m^2}$, $K_\mathrm{T} = 0.153\,\mathrm{N\,m/A}$, $K_\mathrm{b} = 1.926\,\mathrm{V\,s}$, $R = 3.84\,\Omega$, $L_\mathrm{a} = 0.01\,\mathrm{H}$.

Substituting these into (44.35) and (44.36), the continuous state equations of the motor become

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{pmatrix}\theta\\ \dot\theta\\ i_\mathrm{a}\end{pmatrix} = \begin{pmatrix}0 & 1 & 0\\ 0 & -0.111 & 15\\ 0 & -192.6 & -384\end{pmatrix}\begin{pmatrix}\theta\\ \dot\theta\\ i_\mathrm{a}\end{pmatrix} + \begin{pmatrix}0\\ 0\\ 100\end{pmatrix}150\,, \tag{44.47}$$

$$Y = \begin{pmatrix}0 & 1 & 0\end{pmatrix}\begin{pmatrix}\theta\\ \dot\theta\\ i_\mathrm{a}\end{pmatrix}\,. \tag{44.48}$$

The discrete state equations sampled from (44.47) and (44.48) with a time interval of $T = 1200\,\mathrm{s}$ are

$$\begin{pmatrix}\theta_{k+1}\\ \dot\theta_{k+1}\\ i_{\mathrm{a},k+1}\end{pmatrix} = \begin{pmatrix}1 & 0.13098 & 0.0051164\\ 0 & 0 & 0\\ 0 & 0 & 0\end{pmatrix}\begin{pmatrix}\theta_k\\ \dot\theta_k\\ i_{\mathrm{a},k}\end{pmatrix} + \begin{pmatrix}613.91\\ 0.51164\\ 0.0037955\end{pmatrix}150\,, \tag{44.49}$$

$$Y_k = \begin{pmatrix}0 & 1 & 0\end{pmatrix}\begin{pmatrix}\theta_k\\ \dot\theta_k\\ i_{\mathrm{a},k}\end{pmatrix}\,. \tag{44.50}$$

The following parameters are also used to estimate state in this experiment:

1. Sampling interval $T = 20\,\mathrm{min}$, which is the increment time for each of the steps used in Kalman prediction. In order to compare results for shorter and longer T's, another two estimations with different time intervals, $T = 5\,\mathrm{min}$ and $T = 60\,\mathrm{min}$ were tested.
2. Disturbance $\boldsymbol{W}_k$ has a mean of zero and a variance of 0.1 V [44.22].

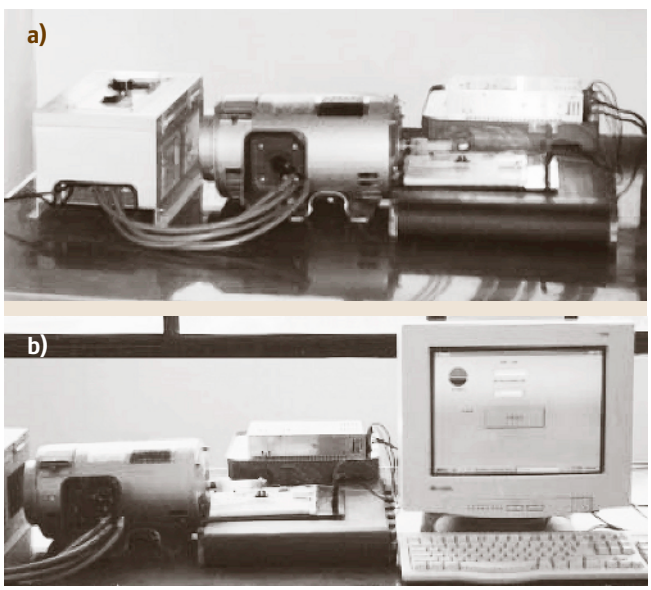

Fig. 44.12 Experiment set-up

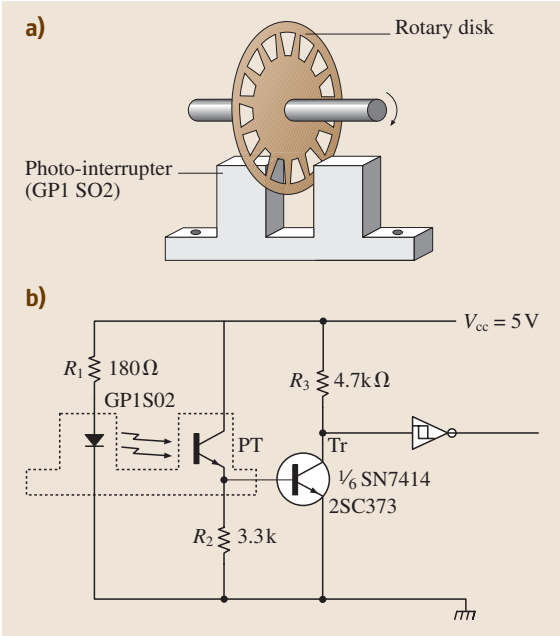

Fig. 44.13 Device and circuit for rotating speed measurement

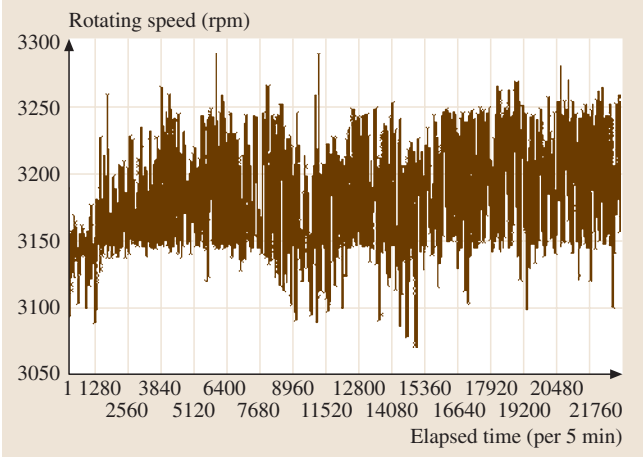

Fig. 44.14 Rotating speed measurements, taken every 5 min

3. The measurement error V_k for $\dot{\theta}$ has a mean of zero and an accuracy of 1% [44.23] of the full-scale measurement.
4. The rated rotation speed of the DC motor is 3180 rpm [44.27], which is therefore the initial value of the state variable $\dot{\theta}$.

Data Acquisition System

The data acquisition system used in this experiment comprises a photo-interrupter circuit, a personal computer (PC), and a RS-232 transmission interface [44.23]. The rotation speed of the DC motor is measured by the photo-interrupter coded GP1S02. The shaft of a rotary disk is connected to the shaft of the DC motor, and the disk is placed between the light-emitting element and the light-receiving element of the photo-interrupter so as to generate pulse-signals while the motor rotates. The device and the circuit are shown in Fig. 44.13.

Pulse-signals are transmitted to the PC through the RS-232 interface, and the PC counts the pulses that are accumulated within 60 seconds in order to derive the rotation speed in rpm (revolution per minute).

44.5.2 Experimental Results

The results of the experiment are presented and discussed in this section.

Measured Data

The rotation speed of the motor was measured and recorded every 5 min day and night for 80 d. Because the experiment lasted for nearly three months, lots of data were accumulated. There are 288 measurements per day and 23 040 data values in total for that period of time. Figure 44.14 shows the results. The data were fed into the estimator, as depicted in Fig. 44.14, in order to estimate the one-step-ahead state variables. The measured data and the resulting estimates for $T = 20$ min (every fourth measurement is used) are shown in Fig. 44.15. The data would be difficult to interpret if all 23 040 of the data values were shown in one chart. To avoid this and therefore to present the results more clearly, the unit used on the time axis of Fig. 44.15 is set to be 24 h (one point per day).

Error in the Estimate

The error in the estimate (in percent) is defined as

$$E_r\% = \frac{\hat{\dot{\theta}}_{k+1/k} - \dot{\theta}_{k+1}}{\dot{\theta}_{k+1}} \times 100\% \,. \qquad (44.51)$$

E_r represents the difference between the predicted value and the actual value. Figure 44.16 shows the results obtained from (44.51) using the data in Fig. 44.15. Reading from Fig. 44.16, the maximum $E_r\%$ is less than 3%.

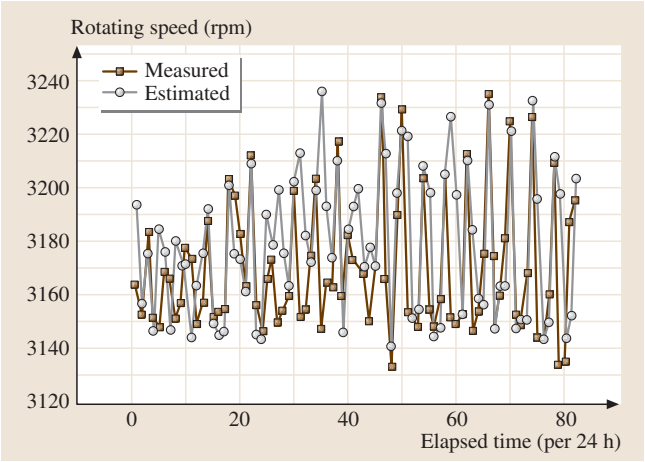

Fig. 44.15 Measured and estimated motor rotating speeds

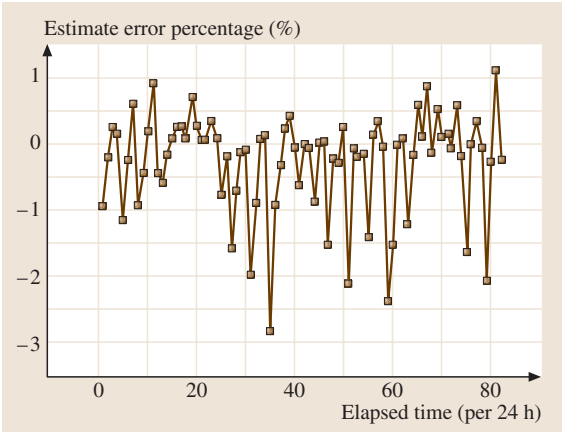

Fig. 44.16 Percent errors in estimates

Mean Value and Variance of the Accuracy of the Estimate

Let

$$X_i = 1 - E_r\%_i \quad i = 1, 2, \ldots, 23\,040 \tag{44.52}$$

be the individual accuracy of each estimate, and

$$\mu = \frac{\sum_{i=1}^{23\,040} X_i}{23040}\,, \tag{44.53}$$

$$\sigma^2 = \frac{\sum_{i=1}^{23\,040} (X_i - \mu)^2}{23\,040} \tag{44.54}$$

be the mean value and the variance [44.25] of the accuracy for the 23 040 samples, respectively. The resulting mean values, variances, and standard deviations (σ) for the estimated accuracy for $T = 5, 20, 60$ min, obtained using (44.52), (44.53), and (44.54), are summarized in Table 44.1.

Table 44.1 Mean values, standard deviations, and variances for different T

T min	μ(%)	σ(%)	σ^2(%)
5	99.74656	0.402957	0.162374
20	99.74060	0.471612	0.222418
60	99.72771	0.652469	0.425716

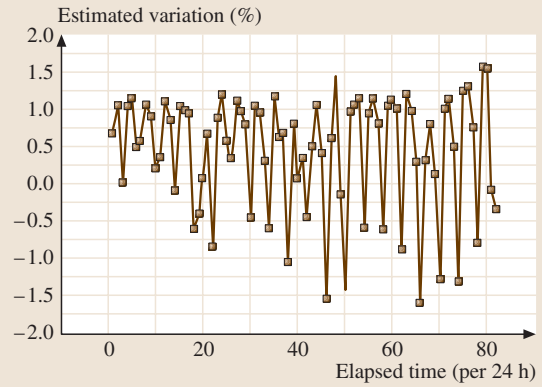

Fig. 44.17 Percent variation in the estimated rotating speed

Variation in Rotation Speed

The variation in estimated rotation speed for the DC motor (in percent) is defined using

$$V\% = \frac{\hat{\theta}_{k+1/k} - 3180}{3180} \times 100\% \,. \tag{44.55}$$

$V\%$ represents the percentage variation in the estimated rotation speed from the rated value 3180 rpm; in other words the abnormality in the motor's performance. It is used to judge whether the motor is going to fail or not. Since the MTBF of the motor is about 100 000 h [44.21], the rotation speed of the motor in this experiment varied by less than 2% of the rated value over the experiment time period. The percentage variation in the estimated rotation speed of the DC motor is shown in Fig. 44.17.

44.5.3 Notes About the Experiment

1. The mean accuracies of the estimates for $T = 5$, 20, and 60 min were all higher than 99.7%, which infers that the one-step-ahead state variable can be accurately predicted using the proposed method.

2. A threshold is a value used to judge whether or not an equipment failure occurs. It is defined as the measurement value that is taken just prior to or at the time of failure [44.28]. For failure prediction, the threshold for the motor should be determined by the user of the motor according to requirements of the specific situation. Once the estimated value reaches the threshold, a failure is predicted.
3. The disturbance amplitude should encompass all possible uncertainties for the motor and the environment.
4. Since the prediction is used for the purposes of PM, the prediction time should be long enough that PM can be performed before failure occurs.
5. The method proposed in this study is exemplified by a motor system, which is treated as a component. The procedure can be performed on a multicomponent system if state equations can be constructed for the components as a whole. It is feasible to perform the procedure on either the multicomponent system or each of the components. For a complicated or large system, the proposed method can be performed on those elements present in minimum cut sets as constructed by fault tree analysis or the Petri net model for failure [44.26].

44.6 Conclusions

Knowing when and where a system needs maintenance and economizing capital investment are two of the major issues associated with maintenance. The proposed scheme optimizes maintenance in the following aspects:

1. Before a system failure occurs, the scheme is able to indicate where and when the failure is going to be.
2. It makes the health of the system and its historical record clear at a glance.
3. Scheduled maintenance is performed according to a statistical average, which still retains an unavoidable risk that the system may fail before the criteria are exceeded, so a failure may occur unexpectedly. On the other hand, the actual duty cycles for a certain part or module may be longer than the average, so it is a waste of investment if they are replaced during scheduled maintenance. The condition-based scheme avoids those drawbacks.

Failure prediction simulation and experiment for PM, performed via state estimation using Kalman filtering, was described in this chapter. In contrast to previous works, this study uses Kalman filtering instead of parameter trends to predict the time of failure and to determine the PM execution time. The resulting prediction errors are acceptable for not only one-step-ahead prediction but also two-steps-ahead prediction. To simulate the aging failure mode, a state variable – the rotation speed – is monitored in the simulation. More measured variables mean that more complicated failure modes can be simulated. Moreover, the chapter also described an experiment on a DC motor used for state estimation via predictive maintenance using the Kalman filter. The resulting prediction errors for one-step-ahead prediction were acceptable. The shorter the increment time for Kalman prediction, the higher the prediction accuracy. Considerations used to determine the PM lead-time and the increment time required for prediction contradict each other. How to work out a compromise and end up with an optimal value is an important issue. By incorporating fault tree analysis or a Petri net model for failure, the proposed method can be performed on only those elements of a complicated or large system that fall into minimum-cut sets instead of all of the elements of the system. Therefore, failure can be prevented in enough time to promote reliability if state estimation using the Kalman filter is applied to predictive maintenance.

45. Statistical Maintenance Modeling for Complex Systems

The first part of this chapter provides a brief introduction to statistical maintenance modeling subject to multiple failure processes. It includes a description of general probabilistic degradation processes.

The second part discusses detailed reliability modeling for degraded systems subject to competing failure processes without maintenance actions. A generalized multi-state degraded-system reliability model with multiple competing failure processes including degradation processes and random shocks is presented. The operating condition of the multi-state system is characterized by a finite number of states. A methodology to generate the system states when multi-failure processes exist is also discussed. The model can be used not only to determine the reliability of the degraded systems in the context of multi-state functions but also to obtain the probabilities of being in a given state of the system.

The third part describes the inspection–maintenance issues and reliability modeling for degraded repairable systems with competing failure processes. A generalized condition-based maintenance model for inspected degraded systems is discussed. An average long-run maintenance cost rate function is derived based on an expression for degradation paths and cumulative shock damage, which are measurable. An inspection sequence is determined based on the minimal maintenance cost rate. Upon inspection, a decision will be made on whether to perform preventive maintenance or not. The optimum preventive maintenance thresholds for degradation processes and inspection sequences are also determined based on a modified Nelder–Mead downhill simplex method.

Finally, the last part is given over to the conclusions and a discussion of future perspectives for degraded-system maintenance modeling.

Technology advances mean that most new products are, on one hand, more reliable, but on the other hand, very difficult to maintain during the product life cycle. Designers have been challenged to find new, effective approaches to evaluate reliability in a timely fashion and to maintain such systems in an optimum way. This chapter presents reliability and maintenance models for degraded systems subject to competing failure processes. The accuracy of reliability estimation through a degradation model cannot be ensured unless the unit-to-unit initial variation and within-unit degradation-rate variation are considered. This chapter also discusses a generalized random-coefficient degradation process and randomized logistic degradation process to model the degradation.

Literature Review

As degradation occurs, system performance changes from perfect functioning to complete failure; the binary assumption used to analyze, model and compute system reliability is relaxed. Using degradation measures to assess reliability has seen some important findings in the literature. *Tomsky* [45.1] investigated two regression models for detecting degradation reliability. *Nelson* [45.2] briefly surveyed the application of accelerated degradation. *Lu* [45.3] introduced a nonlinear mixed-effects model and estimated model parameters in a two-stage way. Recently, multi-state reliability has received considerable attention. *Levitin* [45.4] extended the reliability importance measures for multi-state systems with different measures of performance. When the multi-state nature of a system is addressed, a better understanding of the system reliability behavior is obtained. Our third new development is to build a methodology based on the formulation of degradation in terms of a finite discrete state.

It is well known that the effectiveness of a system depends on both the quality of its design and manufacturing process as well as the proper inspection–maintenance actions to prevent it from failing. Inspection–maintenance issues are considered in the second part of this chapter.

Maintenance has evolved from a simple model that deals with machinery breakdowns, to time-based preventive maintenance, to today's condition-based maintenance. It is of great importance to avoid the failure of a system during its actual operating; especially, when such failures are dangerous and costly. Time-based and condition-based maintenance are the two major approaches for maintenance. Condition-based maintenance is often profitable since it can be used to avoid failure occurrence at the lowest cost and to improve the availability and reliability of complex systems. This chapter examines the problem of developing a mathematical maintenance cost model to determine both the optimal inspection interval time and preventive maintenance threshold of degraded systems with competing failure processes subject to a condition-based maintenance policy.

Pham et al. [45.5] presented a Markov model for predicting the reliability of k-out-of-n systems in which components are subject to multi-stage degradation as well as catastrophic failures. Due to the aging effect, the failure rate of the component will increase. They considered the state-dependent transition rates for the degradation process.

Pham et al. [45.6] derived models for predicting the availability and mean lifetime of multistage degraded systems with partial repairs.

In some production systems failures are not possible to detect but can only be determined by inspection [45.7]. Several authors [45.8–22] have proposed various inspection policies and models for systems with a degradation process. *Grall* et al. [45.8] studied a system subject to a random deterioration process. They developed a model based on a stationary process to determine both the preventive maintenance threshold and inspection dates that minimized the average long-run cost rate. *Chelbi* and *Ait-Kadi* [45.10] addressed optimal inspection strategies for deteriorating equipment subject to preventive and corrective maintenance.

Klutke and *Yang* [45.11] studied the availability of maintained systems subject to both the effects of the degradation and random shocks. They considered the degradation process as a deterministic function of time t and that shocks occurred according to a Poisson process in which the shock magnitudes are independent and identically distributed (iid) random variables. *Pham* and *Xie* [45.13] developed a generalized surveillance model consisting of dual, mutually dependent stochastic processes for surveillance systems. Their model can be used to better understand both the inspection process, the repair unit itself, and to provide information that can be used to assist inspectors in scheduling and prioritizing their future inspections.

The choice of the inspection schedule and preventive maintenance threshold(s) obviously has an important influence on the economic performance of the maintenance policy. The inspection dates and the preventive maintenance threshold(s) are two main decision variables. However, in industrial applications of condition-based maintenance, the preventive maintenance threshold is usually decided based upon the recommendation made by the maintenance people and the inspection schedule often appears to be set by little more than a rule of thumb. Because of the lack of appropriate modeling support, the preventive maintenance threshold is likely to be set conservatively and the inspection schedule may be performed more than is perhaps necessary. The need for a maintenance model with cost consideration is obvious in this case.

The chapter is organized as follows. The basic concepts and a review of maintenance, as well as a brief description of probabilistic processes for the modeling of degradation and random shocks, is discussed in Sect. 45.1. A general reliability model for degraded nonrepairable systems subject to multiple competing

processes is discussed in Sect. 45.2. The inspection–maintenance modeling issues and detection policies for degraded repairable systems considering multiple competing processes are described in Sect. 45.3. Several numerical examples are given in Sects. 45.2 and 45.3. Finally in Sect. 45.4, several future research perspectives and conclusions are briefly discussed.

Acronyms

CM	Corrective maintenance
PM	Preventive maintenance
rv	Random variable

Notation

C_c	Cost per CM action
C_p	Cost per PM action
C_m	Loss per unit idle time
C_i	Cost per inspection
$Y(t)$	Degradation process
$Y_1(t)$	Degradation process 1
$Y_2(t)$	Degradation process 2
$D(t)$	Cumulative shock damage value up to time t
G_1	Critical threshold value for degradation process 1
G_2	Critical threshold value for degradation process 2
S	Critical value for shock damage
L_1	PM critical threshold value for degradation process 1
L_2	PM critical threshold value for degradation process 2
$C(t)$	Cumulative maintenance cost up to time t
$E[C_1]$	Average total maintenance cost during a cycle
$E[W_1]$	Mean cycle length
$E[N_I]$	Mean number of inspections during a cycle
$E[\xi]$	Mean idle time during a cycle
$\{I_i\}_{i\in N}$	Inspection sequence
$\{U_i\}_{i\in N}$	Inter-inspection sequence
$\{W_i\}_{i\in N}$	Renewal times
T	Time to failure
P_{i+1}	Probability that there are a total of $(i+1)$ inspections in a renewal cycle
P_p	Probability that a renewal cycle ends by a PM action
P_c	Probability that a renewal cycle ends by a CM action
$EC(L_1, L_2, I_1)$	Expected long-run cost rate function
Ω_U	$\{M, \ldots, 1, 0, F\}$ a system state space where state M is a perfect (good) state; state 0 is a degraded failure state; states $M-1 \ldots l$ are intermediate degradation states; state F is the catastrophic failure state
Ω	$\{M, \ldots, 1, 0\}$, a system degradation state space without catastrophic failure
Ω_i	$\{M_i, \ldots, 1_i, 0_i\}$, a state space corresponding to the degradation processes of the i-th state, where 0_i is a degraded failure state due to the i-th degradation process, and M_i is a good state of the degradation process i, $i = 1, 2$
R	$\Omega_1 \times \Omega_2$, the Cartesian product of Ω_1 and Ω_2
R_i	i-th equivalence class, $i = 0, 1, \ldots, M$

45.1 General Probabilistic Processes Description

We consider three random processes. The first two are used to model degradation, while the third is a compound Poisson process used for modeling random shocks:

1. $Y(t) = A + Bg(t)$ is called a random-coefficient degradation path, where $A > 0$and $B > 0$ are independent random variables and $g(t)$ is an increasing time-dependent function. The random variable A measures the initial value of degradation due to a different manufacturer, the manufacturing quality control of new items, variable deterioration during storage until the item is put into service, and so forth [45.14]. Therefore, the initial degradation value A is a random variable. The variable B is the degradation rate $(B > 0)$ and represents the variations among the population; $g(t)$ is an increasing function.
2. $Y(t) = \frac{W e^{Bt}}{A+e^{Bt}}$ is called a randomized logistic degradation path function where A and B are independent non-negative random variables, and W is a constant. The random variable A represents the initial threshold level of degradation and B describes the rate at which degradation accumulates. It should be noted that $Y(t) = \frac{W e^{Bt}}{A+e^{Bt}}$ is an S-shaped curve and describes the degradation process well. It matches the

path of the cumulative degradation of many systems in practice. The S-shaped curve reflects an initial run-in period of low usage, followed by a period of steady rate of usage, and finally ending with an increasing rate of use due to the aging of the system. We establish the relationship between the two random variables A and B via some rearrangements as follows:

$$W\frac{e^{Bt}}{A+e^{Bt}} < H \Rightarrow B < \frac{1}{t}\ln\frac{u_1 A}{1-u_1}\,, \qquad (45.1)$$

where $u_1 = \frac{H}{W}$.

3. Let $D(t) = \sum_{i=0}^{N(t)} X_i$ represent a sequence of random shocks in which each shock causes independent damage X_i to the whole system where the X_i are iid with a probability distribution function (pdf) of $f_X(x)$, and a cumulative distribution function (cdf) of $F_X(x)$; $\{N(t), t \geq 0\}$ is a Poisson process with parameter $\lambda > 0$ that is independent of the sequence $\{X_i\}$; $F_X^{(k)}(x)$ denotes the k-th convolution.
The stochastic process $D(t) = \sum_{i=0}^{N(t)} X_i$ is called a compound Poisson process where $N(t)$ is the number of shocks that have occurred up to time t, X_i is the damage caused by the i-th shock and $D(t)$ is the cumulative damage up to time t.

45.2 Nonrepairable Degraded Systems Reliability Modeling

This section addresses reliability models for nonrepairable degraded systems. First, we discuss a model for systems subject to two competing processes. Then, we present a generalized situation where systems are subjected to three competing processes.

45.2.1 Degraded Systems Subject to Two Competing Processes

Model description

The modeling assumptions are as follows:

1. Each system has a state space $\Omega_U = \{M, \ldots, 1, 0, F\}$.
2. The system fails either due to degradation $(Y(t) > G)$ or catastrophic failure $\left[D(t) = \sum_{i=1}^{N_2(t)} X_i > S\right]$. The system may either go from state i to the next degraded state $i-1$ or directly to the catastrophic failure state F, $i = M, \ldots, 1$.
3. No repair or maintenance is performed on the system.
4. Since $Y(t)$ describes the total damage up to time t, it is natural to assume that it is nondecreasing.
5. The two processes $Y(t)$ and $D(t)$ are independent.
6. At time $t = 0$, the system is in state M.

We consider a degradable system suited at a random environment where degradation and random shocks can contribute to an effect of the life of a system. In this section, we discuss the case where systems are subject to two failure processes, called a continuous and increasing degradation process $Y(t)$, and the a andom shock process $D(t)$. Whichever process occurs first causes the system to failure.

Figure 45.1 illustrates the system flow diagram of the two competing failure processes. In Fig. 45.1, we use either of the random processes described in Sect. 45.1 to represent a degradation process where random shocks are represented by a stationary and independent increment process. Then, we discuss a method to formulate these two processes from a multi-state standing point. That is, suppose that the operating conditions of the system at any point in time could be classified into one of a finite number of the states, say $\Omega_U = \{M, \ldots, 1, 0, F\}$. We view the degradation process in terms of a finite number of states. For example, when the value of the degradation process $Y(t)$ falls into a predefined interval then its corresponding state will be determined. Let us define as follows:

$[0, W_M], \ldots, (W_2, W_1]$ are the intervals associated with the degradation process where $W_M < W_{M-1} < \ldots < W_2 < W_1$. A one-to-one relationship between the element of $\Omega = \{M, \ldots, 1, 0\}$ and its corresponding interval is set up as follows:

$$\begin{aligned}
\text{when } Y(t) &\in [0, W_M] \Rightarrow \text{in state } M\,,\\
\text{when } Y(t) &\in \left(W_M, W_{M-1}\right] \Rightarrow \text{in state } M-1\,,\\
&\vdots\\
\text{when } Y(t) &\in \left(W_i, W_{i-1}\right] \Rightarrow \text{in state } i\,,\\
\text{when } Y(t) &\in \left(W_2, W_1\right] \Rightarrow \text{in state } 1\,,\\
\text{when } Y(t) &> W_1 \Rightarrow \text{in state } 0\,.
\end{aligned}$$

Reliability Evaluation

The most general situation is to allow each degradation process to be described by a number of different discrete

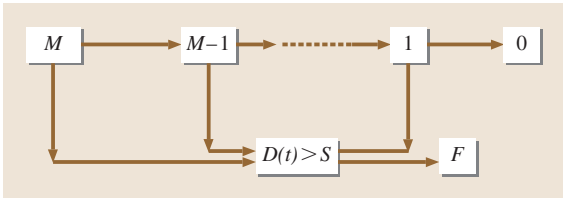

Fig. 45.1 The flow diagram of a system subjected to two competing failure processes

states. We now define the probability in each state. Let $P_i(t)$ be the probability that the value of $Y(t)$ will fall within a predefined interval corresponding to state i with $D(t) \le S$. From state i, the system will make a direct transition to state $i-1$ due to gradual degradation, or to state F due to a random shock.

The reliability function is defined as:

$$\begin{aligned} R_M(t) &= P\,(\text{state} \ge 1) \\ &= \sum_{i=1}^{M} P_i(t) \\ &= P[Y(t) \le G,\, D(t) \le S]\,, \end{aligned} \tag{45.2}$$

where $P_i(t)$ is the probability of being in state i.

Suppose a system fails if the degradation process crosses some threshold, say G; or the shock damage process crosses some threshold, say S; T is defined as:

$$T = \inf\,[t > 0 : Y(t) > G \text{ or } D(t) > S] \tag{45.3}$$

The mean time to failure is expressed as:

$$\begin{aligned} E[T] &= \int_0^\infty P[T > t]\,\mathrm{d}t \\ &= \int_0^\infty P[Y(t) \le G,\, D(t) \le S]\,\mathrm{d}t \\ &= \int_0^\infty P[Y(t) \le G] \sum_{j=0}^{\infty} \frac{(\lambda_2 t)^j\, \mathrm{e}^{-\lambda_2 t}}{j!} F_X^{(j)}(S)\,\mathrm{d}t \end{aligned}$$

or, equivalently, that

$$E[T] = \sum_{j=0}^{\infty} \frac{F_X^{(j)}(S)}{j!} \int_0^\infty P[Y(t) \le G](\lambda_2 t)^j\, \mathrm{e}^{-\lambda_2 t}\,\mathrm{d}t\,. \tag{45.4}$$

The specific expression for $E[T]$ depends on the probability function $P[Y(t) \le G]$. Sometimes, it is hard to find a closed-form solution. In this case, one can use a numerical method to solve the problem in (45.4).

The probability density function of the time to failure, $f_T(t)$ is as follows:

$$\begin{aligned} f_T(t) &= -\frac{\mathrm{d}}{\mathrm{d}t} R(t) \\ &= -\frac{\mathrm{d}}{\mathrm{d}t} \{P\,[Y(t) \le G]\,P\,[D(t) \le S]\} \\ &= -\frac{\mathrm{d}}{\mathrm{d}t} \left\{ P[Y(t) \le G] \sum_{j=0}^{\infty} \frac{(\lambda_2 t)^j\, \mathrm{e}^{-\lambda_2 t}}{j!} F_X^{(j)}(S) \right\} \\ &= -\sum_{j=0}^{\infty} \frac{F_X^{(j)}(S)}{j!} \frac{\mathrm{d}}{\mathrm{d}t} \left\{ P[Y(t) \le G]\,(\lambda_2 t)^j\, \mathrm{e}^{-\lambda_2 t} \right\} \end{aligned}$$

Let $F_G(t) = P[Y(t) \le G]$, then $f_G(t) = \frac{\mathrm{d}}{\mathrm{d}t} F_G(t)$.

$$\begin{aligned} f_T(t) = -\sum_{j=1}^{\infty} \frac{F_X^{(j)}(S)}{j!} \Big[& f_G(t)(\lambda_2 t)^j\, \mathrm{e}^{-\lambda_2 t} \\ & + F_G(t)\, j\lambda_2 (\lambda_2 t)^{j-1}\, \mathrm{e}^{-\lambda_2 t} \\ & - \lambda_2 F_G(t)(\lambda_2 t)^j\, \mathrm{e}^{-\lambda_2 t} \Big]\,. \end{aligned} \tag{45.5}$$

Reliability models

Model 1:

$$\begin{cases} Y(t) = A + Bg(t) \\ D(t) = \sum_{i=0}^{N_2(t)} X_i \end{cases}$$

$$\begin{cases} \text{case 1}: A \sim \text{normal},\ B \sim \text{normal} \\ \text{case 2}: A \sim U[0, a],\ B \sim \text{Exp}(b) \end{cases}$$

Model 2:

$$\begin{cases} Y(t) = W \frac{\mathrm{e}^{Bt}}{A + \mathrm{e}^{Bt}}, \text{ where } A \sim U[0, a],\ B \sim \text{Exp}(b) \\ D(t) = \sum_{i=0}^{N_2(t)} X_i \end{cases}$$

The two reliability models for the system are depicted in Fig. 45.1. In the following, we will take model 2 as an example to illustrate the results in this section. One can also easily apply it for the model 1.

Assume that the degradation process is described by the function $Y(t) = W \frac{\mathrm{e}^{Bt}}{A + \mathrm{e}^{Bt}}$, where the two random variables A and B are independent, and A follows a uniform distribution with parameter interval [0, a] and B follows an exponential distribution with parameter $\beta > 0$. In short, $A \sim U[0, a]$, $a > 0$ and $B \sim \text{Exp}(\beta)$, $\beta > 0$.

The probability that the system is in state M is as follows:

$$
\begin{aligned}
P_M(t) = P\Bigg[& Y(t) = W\frac{\mathrm{e}^{Bt}}{A+\mathrm{e}^{Bt}} \le W_M\,, \\
& D(t) = \sum_{i=0}^{N_2(t)} X_i \le S\Bigg] \\
= & \left[\int_{\forall A} P\left(B < \frac{1}{t}\ln\frac{u_1 A}{1-u_1} | A = x\right) f_{\mathrm{A}}(x)\,\mathrm{d}x\right] \\
& \times P\left[D(t) = \sum_{i=0}^{N_2(t)} X_{\mathrm{i}} \le S\right] \\
= & \left[1 - \frac{1}{a}\left(\frac{1-u_1}{u_1}\right)^{\frac{\beta}{t}}\left(\frac{t}{t-\beta}\right)\left(a^{1-\frac{\beta}{t}} - 1\right)\right] \\
& \times \mathrm{e}^{-\lambda_2 t}\sum_{j=0}^{\infty}\frac{(\lambda_2 t)^j}{j!}F_X^{(j)}(S)\,. \qquad (45.6)
\end{aligned}
$$

The probability that the system is in state i is calculated as follows:

$$
\begin{aligned}
P_{\mathrm{i}}(t) = P\Bigg[& W_{\mathrm{i}+1} < W\frac{\mathrm{e}^{Bt}}{A+\mathrm{e}^{Bt}} \le W_i\,, \\
& D(t) = \sum_{i=0}^{N_2(t)} X_{\mathrm{i}} \le S\Bigg] \\
= & \left[\int_0^a P\left(\frac{1}{t}\ln\frac{u_{\mathrm{i}-1}A}{1-u_{i-1}} < B \right.\right. \\
& \left.\left. \le \frac{1}{t}\ln\frac{u_{\mathrm{i}}A}{1-u_{\mathrm{i}}} | A = x\right) f_{\mathrm{A}}(x)\,\mathrm{d}x\right] \\
& \times \mathrm{e}^{-\lambda_2 t}\sum_{j=1}^{\infty}\frac{(\lambda_2 t)^j}{j!}F_X^{(j)}(S) \\
= & \left\{\frac{1}{a}\left(\frac{t}{t-\beta}\right)\left(a^{1-\frac{\beta}{t}}\right)\left[\left(\frac{1-u_{\mathrm{i}}}{u_{\mathrm{i}}}\right)^{\frac{\beta}{t}} \right.\right. \\
& \left.\left. - \left(\frac{1-u_{i-1}}{u_{i-1}}\right)^{\frac{\beta}{t}}\right]\right\} \\
& \times \mathrm{e}^{-\lambda_2 t}\sum_{j=0}^{\infty}\frac{(\lambda_2 t)^j}{j!}F_X^{(j)}(S)\,, \qquad (45.7)
\end{aligned}
$$

where $\mu_i = \frac{W_i}{W}$, $i = M-1, .., 1$.

Similarly, the probability that the system is in state 0 is as follows:

$$
\begin{aligned}
P_0(t) = P\Bigg[& Y(t) = W\frac{\mathrm{e}^{Bt}}{A+\mathrm{e}^{Bt}} > G\,, \\
& D(t) = \sum_{i=0}^{N_2(t)} X_{\mathrm{i}} \le S\Bigg] \\
= & \left[\frac{1}{a}\left(\frac{1-u_M}{u_M}\right)^{\frac{\beta}{t}}\left(\frac{t}{t-\beta}\right)\left(a^{1-\frac{\beta}{t}}\right)\right]\mathrm{e}^{-\lambda_2 t} \\
& \times \sum_{j=0}^{\infty}\frac{(\lambda_2 t)^j}{j!}F_X^{(j)}(S)\,. \qquad (45.8)
\end{aligned}
$$

The probability for a catastrophic failure state F is given by:

$$
\begin{aligned}
P_{\mathrm{F}}(t) = P\Bigg[& Y(t) = W\frac{\mathrm{e}^{Bt}}{A+\mathrm{e}^{Bt}} \le G\,, \\
& D(t) = \sum_{i=0}^{N_2(t)} X_i > S\Bigg] \\
= & \left[1 - \frac{1}{a}\left(\frac{1-u_1}{u_1}\right)^{\frac{\beta}{t}}\left(\frac{t}{t-\beta}\right)\left(a^{1-\frac{\beta}{t}}\right)\right] \\
& \times \left[1 - \mathrm{e}^{-\lambda_2 t}\sum_{j=0}^{\infty}\frac{(\lambda_2 t)^j}{j!}F_X^{(j)}(S)\right]\,. \qquad (45.9)
\end{aligned}
$$

The reliability $R_M(t)$ is expressed as:

$$
\begin{aligned}
R_M(t) = & \sum_{k=1}^{M} P_{\mathrm{k}}(t) \\
= & \left[1 - \frac{1}{a}\left(\frac{1-u_M}{u_M a}\right)^{\frac{\beta}{t}}\left(\frac{t}{t-\beta}\right)\left(a^{1-\frac{\beta}{t}}\right)\right] \\
& \times \left[\mathrm{e}^{-\lambda_2 t}\sum_{j=0}^{\infty}\frac{(\lambda_2 t)^j}{j!}F_X^{(j)}(S)\right]\,. \qquad (45.10)
\end{aligned}
$$

A Numerical Example

Assume that the degradation is modeled as the function $Y(t) = W\frac{\mathrm{e}^{Bt}}{A+\mathrm{e}^{Bt}}$ where $A \sim U[0, 5]$ and $B \sim \mathrm{Exp}(10)$. The critical values for the degradation and the shock damage are $G = 500$ and $S = 200$, respectively. The random shocks are measured by the function $D(t) = \sum_{i=1}^{N_2(t)} X_{\mathrm{i}}$, where $X_{\mathrm{i}} \sim \mathrm{Exp}(0.3)$ and X_{i}s are

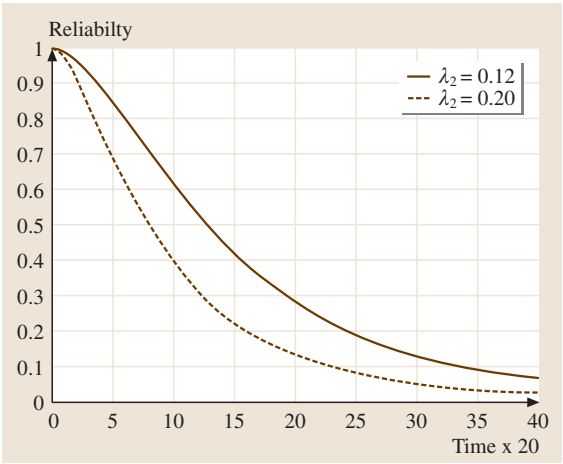

Fig. 45.2 Reliability versus time

iid. Figure 45.2 shows the reliability of the system as a function of time, where the solid line represents $N_2(t)$ with $\lambda_2 = 0.12$ and the dotted line represents $N_2(t)$ with $\lambda_2 = 0.20$.

45.2.2 Systems Subject to Three Competing Processes

System Description

In some applications, the systems are subjected to a variety of governing failure processes. In this section, we consider three independent competing failure processes in which two of them are degradation processes (called degradation process 1, which is measured by the function $Y_1(t)$, and degradation process 2, which is measured by $Y_2(t)$) and the third is a random shock process $D(t)$ [45.15]. Whichever process occurs first causes the system to fail.

Initially, the system is considered to be in its good state (i. e., M_1 and M_2). As time progresses, it can either go to the first degraded state [i. e., $(M-1)_1$ or $(M-1)_2$] upon degradation or can go to a failed state (state F), if subject to random shocks. When a system reaches the first degraded state, it can either stay in that state until the mission time, or it can go to the second degradation state [i. e., $(M-2)_1$ or $(M-2)_2$] upon degradation, or it can go to a failed state (F state) upon random shocks.

The same process will be continued for all stages of degradation except the last degradation, either stage 0_1 or stage 0_2. If the system reaches the last degradation state, it cannot perform its functions satisfactorily and must be treated as a failure (state 0).

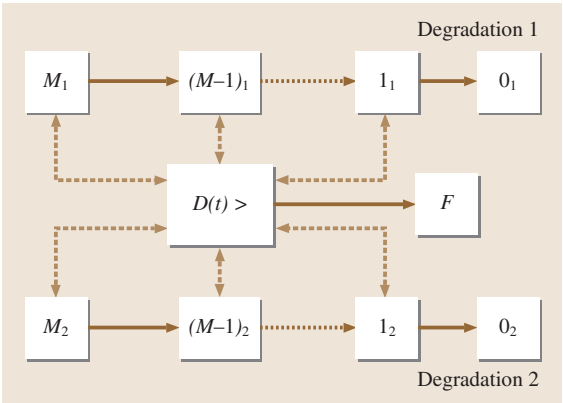

Fig. 45.3 The flow diagram of a system subjected to multiple failure processes [45.15]

Figure 45.3 shows the system flow diagram of the multiple competing transition processes. In Fig. 45.3, the above represents the degradation process 1; the bottom represents the degradation process 2; F represents a catastrophic failure state due to random shocks.

Assumptions.

1. The system consists of $(M+2)$ states where state 0 and state F are both complete failure states. State i is a degradation state, $1 < i < M$.
2. No repair or maintenance is performed on the system.
3. We assume that $Y_i(t)$, $i = 1, 2$ is a nonnegative nondecreasing function at time t, since degradation is an irreversible accumulation of damage.
4. $Y_i(t)$, $i = 1, 2$ and $D(t)$ are statistically independent. The independence assumption implies that the state of one process will have no effect on the state of the others.
5. At time $t = 0$, the system is in state M.
6. The system can fail either due to any of the degradation process when $Y_i(t) > G_i$, $i = 1, 2$ or due to random shocks (in which case it goes to a catastrophic failure state F), i. e. $D(t) = \sum_{i=1}^{N(t)} X_i > S$.
7. The critical threshold value G_i depends upon a function of the states of the degraded systems.

Methodology

In this section, we consider that the degradation paths are modeled by some continuous probabilistic functions. Since the operating condition of the systems is characterized by a finite number of states, let us call the system state space Ω_U. First, we need the discrete continuous

processes. In Step 1 below, we discuss a procedure for forcing two degradation processes to become discrete in order to obtain Ω_1 and Ω_2, which correspond to degradation process 1 and 2, respectively. After we have obtained the degradation process spaces Ω_1 and Ω_2, we present a methodology for how to establish a relationship between the system state space Ω_U and the degradation and random shock state spaces $\{\Omega_1, \Omega_2, F\}$ in Step 2.

Step 1: formulate the degradation processes in terms of discrete state sets. The two-degradation-process case is considered here. The most general situation is to allow each degradation process to be described by a number of different discrete states. The state space denoted by $\Omega_1 = \{M_1, \ldots, 1_1, 0_1\}$ corresponds to degradation process 1 with $M_1 + 1$ states. Similarly, the state space denoted by $\Omega_2 = \{M_2, \ldots, 1_2, 0_2\}$ is associated with degradation process 2, having $M_2 + 1$ states. M_1 and M_2 may or may not be the same, and $M_i < \infty$, $i = 1, 2$.

We view the degradation process from the perspective of a finite number of states. For example, when the value of degradation process 1 $Y_1(t)$ falls into a predefined interval, then its corresponding state will be determined. Let us define as follows:

$[0, W_M], \ldots, (W_2, W_1]$ are the intervals on the degradation 1 curve (Fig. 45.4a) corresponding to state M_1, 0_1, where $W_M < W_{M-1} < \cdots < W_1$ and $[0, A_M], \ldots, (A_2, A_1]$ are intervals associated with the curve for degradation process 2 (Fig. 45.4b) corresponding to state M_2, 0_2, where $A_M < A_{M-1} < \ldots < A_1$.

Mathematically, the relationship between the degradation process states $\Omega_1 = \{M_1, \ldots, 1_1, 0_1\}$, $\Omega_2 = \{M_2, \ldots, 1_2, 0_2\}$, and their corresponding degradation intervals are given as follows:

Degradation process 1

$$0 < Y_1(t) \le W_M, \text{ state } M_1$$
$$W_M < Y_1(t) \le W_{M-1}, \text{ state } (M-1)_1$$
$$\vdots$$
$$W_2 < Y_1(t) \le W_1, \text{ state } 1_1$$
$$G_1 = W_1 < Y_1(t), \text{ state } 0_1$$

Degradation process 2

$$0 < Y_2(t) \le A_M, \text{ state } M_2$$
$$A_M < Y_2(t) \le A_{M-1}, \text{ state } (M-1)_2$$
$$\vdots$$
$$A_2 < Y_2(t) \le A_1, \text{ state } 1_2$$
$$G_2 = A_1 < Y_2(t), \text{ state } 0_2$$

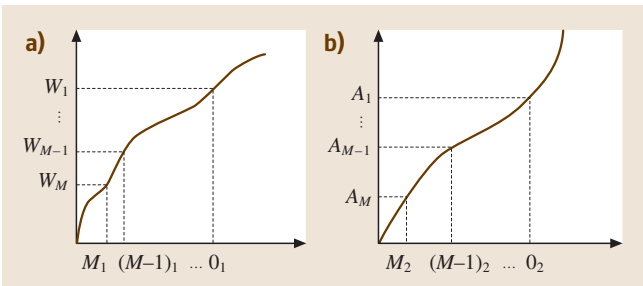

Fig. 45.4a,b The degradation process functions in multi-state terms for: (a) degradation 1, (b) degradation 2

Fig. 45.5 A mapping function

Step 2: generate the system state space. The system state space is defined as $\Omega_U = \{M, \ldots, 1, 0, F\}$, and consists of $M + 2$ states. In this step, we discuss a methodology to develop a function to generate a relationship between the system state space Ω_U and the degradation state spaces $\{\Omega_1, \Omega_2, F\}$. For example, at a given time t, suppose that degradation process 1 is at state $i_1 \in \Omega_1$, and degradation process 2 is at state $j_2 \in \Omega_2$; what is the system state? This question is addressed as follows.

Let us assume that at the current time the system is not in a catastrophic failure state. So state F can be ignored for the time being. Therefore, we can simply look at ways to define a function that has a relationship between Ω and $\{\Omega_1, \Omega_2\}$ instead of Ω_U and $\{\Omega_1, \Omega_2, F\}$.

The operation is described by a mapping function f, which can be written as

$$f : R = \Omega_1 \times \Omega_2 \to \Omega = \{M, .., 1, 0\}$$

where $R = \Omega_1 \times \Omega_2 = \{(i_1, j_2) | i_1 \in \Omega_1, j_2 \in \Omega_2\}$ is a *Cartesian* product as the input space domain, as shown in Fig. 45.5. The matrix H_c given below is an output space consisting of $M + 1$ elements corresponding to

each input-space domain through the function f.

$$H_c = \begin{array}{c} \\ 0_2 \\ 1_2 \\ \vdots \\ M_2 \end{array} \begin{array}{c} \begin{array}{cccc} 0_1 & 1_1 & \cdots & M_1 \end{array} \\ \begin{pmatrix} \times & 0 & \cdots & 0 \\ 0 & \ddots & & \vdots \\ \vdots & & \ddots & \vdots \\ 0 & \cdots & \cdots & M \end{pmatrix} \end{array} .$$

The top row of this matrix H_c represents the state from degradation process 1. The leftmost column represents the state from degradation process 2. The elements of H_c represent $f(i_1, j_2) = k$ where $i_1 \in \Omega_1$, $j_2 \in \Omega_2$ and $k \in \Omega$. Notice that, in the matrix H_c, all the elements in the first row and first column are zero except that denoted by × because the system will go to a degraded failure state (state 0) when either of the degradations reaches state 0_i, $i = 1, 2$. Besides, some elements in the matrix H_c are also zeros since we define that, when degradation 1 is in some low state $l_1(0_1 < l_1 < M_1)$ and degradation 2 is also in some low state $l_2(0_2 < l_2 < M_2)$, we consider it a degradation failure. It is also observed that $f(M_1, M_2) = M$, because initially the system is in a brand-new state (perfect state M).

As we mentioned above, the first element in H_c is marked by ×, which means it does not exist. The reason is presented as follows. We define the time to failure as

$$T = \inf [t : Y_1(t) > G_1, Y_2(t) > G_2 \text{ or } D(t) > S] . \tag{45.11}$$

It should be noted that all three processes are competing against each other for the life of a system. However, only one of the three processes (whichever occurs first when its corresponding critical threshold value is exceeded) causing the system to fail. Hence, the following events will not happen:

$$P[Y_1(t) > G_1, Y_2(t) > G_2, D(t) \le S] = 0 ,$$
$$P[Y_1(t) > G_1, Y_2(t) > G_2, D(t) > S] = 0 ,$$
$$P[Y_1(t) > G_1, Y_2(t) < G_2, D(t) > S] = 0 ,$$

and

$$P[Y_1(t) < G_1, Y_2(t) > G_2, D(t) > S] = 0 .$$

Because $f(0_1, 0_2) = P[Y_1(t) > G_1, Y_2(t) > G_2, D(t) \le S]$, so the combination of $f(0_1, 0_2)$ does not exist.

The function $f : R = \Omega_1 \times \Omega_2 \to \Omega = \{M, .., 1, 0\}$ is defined with following requirements:

1. $f(0_1, b) = f(a, 0_2) = 0$, where $b \in \Omega_2, a \in \Omega_1$
   $f(M_1, M_2) = M$

Fig. 45.6 A representation of a system state-generating box

2. f is monotonic and nondecreasing in each argument.

   For instance,

   $f(a_1, b_2) \ge f(l_1, b_2)$ if $a_1 \ge l_1$,
   $f(a_1, b_2) \ge f(a_1, l_2)$ if $b_2 \ge l_2$.

Figure 45.6 demonstrates the system's state-generating box. There are two inputs i_1 and j_2 and an output k. The inside mapping mechanism is performed by the function f. At time t, suppose that degradation 1 is at state i_1 and degradation 2 is at state j_2; i_1 and j_2 are inputs. Via matrix H_c, the system state k is then generated as output.

In the matrix H_c different state-combination inputs can generate the same results for the system state. To explain this, we need the following definition of the equivalence class.

Definition 45.1

The i-th equivalence class, R_i, is defined as follows:

$$R_i = [(k_1, j_2) \text{ where } k_1 \in \Omega_1, j_2 \in \Omega_2 | f(k_1, j_2) = i] ,$$
$$i = 0, 1, \ldots, M , \tag{45.12}$$

R_i represents all possible state combinations that generate the system state i; $R_0, \ldots, R_M$ are disjointed sets that partition R into $(M+1)$ equivalence classes, so that

$$R = \bigcup_{i=0}^{M} R_i .$$

45.2.3 Reliability Evaluation

In this section, the probability density functions and the system mean time to failure are derived based on the state probabilities given in Sect. 45.2.1. Now, we derive the probability of being in each state. Initially, the system is in a brand-new state; i. e., in state $M = f(R_M)$. The probability for state M is given by

$$P_t(M) = P_t[f(R_M)] . \tag{45.13}$$

As defined previously, R_i represents all possible state combinations generating the system state i. The probability of being in state i is the union of all the elements

in R_i

$$P_t(i) = P[f(R_i)] \,. \tag{45.14}$$

The probability for a catastrophic failure state F is given by

$$P_t(F) = P[Y_1(t) \le G_1, Y_2(t) \le G_2, D(t) > S] \,. \tag{45.15}$$

The reliability $R(t)$ can be calculated as follows:

$$\begin{aligned} R(t) &= P(\text{system state } \ge 1) \\ &= \bigcup_{i=1}^{M} P[f(R_i)] \\ &= \sum_{i=1}^{M} P_t(i) \,, \end{aligned} \tag{45.16}$$

where $P_t(i)$ is the probability of being in state i.

The mean time to failure is expressed as [45.15]:

$$\begin{aligned} E[T] &= \int_0^{\infty} P(T > t)\,\mathrm{d}t \\ &= \int_0^{\infty} P[Y_1(t) \le G_1] P[Y_2(t) \le G_2] \\ &\quad \times \sum_{j=0}^{\infty} \frac{(\lambda_2 t)^j \, \mathrm{e}^{-\lambda_2 t}}{j!} F_X^{(j)}(S) \end{aligned}$$

or, equivalently, that

$$\begin{aligned} E[T] = \sum_{j=0}^{\infty} \frac{F_X^{(j)}(S)}{j!} \int_0^{\infty} & P[Y_1(t) \le G_1] \\ & \times P[Y_2(t) \le G_2] (\lambda_2 t)^j \, \mathrm{e}^{-\lambda_2 t} \, \mathrm{d}t \,. \end{aligned} \tag{45.17}$$

The result in (45.17) obviously would depend on the expression $P[Y_1(t) \le G_1] P[Y_2(t) \le G_2]$. The probability density function of time to failure, $f_T(t)$ is therefore as follows:

$$\begin{aligned} f_T(t) &= -\frac{\mathrm{d}}{\mathrm{d}t} [P(T > t)] \\ &= -\frac{\mathrm{d}}{\mathrm{d}t} \left\{ P[Y_1(t \le G_1)] P[Y_2(t) \le G_2] \right. \\ &\quad \left. \times \sum_{j=0}^{\infty} \frac{(\lambda_2 t)^j \, \mathrm{e}^{-\lambda_2 t}}{j!} F_X^{(j)}(S) \right\} \,. \end{aligned} \tag{45.18}$$

45.2.4 Numerical Examples

This example aims to illustrate the results discussed in the previous sections. Consider a system subjected to two degradation processes and random shocks.

Assume that degradation process 1 is described by the function $Y_1(t) = A + Bg(t)$, where the random variables A and B are independent and both follow normal distributions, with mean 90 and variance 2.5, and mean 78 and variance 6, respectively. In short, $A \sim N(90, 2.5)$ and $B \sim N(78, 6)$. The degradation function is assumed to be $g(t) = t^3$. Also $G_1 = 2500$, $W_3 = 1500$, $W_2 = 2000$, and $W_1 = 2500$.

Assume that degradation process 2 is described by $Y_2(t) = W \frac{\mathrm{e}^{BBt}}{AA + \mathrm{e}^{BBt}}$, where the random variables AA and BB are independent and follow uniform distributions with parameter interval [0,100] and an exponential distribution with parameter 0.1, respectively. In other words, $AA \sim U[0, 100]$ and $BB \sim \mathrm{Exp}(0.01)$. Also $G_2 = 5000$, $A_2 = 2600$, $A_1 = 5000$, and $W = 7000$. Assume that the random shock is represented by $D(t) = \sum_{i=0}^{N(t)} X_i$ with critical value $S = 200$, where $X_i \sim \mathrm{Exp}(0.1)$ and the X_i are iid.

Assume that the states associated with degradation process 1 and degradation 2 are, respectively, $\Omega_1 = \{3_1, 2_1, 1_1, 0_1\}$ and $\Omega_2 = \{2_2, 1_2, 0_2\}$. We define the system state space as $\Omega_\mathrm{U} = \{3, 2, 1, 0, F\}$ and the matrix H_c is given as

$$H_\mathrm{c} = \begin{array}{c} \\ 0_2 \\ 1_2 \\ 2_2 \end{array} \begin{array}{c} \begin{array}{cccc} 0_1 & 1_1 & 2_1 & 3_1 \end{array} \\ \begin{pmatrix} \times & 0 & 0 & 0 \\ 0 & 0 & 2 & 3 \\ 0 & 1 & 2 & 3 \end{pmatrix} \end{array} .$$

Then we obtain

$$\begin{aligned} R = \{&(0_1, 1_2), (0_1, 2_2), (1_1, 0_2), (2_1, 0_2), (3_1, 0_2), \\ &(1_1, 1_2), (2_1, 1_2), (3_1, 1_2), (1_1, 2_2), (2_1, 2_2), \\ &(3_1, 2_2)\} \end{aligned}$$

The equivalence classes can be listed as follows:

$$\begin{aligned} R_0 &= \{(0_1, 1_2), (0_1, 2_2), (1_1, 0_2), (2_1, 0_2), (3_1, 0_2), \\ &\quad (1_1, 1_2)\} \,, \\ R_1 &= \{(1_1, 2_2)\} \,, \\ R_2 &= \{(2_1, 1_2), (2_1, 2_2)\} \,, \\ R_3 &= \{(3_1, 1_2), (3_1, 2_2)\} \,, \\ R &= \sum_{i=0}^{3} R_i \,. \end{aligned}$$

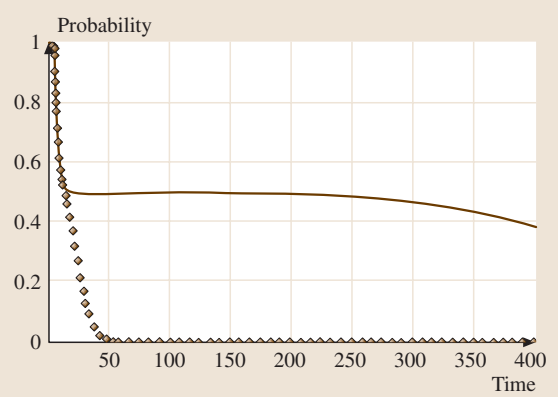

Fig. 45.7 Probability plot for state 3 versus time

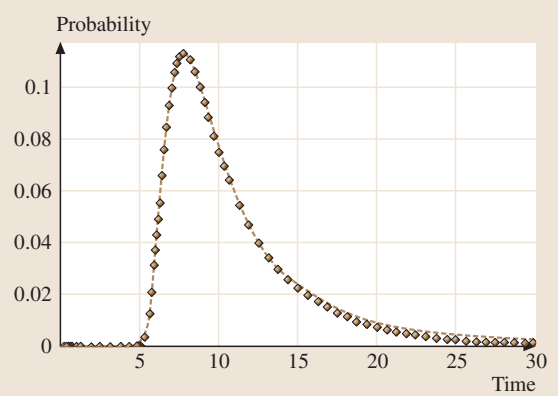

Fig. 45.8 Probability plot for state 2 versus time

According to this expression for H_c, the probability of the system being in state 3 is the sum of the probability $f(3_1, 2_2)$ and of the probability $f(3_1, 1_2)$. That sum is calculated as

$$P_t(3) = P_t\,[f(R_3)] = \Phi\left(\frac{1500-(90+78t)}{\sqrt{2.5+6t^6}}\right)\left[1-\frac{1}{100}\,(0.4)^{\frac{0.01}{t}} \times\left(\frac{t}{t-0.01}\right)\left(0.01^{1-\frac{0.01}{t}}\right)\right] \times \mathrm{e}^{-\lambda_2 t}\sum_{j=0}^{\infty}\left(\frac{\lambda_2 t}{j!}\right)F_X^{(j)}(200)\,. \quad (45.19)$$

Figure 45.7 shows the probability for the system to be in state 3 as a function of time t, where the solid line represents the compound Poisson process $D(t)=\sum_{i=0}^{N(t)} X_i$ with rate $\lambda = 0.04$ and the dotted line represents the compound Poisson process with rate $\lambda = 0.8$. In Fig. 45.7 we observe that, as t progresses to 50, the probability that the system is in state 3 quickly approaches 0 when the rate is given as $\lambda = 0.8$, and is stable with $\lambda = 0.04$.

Because $R_2 = \{(2_1, 1_2), (2_1, 2_2)\}$, the probability of being in state 2 is given by

$$P_t(2) = P_t[f(2_1, 1_2)] + P_t[f(2_1, 2_2)] = (UV)\,\mathrm{e}^{-\lambda_2 t}\sum_{j=0}^{\infty}\left(\frac{\lambda_2 t}{j!}\right)F_X^{(j)}(200)\,, \quad (45.20)$$

where

$$U = \Phi\left(\frac{2000-(90+78t)}{\sqrt{2.5+6t^6}}\right) - \Phi\left(\frac{1500-(90+78t)}{\sqrt{2.5+6t^6}}\right),$$

and

$$V = 1-\frac{1}{100}\left(\frac{t}{t-0.01}\right)(0.4)^{\frac{0.01}{t}} \times\left(\frac{t}{t-0.01}\right)(0.01)^{1-\frac{0.01}{t}}\,.$$

Figure 45.8 shows the probability of being in state 2 as a function of time t, where the solid line represents the compound Poisson process $D(t)=\sum_{i=0}^{N(t)} X_i$ with rate $\lambda = 0.04$, and the dotted line represents the compound Poisson process with rate $\lambda = 0.8$. In Fig. 45.8, we observe that, before the time t progresses to 5, the probability of being in state 2 stays close to zero for both rates $\lambda = 0.8$ and $\lambda = 0.04$. It should be noted that the two curves are almost the same for the different values of the rate $\lambda = 0.8$ and $\lambda = 0.04$.

Similarly, the probability of being in state 1 is calculated as:

$$P_t(1) = P_t[f(1_1, 2_2)] = E_1 E_2\,\mathrm{e}^{-\lambda_2 t}\sum_{j=0}^{\infty}\left(\frac{\lambda_2 t}{j!}\right)F_X^{(j)}(200)\,,$$

where $E_1 = \Phi\left(\frac{2500-(90+78t)}{\sqrt{2.5+6t^6}}\right) - \Phi\left(\frac{2000-(90+78t)}{\sqrt{2.5+6t^6}}\right)$,

$$E_2 = 1-\frac{1}{100}\left(\frac{t}{t-0.01}\right)\left(\frac{22}{13}\right)^{\frac{0.01}{t}}(0.01)^{1-\frac{0.01}{t}}\,. \quad (45.21)$$

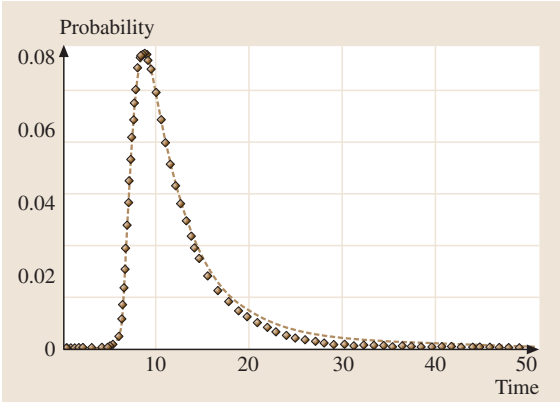

Fig. 45.9 Probability plot for state 1 versus time

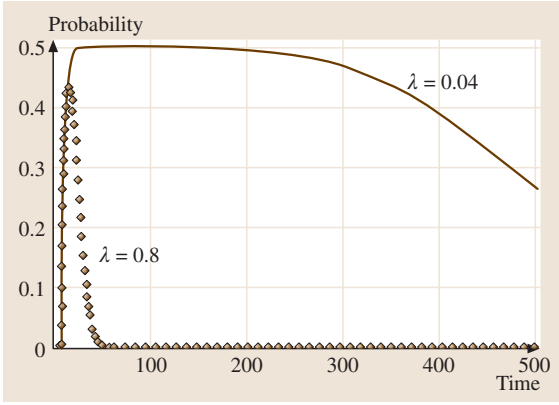

Fig. 45.10 Probability plot for state 0 versus time

Figure 45.9 shows the probability of being in state 1 versus time t, where the solid line represents the compound Poisson process $D(t) = \sum_{i=0}^{N(t)} X_i$ with rate $\lambda = 0.04$, and the dotted line represents the compound Poisson process with rate $\lambda = 0.8$. In Fig. 45.9, we observe that, before the time t progresses to 15, the probability of being in state 1 for both rates $\lambda = 0.8$ and $\lambda = 0.04$ are about the same.

We can also easily obtain the probability of being in state 0 as follows:

$$\begin{aligned} P_t(0) &= P\big[f(0_1, 1_2) + f(0_1, 2_2) + f(1_1, 0_2) \\ &\quad + f(2_1, 0_2) + f(3_1, 0_2) + f(1_1, 1_2)\big] \\ &= (X_1Y_1 + X_2Y_2 + X_3Y_3)\,\mathrm{e}^{-\lambda_2 t} \\ &\quad \times \sum_{j=0}^{\infty} \left(\frac{\lambda_2 t}{j!}\right) F_X^{(j)}(200)\,, \end{aligned}$$

where $X_1 = 1 - \Phi\left(\dfrac{2500-(90+78t)}{\sqrt{2.5+6t^6}}\right)$,

$$X_2 = \Phi\left(\frac{2500-(90+78t)}{\sqrt{25+6t^2}}\right),$$

$$Y_1 = 1 - \frac{1}{100}\,(0.4)^{\frac{0.01}{t}} \left(\frac{t}{t-0.01}\right) \times \left(0.01^{1-\frac{0.01}{t}}\right),$$

$$Y_2 = \frac{1}{100}\,(0.4)^{\frac{0.01}{t}} \left(\frac{t}{t-0.01}\right) \times \left(0.01^{1-\frac{0.01}{t}}\right),$$

$$X_3 = \Phi\left(\frac{2500-(90+78t)}{\sqrt{2.5+6t^6}}\right) - \Phi\left(\frac{2000-(90+78t)}{\sqrt{2.5+6t^6}}\right),$$

$$Y_3 = 1 - \frac{1}{100}\left[\left(\frac{22}{13}\right)^{\frac{0.01}{t}} + (0.4)^{\frac{0.01}{t}}\right] \times \left(\frac{t}{t-0.01}\right)\left(0.01^{1-\frac{0.01}{t}}\right). \qquad (45.22)$$

Figure 45.10 shows the probability that the system is in state 0 versus the time t, where the solid line represents the compound Poisson process $D(t) = \sum_{i=0}^{N(t)} X_i$ with rate $\lambda = 0.04$, and the dotted line represents the compound Poisson process with rate $\lambda = 0.8$. In Fig. 45.10, we observe that the probability of being in state 0 is close to zero when $t > 100$ for the rate $\lambda = 0.8$.

The probability of being in state F is calculated as:

$$\begin{aligned} P_t(F) &= P\left[Y_1(t) \le G_1, Y_2(t) \le G_2, D(t) > S\right] \\ &= KL\left[1 - \mathrm{e}^{-\lambda_2 t} \sum_{j=0}^{\infty} \left(\frac{\lambda_2 t}{j!}\right) F_X^{(j)}(200)\right], \end{aligned}$$

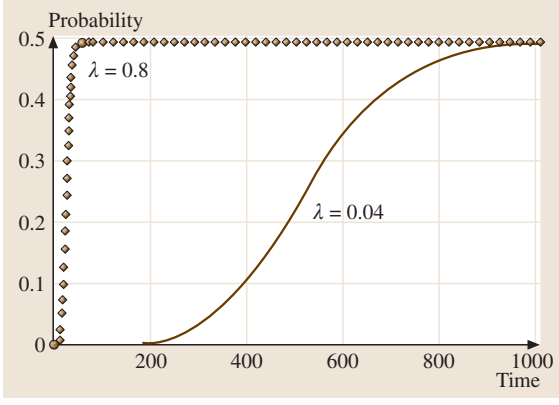

Fig. 45.11 Probability plot for state F versus time

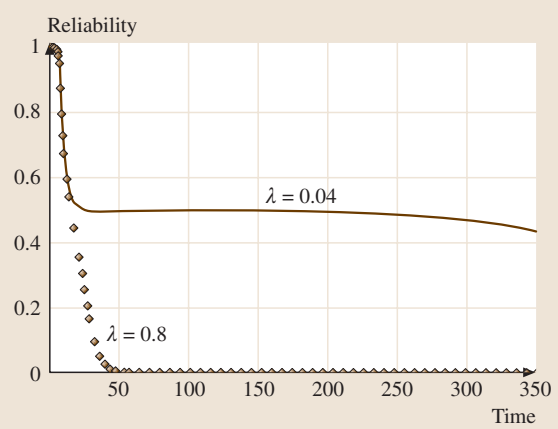

Fig. 45.12 Reliability versus time

$$\text{where}\quad K=\Phi\left(\frac{2500-(90+78t)}{\sqrt{2.5+6t^6}}\right),$$
$$L=1-\frac{1}{100}(0.4)^{\frac{0.01}{t}}\left(\frac{t}{t-0.01}\right)\left(0.01^{1-\frac{0.01}{t}}\right). \tag{45.23}$$

Figure 45.11 shows the probability of being in state F as a function of time t, where the solid line represents the compound Poisson process $D(t)=\sum_{i=0}^{N(t)}X_i$ with rate $\lambda=0.04$, and the dotted line represents the compound Poisson process with rate $\lambda=0.8$.

Finally, the system reliability $R(t)$ is given by

$$\begin{aligned}R(t)&=P(\text{system state}\geq 1)\\&=\sum_{i=1}^{3}P_t(i)\\&=X_3Y_3\,\mathrm{e}^{-\lambda_2 t}\sum_{j=0}^{\infty}\left(\frac{\lambda_2 t}{j!}\right)F_X^{(j)}(200),\end{aligned}$$

$$\text{where } X_3=\Phi\left(\frac{2000-(90+78t)}{\sqrt{2.5+6t^6}}\right)$$
$$\times\left\{1-\frac{1}{100}\left[(0.4)^{\frac{0.01}{t}}+\left(\frac{22}{13}\right)^{\frac{0.01}{t}}\right]\right.$$
$$\left.\times\left(\frac{t}{t-0.01}\right)\left(0.01^{1-\frac{0.01}{t}}\right)\right\},$$
$$Y_3=\left[\Phi\left(\frac{2500-(90+78t)}{\sqrt{2.5+6t^6}}\right)\right.$$
$$\left.-\Phi\left(\frac{2000-(90+78t)}{\sqrt{2.5+6t^6}}\right)\right]$$
$$\times\left[1-\frac{1}{100}\left(\frac{t}{t-0.01}\right)\right.$$
$$\left.\times\left(\frac{22}{13}\right)^{\frac{0.01}{t}}0.01^{1-\frac{0.01}{t}}\right]. \tag{45.24}$$

Figure 45.12 shows the system reliability versus time t, where the solid line represents the compound Poisson process with rate $\lambda=0.04$, and the dotted line represents the compound Poisson process with rate $\lambda=0.8$. As for the rate $\lambda=0.8$ we observe that the system will probably fail after a time t of 50. It seems that the random shock process governs the behavior of the reliability function. Therefore, the dotted line quickly approaches the failure caused by the shock damage.

45.3 Repairable Degraded Systems Modeling

45.3.1 Inspection–Maintenance Model Subject to Two Competing Processes

Model description

Assumptions. The system starts in a new condition. The assumptions are as follows [45.22]:

1. The system is not continuously monitored, its state can be detected only by inspection, but system failure is self-announcing without inspection.
2. After a PM or CM action, the system will be restored back to an as-good-as-new state.
3. A CM action is more costly than a PM, and a PM costs much more than an inspection. This implies $C_c > C_p > C_i$.
4. The two processes $Y(t)$ and $D(t)$ are independent.
5. Repair time is not negligible.

Although continuous monitoring processes are feasible for some systems, the cost to monitor the process and the

labor required would, however, not make it realistic in practice. Therefore, we need to improve the system performance by determining the periodic inspections with maintenance action that will minimize the average total system maintenance cost. Since system deterioration while running leads to system failure, it proves better to assume that the degradation paths are continuous and increasing functions.

Inspection–Maintenance Policy. It is proposed that the system is periodically inspected at times $\{I, 2I, \cdots, nI, \cdots\}$. We assume that the degradation ($\{Y(t)\}_{t\geq 0}$) and random shock processes ($\{D(t)\}_{t\geq 0}$) are independent. Let T denote the time to failure, defined as

$$T = \inf\left[t > 0 : Y(t) > G \text{ or } D(t) > S\right] ,$$

where G is the critical value for $\{Y(t)\}_{t\geq 0}$ and S is the threshold level for $\{D(t)\}_{t\geq 0}$.

The two threshold values L and G (where G is fixed) effectively divide the system state into three regions, as illustrated in Fig. 45.13. They are: the doing-nothing zone; the PM zone; and the CM zone. The maintenance action will be performed when either of the following situations occurs.

1. The current inspection reveals that the system condition falls into the PM zone, and this state was not found on previous inspection. At inspection time iI, the system falls into the PM zone, which means $\{Y[(i-1)I] \leq L, D[(i-1)I] \leq S\} \cap \{L < Y(iI) \leq G, D(iI) \leq S\}$. Then PM action is performed and will take a random time R_1.

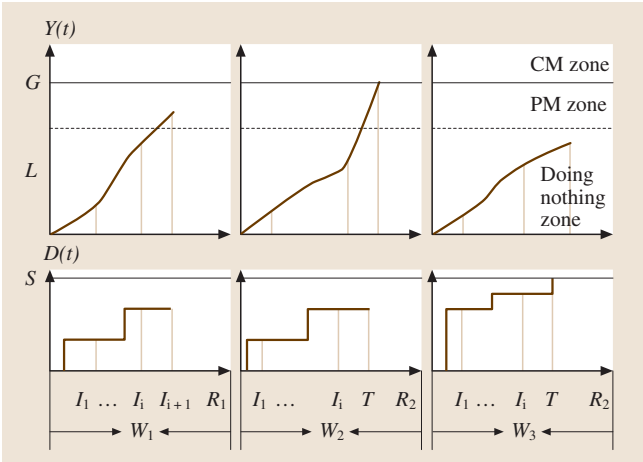

Fig. 45.13 The evolution of the system

2. When the system fails at T, a CM action is taken immediately and takes time R_2.

It is assumed that both PM and CM actions are considered to be perfect. Even though both PM and CM actions bring the system back to an as-good-as-new state, they are, physically, not necessarily the same, since a CM has to performed on a worse system. Hence, CM is likely to be more complex and expensive. Therefore, it is realistic to assume that the repair time is not negligible. This chapter considers that the PM action will take a random amount of time R_1 and that a CM action will take a random amount of time R_2. After a PM or a CM action is performed, the system is renewed. A new sequence of the inspection would start again, defined in the same way.

Maintenance Cost Modeling

In this section, an explicit expression for the average long-run maintenance cost per unit time is derived. The objectives of the model are to determine the optimal PM threshold L and the optimal inspection time I. From the basics of renewal reward theory, we have

$$\lim_{t\to\infty} \frac{C(t)}{t} = \frac{E[C_1]}{E[W_1]} .$$

We now model the average total maintenance cost per unit time on a single renewal cycle instead of $\lim_{t\to\infty} \frac{C(t)}{t}$; then we will analyze $E[C_1]$ and $E[W_1]$.

Expected maintenance cost analysis in a cycle. The expected total maintenance cost during a cycle $E[C_1]$ is expressed as [45.22]:

$$E[C_1] = C_i E[N_I] + C_p E[R_1] P_p + C_c E[R_2] P_c . \quad (45.25)$$

During a renewal cycle, activities in terms of costs include: inspection cost, time to repair, and PM or CM actions. The renewal cycle will end by either a PM or a CM action. With a probability of P_p, the cycle will end with a PM action and it will take on average an amount of time $E[R_1]$ to complete a PM action, with a corresponding cost of $C_p E[R_1] P_p$. Similarly, if a cycle ends with a CM action with probability P_c, it will take on average an amount of time $E[R_2]$ to complete a CM action, with a corresponding cost of $C_c E[R_2] P_c$. In the following, we will perform the analysis of $E[C_1]$.

Calculate $E[N_I]$. Let $E[N_I]$ denote the expected number of inspections during a cycle. $E[N_I]$ can be obtained

as:

$$E[N_I] = \sum_{i=1}^{\infty} (i) P(N_I = i) \,. \tag{45.26}$$

Obviously $\sum_{i=1}^{\infty} P(N_I = i) = 1$. There will be a total of i inspections during a cycle if the first PM trigger falls within the time interval $[(i-1)I, iI]$, or if the system condition is in the doing-nothing zone before time iI and the system fails during the interval $[iI, (i+1)I]$. In other words, the inspection will stop when the i-th inspection finds that a PM condition is satisfied while this situation was not revealed in the previous inspection, or the system fails during the interval $[iI < T \le (i+1)I]$ while the system is in the doing-nothing zone before iI.

Let $P(N_I = i)$ denote the probability that there a total of i inspections occur in a renewal cycle. Then we have

$$\begin{aligned} P(N_I = i) = {} & P\{Y[(i-1)I] \le L, D[(i-1)I] \le S\} \\ & \times P[L < Y(iI) \le G, D(iI) \le S] \\ & + P[Y(iI) \le L, D(iI) \le S] \\ & \times P[iI < T \le (i+1)I] \,. \end{aligned} \tag{45.27}$$

Hence,

$$\begin{aligned} E[N_I] = {} & \sum_{i=1}^{\infty} i\{P\{Y[(i-1)I] \le L, D[(i-1)I] \le S\} \\ & \times P[L < Y(iI) \le G, D(iI) \le S] \\ & + P[Y(iI) \le L, D(iI) \le S] \\ & \times P[iI < T \le (i+1)I]\} \,. \end{aligned} \tag{45.28}$$

We now calculate the probabilities $P\{Y[(i-1)I] \le L, D[(i-1)I] \le S\}$ and $P[L < Y(iI) \le G, D(iI) \le S]$ with the following two different expressions for $Y(t)$.

A) Assume $Y(t) = A + Bg(t)$ where $A \sim N\left(\mu_A, \sigma_A^2\right)$, $B \sim N\left(\mu_B, \sigma_B^2\right)$, and A and B are independent. Given $g(t) = t$. $D(t) = \sum_{i=0}^{N(t)} X_i$ where the X_i are iid and $N(t) \sim Poisson(\lambda)$. Then

$$\begin{aligned} & P\{Y[(i-1)I] \le L, D[(i-1)I] \le S\} \\ & = P[A + B(i-1)I \le L] \\ & \quad \times P\left\{D[(i-1)I] = \sum_{i=0}^{N[(i-1)I]} X_i \le S\right\} \\ & = \Phi\left(\frac{L - (\mu_A + \mu_B(i-1)I)}{\sqrt{\sigma_A^2 + \sigma_B^2((i-1)I)^2}}\right) \mathrm{e}^{-\lambda(i-1)I} \\ & \quad \times \sum_{j=0}^{\infty} \frac{(\lambda(i-1)I)^j}{j!} F_X^{(j)}(S) \end{aligned} \tag{45.29}$$

and

$$\begin{aligned} & P[L < Y(iI) \le G, D(iI) \le S] \\ & = \left[\Phi\left(\frac{G - (\mu_A + \mu_B iI)}{\sqrt{\sigma_A^2 + \sigma_B^2(iI)^2}}\right) \right. \\ & \quad \left. - \Phi\left(\frac{L - (\mu_A + \mu_B iI)}{\sqrt{\sigma_A^2 + \sigma_B^2(iI)^2}}\right)\right] \mathrm{e}^{-\lambda iI} \\ & \quad \times \sum_{j=0}^{\infty} \frac{(\lambda iI)^j}{j!} F_X^{(j)}(S) \,. \end{aligned} \tag{45.30}$$

B) Assume $Y(t) = W\frac{\mathrm{e}^{Bt}}{A + \mathrm{e}^{Bt}}$, where W is a constant, $A \sim U[0, a]$, $a > 0$; $B \sim \mathrm{Exp}(\beta)$, $\beta > 0$, A and B are independent. $D(t) = \sum_{i=0}^{N(t)} X_i$ where the X_i are iid and $N(t) \sim Possion(\lambda)$. Then

$$\begin{aligned} & P\{Y[(i-1)I] \le L, D[(i-1)I] \le S\} \\ & = \left[1 - \frac{1}{a}\left(\frac{1-u_1}{u_1}\right)^{\frac{\beta}{I_{i-1}}} \left(\frac{(i-1)I}{(i-1)I - \beta}\right) \right. \\ & \quad \left. \times \left(a^{1 - \frac{\beta}{(i-1)I_1}} - 1\right)\right] \mathrm{e}^{-\lambda(i-1)I} \\ & \quad \times \sum_{j=0}^{\infty} \frac{[\lambda(i-1)I]^j}{j!} F_X^{(j)}(S) \,, \end{aligned} \tag{45.31}$$

where $u_1 = L/W$. Similarly,

$$\begin{aligned} & P[L < Y(iI) \le G, D(iI) \le S] \\ & = \left\{\frac{1}{a}\left(\frac{iI}{iI - \beta}\right) \right. \\ & \quad \left. \times \left(a^{1 - \frac{\beta}{iI}}\right)\left[\left(\frac{1-u_3}{u_3}\right)^{\frac{\beta}{iI}} - \left(\frac{1-u_2}{u_2}\right)^{\frac{\beta}{iI}}\right]\right\} \mathrm{e}^{-\lambda iI} \\ & \quad \times \sum_{j=0}^{\infty} \frac{(\lambda iI)^j}{j!} F_X^{(j)}(S) \,, \end{aligned} \tag{45.32}$$

where $u_2 = G/W$, $u_3 = L/W$.

Secondly, we discuss the calculation of $P[iI < T \le (i+1)I]$. The definition of T is $T = \inf[t > 0 : Y(t) > G \text{ or } D(t) > S]$. According to the definition, we derive the expression:

$$\begin{aligned} & P[iI < T \le (i+1)I] \\ & = P\{Y(iI) \le L, Y[(i+1)I] > G\} \\ & \quad \times P\{D[(i+1)I] \le S\} \\ & \quad + P\{Y[(i+1)I] \le L\} \\ & \quad \times P\{D(iI) \le S, D[(i+1)I] > S\} \,. \end{aligned} \tag{45.33}$$

In (45.33), since $Y(iI)$, $Y[(i+1)I]$ are not independent, we could obtain the joint pdf $f_{Y(iI),Y[(i+1)I]}(y_1, y_2)$ in order to compute $P\{Y(iI) \le L, Y[(i+1)I] > G\}$. We consider two different expressions for $Y(t)$. The details are as follows:

A) Assume $Y(t) = A + Bg(t)$ where $A > 0$ and $B > 0$ are two independent random variables, and $g(t)$ is an increasing function of time t. Assume that $A \sim f_A(a)$, $B \sim f_B(b)$. Let

$$\begin{cases} y_1 = a + bg(iI) \\ y_2 = a + bg[(i+1)I] \end{cases} .$$

After simultaneously solving the above equations in terms of y_1 and y_2, we obtain:

$$a = \frac{y_1 g[(i+1)I] - y_2 g(iI)}{g[(i+1)I] - g(iI)} = h_1(y_1, y_2) ,$$
$$b = \frac{y_2 - y_1}{g[(i+1)I] - g(iI)} = h_2(y_1, y_2) .$$

The *Jacobian* J is given by

$$J = \begin{vmatrix} \frac{\partial h_1}{\partial y_1} & \frac{\partial h_1}{\partial y_2} \\ \frac{\partial h_2}{\partial y_1} & \frac{\partial h_2}{\partial y_2} \end{vmatrix} = \left| \frac{1}{g(iI) - g[(i+1)I]} \right| .$$

Then the random vector $\{Y(iI), Y[(i+1)I]\}$ has a joint continuous pdf as follows

$$f_{Y(iI),Y[(i+1)I]}(y_1, y_2) = |J| \, f_A[h_1(y_1, y_2)] f_B[h_2(y_1, y_2)] . \quad (45.34)$$

B) Assume $Y(t) = \frac{W e^{At}}{B + e^{At}}$ where $A > 0$ and $B > 0$ are independent. Assume $A \sim f_A(a)$, $B \sim f_B(b)$. Let

$$\begin{cases} y_1 = \frac{W e^{aiI}}{b + e^{aiI}} \\ y_2 = \frac{W e^{a(i+1)I}}{b + e^{a(i+1)I}} \end{cases} .$$

The solutions for a and b can be easily found from the above equations in terms of y_1 and y_2 as follows:

$$\begin{cases} a = \frac{\ln\left(\frac{y_2(y_1 - W)}{y_1(y_2 - W)}\right)}{I} = h_1(y_1, y_2) \\ b = -\frac{e^{\frac{\ln\left(\frac{y_2(y_1 - W)}{y_1(y_2 - W)}\right)(i+1)I}{I}}}{y_2} (y_2 - W) = h_2(y_1, y_2) \end{cases} .$$

It can be shown that the random vector $\{Y(iI), Y[(i+1)I]\}$ has a joint density function given by

$$f_{Y(iI),Y[(i+1)I]}(y_1, y_2) = |J| \, f_A[h_1(y_1, y_2)] f_B[h_2(y_1, y_2)] , \quad (45.35)$$

where the Jacobian determinant J is given in Appendix A.

As for the term $P\{D(iI) \le S, D[(i+1)I] > S\}$ in (45.30), since $D(t) = \sum_{i=0}^{N(t)} X_i$ is a compound Poisson process, the compound Poisson process has a stationary independent increment property. Therefore, the random variables $D(iI)$ and $D[(i+1)I] - D(iI)$ are independent. Using the *Jacobian* transformation, the random vector $\{D(iI), D[(i+1)I] - D(iI)\}$ is distributed in the same way as vector $\{D(iI), D[(i+1)I]\}$. Note that $D(iI)$ and $D(I_{i+1})$ are independent, therefore,

$$P\{D(iI) \le S, D[(i+1)I] > S\} = P[D(iI) \le S] P\{D[(i+1)I] > S\} . \quad (45.36)$$

Calculate P_p. Note that either a PM or CM action will end a renewal cycle. In other words, these two events are mutually exclusive at the renewal time point. As a consequence, $P_p + P_c = 1$. The probability P_p can be obtained as follows:

$$\begin{aligned} P_p &= P(\text{PM ending a cycle}) \\ &= \sum_{i=1}^{\infty} P\{Y[(i-1)I] \le L, L < Y(iI) \le G\} \\ &\quad \times P[D(iI) \le S] . \end{aligned} \quad (45.37)$$

Analysis of expected cycle length. Since the renewal cycle ends either by a PM action with probability P_p or a CM action with probability P_c, the mean cycle length $E[W_1]$ is calculated as follows:

$$\begin{aligned} E[W_1] &= \sum_{i=1}^{\infty} E[(iI + R_1) I_{\text{PM occurs in}[(i-1)I, iI]}] \\ &\quad + E\left[(T + R_2) 1_{\text{CM occurs}}\right] \\ &= \left\{ \sum_{i=1}^{\infty} iI P\{Y[(i-1)I] \le L, \right. \\ &\quad D[(i-1)I] \le S\} P[L < Y(iI) \le G, \\ &\quad \left. D(iI) \le S] \right\} \\ &\quad + E[R_1] P_p + (E[T] + E[R_2]) P_c , \end{aligned} \quad (45.38)$$

where $I_{\text{PM occurs in}[(i-1)I, iI]}$ and $I_{\text{CM occurs}}$ are the indicator functions.

The mean time to failure, $E[T]$ is given by [45.22]:

$$\begin{aligned} E[T] &= \int_0^\infty P\{T > t\}\,\mathrm{d}t \\ &= \int_0^\infty P[Y(t) \le G,\, D(t) \le S]\,\mathrm{d}t \\ &= \int_0^\infty P[Y(t) \le G] \sum_{j=0}^{\infty} \frac{(\lambda_2 t)^j\, \mathrm{e}^{-\lambda_2 t}}{j!} F_X^{(j)}(S)\,\mathrm{d}t \end{aligned}$$

or, equivalently:

$$E[T] = \sum_{j=0}^{\infty} \frac{F_X^{(j)}(S)}{j!} \int_0^\infty P[Y(t) \le G](\lambda_2 t)^j\, \mathrm{e}^{-\lambda_2 t}\,\mathrm{d}t \tag{45.39}$$

The expression $E[T]$ depends on the probability $P[Y(t) \le G]$ and cannot always be easily be obtained in closed form.

Optimization of the maintenance cost rate policy

We determine the optimal inspection time I and PM threshold L such that the long-run average maintenance cost rate $EC(L, I)$ is minimized. Mathematically, we wish to minimize the following objective function [45.22]:

$$\begin{aligned} & EC(L, I) \\ &= \frac{\sum_{i=1}^{\infty} i P_1 P_2}{\left\{\sum_{i=1}^{\infty} I_i P_1 P_2\right\} + E[R_1]P_\mathrm{p} + E[R_2]P_\mathrm{c}} \\ &\quad + \frac{\sum_{i=1}^{\infty} i V_i \{P_3 P_4 + P_5 P_6\}}{\left\{\sum_{i=1}^{\infty} I_i P_1 P_2\right\} + E[R_1]P_\mathrm{p} + E[R_2]P_\mathrm{c}} \\ &\quad + \frac{C_\mathrm{p} E[R_1] \sum_{i=1}^{\infty} P_1 P_2}{\left\{\sum_{i=1}^{\infty} I_i P_1 P_2\right\} + E[R_1]P_\mathrm{p} + E[R_2]P_\mathrm{c}} \\ &\quad + \frac{C_\mathrm{c} E[R_2]\left\{1 - \sum_{i=1}^{\infty} P_1 P_2\right\}}{\left\{\sum_{i=1}^{\infty} I_i P_1 P_2\right\} + E[R_1]P_\mathrm{p} + E[R_2]P_\mathrm{c}}\,, \end{aligned} \tag{45.40}$$

where $I_{i-1} = (i-1)I$, $I_i = iI$, $I_{i+1} = (i+1)I$ and $V_i = P[Y(iI) \le L, D(iI) \le S]$, P_1: $P[Y(I_{i-1}) \le L, D(I_{i-1}) \le S]$, P_2: $P[L < Y(I_i) \le G, D(I_i) \le S]$, P_3: $P[Y(I_i) \le L, Y(I_{i+1}) > G]$, P_4: $P[D(I_{i+1}) \le S]$, P_5: $P[Y(I_{i+1}) \le L]$, P_6: $P[D(I_i) \le S, D(I_{i+1}) > S]$

This complex objective function is a nonlinear optimization problem and it is hard to obtain closed-form optimal solutions for L and I. *Nelder* and *Mead* [45.23] introduced a downhill simplex method that does not require the calculation of derivatives. A simplex is the most elementary geometrical scheme that can be formed in n dimensions and has $(n+1)$ vertices. A brief summary of the steps of the method is: each iteration generates a new vertex for the simplex. If the new point is better than at least one of the existing vertices, it then replaces the worst vertex. The search direction is generated through reflection, expansion and contraction operations.

A step-by-step algorithm proposed by *Li* and *Pham* [45.21] based on the Nelder–Mead downhill simplex method is summarized as follows:

- Step 1: choose (n+1) distinct vertices as an initial set $\left\{Z^{(1)}, \cdots, Z^{(n+1)}\right\}$. Then calculate the function value $f(Z)$ for $i = 1, 2, \ldots, (n+1)$, where $f(Z) = EC(I, L)$. Put the values $f(Z)$ in an increasing order where $f(Z^{(1)}) = \min[EC(I, L)]$ and $f\left(Z^{(n+1)}\right) = \max[EC(I, L)]$. Set $k = 0$.
- Step 2: compute the best-n centroid $X^{(k)} = \frac{1}{n}\sum_{i=1}^{n} Z^{(i)}$.
- Step 3: use the centroid $X^{(k)}$ in Step 2 to compute the away-from-worst move direction

$$\Delta X^{(k+1)} = X^{(k)} - Z^{(n+1)}\,.$$

- Step 4: set $\lambda = 1$ and compute $f(X^{(k)} + \lambda\Delta X^{(k+1)})$. If $f(X^{(k)} + \lambda\Delta X^{(k+1)}) \le f(Z^{(1)})$ then go to Step 5. Otherwise, if $f(X^{(k)} + \lambda\Delta X^{(k+1)}) \ge f(Z^{(n)})$ then go to Step 6. Otherwise, fix $\lambda = 1$ and go to Step 8.
- Step 5: Set $\lambda = 2$ and compute $f(X^{(k)} + 2\Delta X^{(k+1)})$. If $f(X^{(k)} + 2\Delta X^{(k+1)}) \le f(X^{(k)} + \Delta X^{(k+1)})$ then set $\lambda = 2$. Otherwise, set $\lambda = 1$. Then go to Step 8.
- Step 6: If $f(X^{(k)} + \lambda\Delta X^{(k+1)}) \le f(Z^{(n+1)})$ then set $\lambda = 1/2$. Compute $f(X^{(k)} + \frac{1}{2}\Delta X^{(k+1)})$. If $f(X^{(k)} + \frac{1}{2}\Delta X^{(k+1)}) \le f(Z^{(n+1)})$ then set $\lambda = 1/2$ and go to Step 8. Otherwise, set $\lambda = -1/2$ and, if $f(X^{(k)} - \frac{1}{2}\Delta X^{(k+1)}) \le f(Z^{(n+1)})$, then set $\lambda = -1/2$ and go to Step 8. Otherwise, go to Step 7.
- Step 7: shrink the current solution set toward the best $Z^{(1)}$ by $Z^{(i)} = \frac{1}{2}(Z^{(1)} + Z^{(i)})$, $i = 2, \cdots, n+1$. Compute the new $f(Z^{(2)}), \cdots, f(Z^{(n+1)})$, let $k = k+1$, and return to Step 2.
- Step 8: Replace the worst $Z^{(n+1)}$ by $X^{(k)} + \lambda\Delta X^{(k+1)}$. If $\sqrt{\frac{1}{n+1}\sum_{i=1}^{n+1}[f(Z^{(i)}) - \overline{f}\,]^2} < 0.5$, where $\overline{f}$ is an average value, then STOP. Otherwise, let $k = k+1$ and return to Step 2. (It should be noted that the criterion in Step 8 is not unique but will depend on how soon you would like the algorithm to stop when the function values at the vertices are close. Here we do this when the difference be-

tween the maximum and the minimum values of f is less than 0.5.)

A Numerical Example

Here we present an example to illustrate the results and the step-by-step application procedure.

Assume that the degradation process is described by $Y(t) = A + Bg(t)$, where A and B are independent and follow a uniform distribution with parameter interval [0,4] and an exponential distribution with parameter 0.3, i. e., $A \sim U(0, 4)$ and $B \sim \text{Exp}(-0.3t)$, respectively, and $g(t) = \sqrt{t}\,\text{e}^{0.005t}$.

Assume that the random shock damage is described by $D(t) = \sum_{i=1}^{N(t)} X_i$, where X_i follows an exponential distribution, i. e., $X_i \sim \text{Exp}(-0.04t)$ and $N(t) \sim Poisson(0.1)$. Also $G = 50$, $S = 100$, $C_i = 900$/inspection, $C_c = 5600$/CM, $C_p = 3000$/PM, $R_1 \sim \text{Exp}(-0.1t)$, and $R_2 \sim \text{Exp}(-0.04t)$. We now determine both the values of I and L so that the average total cost per unit time $EC(I, L)$ is minimized. Following are step-by-step procedure [45.22]:

- Step 1: since there are two decision variables I and L, we need $(n+1) = 3$ initial distinct vertices, which are $Z^{(1)} = (25, 20)$, $Z^{(2)} = (20, 18)$, and $Z^{(3)} = (15, 10)$. Set $k = 0$. We calculate the value of $f\left(Z^{(\cdot)}\right)$ corresponding to each vertex and sort them in increasing order of $EC(I, L)$.
- Step 2: calculate the centroid: $X^{(0)} = \left(Z^{(1)} + Z^{(1)}\right)/2 = (22.5, 19)$.
- Step 3: generate the search direction: $\Delta X = X^{(0)} - Z^{(2)} = (7.5, 9)$.
- Step 4: set $\lambda = 1$, which will produce a new minimal $EC(30, 28) = 501.76$ that leads us to try an expansion with $\lambda = 2$, that is (37.5, 38).
- Step 5: set $\lambda = 2$. Similarly, calculate $f(Z)$, which leads to $EC(37.5, 38) = 440.7$. Go to Step 8. This result turns out to be a better solution, hence (15, 10) is replaced by (37.5, 38).

The iteration continues and stops at $k = 6$ (Table 45.1) since $\sqrt{\frac{1}{3}\sum_{i=1}^{3}\left[EC(Z^{(i)}) - \overline{EC(I, L)}\right]^2} < 0.5$, where $\overline{EC(I, L)}$ is the average value.

Table 45.1 illustrates the process of the Nelder–Mead algorithm. In Table 45.1, $Z^{(\cdot)} = (I, L)$. From Table 45.1, we observe that a set of the optimal values is

$$I^* = 37.5,\ L^* = 38$$

and the corresponding cost value is $EC^*(I, L) = 440.7$.

Table 45.2 illustrates the various values of L on P_c for given $I = 37.5$. From Table 45.2, we observe that the probability P_c increases as L increases. In other words, a larger value for L will put the system at high risk of failure.

Figure 45.14 shows the relationship between L and P_c for different I values, such as $I = 35$, $I = 37.5$, and $I = 40$. From Fig. 45.14, we observe that P_c is an increasing function of L. This means a higher preventive-maintenance threshold is more likely to result in a failure.

Figure 45.15 depicts the effect of the first inspection time on P_p for various L values such as $L = 33$, $L = 35$, $L = 37$ and $L = 39$. Shorter inspection times will cause more-frequent inspection and, as

Table 45.1 Optimal values I and L

39	0.759

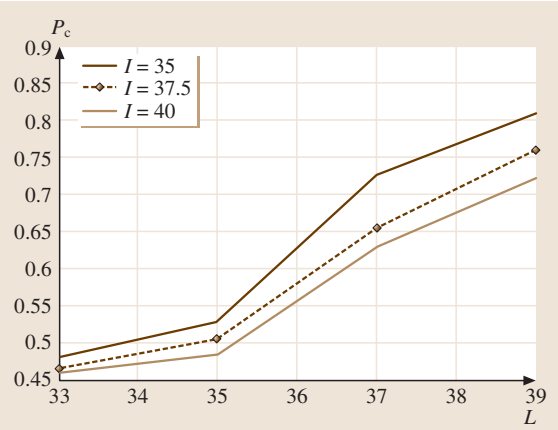

Fig. 45.14 P_c versus L

a result, will increase the probability of a PM. From Fig. 45.15, we also observe that, for smaller L values ($L = 33$ and $L = 35$), the curve decreases slightly as I increases; while, for larger values of L such as $L = 37$ and $L = 39$, the curve has a larger decrease as I increases. We also observe that the curve is more sensitive to the value of L, especially when L is large.

In summary, we observe that, on one hand, a lower value of L will result in frequent PM action and prevents full usage of the residual life of the systems. Frequent PM actions might reduce the chance of high deterioration and failures, but will also be costly. On the other hand, a higher L value will keep the system working in a higher-risk condition. Also, frequent inspections will reduce the probability of failure, while incurring additional cost.

45.3.2 Inspection–Maintenance Model for Degraded Systems with Three Competing Processes

General Inspection–Maintenance Description

This section considers systems with inspection-based maintenance subject to three failure processes that

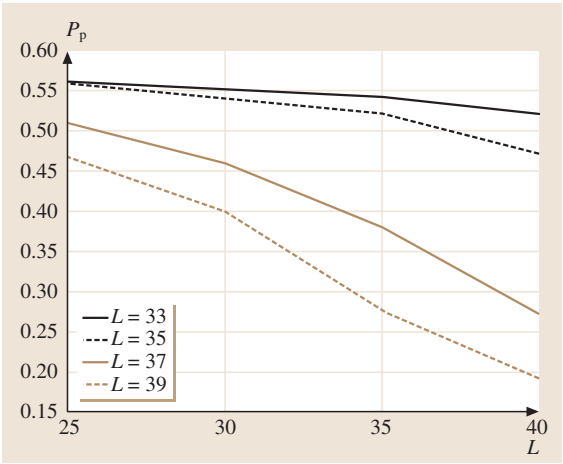

Fig. 45.15 The effect of the inspection sequence on P_p for given L

are competing for the life of such systems: two of these are degradation processes called degradation process i (measured by $Y_i(t)$ for $i = 1, 2$) and the third is a random shock process measured by the function $D(t)$ [45.21].

We assume that the three processes are independent and whichever process occurs first will cause the system to fail, where the failure of the system is defined as when $Y_1(t) > G_1$, $Y_2(t) > G_2$ or $D(t) > S$. The state of the system can only be revealed through inspection.

Assumptions.

1. System failure is only detected by inspection. Inspections are assumed to be instantaneous, perfect and nondestructive. Since the system is not continuously monitored, if the system fails it will remain failed until the next inspection, which causes a loss of C_m per unit time. In this case, a maintenance action is begun instantaneously at the inspection time.
2. After a maintenance action, either PM or CM, the system state will start as good as new.
3. A CM action will cost more than a PM action. Similarly, a PM action will cost much more than an inspection itself. This implies that $C_c > C_p > C_i$.
4. The three nondecreasing processes $Y_1(t)$, $Y_2(t)$, and $D(t)$ are independent.
5. No continuous monitoring is performed on the system.
6. The time for a CM or PM action is negligible.

We consider a system subject to three competing processes; two of them are continuous, gradual degradation processes with different characteristics, and the third is a random shock process. Applications of such systems can be found in the Space Shuttle computer complex due to critical mission phases such as boost, reentry and landing and in electric generator power systems due to the loss of commercial power systems. More related applications can be found in [45.13].

Although a continuous monitoring process is feasible for some systems, the cost of monitoring the process and the labor required would not make it realistic in practice. Therefore the criteria we consider here is to improve the system performance by performing periodic inspections, with a maintenance action if necessary, to minimize the total system maintenance cost.

Inspection–maintenance policy. The length of the inspection will be reduced as the system ages. In other words, the intervals between successive inspections become shorter as the system ages. A geometric sequence is applied in this study to develop the inter-inspection sequence. The inspection time is constructed as $I_n = \sum_{j=1}^{n} \alpha^{j-1} I_1$, where $0 < \alpha \leq 1$ and I_1 is the first inspection time. We define $U_n = I_n - I_{n-1} = \alpha^{n-1} I_1$ as the inter-inspection interval and $(U_i)_{i \in N}$ as a decreasing geometric sequence. According to the state detected at the inspection $I_n, n = 1, \cdots$, one of the following actions will happen [45.21]:

1. If both degradation values are below their PM thresholds and the shock damage value is less than its threshold, in other words $[Y_1(I_n) \leq L_1, Y_2(I_n) \leq L_2] \cap [D(I_n) \leq S]$, then the system is still in a good condition. In this case, we do nothing but determine the next inspection at $I_{n+1} = I_n + U_n$, where U_n is the inter-inspection time between the n-th and the $n+1$-th inspection interval.
2. If a degradation process falls into the PM zone $[L_i < Y_i(I_n) \leq G_i, i = 1, 2]$ and the other two processes are less than their corresponding critical thresholds, then the system calls for a PM action and it is instantaneously performed accordingly.
3. If any of the process values exceed their corresponding critical thresholds $[Y_i(t) > G_i, i = 1, 2,$ or $D(t) > S]$, then the system calls for a CM action and it is instantaneously performed. In this case, the system has failed and a CM is performed on the system.

We assume that, after a maintenance action, i. e., PM or CM, the system will be restored to as good as new. A new sequence of inspection begins, defined in the same way, and the system maintenance follows the same decision rules outlined above. Figure 45.16 shows the evolution of the system, where $Y_1(t)$ and $Y_2(t)$ represent the degradation processes 1 and 2, respectively, and $D(t)$ represents a cumulative shock damage. $(W_i)_{i \in N}$ is a renewal sequence. Figure 45.17 shows the maintenance zone projected onto the $Y_1(t)$, $Y_2(t)$ planes; G_i and L_i are the CM and PM critical thresholds for $Y_1(t)$, and $Y_2(t)$ respectively.

Maintenance cost analysis

The expected total maintenance cost per cycle, $E[C_1]$, is given as:

$$E[C_1] = C_i E[N_I] + C_p P_p + C_c P_c + C_m E[\zeta] , \tag{45.41}$$

where C_i is the cost associated with each inspection, C_p is the cost associated with a PM action, and C_c is the CM action cost. Since failure is not self-announcing and it can occur at any given instant time T within the inspection time interval $[I_i, I_{i+1}]$, the system will remain idle during the interval $[T, I_{i+1}]$. The cost coefficient C_m

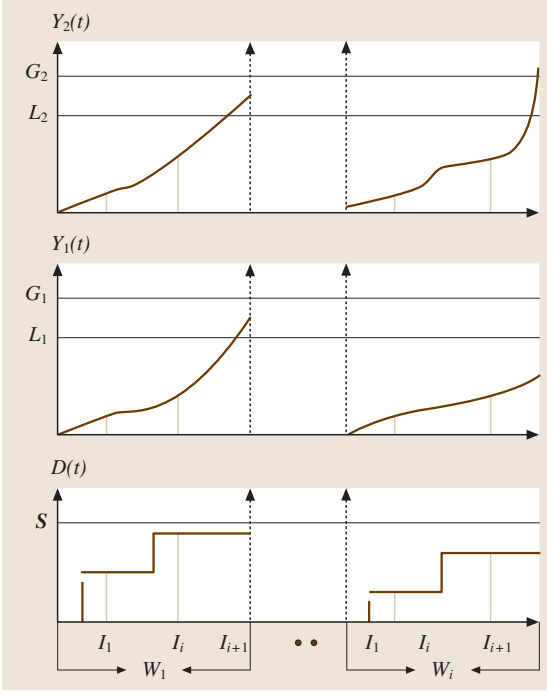

Fig. 45.16 The evolution of the system condition

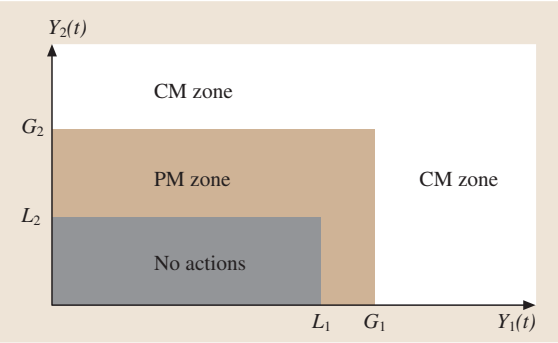

Fig. 45.17 Maintenance zone projected onto $Y_1(t)$, $Y_2(t)$

is defined as the penalty cost per unit time associated with such an event.

Calculation.

1. Let $P(N_I = i+1)$ be the probability that there are a total of $(i+1)$ inspections in the cycle. The expected number of inspections during a cycle, $E[N_I]$, is

$$E[N_I] = \sum_{i=0}^{\infty} (i+1) P_{i+1} \tag{45.42}$$

where $P_{i+1} = P(N_I = i+1)$. Note that

$$P_{i+1} = P(N_I = i+1) = \bigcup_{j=1}^{17} P\left(E_j^{(i+1)}\right) ,$$

where $E_j^{(i+1)} (j = 1, \cdots, 17)$ denotes the renewal cycle that ends at the j-th possibile time I_{i+1}. The details of all $E_j^{(i+1)}$, where the $E_j^{(i+1)}$ are mutually disjoined events for $j = 1, \cdots, 18$ are listed in Appendix B.

There are a total of 18 system state combinations revealed at any given interval $(I_i, I_{i+1}]$ where there is only one state event, $E_{18}^{(i+1)}$ (Appendix B) representing that the system is in a good condition and that no maintenance action will be required. Any other remaining state events will trigger either a PM or a CM action at time I_{i+1}.

After some simplifications, we have

$$\begin{aligned} P_{i+1} = {} & P[Y_1(I_i) \le L_1, Y_2(I_i) \le L_2, D(I_i) \le S] \\ & - P[Y_1(I_{i+1}) \le L_1, Y_2(I_{i+1}) \\ & \le L_2, D(I_{i+1}) \le S] . \end{aligned} \tag{45.43}$$

Therefore,

$$\begin{aligned} E[N_1] = \sum_{i=0}^{\infty} (i+1) \{ & P[Y_1(I_i) \le L_1, Y_2(I_i) \\ & \le L_2, D(I_i) \le S] \\ & - P[Y_1(I_{i+1}) \le L_1, Y_2(I_{i+1}) \\ & \le L_2, D(I_{i+1}) \le S] \} . \end{aligned}$$

2. There will be either a PM or CM action to end a renewal cycle. It is obvious that the two events (PM and CM) are mutually exclusive at the renewal time point: $P_p + P_c = 1$. We now calculate P_p as follows:

$$\begin{aligned} P_p &= P(\text{the cycle ends due to a PM action}) \\ &= \sum_{i=0}^{\infty} \sum_{j=1}^{3} P\left[E_j^{(i+1)}\right] . \end{aligned}$$

After some simplifications, we obtain

$$\begin{aligned} P_p = \sum_{i=0}^{\infty} \{ & P[Y_1(I_i) \le L_1, L_1 < Y_1(I_{i+1}) \le G_1] \\ & \times P[Y_2(I_i) \le L_2, Y_2(I_{i+1}) \le G_2] \\ & \times P[D(I_{i+1})] + P[Y_1(I_{i+1}) \le L_1] \\ & \times P[Y_2(I_i) \le L_2, L < Y_2(I_{i+1}) \le G_2] \\ & \times P[D(I_{i+1})] \} \end{aligned} \tag{45.44}$$

and $P_c = 1 - P_p$. We can obtain the joint probability density function $f_{Y(I_i),Y(I_{i+1})}(y_1, y_2)$ of $Y(I_i)$ and $Y(I_{i+1})$ by computing $P[Y_1(I_i) \le L_1, Y_1(I_{i+1}) \le G_1]$ and $P[Y_2(I_i) \le L_2, Y_2(I_{i+1}) \le G_2]$.

3. Let T denote the time to failure. That is $T = \inf[t : Y_1(t) > G_1, Y_2(t) > G_2 \text{ or } D(t) > S]$. If $I_i < T \le I_{i+1}$, the unit will be idle during the interval $[T, I_{i+1}]$. Let $E[\zeta]$ denote the average idle time between the failure occurrence epoch and its inspection during the cycle. Then $E[\xi]$ is calculated as follows:

$$\begin{aligned} E[\xi] &= \sum_{i=0}^{\infty} E\left[(I_{i+1} - T) 1_{I_i < T \le I_{i+1}}\right] \\ &= \sum_{j=0}^{\infty} R_j \int_{I_i}^{I_{i+1}} (I_{i+1} - t) \mathrm{d}F_T(t) \end{aligned} \tag{45.45}$$

where

$$
\begin{aligned}
R_j = \big\{ & P[Y_1(I_i) \le L_1, L_1 < Y_1(I_{i+1}) \le G_1] \\
& \times P[Y_2(I_i) \le L_2, L_1 < Y_1(I_{i+1})] \\
& + P[Y_2(I_i) \le L_2] \\
& \times P[Y_1(I_i) \le L_1, Y_1(I_{i+1}) > G_1] \\
& + P[Y_1(I_{i+1}) \le L_1] \\
& \times P[Y_2(I_i) \le L_2] \big\} P[D(I_i) \le S] \\
F(t) = {} & P[Y_1(t) > G_1, Y_2(t) \le G_2, D(I_i) \le S] \\
& + P[Y_1(t) \le G_1, Y_2(t) > G_2, D(I_i) \le S] \\
& + P[Y_1(t) \le G_1, Y_2(t) \le G_2, D(I_i) > S]
\end{aligned}
$$

and $1_{I_i < T \le I_{i+1}}$ is an indicator function.

Expected cycle length. The expected cycle length $E[W_1]$ is given as follows:

$$
\begin{aligned}
E[W_1] &= E[E[W_1|N_I]] \\
&= \sum_{i=0}^{\infty} E[W_1|N_I = i] P(N_i = i) \\
&= \sum_{i=0}^{\infty} I_{i+1} P_{i+1} \,, \qquad (45.46)
\end{aligned}
$$

where $P_{i+1}$is given in (45.43).

Therefore, the average long-run maintenance cost rate function $EC(L_1, L_2, I_1)$ is a function of the inspection times $\{I_1, \cdots, I_i, \cdots\}$ and the PM critical threshold values (L_1, L_2) through the functions P_p, P_c, $E[N_I]$, $E[\zeta]$ and $E[W_1]$. The average long-run maintenance cost rate is, in other words, $EC(L_1, L_2, I_1) = \frac{E[C_1]}{E[W_1]}$, and can be obtained by computing the two functions given in (45.41) and (45.46).

Optimization of the maintenance cost rate

The geometric inspection sequence $\{I_1, \cdots, I_i, \cdots\}$, where $I_n = \sum_{j=1}^{n} \alpha^{j-1} I_1$, depends on I_1 for given α. In this section, we develop a step-by-step algorithm based on the Nelder–Mead downhill simplex method to obtain the optimum decision variables (I_1, L_1, L_2) such that the long-run average maintenance cost rate $EC(L_1, L_2, I_1)$ is minimized. Mathematically, the optimization problem of the cost rate function can be formulated as follows [45.21]:

Optimization problem. Find I_1, L_1 and $L_2 (0 < L_1 \le G_1, 0 < L_2 \le G_2)$ such that

$$
\begin{aligned}
EC(L_1, L_2, I_1) = {} & \frac{C_\mathrm{i} \sum_{i=0}^{\infty} (i+1) \left\{ P\left[Y_1\left(\sum_{j=1}^{i} \alpha^{j-1} I_1\right) \le L_1, Y_2\left(\sum_{j=1}^{i} \alpha^{j-1} I_1\right) \le L_2, D\left(\sum_{j=1}^{i} \alpha^{j-1} I_1\right) \le S \right] - P\left[Y_1\left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1\right) \le L_1, Y_2\left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1\right) \le L_2, D\left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1\right) \le S \right] \right\}}{\sum_{i=0}^{\infty} \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1\right) \left\{ P\left[Y_1\left(\sum_{j=1}^{i} \alpha^{j-1} I_1\right) \le L_1, Y_2\left(\sum_{j=1}^{i} \alpha^{j-1} I_1\right) \le L_2, D\left(\sum_{j=1}^{i} \alpha^{j-1} I_1\right) \le S \right] - P\left[Y_1\left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1\right) \le L_1, Y_2\left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1\right) \le L_2, D\left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1\right) \le S \right] \right\}} \\
& + \frac{C_\mathrm{p} \sum_{i=0}^{\infty} \left\{ P\left[Y_1\left(\sum_{j=1}^{i} \alpha^{j-1} I_1\right) \le L_1, Y_2\left(\sum_{j=1}^{i} \alpha^{j-1} I_1\right) \le G_2 \right] P\left[Y_2\left(\sum_{j=1}^{i} \alpha^{j-1} I_1\right) \le L_2, Y_2\left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1\right) \le G_2 \right] P\left[D\left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1\right) \le S \right] \right\}}{\sum_{i=0}^{\infty} \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1\right) \left\{ P\left[Y_1\left(\sum_{j=1}^{i} \alpha^{j-1} I_1\right) \le L_1, Y_2\left(\sum_{j=1}^{i} \alpha^{j-1} I_1\right) \le L_2, D\left(\sum_{j=1}^{i} \alpha^{j-1} I_1\right) \le S \right] - P\left[Y_1\left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1\right) \le L_1, Y_2\left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1\right) \le L_2, D\left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1\right) \le S \right] \right\}} \\
& + \frac{C_\mathrm{c} \left(1 - \sum_{i=0}^{\infty} \left\{ P\left[Y_1\left(\sum_{j=1}^{i} \alpha^{j-1} I_1\right) \le L_1, Y_2\left(\sum_{j=1}^{i} \alpha^{j-1} I_1\right) \le G_2 \right] P\left[Y_2\left(\sum_{j=1}^{i} \alpha^{j-1} I_1\right) \le G_2 \right] P\left[D\left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1\right) \le S \right] \right\} \right)}{\sum_{i=0}^{\infty} \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1\right) \left\{ P\left[Y_1\left(\sum_{j=1}^{i} \alpha^{j-1} I_1\right) \le L_1, Y_2\left(\sum_{j=1}^{i} \alpha^{j-1} I_1\right) \le L_2, D\left(\sum_{j=1}^{i} \alpha^{j-1} I_1\right) \le S \right] - P\left[Y_1\left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1\right) \le L_1, Y_2\left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1\right) \le L_2, D\left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1\right) \le S \right] \right\}} \\
& + \frac{C_\mathrm{m} \sum_{i=0}^{\infty} \left\{ (R_{1i} + R_{2i} + R_{3i}) P\left[D\left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1\right) \le S \right] \right\} \int_{\sum_{j=1}^{i} \alpha^{j-1} I_1}^{\sum_{j=1}^{i+1} \alpha^{j-1} I_1} \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 - t\right) \mathrm{d}F_\mathrm{T}(t)}{\sum_{i=0}^{\infty} \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1\right) \left\{ P\left[Y_1\left(\sum_{j=1}^{i} \alpha^{j-1} I_1\right) \le L_1, Y_2\left(\sum_{j=1}^{i} \alpha^{j-1} I_1\right) \le L_2, D\left(\sum_{j=1}^{i} \alpha^{j-1} I_1\right) \le S \right] - P\left[Y_1\left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1\right) \le L_1, Y_2\left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1\right) \le L_2, D\left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1\right) \le S \right] \right\}}
\end{aligned}
$$

is minimum, where

$$R_{1i} = P\left[Y_1\left(\sum_{j=1}^{i}\alpha^{j-1}I_1\right) \le L_1,\ L_1 < Y_1\left(\sum_{j=1}^{i+1}\alpha^{j-1}I_1\right) \le G_1\right] \times P\left[Y_2\left(\sum_{j=1}^{i}\alpha^{j-1}I_1\right) \le L_2,\ L_1 < Y_1\left(\sum_{j=1}^{i+1}\alpha^{j-1}I_1\right)\right],$$

$$R_{2i} = P\left[Y_1\left(\sum_{j=1}^{i}\alpha^{j-1}I_1\right) \le L_1,\ G_1 < Y_1\left(\sum_{j=1}^{i+1}\alpha^{j-1}I_1\right)\right] \times P\left[Y_2\left(\sum_{j=1}^{i}\alpha^{j-1}I_1\right) \le L_2\right],$$

$$R_{3i} = P\left[Y_1\left(\sum_{j=1}^{i}\alpha^{j-1}I_1\right) \le L_1\right] \times P\left[Y_2\left(\sum_{j=1}^{i}\alpha^{j-1}I_1\right) \le L_2\right].$$

This optimization function is a complex nonlinear function, the optimum solution of which is difficult to find. The Nelder–Mead downhill simplex method (discussed in Sect. 45.3.1) is the most popular direct-search method for obtaining the optimum solution of an unconstrained nonlinear function, and does not require the calculation of derivatives.

Numerical examples

This section illustrates the results in the Sect. 45.3.2. Assume that degradation process 1 is described as the function $Y_1(t) = \frac{W e^{B_1 t}}{A_1 + e^{B_1 t}}$, where the random variables A_1 and B_1 are independent and follow a uniform distribution with parameter interval [0,40], and exponential distribution with parameter 1, respectively. In short, $A_1 \sim U[0, 40]$ and $B_1 \sim \text{Exp}(1)$.

Similarly, assume that degradation process 2 is modeled as $Y_2(t) = A_2 + B_2 g(t)$ where $A_2 \sim U[0, 2]$, $B_2 \sim \text{Exp}(0.2)$ and $g(t) = \sqrt{t}e^{0.01t}$. Assume that the random shock is represented by the function $D(t) = \sum_{i=0}^{N_2(t)} X_i$, where $X_i \sim \text{Exp}(0.04)$ and $N(t) \sim Poisson(0.1)$. Also $G_1 = 300$, $G_2 = 70$ and $S = 100$.

Assume that the cost parameters are as follows: $C_c = 560$ units/CM, $C_p = 400$ units/PM, $C_i = 100$ units/inspection, $C_m = 500$ units/unit time and $\alpha = 0.97$.

The inspection sequence $\{I_1, \cdots, I_n, \cdots\}$ is constructed with $I_n = \sum_{j=1}^{n} \alpha^{j-1} I_1$. We want to determine the values of I_1 and (L_1, L_2) so that the average long-run maintenance cost rate per unit time is minimized.

Following are step-by-steps using our proposed algorithm in Sect. 45.3.1:

- Step 1: there are three decision variables, say L_1, L_2, and I_1, so we need four distinct vertices as an initial set of values: $Z^{(1)} = (270, 56, 76)$, $Z^{(1)} = (280, 60, 72)$, $Z^{(2)} = (290, 52, 66)$ and $Z^{(3)} = (300, 50, 57)$. Set $k = 0$.

We now calculate the function value $f(Z)$ corresponding to each vertex and put them in increasing order of the objective value $EC(L_1, L_2, I_1)$ from smallest to highest.

- Step 2: compute the centroid: $X^{(0)} = \frac{1}{3}\left(Z^{(1)} + Z^{(2)} + Z^{(3)}\right) = (280, 56, 71.3)$.
- Step 3: search for the away-from-worst direction: $\Delta X = X^{(0)} - Z^{(4)} = (-20, 6, 14.3)$.
- Step 4: set $\lambda = 1$, which will generate a new minimal $EC(260, 60, 85.6) = 291.9$ that leads to an expansion with $\lambda = 2$ that is (240, 60, 99.9).
- Step 5: set $\lambda = 2$. Similarly, compute $f(Z)$, which leads to 247.9. Go to Step 8

This result turned out to be a better solution, hence (300, 50, 57) is replaced by (240, 60, 99.9).

The iteration continues and stops at $k = 4$ (see Table 45.3) since

$$\sqrt{\frac{1}{4}\sum_{i=1}^{4}\left[EC(Z^{(i)}) - \overline{EC(L_1, L_2, I_1)}\right]^2} = 0.449 < 0.5\,,$$

where $\overline{EC(L_1, L_2, I_1)}$ is the average value.

From Table 45.3, we obtain the optimal solution for (L_1, L_2, I_1) as: $\left(L_1^* = 172, L_2^* = 60, I_1^* = 144\right)$ and the corresponding average long-run maintenance cost rate is $EC\left(L_1^*, L_2^*, I_1^*\right) = 245.9$. Figure 45.18 depicts the average long-run maintenance cost-rate curve $EC(L_1, L_2, I_1)$ as a function of the inspection time interval I_1 for $L_1 = 172$ and $L_2 = 60$.

Table 45.4 presents a sensitivity analysis in terms of the probability that the cycle will end due to a PM action, P_p, for various values of (L_1, L_2) for $\alpha = 0.97$

Table 45.4 The effect of (L_1, L_2) on P_p for a given inspection sequence

L_1	L_2	P_p
200	60	0.5910
190	58	0.5928
180	56	0.5936
170	54	0.5948
160	52	0.5950
150	50	0.5968

Table 45.5 The effect of the inspection sequence on P_p for fixed PM values

I_1	P_p
110	0.642
120	0.610
130	0.578
140	0.510
150	0.480
160	0.430

and $I_1 = 144$. From Table 45.4, we observe that the probability P_p slightly increases as both L_1 and L_2 decrease. This in fact shows that one would perform more PMs than CMs when L_1 and L_2 both become smaller.

Similarly, Table 45.5 presents the probability that the cycle will end due to a PM action, P_p, for various values of I_1 given $L_1 = 172$, $L_2 = 60$ and $\alpha = 0.97$. From Table 45.5, we observe that the probability P_p decreases as I_1 increases. In other words, the maintenance cycle will be more likely to end due to corrective rather than preventive maintenance if one delays in-

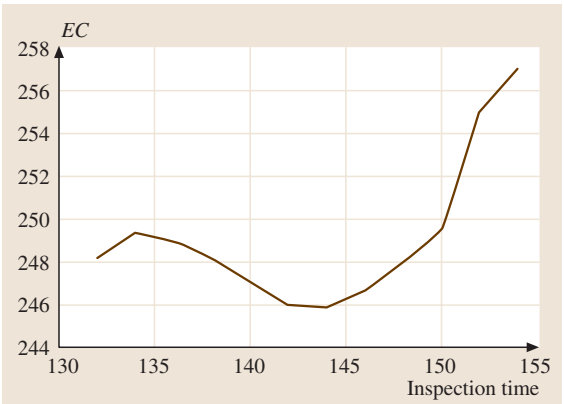

Fig. 45.18 The average maintenance cost $EC(L_1, L_2, I_1)$ versus I_1

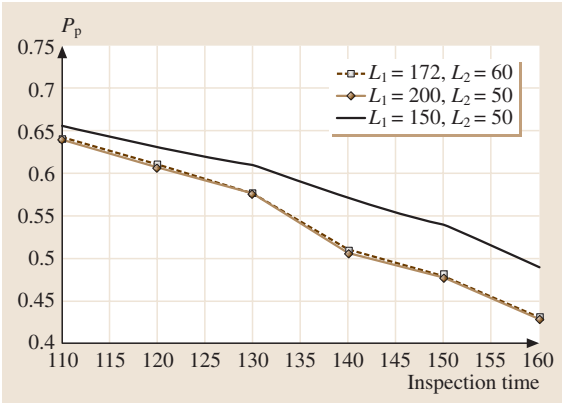

Fig. 45.19 The probability P_p versus I_1 for various pairs (L_1, L_2)

spection. This result can help maintenance managers or inspectors to allocate resources as well as time allocations.

Figure 45.19 shows the results for the probability that the cycle ends due to PM versus the inspection interval time I_1 for given values of the threshold PM levels (L_1, L_2). It is interesting to observe from Fig. 45.19 that the results are about the same for the two combinations of $(L_1 = 172,\ L_2 = 60)$ and $(L_1 = 200,\ L_2 = 50)$.

45.4 Conclusions and Perspectives

In this chapter, we present reliability and maintenance models for degraded systems with multiple competing failure processes. For mathematical modeling, it is always necessary to make some assumptions in order to make the model applicable in practice. For reliability and maintenance modeling, assumptions have often played an important role in determining the structure and complexity of the models.

The results of the maintenance models in this chapter can be used to help practitioners and inspectors as well as marketing managers to allocate resources and for the promotion strategies for new products. It would be of interest for future research to implement these results by collecting data and observing product system degradations in practice. Other research problems worth exploring in the future are as follows [45.22].

1. The objective function discussed in this chapter is to minimize the expected long-run maintenance cost. In practice, costs associated with inspections, preventive maintenance, corrective maintenance, and downtime are sometimes difficult to obtain, even when used in practice. For some critical systems, the overriding goal is to ensure that the system should be available when needed; availability is, therefore, of primary interest, and cost is secondary.
   To achieve a high level of availability for a specified inspection rate, it is worth to determine the optimum number of inspections with respect to imperfect repairs, such as minimal and opportunistic schemes, that maximizes the system availability. The time required for imperfect repairs and for replacement policies are random.
2. This chapter assumed that at any time there is unlimited supply of systems available for replacement. In reality, this assumption might not be true due to budget allocation and other constraints. In this case, a random lead time for delivering the new system when needed should be considered. It is essential and practical to analyze the effect of this random lead time on availability. When incorporating random lead time, the expected downtime will increase; therefore, system availability will decrease.

Jacobian determinant

Below is a 2×2 *Jacobian* determinant

$$J = \frac{y_1(y_2-W)\left(\frac{y_2}{y_1(y_2-W)} - \frac{y_2(y_1-W)}{y_1^2(y_2-W)}\right)[-d(y_1,y_2)-d_1(y_1,y_2)+d_2(y_1,y_2)]}{y_2(y_1-W)(I_{i+1}-I_i)} + d_3(y_1,y_2)\,,\text{where}$$

$$d(y_1,y_2) = \frac{\left[\left(\frac{y_1-W}{y_1(y_2-W)} - \frac{y_2(y_1-W)}{y_1(y_2-W)^2}\right) y_1(y_2-W)^2 I_{i+1}\, e^{\left(\frac{\ln\left(\frac{y_2(y_1-W)}{y_1(y_2-W)}\right)I_{i+1}}{I_{i+1}-I_i}\right)}\right]}{y_2^2(y_1-W)(I_{i+1}-I_i)},\ y_1 \neq W,\ y_2 \neq W\,,$$

$$d_1(y_1, y_2) = \frac{\mathrm{e}^{\left(\frac{\ln\left(\frac{y_2(y_1-W)}{y_1(y_2-W)}\right)I_{i+1}}{I_{i+1}-I_i}\right)}}{y_2}, \; y_2 \neq W,$$

$$d_2(y_1, y_2) = \frac{\mathrm{e}^{\left(\frac{\ln\left(\frac{y_2(y_1-W)}{y_1(y_2-W)}\right)I_{i+1}}{I_{i+1}-I_i}\right)}(y_2-W)}{y_2^2}, \; y_2 \neq W\,,$$

$$d_3(y_1, y_2) = \frac{d_{31}(y_1, y_2)d_{32}(y_1, y_2)}{y_2^3(y_1-W)^2(I_{i+1}-I_i)^2}, \; y_1 \neq W\,,$$

$$d_{31}(y_1, y_2) = \left(\frac{y_1-W}{y_1(y_2-W)} - \frac{y_2(y_1-W)}{y_1(y_2-W)^2}\right) y_1^2(y_2-W)^3, \; y_2 \neq W\,,$$

$$d_{32}(y_1, y_2) = \left(\frac{y_2}{y_1(y_2-W)} - \frac{y_2(y_1-W)}{y_1^2(y_2-W)}\right) I_{i+1}\,\mathrm{e}^{\left(\frac{\ln\left(\frac{y_2(y_1-W)}{y_1(y_2-W)}\right)I_{i+1}}{I_{i+1}-I_i}\right)}, \; y_2 \neq W\,.$$

45.6 Appendix B

A list of all 18 events:

$$E_1^{(i+1)} = \left[Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S\right] \cap \left[L_1 < Y_1(I_{i+1}) \leq G_1, L_2 < Y_2(I_{i+1}) \leq G_2, D(I_{i+1}) \leq S\right]$$

$$E_2^{(i+1)} = \left[Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S\right] \cap \left[L_1 < Y_1(I_{i+1}) \leq G_1, Y_2(I_{i+1}) \leq L_2, D(I_{i+1}) \leq S\right]$$

$$E_3^{(i+1)} = \left[Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S\right] \cap \left[Y_1(I_{i+1}) \leq L_1, L_2 < Y_2(I_{i+1}) \leq G_2, D(I_{i+1}) \leq S\right]$$

$$E_4^{(i+1)} = \left[Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S\right] \cap \left[L_1 < Y_1(I_{i+1}) \leq G_1, Y_2(I_{i+1}) > G_2, D(I_{i+1}) \leq S\right]$$

$$E_5^{(i+1)} = \left[Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S\right] \cap \left[L_1 < Y_1(I_{i+1}) \leq G_1, L_2 < Y_2(I_{i+1}) \leq G_2, D(I_{i+1}) > S\right]$$

$$E_6^{(i+1)} = \left[Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S\right] \cap \left[L_1 < Y_1(I_{i+1}) \leq G_1, Y_2(I_{i+1}) > G_2, D(I_{i+1}) > S\right]$$

$$E_7^{(i+1)} = \left[Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S\right] \cap \left[Y_1(I_{i+1}) > G_1, L_2 > Y_2(I_{i+1}), D(I_{i+1}) \leq S\right]$$

$$E_8^{(i+1)} = \left[Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S\right] \cap \left[Y_1(I_{i+1}) > G_1, L_2 < Y_2(I_{i+1}) \leq G_2, D(I_{i+1}) \leq S\right]$$

$$E_9^{(i+1)} = \left[Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S\right] \cap \left[Y_1(I_{i+1}) > G_1, L_2 > Y_2(I_{i+1}), D(I_{i+1}) > S\right]$$

$$E_{10}^{(i+1)} = \left[Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S\right] \cap \left[Y_1(I_{i+1}) > G_1, L_2 < Y_2(I_{i+1}) \leq G_2, D(I_{i+1}) > S\right]$$

$$E_{11}^{(i+1)} = \left[Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S\right] \cap \left[Y_1(I_{i+1}) > G_1, Y_2(I_{i+1}) > G_2, D(I_{i+1}) \leq S\right]$$

$$E_{12}^{(i+1)} = \left[Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S\right] \cap \left[Y_1(I_{i+1}) > G_1, Y_2(I_{i+1}) > G_2, D(I_{i+1}) > S\right]$$

$$E_{13}^{(i+1)} = \left[Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S\right] \cap \left[L_1 < Y_1(I_{i+1}) \leq G_1, L_2 > Y_2(I_{i+1}), D(I_{i+1}) > S\right]$$

$$E_{14}^{(i+1)} = \left[Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S\right]$$

$$\cap\left[L_1 > Y_1(I_{i+1}), L_2 > Y_2(I_{i+1}), D(I_{i+1}) \le S\right]$$

$$E_{15}^{(i+1)} = \left[Y_1(I_i) \le L_1, Y_2(I_i) \le L_2, D(I_i) \le S\right] \cap\left[L_1 > Y_1(I_{i+1}), L_2 > Y_2(I_{i+1}), D(I_{i+1}) > S\right]$$

$$E_{16}^{(i+1)} = \left[Y_1(I_i) \le L_1, Y_2(I_i) \le L_2, D(I_i) \le S\right] \cap\left[L_1 > Y_1(I_{i+1}), L_2 < Y_2(I_{i+1}) \le G_2, D(I_{i+1}) > S\right]$$

$$E_{17}^{(i+1)} = \left[Y_1(I_i) \le L_1, Y_2(I_i) \le L_2, D(I_i) \le S\right] \cap\left[L_1 > Y_1(I_{i+1}), Y_2(I_{i+1}) > G_2, D(I_{i+1}) \le S\right]$$

$$E_{18}^{(i+1)} = \left[Y_1(I_i) \le L_1, Y_2(I_i) \le L_2, D(I_i) \le S\right] \cap\left[Y_1(I_{i+1}) \le L_1, Y_2(I_{i+1}) \le L_2, D(I_{i+1}) \le S\right]$$

46. Statistical Models on Maintenance

This chapter discusses a variety of approaches to performing maintenance. The first section describes the importance of preparing for maintenance correctly, by collecting data on unit lifetimes and estimating the reliability of the units statistically using quantities such as their mean lifetimes, failure rates and failure distributions.

Suppose that the time that the unit has been operational is known (or even just the calendar time since it was first used), and its failure distribution has been estimated statistically. The second section of the chapter shows that the time to failure is approximately given by the reciprocal of the failure rate, and the time before preventive maintenance is required is simply given by the pth percentile point of the failure distribution. Standard replacement policies, such as age replacement, in which a unit undergoes maintenance before it reaches a certain age, and periodic replacement, where the unit undergoes maintenance periodically, are also presented.

Suppose that the failure of a unit can only be recorded at discrete times (so the unit completes a specific number of cycles before failure). In the third section, the age replacement and periodic replacement models from the previous section are converted into discrete models. Three replacement policies in which the unit undergoes maintenance after a specific number of failures, episodes of preventive maintenance or repairs, are also presented. The optimum number of units for a parallel redundant system is derived for when each unit fails according to a failure distribution and fails upon some shock with a certain probability.

Suppose that the unit fails when the total amount of damage caused by shocks has exceeded a certain failure level. The fourth section describes the replacement policy in where the unit undergoes maintenance before failure for a cumulative damage model. The optimum damage level at which the unit should be replaced when it undergoes minimal repair upon failure is also derived analytically.

The last part introduces the repair limit policy, where the unit is replaced instead of being repaired if the repair time is estimated to be more than a certain time limit, as well as the inspection with human error policy, where units are checked periodically and failed units are only detected and replaced upon inspection. Finally, the maintenance of a phased array radar is analyzed as an example of the practical use of maintenance models. Two maintenance models are considered in this case, and policies that minimize the expected cost rates are obtained analytically and numerically.

Although system maintenance is important, performing it without understanding the operational parameters of the system first would probably do more harm than good. Therefore, the first step of maintenance is preparation: we have to collect data on the components used in the system, in order to be able to statistically estimate quantities such as mean lifetimes, failure rates, failure distributions, and so on. Secondly, designers, engineers and managers engaged in maintenance work need to be taught standard maintenance techniques from reliability theory, and how to apply them to real systems. After any necessary training has been performed, and data has been collecting about the system, we construct a maintenance plan, which depends upon the system environment and the resources (monetary and manpower) available. After much trial and error, we establish an maintenance scheme that is optimized for the system in question. This approach allows us to minimize or even eliminate any need for hasty maintenance after a severe system failure.

This chapter summarizes standard maintenance policies that can be applied (statistically and stochastically) to practical models. These policies are largely based upon the author's work [46.1]. If we monitor the age of a unit (in either the calendar time, the operating time or the usage time), it is best to perform maintenance at certain times. On the other hand, if we monitor the number of cycles or system uses, or the amount of total damage, wear or stress incurred by a unit, it is best to perform maintenance after a certain number of cycles or amount of wear, respectively. Moreover, it might be necessary to adopt combinations of these approaches.

In this chapter, we begin (in Sect. 46.1) by estimating the "mean time to failure" using the reciprocal of the failure rate. Then we introduce standard replacement policies, such as "age replacement" and "periodic replacement". Section 46.2 considers discrete versions of the general replacement models derived in Sect. 46.1 (in other words, where the maintenance can only be performed at certain times, which is a more realistic scenario). It also presents three models where replacement occurs after a certain number of events, including the number of system failures, the number of times it has undergone preventive maintenance, or the number of repairs that have been made to the system. Further, we discuss how many units should be allowed to fail in a parallel redundant system before the system is replaced. Section 46.3 introduces maintenance models based on cumulative damage; in other words, those where maintenance occurs after a certain amount of wear, stress, fatigue, corrosion, erosion and garbage. Finally, Sect. 46.4 presents another two useful maintenance models. In the first, known as the "repair limit policy", a failed unit is repaired unless the repair time is too long, in which case it is replaced. Second, we consider the "inspection model", with two types of human error. Finally, we give a practical example – the maintenance of a phased array radar – in which failed elements are either replaced at planned times or when they exceed a managerial number.

46.1 Time-Dependent Maintenance

If the failure of a unit during operation would cause serious damage to the whole system, it is important to know the total amount of time the unit has been in operation and to determine when to replace units or perform maintenance before the failure occurs. This is called *age replacement* or *preventive maintenance* (PM). The optimum age replacement policy (which minimizes the expected cost) and the optimum PM policy (which maximizes the availability are derived in *Barlow* and *Proschan* [46.2] and *Nakagawa* [46.1].

If only the unit's calendar operational time (the period of time since the unit was first used; its "age") is known and its failure is not a relatively minor or inexpensive event, it is necessary to perform PM or replace it periodically. This section describes maintenance policies in which a unit undergoes maintenance according to its total operating time (the total amount of time that the unit has been operational) or the age of the unit.

Suppose that X is a random variable that represents this age or total operating time. We then denote the failure distribution by $F(t) \equiv \Pr(X \le t)$ for $0 \le t < \infty$. Let μ and $h(t)$, respectively, be the finite mean time to failure of X and the failure rate, so $\mu \equiv \int_0^\infty \overline{F}(t)\,\mathrm{d}t$ and $h(t) \equiv f(t)/\overline{F}(t)$ where f is the density of F and $\overline{F} \equiv 1 - F$. Further, $H(t) \equiv \int_0^t h(u)\,\mathrm{d}u$ is called the cumulative hazard function, and is given by the relation

$$\overline{F}(t) = \exp\left[-\int_0^t h(u)\mathrm{d}u\right] = \mathrm{e}^{-H(t)}\,. \qquad (46.1)$$

Thus, $F(t)$, $\overline{F}(t)$, $f(t)$, $h(t)$ and $H(t)$ determine one another. Throughout this paper, we use these notations.

46.1.1 Failure Distribution

The most important statistical parameter is to find the mean time to failure (MTTF) of the unit. This is obtained comparatively easily by collecting data on the unit lifetime. Given the estimated failure distribution $F(t)$ of a unit, then the MTTF is given by $\mu \equiv \int_0^\infty \overline{F}(t)\,\mathrm{d}t$.

Next, since the probability that a unit with age T will fail in an interval $(T, t+T)$ is $[F(t+T)-F(T)]/\overline{F}(T)$, its MTTF (which is called the mean residual life) is

$$\frac{1}{\overline{F}(T)}\int_0^\infty \overline{F}(t+T)\,\mathrm{d}t = \frac{1}{\overline{F}(T)}\int_T^\infty \overline{F}(t)\,\mathrm{d}t \qquad (46.2)$$

which decreases from μ to $1/h(\infty)$ when $F(t)$ is an IFR property [46.2]; in other words when $h(t)$ is increasing. Also, in this case

$$\frac{1}{\overline{F}(T)}\int_T^\infty \overline{F}(t)\,\mathrm{d}t \le \frac{1}{h(T)}\,. \qquad (46.3)$$

Thus, $1/h(T)$ is used as an upper estimator for the MTTF of a unit with age T.

When failures occur in a nonhomogeneous Poisson process, the expected number of failures during $(0\,,\,T]$ is given by $H(T)$ [46.3]. Thus, if T_k corresponds to the time that the expected number of failures is k ($k=1\,,\,2\,,\ldots$), so $H(T_k)=k$, we have

$$\int_{T_{k-1}}^{T_k} h(t)\,\mathrm{d}t = 1 \quad \text{or} \quad \int_0^{T_k} h(t)\,\mathrm{d}t = k$$
$$(k=1\,,\,2\,,\ldots)\,. \qquad (46.4)$$

In particular, when $F(t)$ is IFR,

$$T_k \le \frac{1}{h(T_{k-1})} + T_{k-1} \qquad (46.5)$$

In other words, the time where the expected number of failures from T_{k-1} is 1 is less than $1/h(T_{k-1})$. Note that the equations hold in (46.3) and (46.5) when F is exponential.

From the above discussions, it is possible to estimate that the time to the next failure, if it fails at time t, is about $1/h(t)$.

The simplest way to prevent failure is to make sure that the probability of failure is less than $p(0<p<1)$; in other words to compute a pth percentile point that satisfies $F(T_p)=p$. Then, a unit will undergo replacement at time T_p. Of course, we may consider this replacement to be PM.

Another simple method of replacement is to balance the cost of replacement after failure against that of replacement before failure. A cost c_1 is incurred for each failed unit and c_2 ($<c_1$) is incurred for each operational unit. Then, we have $c_1F(T)=c_2\overline{F}(T)$, so $F(T)=c_2/(c_1+c_2)$. We may compute a $p[=c_2/(c_1+c_2)]$th percentile point for the failure distribution $F(t)$.

46.1.2 Age Replacement

Suppose that the operating record of a unit and its failure distribution $F(t)$ are known, and that its failure rate increases with operating time. In this case, if a unit is replaced by a new one, it is called age replacement. The optimum policy for minimizing the expected cost rate is discussed. If a unit is preventively maintained and becomes as good as new, this is called perfect PM [46.3]. The optimum policy for maximizing the availability is discussed [46.2].

Suppose that a unit is replaced at failure or at a planned time T ($0<T\le\infty$), whichever occurs first. Then the expected cost rate is [46.2]

$$C(T) = \frac{c_1F(T)+c_2\overline{F}(T)}{\int_0^T \overline{F}(t)\,\mathrm{d}t}\,, \qquad (46.6)$$

where c_1 is the cost of replacement at failure and c_2 is the cost of replacement at planned time T, with $c_2<c_1$. If $T=\infty$, then the policy corresponds to replacement upon failure, and the expected cost rate is $C(\infty)=c_1/\mu$.

We find an optimum time T^* which minimizes $C(T)$ in (46.6), provided the failure rate $h(t)$ is strictly increasing, with $h(\infty)\equiv\lim_{t\to\infty}h(t)$. Evidently, since $\lim_{T\to0}C(T)=\infty$, a positive T^* ($0<T^*\le\infty$) must exist. Differentiating $C(T)$ with respect to T and setting it equal to zero, we have

$$h(T)\int_0^T \overline{F}(t)\,\mathrm{d}t - F(T) = \frac{c_2}{c_1-c_2}\,. \qquad (46.7)$$

It is easily to see that the left-hand side of (46.7) strictly increases from 0 to $h(\infty)\mu-1$ because $h(t)$ strictly increases. Thus, if $h(\infty)>c_1/[\mu(c_1-c_2)]$, then there is a finite and unique T^* ($0<T^*<\infty$) which satisfies (46.7), and the expected cost rate is

$$C(T^*) = (c_1-c_2)h(T^*)\,. \qquad (46.8)$$

On the other hand, if $h(\infty)\le c_1/[\mu(c_1-c_2)]$ then $T^*=\infty$; in other words, the unit should be replaced at failure.

Next, the unit is repaired at failure or undergoes PM before failure at planned time T ($0<T\le\infty$), whichever

occurs first. Then, the steady-state availability is

$$A(T) = \frac{\int_0^T \overline{F}(t)\,\mathrm{d}t}{\int_0^T \overline{F}(t)\,\mathrm{d}t + \beta_1 F(T) + \beta_2 \overline{F}(T)}\,, \qquad (46.9)$$

where β_1 is the mean time of repair for a failed unit and β_2 is the mean time of PM for an operational unit at time T with $\beta_1 > \beta_2$. Thus, the policy that maximizes the availability is the same one that minimizes the expected cost $C(T)$ in (46.6), except that c_i is replaced by β_i $(i = 1\,,\,2)$.

46.1.3 Periodic Replacement

If a system consists of many kinds of components and only its age is only known, it would be wise to make planned maintenances at periodic times $kT (k = 1\,,\,2\,,\ldots)$ $(0 < T \le \infty)$. We consider three periodic replacements in which a failed unit is replaced, undergoes minimal repair or remains failed.

A new unit begins to operate at time $t = 0$, and a failed unit is discovered instantly and replaced by a new one. Further, a unit is replaced at the periodic time kT, whatever its age. Let $M(t)$ be a renewal function of $F(t)$, so $M(t) \equiv \sum_{j=1}^{\infty} F^{(j)}(t)$, where $F^{(j)}(t)$ $(j = 1\,,\,2\,,\ldots)$ is the j-fold Stieltjes convolution of $F(t)$ with itself and $F^{(0)}(t) = 1$ for $t \ge 0$. Then, the expected cost rate is [46.2],

$$C_1(T) = \frac{c_1 M(T) + c_2}{T}\,, \qquad (46.10)$$

where c_1 is the cost of replacement at each failure.

We seek an optimum time T^* which minimizes the expected cost rate $C_1(T)$ in (46.10). Differentiating $C_1(T)$ with respect to T and setting it equal to zero implies

$$Tm(T) - \int_0^T m(t)\,\mathrm{d}t = \frac{c_2}{c_1}\,, \qquad (46.11)$$

where $m(t)$ is the renewal density of $M(t)$, so $m(t) \equiv \mathrm{d}M(t)/\mathrm{d}t$. This equation is a necessary condition for a finite T^*, and in this case, the expected cost rate is

$$C_1(T^*) = c_1 m(T^*)\,. \qquad (46.12)$$

Next, a unit is always replaced at times kT, but it is not replaced at failure, and hence it remains a failure for the time interval from its failure to its replacement. Then, the expected cost rate is [46.1]

$$C_2(T) = \frac{c_1 \int_0^T F(t)\,\mathrm{d}t + c_2}{T}\,, \qquad (46.13)$$

where c_1 is the cost for the time elapsed between the failure and the replacement of the unit per unit of time.

Differentiating $C_2(T)$ with respect to T and setting it equal to zero,

$$TF(T) - \int_0^T F(t)\,\mathrm{d}t = \frac{c_2}{c_1}\,. \qquad (46.14)$$

Thus, if $\mu > c_2/c_1$ then an optimum and unique T^* exists which satisfies (46.14), and the expected cost rate is

$$C_2(T^*) = c_1 F(T^*)\,. \qquad (46.15)$$

Finally, a unit undergoes only minimal repair at failure; in other words its failure rate remains undisturbed by minimal repair. Let $H(t)$ be a cumulative hazard function. Then, the expected cost rate is [46.2]

$$C_3(T) = \frac{c_1 H(T) + c_2}{T}\,, \qquad (46.16)$$

where c_1 is the cost of minimal repair at failure. Differentiating $C_3(T)$ with respect to T and setting it equal to zero,

$$Th(T) - \int_0^T h(t)\,\mathrm{d}t = \frac{c_2}{c_1}\,. \qquad (46.17)$$

When the failure rate $h(t)$ is strictly increasing, the left-hand side of (46.17) is also strictly increasing. Thus, if a solution T^* exists to (46.17), it is unique and the expected cost rate is

$$C_3(T^*) = c_1 h(T^*)\,. \qquad (46.18)$$

46.2 Number-Dependent Maintenance

Most maintenance models are based on the continuous time failure distributions shown in Sect. 46.1. However, the time to failure of a unit might be discrete; in other words it can be measured by the number of cycles of some kind (such as the number of rotations) before failure. Units such as switching devices, railroad tracks, ball bearings and airplane tires fall into this category. We would often choose to do this if

the unit is used very frequently. In another case, the exact instant of failure of a unit is not recorded; instead the day or even year in which it occurred is noted.

This section summarizes maintenance models where the maintenance depends on the number of cycles completed by a property of the unit [46.4,5]. First, we convert the standard replacement models from the previous section into discrete time models. Second, we consider the case where a unit is maintained preventively by monitoring the number of occurrences of failure, preventive maintenance or repair. Thirdly, we consider a parallel redundant system where the system is replaced preventively if a specified number of units have failed.

46.2.1 Replacement Policies

Often, an operating unit cannot be replaced at the optimum time for some reason, such as a shortage of spare units, a lack of money or workers, and the inconvenience of having the system out of operation when the unit is replaced. Indeed, some units can only be replaced at idle times: a weekend, month-end or year-end.

This section converts the standard age and periodic replacement models in Sect. 46.1.2 and Sect. 46.1.3 into discrete ones. Units are only replaced at times kT where T $(0 < T < \infty)$ has been specified previously. The other notations we use here are the same ones as those used in Sect. 46.1.

Age Replacement

Only the total operating time of the unit is measured. It is assumed that replacement can occur at times kT $(k = 1, 2, \ldots)$: replacement is only allowed in certain time periods kT. A unit is replaced at time NT or at failure, whichever occurs first, and failures are detected immediately when they occur.

From (46.6), the expected cost rate is given by

$$C(N) = \frac{c_1 F(NT) + c_2 \overline{F}(NT)}{\int_0^{NT} \overline{F}(t)\,\mathrm{d}t} \quad (N = 1, 2, \ldots). \tag{46.19}$$

We want to find an optimum number N^* that minimizes $C(N)$ when the failure rate $h(t)$ is strictly increasing. Forming the inequality $C(N+1) - C(N) \geq 0$, we have

$$\frac{F[(N+1)T] - F(NT)}{\int_{NT}^{(N+1)T} \overline{F}(t)\,\mathrm{d}t} \int_0^{NT} \overline{F}(t)\,\mathrm{d}t - F(NT) \geq \frac{c_2}{c_1 - c_2} \quad (N = 1, 2, \ldots). \tag{46.20}$$

It is easy to see that the left-hand side of (46.20) strictly increases to $h(\infty)\mu - 1$ because $h(t)$ strictly increases. Thus, if $h(\infty) > c_1/[\mu(c_1 - c_2)]$ then a finite and unique minimum N^* $(1 \leq N^* < \infty)$ exists that satisfies (46.20).

On the other hand, if $h(\infty) \leq c_1/[\mu(c_1 - c_2)]$ then $N^* = \infty$; in other words the unit should be replaced at failure.

Table 46.1 shows T_p, T^* and N^* values for a given c_1/c_2 ratio, where $T = 1$, $F(T_p) = c_2/(c_1 + c_2)$, and $F(t) = 1 - \exp(-t/100)^2$. This indicates that T^* and N^* have similar values for a given c_1/c_2. T_p is less than T^* at small c_1/c_2, but T_p becomes a good approximation to T^* for large c_1/c_2. This shows that if the replacement cost at time N^*T is lower that that at time T^*, number-dependent maintenance is more useful that time-dependent maintenance.

Periodic Replacement

Let's assume that the unit is replaced at a time NT and upon each failure, and that failures are detected immediately. From (46.10), the expected cost rate is

$$C_1(N) = \frac{c_1 M(NT) + c_2}{NT} \quad (N = 1, 2, \ldots). \tag{46.21}$$

Forming the inequality $C_1(N+1) - C_1(N) \geq 0$ implies that

$$NM[(N+1)T] - (N+1)M(NT) \geq \frac{c_2}{c_1} \quad (N = 1, 2, \ldots).$$

Next, let's suppose that a unit is replaced at time NT, but this time, if it fails, the unit is not replaced until the next scheduled replacement time. Then, from (46.13), the expected cost rate is

$$C_2(N) = \frac{c_1 \int_0^{NT} F(t)\,\mathrm{d}t + c_2}{NT} \quad (N = 1, 2, \ldots). \tag{46.22}$$

Table 46.1 Optimum T^*, N^* for $T = 1$ and percentile T_p when $F(t) = 1 - \exp(-t/100)^2$

c_1/c_2	T^*	N^*	T_p
2	110	109	64
4	59	59	47
6	46	45	39
10	34	34	31
20	23	23	22
40	16	16	16
60	13	13	13
100	10	10	10

Forming the inequality $C_2(N+1)-C_2(N)\geq 0$ implies that

$$\int_0^{NT}\overline{F}(t)\,\mathrm{d}t - N\int_{NT}^{(N+1)T}\overline{F}(t)\,\mathrm{d}t \geq \frac{c_2}{c_1} \quad (N=1,2,\ldots). \tag{46.23}$$

Since $\overline{F}(t)$ decreases to 0, the left-hand side of (46.23) increases to μ. Thus, if $\mu > c_2/c_1$, a finite and unique minimum N^* $(1\leq N^*<\infty)$ exists which satisfies (46.23).

Finally, a unit is replaced at time NT and undergoes only minimal repair at failures between replacements. Then, from (46.16), the expected cost rate is

$$C_3(N)=\frac{c_1H(NT)+c_2}{NT} \qquad (N=1,2,\ldots). \tag{46.24}$$

Forming the inequality $C_3(N+1)-C_3(N)\geq 0$ implies that

$$NH[(N+1)T]-(N+1)H(NT)\geq \frac{c_2}{c_1} \quad (N=1,2,\ldots). \tag{46.25}$$

When the failure rate $h(t)$ strictly increases to ∞, the left-hand side of (46.25) also strictly increases to ∞. In this case, a finite and unique minimum N^* $(1\leq N^*<\infty)$ exists which satisfies (46.25).

46.2.2 Number-Dependent Replacement

We now consider three replacement models where a unit is replaced after a certain number of events (failures, PMs, repairs).

Number of Failures

Consider the periodic replacement in which a unit is replaced at failure N $(N=1,2,\ldots)$ after its installation, and undergoes only minimal repair upon failure between replacements [46.6, 7]. The notation used is the same as in Sect. 46.1.3. Then, the expected cost rate is

$$C(N)=\frac{(N-1)c_1+c_2}{\sum_{j=0}^{N-1}\int_0^\infty p_j(t)\,\mathrm{d}t} \quad (N=1,2,\ldots), \tag{46.26}$$

where $p_j(t)\equiv\{[H(t)]^j/j!\}\mathrm{e}^{-H(t)}$ $(j=0,1,2,\ldots)$ represents the probability that j failures occur in an interval $(0,t]$.

From the inequality $C(N+1)-C(N)\geq 0$, we have

$$\frac{\sum_{j=0}^{N-1}\int_0^\infty p_j(t)\,\mathrm{d}t}{\int_0^\infty p_N(t)\,\mathrm{d}t}-(N-1)\geq\frac{c_2}{c_1} \quad (N=1,2,\ldots). \tag{46.27}$$

When $h(t)$ strictly increases, the left-hand side of (46.27) also strictly increases, since $\int_0^\infty p_N(t)\,\mathrm{d}t$ decreases to $1/h(\infty)$ [46.7]. Thus, if $h(\infty)>c_2/(\mu c_1)$, a finite and unique minimum N^* exists which satisfies (46.27).

Number of PM Events

Assume that the unit undergoes PM at the planned times kT $(k=1,2,\ldots)$ and its operational age becomes x units of time younger at each PM event, where both x and T $(0\leq x\leq T)$ are constant and have been specified previously. Only minimal repair is performed when the unit fails between replacements. Suppose that the unit is replaced if it operates for the time interval NT. Then, the expected cost rate is (from [46.5])

$$C(N)=\frac{1}{NT}\left[c_1\sum_{j=0}^{N-1}\int_{j(T-x)}^{T+j(T-x)}h(t)\,\mathrm{d}t+(N-1)c_2+c_3\right] \quad (N=1,2,\ldots),$$

where c_1 is the cost of the minimal repair, c_2 is the cost of PM, and c_3 is the cost of replacement, with $c_3>c_2$.

From the inequality $C(N+1)-C(N)\geq 0$, we have

$$N\int_{N(T-x)}^{T+N(T-x)}h(t)\,\mathrm{d}t-\sum_{j=0}^{N-1}\int_{j(T-x)}^{T+j(T-x)}h(t)\,\mathrm{d}t\geq\frac{c_3-c_2}{c_1} \quad (N=1,2,\ldots). \tag{46.28}$$

When $h(t)$ strictly increases, the left-hand side of (46.28) also strictly increases in N. Thus, if a finite N^* which satisfies (46.28) exists, it is unique and it minimizes $C(N)$.

Number of Repairs

Consider a single unit which is repaired upon failure and then returned to operation. It is assumed that the unit begins to operate at time 0 and that it has a failure distribution $F_1(t)$ with a finite mean μ_1, and after the $(j-1)$th repair $(j=2,3,\ldots)$, it has a new distribution $F_j(t)$ with a mean μ_j, which is different and independent from the previous $F_{j-1}(t)$. The jth repair time has the distribution $G_j(t)$ with a mean β_j $(j=1,2,\ldots)$.

A unit is replaced by a new one upon failure N after its installation; in other words, after the completion of the $(N-1)$th repair, the unit is not repaired – it is simply replaced with a new unit. Then, the expected cost rate is, from [46.5]:

$$C(N)=\frac{(N-1)c_1+c_2}{\sum_{j=1}^{N}\mu_j+\sum_{j=1}^{N-1}\beta_j} \quad (N=1\,,2\,,\dots)\,, \tag{46.29}$$

Here c_1 is the cost of each repair and c_2 is the cost of the replacement.

From the inequality $C(N+1)-C(N)\ge 0$, we have

$$\frac{\sum_{j=1}^{N+1}\mu_j+\sum_{j=1}^{N}\beta_j}{\mu_N+\beta_N}-N\ge\frac{c_2}{c_1} \quad (N=1,2,\dots)\,. \tag{46.30}$$

If $\mu_{j+1}+\beta_j>\mu_{j+2}+\beta_{j+1}$ $(j=0\,,1\,,2\,,\dots)$ where $\beta_0\equiv 0$ in other words the mean time of the cycle from one failure to the next decreases with the number of failures – then the optimum number N^* which satisfies (46.30) is unique.

In particular, suppose that $\mu_{j+1}\equiv a^{j-1}\mu$ and $\beta_j\equiv\beta$ $(j=1\,,2\,,\dots\,;0<a<1)$. Then, if $\mu/\beta>(1-a)(c_2/c_1)$, a finite and unique minimum N^* exists which minimizes $C(N)$.

46.2.3 Parallel System

Consider an n-unit parallel redundant system in which the system is replaced if all units have failed. First, we are interested in the number of units that is the most economical [46.8].

Suppose that each unit has an identical failure distribution $F(t)$ with a finite mean μ. Then an n-unit parallel system has a failure distribution of $[F(t)]^n$, and so the mean time to system failure is $\int_0^\infty[1-F(t)^n]\,\mathrm{d}t$. Thus, the expected cost rate is

$$C(n)=\frac{nc_1+c_2}{\int_0^\infty[1-F(t)^n]\,\mathrm{d}t} \qquad (n=1\,,2\,,\dots)\,, \tag{46.31}$$

where c_1 is the cost of one unit and c_2 is the cost of the replacement.

From the inequality $C(n+1)-C(n)\ge 0$, we have

$$\frac{\int_0^\infty[1-F(t)^n]\,\mathrm{d}t}{\int_0^\infty[F(t)^n-F(t)^{n+1}]\,\mathrm{d}t}-n\ge\frac{c_2}{c_1} \quad (n=1\,,2\,,\dots)\,. \tag{46.32}$$

It is easy to see that the left-hand side of (46.32) strictly increases to ∞. A finite and unique minimum n^* exists which satisfies (46.32) and minimizes $C(n)$.

In particular, when $F(t)=1-\mathrm{e}^{-\lambda t}$, n^* is given by a finite and unique minimum such that

$$(n+1)\sum_{j=1}^{n}\frac{1}{j}-n\ge\frac{c_2}{c_1}\,.$$

Next, consider a parallel redundant system with n units in which units fail through shock at a mean interval of θ. It is assumed that the probability that an operating unit fails at shock j is p_j $(j=1\,,2\,,\dots)$, depending on the number of shocks.

The system is replaced preventively before failure if the total number of failed units is $N+1$, $N+2$, …, $n-1$, or it is replaced if all units have failed; otherwise it is left alone. Then, the expected cost rate is [46.8, 9]

$$C(N)=\frac{c_2+(c_1-c_2)\times\sum_{j=1}^{\infty}\sum_{r=0}^{N}\binom{n}{r}[p(j)]^{n-r}[P(j-1)]^r}{\theta\sum_{j=1}^{\infty}j\sum_{m=N+1}^{n}\binom{n}{m}[1-P(j)]^{n-m}\times\sum_{r=0}^{N}\binom{m}{r}[p(j)]^{m-r}[P(j-1)]^r} \quad (N=0\,,1\,,2\,,\dots\,,n-1)\,, \tag{46.33}$$

where c_1 is the cost of replacement for a failed system and c_2 is the cost of replacement for a system before failure with $c_2<c_1$, $P(j)\equiv\sum_{i=1}^{j}p(i)$ $(j=1\,,2\,,\dots)$ and $P(0)\equiv 0$.

If n and p_j are given, we can determine an optimum number N^* that minimizes the expected cost rate $C(N)$ in (46.33) by comparing $N=0\,,1\,,2\,,\dots\,,n-1$. If p_j is a geometric distribution, so $p_j=pq^{j-1}$ $(j=1\,,2\,,\dots\,;q\equiv 1-p,0<p<1)$, then

$$C(N)=\frac{c_2+(c_1-c_2)\sum_{r=0}^{N}\binom{n}{r}(-1)^r p^{n-r}\times\sum_{i=0}^{r}(-1)^i\left[1/(1-q^{n-i})\right]}{\theta\sum_{r=0}^{N}\binom{n}{r}(-1)^r\times\sum_{i=0}^{N-r}\binom{n-r}{i}\left[1/\left(1-q^{n-i}\right)\right]} \quad (N=0\,,1\,,2\,,\dots\,,n-1)\,. \tag{46.34}$$

In particular, when $n=2$,

$$C(0)=\left[c_1p^2+c_2\left(1-p^2-q^2\right)\right]/\theta\,, \tag{46.35}$$

$$C(1) = \frac{c_1}{\theta}\frac{1-q^2}{1+2q} \,. \tag{46.36}$$

Thus, if $c_2/c_1 < q/(1+2q)$, then the system is replaced when one unit fails, and if $c_2/c_1 \geq q/(1+2q)$ then it is replaced when two units have failed. Since $q/(1+2q) < 1/3$, if $c_1 \leq 3c_2$ then the system is replaced when two units have failed.

46.3 Amount-Dependent Maintenance

Some units are maintained preventively by monitoring their amount of wear, stress, fatigue, corrosion, erosion and garbage. A typical model in this case is the "cumulative damage model" or the "shock model", in which a unit fails when the cumulative amount of damage from shocks has exceeded a particular failure level [46.10].

This section discusses the replacement policy for a cumulative damage model where a unit is replaced before failure at damage Z, or upon failure, whichever occurs first. Then we consider the replacement policy for the scenario where a unit undergoes minimal repair upon failure. Optimum damage levels Z^* which minimize the expected cost rates are analytically derived for both replacement policies. The methods and results in this section can be applied to actual units by cmonitoring their deterioration, and using this to decide which form of maintenance is appropriate. If the amount of total damage is proportional to the total operating time and the number of uses, these correspond to the time- and number-dependent maintenance models, respectively.

46.3.1 Replacement Policies

Consider a unit that should operate for an infinite time span. It is assumed that shocks occur at time intervals of X_i and that each shock causes an amount of damage W_i to the unit. The total damage to the unit is additive. A unit fails when the total damage has exceeded a failure level K. Unit failure shoudl be avoided during actual operation if it is costly or dangerous. In such situations, it would be wise to replacement the unit or perform preventive maintenance before failure, since it would be less expensive.

It would be better to adopt the damage level as the trigger for replacement if we know the total damage at any time. We replace a unit before failure when the total damage has exceeded a threshold level Z $(0 \leq Z \leq K)$. That is, we can investigate the total damage immediately after each shock occurs. If the total damage exceeds Z and is less than K, we replace the unit before it fails. If the total damage has exceeded K, it has failed and is replaced; otherwise we leave it alone.

We denote that $F(t) \equiv \Pr(X_i \leq t)$ and $G(x) \equiv \Pr(W_i \leq x)$ $(i = 1, 2, \ldots)$, where $\theta \equiv E(X_i) < \infty$ and $\beta \equiv E(W_i) < \infty$. Therefore, the expected cost rate is (from [46.11]):

$$C(Z) = \frac{c_2}{\theta[1+M(Z)]} + \frac{(c_1-c_2)}{\theta[1+M(Z)]} \times \left\{1 - G(K) + \int_0^Z [1-G(K-x)]\,\mathrm{dM}(x)\right\} , \tag{46.37}$$

where c_1 is the cost of replacement at failure level K, c_2 is the cost of replacement at threshold level Z with $c_2 < c_1$, and $M(x) \equiv \sum_{j=1}^{\infty} G^{(j)}(x)$ represents the number of shocks expected before the total damage exceeds x. It is evident that

$$C(0) = \{c_1[1-G(K)] + c_2 G(K)\}/\theta \,,$$
$$C(\infty) = \frac{c_1}{\theta[1+M(K)]} \,.$$

We find an optimum threshold level Z^* which minimizes the expected cost rate $C(Z)$. Differentiating $C(Z)$ with respect to Z and setting it equal to zero,

$$\int_{K-Z}^{K} [1+M(K-x)]\,\mathrm{d}G(x) = \frac{c_2}{c_1-c_2} \,. \tag{46.38}$$

The left-hand side of (46.38) strictly increases from 0 to $M(K)$. Thus, if $M(K) > c_2/(c_1-c_2)$ then a finite and unique Z^* $(0 < Z^* < K)$ exists which satisfies (46.38), and the expected cost rate is

$$C(Z^*) = (c_1-c_2)[1-G(K-Z^*)]/\theta \,. \tag{46.39}$$

On the other hand, if $M(K) \leq c_2/(c_1-c_2)$ then $Z^* = K$, so the unit should be replaced after failure.

Also, if the unit is replaced upon failure, at damage Z, at time T or upon shock number N (whichever occurs

first), the expected cost rate is

$$C(Z,T,N)=\left(c_2+(c_1-c_2)\sum_{j=0}^{N-1}F^{(j+1)}(T)\times\int_0^Z[1-G(K-x)]\,\mathrm{d}G^{(j)}(x)+(c_3-c_2)\sum_{j=0}^{N-1}\left[F^{(j)}(T)-F^{(j+1)}(T)\right]G^{(j)}(Z)+(c_4-c_2)F^{(N)}(T)G^{(N)}(Z)\right)\times\left(\sum_{j=0}^{N-1}G^{(j)}(Z)\int_0^T\left[F^{(j)}(t)-F^{(j+1)}(t)\right]\mathrm{d}t\right)^{-1},$$

where c_3 is the cost of replacement at time T and c_4 is the cost of replacement at shock N.

46.3.2 Replacement with Minimal Repair

Suppose that a unit fails with probability $p(z)$ upon each shock (z is the total damage), where $p(0)\equiv 0$ and $p(\infty)=1$ [46.12], and that the unit undergoes only minimal repair upon failure. Further, a unit is replaced upon damage Z, at time T or upon shock number N (whichever occurs first). Therefore, the expected cost rate is (from [46.13]):

$$C(Z,T,N)=\frac{c_1\sum_{j=1}^{N-1}F^{(j)}(T)\int_0^Z p(z)\,\mathrm{d}G^{(j)}(z)+c_2\sum_{j=1}^{N}F^{(j)}(T)\left[G^{(j-1)}(Z)-G^{(j)}(Z)\right]+c_3\sum_{j=0}^{N-1}\left[F^{(j)}(T)-F^{(j+1)}(T)\right]G^{(j)}(Z)+c_4F^{(N)}(T)G^{(N)}(Z)}{\sum_{j=0}^{N-1}G^{(j)}(Z)\int_0^T\left[F^{(j)}(t)-F^{(j+1)}(t)\right]\mathrm{d}t},\tag{46.40}$$

where c_1 is the cost of minimal repair upon failure, c_2 is the cost of replacement upon damage Z, c_3 is the cost of replacement at time T, and c_4 is the cost of replacement upon shock N.

The expected cost rate when a unit is only replaced at damage Z is

$$C(Z)\equiv\lim_{\substack{T\to\infty\\N\to\infty}}C(T,N,Z)=\frac{c_1\int_0^Z p(x)\,\mathrm{d}M(x)+c_2}{\theta[1+M(Z)]}.\tag{46.41}$$

Differentiating $C(Z)$ with respect to Z and setting it equal to zero, we have

$$\int_0^Z[1+M(x)]\,\mathrm{d}p(x)=\frac{c_2}{c_1}\tag{46.42}$$

which strictly increases in Z when $p(x)$ strictly increases. Thus, if a solution satisfying (46.42) exists then it is unique.

In particular, when $p(x)=1-\mathrm{e}^{-sx}$ for $s>0$,

$$\int_0^\infty[1+M(x)]\,\mathrm{d}p(x)=\frac{1}{1-G^*(s)},$$

where $G^*(s)$ is the Laplace–Stieltjes transform of $G(x)$. Therefore, if $1/[1-G^*(s)]>c_2/c_1$, then a finite and unique Z^* exists which satisfies (46.42), and the expected cost rate is $c_1p(Z^*)$. On the other hand, if $1/[1-G^*(s)]\le c_2/c_1$ then $Z^*=\infty$ and $C(\infty)=c_1/\theta$.

Similarly,

$$C(T)\equiv\lim_{\substack{N\to\infty\\Z\to\infty}}C(T,N,Z)=\frac{c_1\sum_{j=1}^{\infty}F^{(j)}(T)\int_0^\infty p(z)\,\mathrm{d}G^{(j)}(z)+c_3}{T},\tag{46.43}$$

$$C(N)\equiv\lim_{\substack{T\to\infty\\Z\to\infty}}C(T,N,Z)=\frac{c_1\sum_{j=1}^{N-1}\int_0^\infty p(z)\,\mathrm{d}G^{(j)}(z)+c_4}{\theta N}.\tag{46.44}$$

We can discuss the optimum T^* and N^*, which minimize the expected cost rates $C(T)$ and $C(N)$, respectively.

46.4 Other Maintenance Models

We now introduce two maintenance models that are interesting statistically. One is the *repair limit policy* and the other is *inspection with human errors*. Further, we give an example of the practical application of a maintenance policy, for a phased array radar.

46.4.1 Repair Limit Policy

In the previous sections, we have dealt with replacement and PM policies in which a unit undergoes maintenances at time T or upon failure (whichever occurs first). One alternative, considered here, is to repair a failed unit if the repair time is short but to replace it if the repair time is long. That is, if the estimated repair time of a failed unit is greater than a specified time T, which is called the *repair limit time*, then it is replaced.

It is assumed that the repair time has a general distribution $G(t)$ with a finite mean β. Let c_1 be the replacement cost of the failed unit and $c_r(t)$ be the expected repair cost during $(0, t]$ when the failed unit undergoes repair. Suppose that when the unit fails, its repair time is estimated. If the repair time is estimated to be less than T, it is repaired; otherwise it is replaced. The expected cost rate is, from [46.14],

$$C(T) = \frac{c_1 \overline{G}(T) + \int_0^T c_r(t)\,\mathrm{d}G(t)}{\mu + \int_0^T t\,\mathrm{d}G(t)} . \qquad (46.45)$$

Evidently

$$C(0) = c_1/\mu ,$$
$$C(\infty) = \frac{\int_0^\infty c_r(t)\,dG(t)}{\mu+\beta} .$$

In particular, when $c_r(t) = ct$, the expected cost rate is

$$C(T) = \frac{c_1 \overline{G}(T) + c\int_0^T t\,\mathrm{d}G(t)}{\mu + \int_0^T t\,\mathrm{d}G(t)} . \qquad (46.46)$$

Differentiating $C(T)$ with respect to T and setting it equal to zero, we have

$$\frac{\mu c}{c_1} = \frac{\mu + \int_0^T \overline{G}(t)\,\mathrm{d}t}{T} \qquad (46.47)$$

whose right-hand side strictly decreases from ∞ to 0. Thus, a finite and unique optimum repair limit time T^* exists which satisfies (46.47).

46.4.2 Inspection with Human Errors

Suppose that an operating unit is checked at times kT $(k = 1, 2, \ldots)$ for $0 < T < \infty$, and that failed units are detected only through inspection and are then replaced. Now, two types of human error can occur when the standby unit is checked at periodic times kT $(k = 1, 2, \ldots)$ [46.15]:

1. *Type I human error*: The operational unit is judged to have failed.
2. *Type II human error*: The failed unit is judged to be operational.

It is assumed that the probabilities of type I and type II errors occurring are, respectively, p_1 and p_2, where $0 \le p_1 + p_2 < 1$. In this case, the number of inspections needed to detect and replace a failed unit is

$$\sum_{j=0}^{\infty} j p_2{}^{j-1}(1-p_2) = \frac{1}{1-p_2} .$$

Consider one cycle from time $t = 0$ to the time when a failed unit is detected by perfect inspection or a good unit is replaced in a type I error, whichever occurs first. Let c_1 be the cost of each inspection and c_2 be the cost of the lost operational time elapsed between a failure and its detection per unit of time. Then, the total expected cost of one cycle is

$$\begin{aligned} C(T) = \sum_{j=0}^{\infty}(1-p_1)^j \Bigg\{ \int_{jT}^{(j+1)T} \Bigg[c_1 \left(j + \frac{1}{1-p_2} \right) \\ + c_2 \left(jT + \frac{T}{1-p_2} - t \right) \Bigg] \mathrm{d}F(t) \\ + p_1 c_1 (j+1) \overline{F}((j+1)T) \Bigg\} \\ = (c_1 + c_2 T) \Bigg\{ \frac{1}{1-p_2} \sum_{j=0}^{\infty} (1-p_1)^j \\ \left[\overline{F}(jT) - \overline{F}((j+1)T) \right] \\ + \sum_{j=0}^{\infty} (1-p_1)^j \overline{F}[(j+1)T] \Bigg\} \\ - c_2 \sum_{j=0}^{\infty} (1-p_1)^j \int_{jT}^{(j+1)T} \overline{F}(t)\,\mathrm{d}t . \end{aligned} \qquad (46.48)$$

When $p_1 = p_2 = 0$ (the inspection is perfect), the expected cost is

$$C(T) = (c_1 + c_2 T) \sum_{j=0}^{\infty} \overline{F}(jT) - c_2 \mu \qquad (46.49)$$

which agrees with that of the standard inspection policy [46.1].

In particular, when $F(t) = 1 - \mathrm{e}^{-\lambda t}$, the expected cost can be rewritten as

$$\begin{aligned} C(T) = & (c_1 + c_2 T) \frac{\left(1 - \mathrm{e}^{-\lambda T}\right)/(1-p_2) + \mathrm{e}^{-\lambda T}}{1 - (1-p_1)\mathrm{e}^{-\lambda T}} \\ & - \frac{c_2}{\lambda} \frac{1 - \mathrm{e}^{-\lambda T}}{1 - (1-p_1)\mathrm{e}^{-\lambda T}} . \end{aligned} \qquad (46.50)$$

Differentiating $C(T)$ with respect to T and setting it equal to zero,

$$\frac{e^{\lambda T}-1}{\lambda}[1-p_2(1-p_1)e^{-\lambda T}]-(1-p_1-p_2)T = \frac{c_1}{c_2}(1-p_1-p_2)\,. \tag{46.51}$$

It is evident that the left-hand side of (46.51) strictly increases from 0 to ∞. Therefore, a finite and unique T^* exists which satisfies (46.51).

46.4.3 Phased Array Radar

Finally, we consider an example scenario of the maintenance of a phased array radar (PAR) [46.16]. A PAR consists of a large number of small and homogeneous elements, and it steer the electromagnetic wave used for detection by shifting the signal phases of waves that are radiated from these individual elements [46.17].

Keithely [46.18] showed that the maintenance model applied to a PAR with 1024 elements had a strong influence on its availability. *Heresh* [46.19] discussed the following three maintenance models for a PAR in which all failed elements were detected immediately, calculated the average time to failures of the equipment, and derived its availability:

1. *Immediate maintenance*: Failed elements are detected, localized and replaced immediately.
2. *Cyclic maintenance*: Failed elements are detected, localized and replaced periodically.
3. *Delayed maintenance*: Failed elements are detected and localized periodically, and replaced when they have exceeded a prespecified managerial number.

In real world scenarios, immediate maintenance is rarely adopted because frequent maintenance degrades the availability of the system. Cyclic or delayed maintenance are the most common approaches.

In this section, we investigate the periodic detection of failed elements of the PAR. The PAR consists of N_0 elements, and failures are detected at periodic times kT $(k=1\,,2\,,\dots)$ for a given T $(0<T<\infty)$. If the number of failed elements has exceeded a failure number n $(0<n\le N_0)$, the PAR cannot maintain the required level of radar performance, resulting in operational errors such as target oversight

Cyclic Maintenance

We consider the following cyclic maintenance of the PAR:

1. The PAR consists of N_0 elements which have an identical constant failure rate λ_0. The number of failed elements during $(0\,,t]$ has a binomial distribution with a mean $N_0[1-\exp(-\lambda_0 t)]$. Since N_0 is large and λ_0 is very small, it can be assumed that failures occur approximately according to a Poisson process with a mean $\lambda\equiv N_0\lambda_0$. That is, the probability that j failures occur during $(0\,,t]$ is
$$p_j(t)\equiv\frac{(\lambda t)^j}{j!}e^{-\lambda t}\qquad(j=0\,,1\,,2\,,\dots)\,.$$
2. When the number of failed elements has exceeded a failure number n, the PAR cannot maintain the required level of radar performance.
3. Failed elements are checked at periodic times kT $(k=1,2,\dots)$, and the checking time is negligible.
4. Failed elements are replaced by new ones at time KT $(K=1,2,\dots)$ or at the time when they exceed n, whichever occurs first.

We now introduce some costs. Cost c_1 is the replacement cost of one failed element; c_2 is the cost of the operational loss during replacement, and c_3 is the cost of the degradation of radar performance per unit time. Then, the expected cost to replace the failed element is [46.16]

$$\begin{aligned}&\sum_{j=0}^{n-1}(jc_1+c_2)p_j(KT)+\sum_{k=1}^{K}\sum_{j=0}^{n-1}p_j[(k-1)T]\\&\quad\times\sum_{i=n-j}^{\infty}\left\{[(i+j)c_1+c_2]p_i(T)\right.\\&\quad\left.+c_3\int_{(k-1)T}^{kT}(kT-t)\,\mathrm{d}p_i[t-(k-1)T]\right\}\\&=c_2+c_1\lambda T\sum_{k=0}^{K-1}\sum_{j=0}^{n-1}p_j(kT)+\frac{c_3}{\lambda}\sum_{k=0}^{K-1}\sum_{j=0}^{n-1}p_j(kT)\\&\quad\times\sum_{i=n-j}^{\infty}(i+j-n)p_i(T)\end{aligned}$$

and the mean time to replace the element is

$$\begin{aligned}&\sum_{j=0}^{n-1}(KT)p_j(KT)+\sum_{k=1}^{K}\sum_{j=0}^{n-1}p_j[(k-1)T]\\&\quad\times\sum_{i=n-j}^{\infty}(kT)p_k(T)\\&=T\sum_{k=0}^{K-1}\sum_{j=0}^{n-1}p_j(kT)\,.\end{aligned}$$

Thus, the expected cost is

$$C_1(K) = c_1\lambda + \frac{c_2}{T\sum_{k=0}^{K-1}\sum_{j=0}^{n-1} p_j(kT)} + \frac{(c_3/\lambda)}{T\sum_{k=0}^{K-1}\sum_{j=0}^{n-1} p_j(kT)} \times \sum_{k=0}^{K-1}\sum_{j=0}^{n-1} p_j(kT) \sum_{i=n-j}^{\infty}(i+j-n)p_i(T)\,, \quad (K=1\,,2\,,\ldots)\,. \tag{46.52}$$

We seek an optimum number K^* which minimizes (46.52). From the inequality $C_1(K+1)-C_1(K)\geq 0$, we have

$$\sum_{k=0}^{K-1}\sum_{m=0}^{n-1} p_m(kT)\sum_{j=0}^{n-1} p_j(KT)\sum_{i=n-j}^{\infty}(i+j-n)p_i(T) - \sum_{k=0}^{K-1}\sum_{j=0}^{n-1} p_j(kT)\sum_{i=n-j}^{\infty}(i+j-n)p_i(T) \geq \frac{\lambda c_2}{c_3}\,, \quad (K=1\,,2\,,\ldots)\,. \tag{46.53}$$

Denoting the left-hand side of (46.53) by $Q_1(K)$, it is clear that $Q_1(K)$ increases to $Q_1(\infty)$ in K. Thus, if $Q_1(\infty) > \lambda c_2/c_3$ then a finite and unique minimum K^* exists which satisfies (46.53).

Delayed Maintenance

We now consider a delayed maintenance model for the PAR, which is similar to the model before, but:

4. Failed elements are replaced by new ones only when they have exceeded a managerial number N ($N \leq n$).

Other assumptions are the same as the ones used for cyclic maintenance.

The expected cost to replace the element is [46.16]

$$\sum_{k=1}^{\infty}\sum_{j=0}^{N-1} p_j[(k-1)T]\sum_{i=N-j}^{n-j+1}[(i+j)c_1+c_2]p_i(T) + \sum_{k=1}^{\infty}\sum_{j=0}^{N-1} p_j[(k-1)T]\sum_{i=n-j}^{\infty}\left\{[(i+j)c_1+c_2] \times p_i(T) + c_3\int_{(k-1)T}^{kT}(kT-t)\,\mathrm{d}p_i[t-(k-1)T]\right\}$$

$$= c_2 + c_1\lambda T\sum_{k=0}^{\infty}\sum_{j=0}^{N-1} p_j(kT) + \frac{c_3}{\lambda}\sum_{k=0}^{\infty}\sum_{j=0}^{N-1} p_j(kT) \times \sum_{i=n-j}^{\infty}(i+j-n)p_i(T)$$

and the mean time to replacement is

$$\sum_{k=1}^{\infty}\sum_{j=0}^{N-1} p_j[(k-1)T]\sum_{i=N-j}^{n-j+1}(kT)p_i(T) + \sum_{k=1}^{\infty}\sum_{j=0}^{N-1} p_j[(k-1)T]\sum_{i=n-j}^{\infty}(kT)p_i(T) = T\sum_{k=0}^{\infty}\sum_{j=0}^{N-1} p_j(kT)\,.$$

Thus, the expected cost rate is

$$C_2(N) = c_1\lambda + \frac{c_2}{T\sum_{k=0}^{\infty}\sum_{j=0}^{N-1} p_j(kT)} + \frac{(c_3/\lambda)}{T\sum_{k=0}^{\infty}\sum_{j=0}^{N-1} p_j(kT)} \times \sum_{k=0}^{\infty}\sum_{j=0}^{N-1} p_j(kT)\sum_{i=n-j}^{\infty}(i+j-n)p_i(T) \quad (N=1\,,2\,,\ldots\,,n)\,. \tag{46.54}$$

We seek an optimum number N^* which minimizes (46.54). From the inequality $C_2(N+1)-C_2(N)\geq 0$, we have

$$\sum_{k=0}^{\infty}\sum_{j=0}^{N-1} p_j(kT)\sum_{i=1}^{\infty} i[p_{n+i-N}(T)-p_{n+i-j}(T)] \geq \frac{\lambda c_2}{c_3} \quad (N=1\,,2\,,\ldots\,,n)\,. \tag{46.55}$$

Denoting the left-hand side of (46.55) by $Q_2(N)$, it is clear that $Q_2(N)$ increases to $Q_2(\infty)$ in N. Therefore, if $Q_2(\infty) > \lambda c_2/c_3$ then a finite and unique minimum N^* exists which satisfies (46.55).

We now show a numerical example for when $c_1 = 0$, because it does not affect K^* and N^*. Table 46.2 gives the optimum numbers K^* and N^* and the expected costs $C_1(K^*)$ and $C_2(N^*)$ for $T = 24$, 48, 72, ..., 168 h and $\lambda_0 = 1$, 2, 3, ..., 10×10^{-4} h, when $N_0 = 1000$, $n = 100$ and $c_2 = c_3 = 1$. Table 46.2 indicates that both K^* and N^* decrease when T

Table 46.2 Optimum replacement number K^*, failed element number N^*, and the expected costs $C_1(K^*)$ and $C_2(N^*)$

λ_0	T	K^*	K^*T	$C_1(K^*)$	N^*	$C_2(N^*)$	$C_1(K^*)/C_2(N^*)$
	24	31	744	1.38×10^{-3}	93	1.07×10^{-3}	1.29
	48	15	720	1.41×10^{-3}	89	1.10×10^{-3}	1.28
	72	10	720	1.42×10^{-3}	86	1.13×10^{-3}	1.26
1×10^{-4}	96	7	672	1.49×10^{-3}	83	1.16×10^{-3}	1.28
	120	6	720	1.42×10^{-3}	80	1.18×10^{-3}	1.20
	144	5	720	1.42×10^{-3}	77	1.21×10^{-3}	1.17
	168	4	672	1.49×10^{-3}	74	1.24×10^{-3}	1.20
2×10^{-4}		16	384	2.75×10^{-3}	90	2.19×10^{-3}	1.26
3×10^{-4}		11	264	4.19×10^{-3}	87	3.34×10^{-3}	1.25
4×10^{-4}		8	192	5.41×10^{-3}	85	4.54×10^{-3}	1.19
5×10^{-4}		6	144	6.98×10^{-3}	82	5.77×10^{-3}	1.21
6×10^{-4}	24	5	120	8.36×10^{-3}	80	7.03×10^{-3}	1.19
7×10^{-4}		5	120	1.04×10^{-2}	77	8.34×10^{-3}	1.25
8×10^{-4}		4	96	1.06×10^{-2}	75	9.69×10^{-3}	1.09
9×10^{-4}		3	72	1.39×10^{-2}	73	1.10×10^{-2}	1.26
10×10^{-4}		3	72	1.39×10^{-2}	71	1.26×10^{-2}	1.10

and λ_0 increase. It is interesting that the value of K^*T are approximately 720 h when $\lambda_0 = 1\times10^{-4}$. In this example, $C_1(K^*)$ is always greater than $C_2(N^*)$ and $C_1(K^*)/C_2(N^*) \approx 1.2$. Therefore, in this case it is clear that delayed maintenance is more efficient than cyclic maintenance from an economic point of view.

Up to now, we have only discussed the best policies for minimizing costs, without considering another important factor: the availability of the system. To finish this chapter, we now obtain the availabilities for these two maintenance models. Let T_0 be the time required for checks at times kT $(k = 1, 2, \dots)$ and T_1 be the time required for each replacement that occurs at time kT when the number of failed elements exceeds a failure number n or a managerial number N. Then, in a similar way to the way that the expected costs were derived, we can obtain the availabilities. For cyclic maintenance, the availability is given by

$$A_1(K) = \frac{T\sum_{k=0}^{K-1}\sum_{j=0}^{n-1} p_j(kT) - (1/\lambda) \times \sum_{k=0}^{K-1}\sum_{j=0}^{n-1} p_j(kT)\sum_{i=n-j}^{\infty}(i+j-n)p_i(T)}{T_1 + (T+T_0)\sum_{k=0}^{K-1}\sum_{j=0}^{n-1} p_j(kT)}, \quad (K = 1, 2, \dots) \tag{46.56}$$

and for delayed maintenance it is given by

$$A_2(N) = \frac{T\sum_{k=0}^{\infty}\sum_{j=0}^{N-1} p_j(kT) - (1/\lambda) \sum_{k=0}^{\infty}\sum_{j=0}^{N-1} p_j(kT)\sum_{i=n-j}^{\infty}(i+j-n)p_i(T)}{T_1 + (T+T_0)\sum_{k=0}^{\infty}\sum_{j=0}^{N-1} p_j(kT)}, \quad (N = 1, 2, \dots, n). \tag{46.57}$$

Part F Applications

Part F Applications in Engineering Statistics

Part F contains eight chapters and focuses on applications in engineering statistics. The first chapter in this part, Chapt. 47, introduces the essential mathematical techniques and financial economic concepts that are used to assess the risks of and deal with asset pricing, and the maximum-entropy approach for calculating an approximate risk-neutral distribution. Chapter 48 concentrates on demand-forecasting problems and their applications in industry. It also reviews various common forecasting methods and discusses models that are used to obtain the optimal stock level for spare parts based on some industrial applications. Chapter 49 introduces various approaches including arithmetic and geometric processes to model sequential data with and without trends as alternative ways to model maintenance problems better. The chapter also introduces repair–replacement models for a deteriorating system based on an arithmetico-geometric process. Chapter 50 focuses on Six Sigma and highlights several methodologies and techniques for product development and service design as well as the core methodologies of Six Sigma. The chapter also includes a real case study on printed circuit boards to illustrate the application of Six Sigma.

Chapter 51 discusses multivariate modeling with copulas and its applications in engineering. The chapter describes the concept and classes of copulas, such as elliptical and Archimedean copulas, and statistical inferences of copula-based connections to multivariate distributions given by the data. Chapter 52 focuses on the application of queuing theory to communication systems. The chapter details theoretical and practical aspects of analyzing the traffic-flow control and load-balancing problems in order to reduce congestion and improve load balancing in modern communication systems. Chapter 53 describes the basic principles of support-vector machines for constructing classification and the development of nonlinear regression prediction models for data modeling using support-vector machine algorithms. Finally, Chapt. 54 focuses on the presentation of various spares-optimization models and the importance of optimal system design. The chapter describes the detailed formulation of cost-effective models for repairable and nonrepairable systems and the solution techniques and algorithms used for obtaining optimal design solutions.

47. Risks and Assets Pricing

This chapter introduces the basic elements of risk and financial assets pricing. Asset pricing is considered in two essential situations, complete and incomplete markets, and the definition and use of a number of essential financial instruments is described. Specifically, stocks (as underlying processes), bonds and derivative products (and in particular call and put European and American options) are considered. The intent of the chapter is neither to cover all the many techniques and approaches that are used in asset pricing, nor to provide a complete introduction to financial asset pricing and financial engineering. Rather, the intent of the chapter is to outline through applications and problems the essential mathematical techniques and financial economic concepts used to assess the value of risky assets. An extensive set of references is also included to direct the motivated reader to further and extensive research in this broad and evolving domain of economic and financial engineering and mathematics that deals with asset pricing. The first part of the chapter (The Introduction and Sect. 47.1) deals with a definition of risk and outlines the basic terminology used in asset pricing. Further, some essential elements of the Arrow–Debreu framework that underlies the fundamental economic approach to asset pricing are introduced. A second part (Sect. 47.2), develops the concepts of risk-neutral pricing, no arbitrage and complete markets. A number of examples are used to demonstrate how we can determine a probability measure to which risk-neutral pricing can be applied to value assets when markets are complete. In this section, a distinction between complete and incomplete markets is also introduced. Sections 47.3, 47.4 and 47.5 provide an introduction to and examples of basic financial approaches and instruments. First, Sect. 47.3, outlines the basic elements of the consumption capital asset-pricing model (with the CAPM stated as a special case). Section 47.4 introduces the basic elements of net present value and bonds, calculating the yield curve as well as the term structure of interest rates and provides a brief discussion of default and rated bonds. Section 47.5 is a traditional approach to pricing of options using the risk-neutral approach (for complete markets). European and American options are considered and priced by using a number of examples. The Black–Scholes model is introduced and solved, and extensions to option pricing with stochastic volatility, underlying stock prices with jumps as well as options on bonds are introduced and solved for specific examples. The last section of the chapter focuses on incomplete markets and an outline of techniques that are used in pricing assets when markets are incomplete. In particular, the following problems are considered: the pricing of rated bonds (whether they are default-prone or not), engineered risk-neutral pricing (based on data regarding options or other derivatives) and finally we also introduce the maximum-entropy approach for calculating an approximate risk-neutral distribution.

Risk results from the direct and indirect adverse consequences of outcomes and events that were not accounted for or that we were ill prepared for, and concerns their effects on individuals, firms, financial markets or society at large. It can result from many reasons, internally, externally and strategically induced or resulting from risk externality – namely, when all costs or benefits are not incorporated by the market in the price of the asset, the product or the service received. A definition of risk involves several factors including: (i) consequences, (ii) their probabilities and their distribution, (iii) individual preferences, (iv) collective preferences and (v) sharing, contracts or risk-transfer mechanisms. These are relevant to a broad number of fields as well, each providing a different approach to the measurement, the valuation and the management of risk which *is motivated by psychological needs and the need to deal with problems that result from uncertainty and the adverse consequences they may induce* [47.1, 2]. In this chapter we are primarily concerned with risk and pricing and specifically financial assets pricing.

The definition of risk, risk measurement, risk pricing and risk management are intimately related, one feeding the other to determine the proper levels of risks that an individual seeks to sustain and the market's intended price [47.3–6]. Financial asset pricing has sought primarily to determine approaches and mechanisms for market pricing of these risks while financial risk management and engineering are concerned with the management of financial risks, seeking on the one hand to price private risks and on the other responding to the managerial finance considerations that these risks entail. Financial risk management, for example, deals extensively with hedging problems in order to reduce the risk of a particular portfolio through a trade or a series of trades, or contractual agreements reached to share and induce an efficient risk allocation by the parties involved [47.1, 7–12]. To do so, a broad set of financial instruments were developed, including bonds of various denominations, options of various types etc., in some cases broadly traded, thereby allowing a market mechanism to price these risks. For example, by a judicious use of options, contracts, swaps, insurance and investment portfolios etc. risks can be brought to bearable economic costs and shared by the parties involved in market transactions. These tools are not costless however, and require a careful balancing of the numerous factors that affect risk, the costs of applying these tools and a specification of tolerable risk. For example, options require that a premium be paid to limit the size of losses just as the insured are required to pay a premium to buy an insurance contract to protect them in case of unforeseen accidents, theft, diseases, unemployment, fire, etc. For this reason, private tools such as portfolio investment strategies, value at risk ([47.13–18] based on a quantile risk measurement providing an estimate of risk exposure) are used to manage individual risks. Financial engineering in particular has devoted a substantial attention to reconciling the management of individually priced risks and market-priced risks such that risks can be managed more efficiently. These concerns also reflect the basic approach of finance and the use of financial instruments, currently available through brokers, mutual funds, financial institutions, commodity and stock derivatives etc., which are motivated by three essential reasons [47.19–25]:

- To price the multiplicity of claims, accounting for risks and dealing with the adverse effects of uncertainty or risk (that can be completely unpredictable, partly or wholly predictable)
- To explain and account for investors' behavior. To counteract the effects of regulation and taxes by firms and individual investors (who use a wide variety of financial instruments to bypass regulations and

increase the amount of money investors can make while reducing the risk they sustain).
- To provide a rational framework for individuals' and firms' decision-making and to suit investors needs in terms of the risks they are willing to assume and pay for.

Financial instruments deal with uncertainty and the management of the risks they imply in many different ways. Some instruments merely transfer risk from one period to another and in this sense they reckon with the time phasing of events. One of the more important aspects of such instruments is to supply *immediacy* – i. e. the ability not to wait for a payment. Other instruments provide *spatial diversification* (in other words the distribution of risks across independent investments, classes or geography) and *liquidity*. By liquidity, we mean the cost to convert instantly an asset into cash at its fair price. This liquidity is affected both by the existence of a market (in other words, buyers and sellers) as well as the cost of transactions associated with the conversion of the asset into cash. As a result, essential financial risks include: (a) market-industry specific risks and (b) term structure – currency–liquidity risks. Throughout these problems financial engineering provides a comprehensive set of approaches, techniques and tools that seek to bridge the gap between theory and practice, between individual preferences and market pricing and seeks to provide numerical and computer-aided techniques that respond to the needs of individual investors and financial institutions. Further, it recognizes the centrality of money in decision-making processes: making money, not losing it and protecting investors from adverse consequences. To do so, asset pricing (valuation), forecasting, speculating and risk reduction through fundamental analysis, trading (hedging) are essential activities of traders, bankers and investors alike. Financial engineering, for example, deals extensively with the construction of portfolios, consisting of assets of broadly defined risk–return characteristics, derivatives assets etc. with risk profiles desired by individual investors [47.20, 26–38]. For these reasons, risk and financial engineering are applied not only to financial decision-making. Applications to engineering project valuation, management science, engineering risk economics and so on, are a clear indication of the maturity and the usefulness of financial asset pricing, financial engineering and financial risk management. The purpose of this chapter is to outline and explain the salient factors of these continually renewed and expanding fields of research and applications of asset pricing. At the same time we shall seek to bridge the gap between theory and practice while maintaining a mathematical level accessible to typical finance, risk, management and engineering students familiar with basic notions in probability and stochastic processes.

47.1 Risk and Asset Pricing

Asset pricing, broadly, seeks to reduce assets to the identification of *state prices*, a notion that Arrow has coined, and from which any security has an implied value as the weighted sum of its cash flows, state by state, time by time, with weights given by the associated state prices [47.19, 38, 39]. Such state prices may therefore be viewed as the marginal rates of substitution among state-time consumption opportunities, for an unconstrained investor, with respect to a numeraire good [47.23]. We shall focus first on complete markets, where state prices that make it possible to uniquely value assets do exist. Issues and topics relating to incomplete markets, stochastic volatility etc., are discussed as well. However, this is far too important and far too broad a field to be treated in this chapter's space. We begin by outlining some key terms commonly used in the language of asset pricing. A more explicit and detailed outline of such terms can be found in *Duffie* [47.22, 23], *Karatzas* and *Shreve* [47.40, 41]. We shall also outline the basic ideas of the Arrow–Debreu framework which underlies asset pricing.

47.1.1 Key Terms

In most financial models of asset pricing we use a set of states Ω, with associated probabilities to characterize the model underlying uncertainty. Such a set may be finite or infinite. A set of events is then expressed by $\mathfrak{I}$, also called a tribe and by some a σ-algebra. $\mathfrak{I}$ is a collection of subsets of Ω that can be assigned a probability $P(A)$ denoting the probability of a specific event A. In an intertemporal framework defined by the dates 0, 1, . . . , T+1, there is at each date a tribe $\mathfrak{I}_t \subset \mathfrak{I}$, corresponding to the events based on the information available at that time t. Any event in $\mathfrak{I}_t$ is known at time t to be true or false. The convention $\mathfrak{I}_t \subset \mathfrak{I}_s$, $t \leq s$ is used at all times, meaning

that events are never *forgotten* and therefore information accessed over time provides ever expanding *knowledge*. For simplicity, we let events in $\Im_0$ have probability 0 or 1, meaning that there is no information at time t=0. A filtration is defined by $\Phi = \{\Im_0, \Im_1, \Im_2, \ldots, \Im_T\}$, sometimes called an information structure, representing how information is revealed over time. For any random variable Y, we thus use at time t, $E_t(Y) = E(Y|\Im_t)$, to denote the conditional expectation of Y given $\Im_t$. For notational simplicity, we also let $Y = Z$ for any two random variables Y and Z, if the probability that $Y \neq Z$ is zero (for a review of essential elements in probability see for example, [47.42–48]).

An adapted process, defined by a sequence $X = \{X_0, X_1, X_2, \ldots, X_T\}$ such that, for each t, X_t is a random variable with respect to $(\Omega, \Im_t)$ means, informally, that X_t is observable at time t. An important characteristic of such processes in asset pricing is that an adapted process X is a martingale if, for any times t and $s > t$, we have $E_t(X_s) = X_t$. For example, if the conditional expectation of an asset price equals the currently observed price, then the adapted price process is a martingale. For this reason, important facets of financial asset pricing revolve around the notion of martingales. Another term of importance we use with respect to stochastic price processes is *non-anticipating*. This means that, for any time $t < s$ the function (price) is statistically independent of the *future uncertainty*, or the current price is independent of the future Wiener process $W(s) - W(t)$. These mathematical properties are extremely useful in proving basic results in the theoretical analysis of financial markets. However, in practice, underlying processes might not be martingales and further be anticipative processes. Of course, this will also imply a temporal dependence and our theoretical and financial constructs may be violated.

A security is a claim to an adapted (and non-anticipating) dividend process, say D, with D_t denoting the dividend paid by the security at time t. Each security has an adapted security-price process S, so that S_t is the price of the security, ex dividend, at time t. That is, at each time t, the security pays its dividend D_t and is then available for trade at price S_t. This convention implies that D_0 plays no role in determining ex-dividend prices. The cum-dividend security price at time t is $S_t + D_t$. A trading strategy is an adapted process $\boldsymbol{n}$ in $\mathbb{R}^N$. Here, n_t represents the portfolio held after trading at time t. The dividend process $D^{\boldsymbol{n}}$ generated by a trading strategy $\boldsymbol{n}$ is thus defined by $D_t^{\boldsymbol{n}} = n_{t-1}(S_{t-1} + D_t) - n_t S_t$ with n_{-1} taken to be zero by convention. Consider a portfolio that invests wealth in the security and in a bond B_{t-1}; and say that at time $t-1$, the portfolio wealth state is given by:

$$X_{t-1}^{\boldsymbol{n},m} = n_{t-1} S_{t-1} + m_{t-1} B_{t-1} .$$

We then state that a strategy is said to be self-financing if:

$$X_t^{\boldsymbol{n},m} - X_{t-1}^{\boldsymbol{n},m} = n_{t-1}\,(S_t - S_{t-1}) + m_{t-1}\,(B_t - B_{t-1}) .$$

For example, a bonds-only strategy is defined by $n_{t-1} = 0$, while buy-and-hold (long) strategies (that do not depend on time) imply that $n_{t-1} = n > 0$. A short position is defined when $n_{t-1} < 0$. Finally, a strategy consisting of maintaining a constant proportion of our wealth in bonds and stock means that: $n_t S_t / X_t^{\boldsymbol{n},m} = \alpha$ while $m_t B_t / X_t^{\boldsymbol{n},m} = 1 - \alpha$.

The important notion of arbitrage in asset pricing is used to define a trading strategy that costs nothing to form, never generates losses, and, with positive probability, will produce strictly positive gains at some time. The notion of efficient markets in particular presumes that, for efficient markets to exist, there must not be arbitrage trading strategies. The search for profits by traders and investors is therefore motivated explicitly by the search for arbitrage opportunities. This is of course a rational investment approach, for in the presence of an arbitrage, any rational investor who prefers to increase his dividends would undertake such arbitrage without limit, so markets could not be in equilibrium (in a sense that we shall see later on). As a result, the notion of no arbitrage, and the associated concepts of martingales, risk-neutral pricing and complete markets are fundamental key terms that must be understood to appreciate the scope and the spirit of asset pricing, financial engineering and financial risk management. Further, we shall also distinguish clearly between individual and collective (market) valuation. In the former, the agent-investor is assumed to optimize an expected utility of consumption, subject to an endowment constraint, while in the latter case, that investor will be fully aware of the market valuation of risk, based on an equilibrium in state prices in order to tailor an appropriate and fitting strategy to his preferences. An essential objective of dynamic asset pricing, which deals with the intertemporal and risk effects of asset pricing is to link the collective (multi-agent) equilibrium valuation (pricing) of assets to macroeconomic variables, hopefully, observable. This latter field of study requires an extensive familiarity with economic theory, finance and stochastic calculus.

47.1.2 The Arrow–Debreu Framework

The Arrow–Debreu framework underlies the approach to asset pricing. It is therefore useful to present it, even if briefly (see also [47.19,22,49,50]). Assume that there are N securities, $S_1 \dots S_N$, each of which can be held long or short in a portfolio consisting of these securities. Let $n_i > 0$ be the number of securities S_i currently priced at p_i. Thus, the vectorial product $\boldsymbol{n} \cdot \boldsymbol{p}, \boldsymbol{n} \cdot \boldsymbol{p} = \sum_{i=1}^{N} n_i p_i$ denotes the value (price) of the portfolio held. To each security i, there are associated potential cash flows D_{ij}, $j = 1, 2, \dots, M$ where M is the number of all possible *states* of the market at the end of the trading period. For example, if over one period, the market can assume only two states (say high and low) then the market is binomial and $M = 2$. If it assumes three potential states, then $M = 3$ and the market is trinomial etc. For the portfolio as a whole, we thus have the cash flow matrix:

$$\boldsymbol{nD}_{\cdot j} = \sum_{i=1}^{N} n_i D_{ij},$$
$$\boldsymbol{D} = (D_{ij}), \quad i = 1, \dots, n; \quad j = 1, \dots, M.$$

Where $\boldsymbol{D}_{\cdot j}$ denotes the vector of cash flows for all securities held if state j occurs, while the j-th row of the matrix $\boldsymbol{D}$ represents all possible cash flows associated with holding one unit of the j-th security, including dividend payment and market profit/losses (in dollars). If $n_i > 0$, the investor is long and the investor collects $n_i D_{ij}$ at the end of the period. If $n_i < 0$, the investor is short and the investor has a liability at the end of the period (taken by borrowing securities and selling them at the market price). Further, we assume that the transaction costs, commissions, taxes, etc. are neglected. The cash flow of the portfolio at the j-th state is thus, $\boldsymbol{nD}_{\cdot j}, \forall j \in [1, \dots M]$ as stated above. The cash flow thus defined allows us a formal definition of arbitrage.

Definition (Arbitrage)
An arbitrage portfolio is a portfolio $\boldsymbol{n}$ such that

1. Either $\boldsymbol{nP} = 0$, $\boldsymbol{nD}_{\cdot j} \geq 0$, $\forall j \in [1, \dots M]$ and $\boldsymbol{nD}_{\cdot j} > 0$ for some $j \in [1, \dots M]$,
2. or $\boldsymbol{nP} \leq 0$ and $\boldsymbol{nD}_{\cdot j} \geq 0$ $\forall j \in [1, \dots M]$.

That is, an arbitrage portfolio is a position that either has zero initial cost or has no *downside* regardless of the market outcome, and thus offers the possibility to make money without investment and finally can realize an immediate profit that has no downside.

Inversely, there is no arbitrage if an arbitrage portfolio cannot be constructed. The implication of no arbitrage has a direct implication on asset pricing and to the definition of risk-neutral probabilities which are used to define a price linearly in terms of the markets' cash flows. This is summarized by the following Theorem 47.1 whose proof can be found in *Duffie* [47.23]:

Theorem 47.1 (The fundamental theorem of asset pricing with no arbitrage)
If there exist a vector of positive numbers (also called asset prices) $\pi_j (j = 1 \dots M)$ such that:

$$P_i = \sum_{j=1}^{M} D_{ij} \pi_j, \quad j = 1 \dots M$$

or in vector notation $\boldsymbol{P} \equiv \boldsymbol{D\pi}$

Then there exist no arbitrage portfolios. And conversely, if there are no arbitrage portfolios, there exists a vector $\boldsymbol{\pi}$ with positive entries satisfying $\boldsymbol{P} \equiv \boldsymbol{D\pi}$ [47.23,50].

In this framework, risk-neutral probabilities or equivalently, risk-adjusted probabilities, are defined by

$$\hat{\pi}_j = \frac{\pi_j}{\sum_{j=1}^{M} \pi_k}, \quad j = 1, \dots M, \quad \hat{\pi}_j \geq 0,$$
$$\sum_{j=1}^{M} \hat{\pi}_j = 1.$$

Using these probabilities we can write, based on Theorem 47.1, that an asset price is equal to the discounted value of future cash-flow payments, at a risk-less discount rate R_f, or:

$$P_i = \frac{1}{1 + R_f} \sum_{j=1}^{M} D_{ij} \hat{\pi}_j.$$

To see that this is the case, suppose that there exists an investment opportunity (a pure, risk-free zero bond or a money market deposit) which guarantees (for sure) \$1 at the end of the period. The payoff of a bond is thus $1 \leq j \leq M$, $(1, 1, \dots 1)$ (for all states R in $\mathbb{R}^M$) and, according to Theorem 47.1, $P_{\text{BOND}} = \sum_{j=1}^{M} \pi_j = 1/(1 + R_f)$. Thus, $1 + R_f = 1/\sum_{j=1}^{M} \pi_j$, and R_f is called the bond (in this case risk-free) yield. This can be written as $P_i = \frac{1}{1+R_f} \sum_{j=1}^{M} D_{ij} \hat{\pi}_j$ as stated above, which is the expected value under the risk-adjusted (risk-neutral)

probabilities, which we denote by $E_{\mathrm{RN}}\{\cdot\}$ (not to be confused with the historical distribution of prices). Namely, $E_{\mathrm{RN}}\{\cdot\}$ denotes the expectation associated with the operator associated with probabilities $\hat{\pi}_j$, $1 \le j \le M$. The implications of no arbitrage are summarized by the following Theorem 47.2.

Theorem 47.2 (The fundamental theorem of risk-neutral pricing)
Assume that the market admits no arbitrage portfolios and that there exists a risk-less lending/borrowing at rate R_{f}. Then, there exists a probability measure (risk neutral) defined on the set of feasible market outcomes, $\{1, 2, \ldots M\}$, such that the value of any security is equal to the expected value of its future cash flows discounted at the risk-less lending rate.

To calculate these risk-neutral probabilities, we use a portfolio replication which is defined as follows. Given a security S, and a set of securities $S_1, \ldots S_k$, we say that the portfolio $(n_1, n_2, \ldots n_N)$ *replicates* S if the security and the portfolio have identical cash flows. Further, given two identical cash flows, their price is, necessarily the same, as otherwise there would be an opportunity for arbitrage. This is also called the law of the single price. On the basis of the current analysis, we turn at last to a formal definition of complete markets.

Definition (Complete markets)
A securities market with M states is said to be *complete* if, for any vector cash-flow $(D_{.1} \ldots D_{.M})$, there exists a portfolio of traded securities $(n_1, n_2, \ldots n_N)$ which has cash flow D_j in state $j \in [1, \ldots M]$. Thus market completeness implies that:

$$\boldsymbol{nD} \equiv \boldsymbol{D}, \quad \text{or} \quad \sum n_i D_{ij} = D_j\,,$$
$$j \in [1, \ldots M] \quad \text{has a solution} \quad \boldsymbol{n} \in \mathbb{R}^N$$
$$\text{for any} \quad D \in \mathbb{R}^M\,.$$

This is equivalent to the condition: rank $\boldsymbol{D} \equiv M$.

The implication of this definition is that, if a portfolio can be replicated uniquely (the rank condition $\boldsymbol{D} \equiv M$, providing a unique solution to the linear pricing equations) then there is one price and complete markets can exist. Inversely, the uniqueness of asset prices determines a complete market. This is summarized by the proposition below.

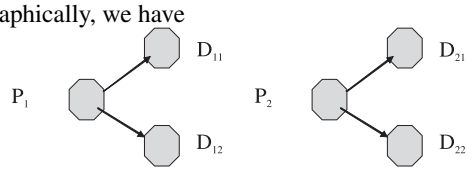
Proposition
Suppose that the market is complete. Then there is a unique set of state prices $(\pi_1 \ldots \pi_M)$ and hence a unique set of risk-neutral probabilities $(\hat{\pi}_1 \ldots \hat{\pi}_M)$. Conversely, if there is a unique set of state prices, then the market is complete, with risk-neutral probabilities $(\hat{\pi}_1 \ldots \hat{\pi}_M)$.

We shall find that the generality of these results is maintained in inter-temporal (dynamic) asset pricing. We consider first some simple examples to demonstrate the pricing implications of the Arrow–Debreu framework.

Example 47.1: Assume a binomial model for a security that assumes two possible future outcomes $\boldsymbol{D} = \{D_1, D_2\}$, $M = 2$. Consider as well two securities with current price P_i, $i = 1, 2$ (for example, a portfolio consisting of a stock and and a bond and a call option on the security with P_1 known and P_2 to be priced), each of these is generating a cash flow (D_{i1}, D_{i2}), $i = 1, 2$. We have no arbitrage if there are risk-neutral probabilities such that, for each security we have

$$P_i = \frac{1}{1+R_{\mathrm{f}}}\left(\hat{\pi}_1 D_{i1} + \hat{\pi}_2 D_{i2}\right), \quad i = 1, 2\,.$$

Graphically, we have



Since $\hat{\pi}_1 + \hat{\pi}_2 = 1$, both the risk-neutral probabilities are given by solving the system of equations in two unknowns for a unique solution (and therefore markets are complete):

$$P_1 = \frac{1}{1+R}\left[\hat{\pi}_1 D_{11} + (1-\hat{\pi}_1) D_{12}\right];$$
$$P_2 = \frac{1}{1+R}\left[\hat{\pi}_1 D_{21} + (1-\hat{\pi}_1) D_{22}\right],$$

where $\hat{\pi}_1$ and P_2 are to be calculated by a solution of these two equations, as:

$$\hat{\pi}_1 = \frac{(1+R)P_1 - D_{12}}{D_{11} - D_{12}}\,,$$
$$P_2 = \frac{P_1}{D_{11} - D_{12}}\,(D_{21} - D_{22}) + \frac{1}{1+R}\left(\frac{D_{11}D_{22} - D_{12}D_{21}}{D_{11} - D_{12}}\right).$$

Equivalently, the matrix $\boldsymbol{D}$ has to be of full rank 2. However, if both assets assume three potential states,

leading to a trinomial model, then of course $M = 3$, while rank $(\boldsymbol{D}) = 2$ and therefore the market is not complete since the number of solutions to this system of equations is infinite. If we add a third asset whose price is based on the same events we obtain a 3×3 matrix with rank 3 whose solution is again unique and therefore the market is complete again. In other words, adding another asset has made it possible to obtain the risk-neutral probabilities, needed for asset pricing and *complete* the market. Similar examples can be used to price simple models of forward futures contracts as well as prove some fundamental equalities in options' finance (put–call parity for example, which we will see subsequently). The Arrow–Debreu framework underlies the basic approach of modern financial economics for asset pricing and therefore it is important to appreciate its basic assumptions as stated here.

47.2 Rational Expectations, Risk-Neutral Pricing and Asset Pricing

Rational (risk neutral) expectations, risk-neutral pricing, complete and incomplete markets, as shown in the Arrow–Debreu framework, underlie the valuation of risk and the use of financial engineering for asset pricing. Rational expectations imply that current prices reflect future uncertainties and their price, and also mean that current prices are based on the unbiased, minimum-variance mean estimate of future prices. This property provides the means to value assets and securities, although in this approach, bubbles are not possible, since they seem to imply a persistent error or bias in forecasting. Rational-expectation pricing will not allow investors to earn above-average returns without taking above-average risks. In such circumstances, arbitrageurs, those *smart investors* who seek to identify returns that have no risk and yet provide a return, will not be able to profit without assuming risks.

The concept of rational expectation is due to *Muth* [47.51], however, who formulated it as a decision-making hypothesis in which agents are informed, constructing a model of the economic environment and using all the relevant and appropriate information at a time a decision is made (see also [47.52], p. 23):

> *I would like to suggest that expectations, since they are informed predictions of future events, are essentially the same as the predictions of the relevant economic theory . . . We call such expectations "rational" . . . This hypothesis can be rephrased a little more precisely as follow: that expectations . . . (or more generally, the subjective probability distribution of outcomes) tend to be distributed, for the same information set, about the prediction of the theory (the objective probability of outcomes).*

In other words, if investors are "smart" and base their decisions on informed and calculated predictions, then, prices equal their discounted expectations. In other words, it implies that investors' subjective beliefs are the same as those of the real world – they are neither pessimistic nor optimistic. When this is the case and a *rational expectations equilibrium* holds, we say that markets are complete or efficient. Samuelson pointed out this notion in 1965 as the martingale property leading *Fama*, *Lucas* and *Harrison* and *Kreps* [47.53–56] to characterize such properties as market efficiency.

Lucas used a concept of rational expectations similar to Muth to confirm Milton Friedman's 1968 hypothesis of the long-run neutrality of monetary policy. Specifically, *Lucas* [47.54] and *Sargent* [47.57] have shown that economic agents alter both their expectations and their decisions to neutralize the effects of monetary policy.

Martingale and the concept of market efficiency are intimately connected, as shown in the Arrow–Debreu framework and pointed out by *Harrison* and *Pliska* [47.39] in their seminal paper. If prices follow a martingale, then only the information available today is relevant to make a prediction on future prices. In other words, the present price has all the relevant information embedding investors' expectations. This means that in practice (the weak form of efficiency) past prices should be of no help in predicting present prices or equivalently prices have no memory. Similarly, if prices follow a martingale and are unpredictable, markets are efficient. In this case, arbitrage is not possible and there is always a party to take on a risk irrespective of how high it is. Hence, risk can be perfectly diversified away and made to disappear. In such a world without risk, all assets behave as if they are risk-free and therefore prices can be discounted at a risk-free rate. This property, justifies our use of risk-neutral pricing (RNP). It breaks down however if any of the previous hypotheses (martingale, rationality, no arbitrage, absence of transaction costs etc.) are invalid. In such a case, prices can no longer be unique and markets are said to be incomplete.

There is a confrontation between economists however, some of whom believe that markets are efficient and some who do not. Obviously, market efficiency fails

to account for market anomalies such as bubbles and bursts, firms' performance and their relationship to size etc. As a result, behavioral finance has sought to provide an alternative dogma (based on psychology) to explain the behavior of financial markets. Whether these dogmas will converge back together as classical and Keynesian economics have, remains yet to be seen. In summary, however, some believe that the current price imbeds all future information, and some presume that past prices and behavior can be used to predict future prices. If the test is to make money, then the verdict is far from reached. Richard Roll, a financial economist and money manager argues:

> *I have personally tried to invest money, my clients and my own, in every single anomaly and predictive result that academics have dreamed up. And I have yet to make a nickel on these supposed market inefficiencies. An inefficiency ought to be an exploitable opportunity. If there is nothing that investors can exploit in a systematic way, time in and time out, then it is very hard to say that information is not being properly incorporated into stock prices. Real money investment strategies do not produce the results that academic papers say they should . . . . . but there are some exceptions including long term performers that have over the years systematically beat the market (Burton Malkiel, The Wall Street Journal, December, 28, 2000).*

Information and power can also be sources of incompleteness. There are many situations when this is the case. Information asymmetries, insider trading and advantages of various sorts can provide an edge to individual investors and thereby violate the basic tenets of market efficiency. Further, the interaction of markets can lead to instabilities due to very rapid and positive feedback or to expectations that are becoming trader- and market-dependent. Such situations lead to a growth of volatility, instabilities and perhaps, in some special cases, to chaos. Nonetheless, whether it is fully right or wrong, it seems to work sometimes. Thus, it should be used carefully for making money. Of course, it is used for simple models for pricing options and derivatives in general. Throughout these approaches we shall use a known risk-free rate. In contrast, economic equilibrium theory based on the clearing of markets by equating supply to demand for all financial assets provides an equilibrium where interest rates are endogenous. It assumes however, that beliefs are homogenous, markets are frictionless (with no transaction costs, no taxes, no restriction on short sales and divisible assets) as well as competitive markets (in other words, investors are price takers) and finally it also assumes no arbitrage. Thus, general equilibrium is more elaborate than rational expectations (and arbitrage-free pricing) and provides more explicit results regarding market reactions and prices than the traditional finance-only approach [47.54].

47.2.1 Risk-Neutral Pricing and Complete Markets

In complete markets, we use risk-neutral probabilities which allow, conveniently, linear pricing measures. If there are such probabilities, and it is so in complete markets, then the current price ought to be determined by its future values. Since these probabilities are endogenous, based on an exchange between investors and speculators, *it is the market that determines prices and not uncertainty*. Uncertainty arises then only from an individual assessment of potential future events based on private information, on the one hand, or based on investors and speculators not aware of publicly available common information, on the other. In such situations the complete-markets mechanism (based on risk-neutral pricing) for determining asset prices is no longer viable.

Our ability to construct a unique set of risk-neutral probabilities depends on a number of assumptions which are of critical importance in finance and must be maintained theoretically and practically. These include: no arbitrage opportunities; no dominant trading strategies; and the law of the single price. No arbitrage occurs when it is not possible for an agent to make money for sure without having to invest any in the first place. The single-price hypothesis was elaborated by Modigliani and Miller in 1958, stating that two prospective future cash flows with identical risks must be priced equally. In other words, if we can replicate an asset price by a (synthetic) portfolio whose value can be ascertained, then if there is no arbitrage, the price of the asset and the synthetic portfolio are necessarily the same. This also implies market completeness, requiring that there be: no transaction costs; no taxes; infinitely divisible assets; that gents can borrow or lend at the same rates; no information asymmetry regarding future state prices; an impossibility to short sell; and finally, rational investors. Any violation or restrictions that will violate market completeness will open an opportunity for arbitrage. Although in practice, at least one of these assumptions is often violated, in theory and for many fundamental and useful results in finance theory, the assumption of no arbitrage is maintained. When this is not the case, and the assumption of market completeness is violated, it is no longer possible to obtain a unique set of *risk-*

neutral probabilities, but there may be several sets of such *risk-neutral* probabilities. To price an asset in such circumstances, statistical and numerical techniques are applied to select the martingale that best fits the observed behavior of financial markets and at the same time is consistent with basic economic and financial considerations. There are a number of approaches that we might follow in such circumstances, some of which will be used in the sequel. When markets are complete, replication of assets by a synthetic portfolio is a powerful tool to determine asset prices. Such as, pricing forward contracts, put–call parity, future prices and other derivatives that use replicating portfolios. For example, say that a stock spot price is S and let R_f be the period's risk-less lending rate. Next consider a forward contract consisting of an agreement to buy the stock at the end of the period at a set price F. If no dividends are paid and there is no arbitrage, then the contract profit (price) is $Q = S - F/(1+R_f) = 0$ (since the contract is costless and no money exchanges hands initially). As a result, the forward price is $F = S(1+R_f)$. Similarly, for put–call parity we consider a stock and derived call and put contracts with the same strike price and time. The former gives the right to buy the stock at the strike price and the latter the right to sell at time T and price K. If their prices at maturity are $c_T = \max(S_T - K, 0)$ and $p_T = \max(K - S_T, 0)$, respectively, then the current put price can be replicated by a portfolio consisting of the call, a risk-less bond with price K at maturity T – the option's exercise price as well as the underlying stock. This will be considered later but it suffices for the moment to state that the put (and thereby its synthetic portfolio) price at time $t = 0$ is given by $p = c - S + K\,\mathrm{e}^{-R_f T}$. Other cases will be considered subsequently. Below, we consider the implications and the mechanics of risk-neutral pricing using a number of stochastic price models.

47.2.2 Risk-Neutral Pricing in Continuous Time

The purpose of this section is to consider the mechanics of risk-neutral pricing in complete markets in a continuous time model. For simplicity, we restrict our attention to an underlying log-normal asset-price process, meaning that the rates of returns of the asset are normal with known mean and known variance. We set $S(t)$ as the asset price at time t with normally distributed rates of returns $\mathrm{d}S(t)/S(t)$. This can be written as an Ito stochastic differential equation as follows:

$$\frac{\mathrm{d}S}{S} = \alpha\,\mathrm{d}t + \sigma\,\mathrm{d}W, \quad S(0) = S_0 \quad \text{or}$$

$$S(t) = S(0)\,\mathrm{e}^{\left(\alpha - \frac{\sigma^2}{2}\right)t + \sigma W(t)}, \quad W(t) = \int_0^t \mathrm{d}W(t)\,,$$

where the rates of returns are normally distributed with mean and variance, both linear functions of time, given by αt and $\sigma^2 t$ respectively. Further, $W(t)$ denotes a Brownian motion, which is defined as normal (Wiener) prices with mean zero and variance t. Formally, we first note that with this probability measure, there is no risk-neutral pricing since:

$$\begin{aligned} S(0) &\neq \mathrm{e}^{-R_f t} E\left[S(t)\right] \\ &= \mathrm{e}^{-R_f t}\,\mathrm{e}^{\left(\alpha - \frac{\sigma^2}{2}\right)t} S(0) E\left(\mathrm{e}^{\sigma W(t)}\right) \\ &= \mathrm{e}^{(\alpha - R_f)t} S(0)\,. \end{aligned}$$

This is the case since for normal distributions $E\big(\exp[\sigma W(t)]\big) = \exp\left[(\sigma^2 t/2)\right]$. However, if we define a numeraire $W^*(t) = W(t) + \frac{\alpha - R_f}{\sigma} t$ with respect to which the risk-neutral process will be defined, then we can write the price as

$$\begin{aligned} S(t) &= S(0)\,\mathrm{e}^{\left(R_f - \frac{\sigma^2}{2}\right)t + \sigma\left[W(t) + \frac{\alpha - R_f}{\sigma} t\right]} \\ &= S(0)\,\mathrm{e}^{\left(R_f - \frac{\sigma^2}{2}\right)t + \sigma W^*(t)}\,, \end{aligned}$$

which, of course, corresponds to an underlying price process (where $\alpha = R_f$) and therefore,

$$\frac{\mathrm{d}S}{S} = R_f\,\mathrm{d}t + \sigma\,\mathrm{d}W^*(t), \quad S(0) = S_0\,,$$

and:

$$S(0) = \mathrm{e}^{-R_f t} E^*\left[S(t)\right] = \mathrm{e}^{(R_f - R_f)t} S(0) = S(0)\,,$$

where E^* is an expectation taken with respect to the (numeraire) process $W^*(t)$. Thus, the current price equals an expectation of the future price, just as the risk-neutral valuation framework indicated. It is important to remember however that the proof of such a result is based on our ability to replicate such a process by a risk-free process (and thereby value it by the risk-free rate, something that will be done later on). If such a numeraire can be defined, then of course, even an option can be valued, under the risk-neutral process, by a linear expectation. For example, for a European call option whose exercise price is K at time T, its price is necessarily:

$$C(0) = \mathrm{e}^{-R_f T} E^*\left(\max\left[S(T) - K, 0\right]\right)\,.$$

In fact, under the risk-neutral framework, any asset price equals is risk-free rate discounted expectation

under the risk-neutral distribution. For this reason, much effort is expanded, theoretically and practically, on determining the appropriate risk-neutral distribution (the martingale) that can be used to determine asset prices. In particular, it is worthwhile reconsidering the example treated by letting $\lambda = \frac{\alpha - R_f}{\sigma}$ define the market risk. In this case, the measure we have adopted above is equal to the original process plus the price of risk cumulated over time, or: $W^*(t) = W(t) + \lambda t$ and therefore: $(\alpha - R_f)\,dt + \sigma W(t) = \sigma W^*(t)$. Hence, $dS = S[\alpha\,dt + \sigma\,dW(t)] = S\sigma\,dW^*(t)$. Clearly, under the transformed measure $W^*(t)$, the stock process is a martingale but the remaining question is, can we treat this measure as a Wiener process The important theorem of Giranov allows such a claim under specific conditions, which we summarize below. Explicitly, say that Novikov's condition is satisfied, that is:

$$E\left(\exp\left(\frac{1}{2}\int_0^T \left|\frac{\alpha - R_f}{\sigma}\right| dt\right)\right) < +\infty\,.$$

Let the new measure be defined by the Radon–Nykodim derivative,

$$\frac{dP^*}{dP} = \mathbb{Z}, \quad E\mathbb{Z} = 1, \quad \text{where}$$

$$\mathbb{Z} \triangleq \exp\left[-\int_0^T \lambda\,dW(s) - \frac{1}{2}\int_0^T (\lambda)^2\,dW(s)\right],$$

$$E\mathbb{Z} = 1\,,$$

where P^* is the probability equivalent of the original measure. Note that: $P^*(A) = \int_A \mathbb{Z}(W)P(dW), \forall A \in \Im$. The Girsanov theorem then states that under these (Novikov) conditions and given the measure defined by the Radon–Nykodim derivative, the process $W^*(t)$ is a Wiener process under the measure P^*. This theorem is of course extremely important in asset pricing as it allows the determination of martingales to which risk-neutral pricing can be applied.

47.2.3 Trading in a Risk-Neutral World

Under a risk-neutral process, there is no trading strategy that can make money. To verify this hypothesis, we consider an investor's decision to sell an asset he owns (whose current price is S_0) as soon as it reaches an optimal (profit-rendering) price $S^* > S_0$. Let this profit be:

$$\pi_0 = E^*\,e^{-R_f\tau}S^* - S_0 \quad \text{with}$$
$$\tau = \text{Inf}\left\{t > 0,\, S(t) \geq S^*;\, S(0) = S_0\right\}\,,$$

where τ is the stopping (sell) time, defined by the first time that the optimal target sell price is reached. We shall prove that, under the risk-neutral framework, there is an *equivalence* between selling now or at a future date. Explicitly, we will show that $\pi_0 = 0$. Again, let the risk-neutral price process be:

$$\frac{dS}{S} = R_f\,dt + \sigma\,dW^*(t)$$

and consider the equivalent return process $y = \ln S$. By an application of Ito's calculus, we have

$$dy = \left(R_f - \frac{\sigma^2}{2}\right)dt + \sigma\,dW^*(t), \quad y(0) = \ln(S_0)$$

and

$$\tau = \text{Inf}\left\{t > 0,\, y(t) \geq \ln(S^*);\, y(0) = \ln(S_0)\right\}\,.$$

As a result, $E^*_S\left(e^{-R_f\tau}\right) = E^*_y\left(e^{-R_f\tau}\right)$, which is the Laplace transform of the sell stopping time when the underlying process has a mean rate and volatility given by $\mu = R_f - \sigma^2/2$ and σ respectively, [47.56, 58–60]:

$$g^*_{R_f}(S^*, \ln S_0) = \exp\left[\frac{\ln S_0 - \ln S^*}{\sigma^2}\left(-\mu + \sqrt{\mu^2 + 2R_f\mu\sigma^2}\right)\right],$$
$$\sigma > 0, -\infty < \ln S_0 \leq \ln S^* < \infty\,.$$

The expected profit arising from such a transaction is thus

$$\pi_0 = S^*E^*\left(e^{-R_f\tau}\right) - S_0 = S^*g^*_{R_f}(\ln S^*, \ln S_0) - S_0\,.$$

Namely, such a strategy will, in a risk-neutral world, yield a positive return if $\pi_0 > 0$. Elementary manipulations show that this is equivalent to:

$$\pi_0 > 0 \quad \text{If} \quad \frac{\sigma^2}{2} > (R_f - 1)\,\mu \quad \text{or}$$
$$\frac{\sigma^2}{2} > (1 - R_f)\left(\frac{\sigma^2}{2} - R_f\right) \quad \text{if} \quad R_f > \frac{\sigma^2}{2}\,.$$

As a result,

$$\pi_0 = \begin{cases} > 0 & \text{If } R_f > \frac{\sigma^2}{2} \\ < 0 & \text{If } R_f < \frac{\sigma^2}{2}\,. \end{cases}$$

The decision to sell now or wait is thus reduced to the simple condition stated above. An optimal selling price in these conditions can be found by optimizing the return of such a sell strategy, which is found by noting that either it is optimal to have a selling price as large as

possible (and thus never sell) or select the smallest price, implying selling now at the current (any) price. If the risk-free rate is *small* compared to the volatility, then it is optimal to wait, and vice versa, a small volatility will induce the holder of the stock to sell. In other words, for an optimal sell price:

$$\frac{\mathrm{d}\pi_0}{\mathrm{d}S^*} = \begin{cases} > 0 & R_\mathrm{f} < \sigma^2/2 \\ < 0 & R_\mathrm{f} > \sigma^2/2\,. \end{cases}$$

Combining this result with the profit condition of the trade, we note that

$$\begin{cases} \frac{\mathrm{d}\pi_0}{\mathrm{d}S^*} > 0, \pi_0 < 0 & \text{If } R_\mathrm{f} < \sigma^2/2\,, \\ \frac{\mathrm{d}\pi_0}{\mathrm{d}S^*} < 0, \pi_0 > 0 & \text{If } R_\mathrm{f} > \sigma^2/2\,. \end{cases}$$

An therefore the only solution that can justify these conditions is: $\pi_0 = 0$, implying that whether one keeps the asset or sell is irrelevant, for under risk-neutral pricing, the profit realized from trading of maintaining the stock is equivalent. Say that $R_\mathrm{f} < \sigma^2/2$ then a *wait-to-sell* transaction induces an expected trade loss and therefore it is best to obtain the current price. When $R_\mathrm{f} > \sigma^2/2$, the expected profit from the trade is positive but it is optimal to select the lowest selling price, which is of course the current price and then again, the profit transaction, $\pi_0 = 0$, will be null, as our contention states. For a risk-sensitive investor (trader or speculator), however, whose utility for money is $u(.)$, a decision to sell will be defined in terms of his preference, given by the utility function. Buy–sell strategies differ therefore because investors have preferences (utilities) that are not the same.

Example 47.2 (Buying and selling on a trinomial random walk): Consider the risk-neutral log-normal risk process:

$$\mathrm{d}S/S = R_\mathrm{f}\,\mathrm{d}t + \sigma\,\mathrm{d}W, \quad S(0) = S_0$$

and apply Ito's lemma to the transformation $y = \ln(S)$ to obtain the rate of return process:

$$\mathrm{d}y = \left(R_\mathrm{f} - \frac{1}{2}\sigma^2\right)\mathrm{d}t + \sigma\,\mathrm{d}W, \quad y(0) = y_0\,.$$

Given this normal (logarithmic) price process, consider the trinomial random-walk approximation:

$$Y_{t+1} = \begin{cases} Y_t + f_1 & \text{w. p.} \quad p \\ Y_t + f_2 & \text{w. p.} \quad 1-p-q \\ Y_t + f_3 & \text{w. p.} \quad q \end{cases}$$

Where p, q and $1-p-q$ are the probabilities that returns increase (or decrease) by, f_1, f_3, f_2 respectively. The first two moments of this process are given by

$$\begin{aligned} E\left(Y_{t+1} - Y_t\right) &= f_2 + p\left(f_1 - f_2\right) + q\left(f_3 - f_2\right) \\ &\approx \left(R_\mathrm{f} - \frac{1}{2}\sigma^2\right), \\ E\left(Y_{t+1} - Y_t\right)^2 &= f_2^2 + p\left(f_1^2 - f_2^2\right) + q\left(f_3^2 - f_2^2\right) \\ &\approx \sigma^2\,. \end{aligned}$$

Thus, an appropriate selection of the parameters p, q, f_1, f_2 and f_3 will provide an approximation to the risk-neutral pricing process. However, note that we have two known parameters (the mean and the variance of the process) while there are five parameters to choose. This corresponds to many potential discrete-time processes that can be considered as approximations to the continuous one. For this reason, a discretization of a risk-neutral process can often lead to incomplete processes (where risk-neutrality cannot be applied). In most cases, therefore, the underlying process has to be carefully applied [47.48]. For an asymmetric trinomial random walk we may set for simplicity $f_1 = 1$, $f_2 = 0$ and $f_3 = -1$, in which case

$$P\left(\Delta Y_i = +1\right) = p, \quad P\left(\Delta Y_i = -1\right) = q, \quad \text{and}$$
$$P\left(\Delta Y_i = 0\right) = r = 1 - p - q.$$

It is well known (for example see *Cox* and *Miller* [47.42], p. 75) that the probability of reaching one of the two boundaries in this case is given by,

$$P\left(Y_t = -a\right) = \begin{cases} \frac{1-(1/\lambda)^b}{1-(1/\lambda)^{a+b}} & \lambda \neq 1 \\ b/(a+b) & \lambda = 1 \end{cases},$$

$$P\left(Y_t = b\right) = \begin{cases} \frac{(1/\lambda)^b - (1/\lambda)^{a+b}}{1-(1/\lambda)^{a+b}} & \lambda \neq 1 \\ a/(a+b) & \lambda = 1 \end{cases},$$

where $\lambda = q/p$. Further, the expected first time to reach one of these two boundaries is

$$E\left(T_{-a,b}\right) = \begin{cases} \left(\frac{1}{1-r}\right)\left(\frac{\lambda+1}{\lambda-1}\right)\left(\frac{a\left(\lambda^b-1\right)+b\left(\lambda^{-a}-1\right)}{\lambda^b-\lambda^{-a}}\right) & \lambda = q/p \\ \frac{ab}{1-r} & \lambda = 1\,. \end{cases}$$

Thus, if we own an asset whose current value is null and if it is sold either when the loss incurred is $-a$ or at b when a profit is realized, then the probability of making money is $P\left(S_{T(-a,b)} = b\right)$ while the probability

of losing it is $P\left(S_{T(-a,b)}=-a\right)$, as calculated above. The expected amount of time the trade will be active is of course $E\left(T_{-a,b}\right)$. The trader profit or loss is thus a random variable given by

$$\tilde{\pi}=\begin{cases}-a & \text{w. p.} \begin{cases}\frac{1-(1/\lambda)^b}{1-(1/\lambda)^{a+b}} & \lambda\neq 1\\ b/(a+b) & \lambda=1\end{cases}\\ b & \text{w. p.} \begin{cases}\frac{(1/\lambda)^b-(1/\lambda)^{a+b}}{1-(1/\lambda)^{a+b}} & \lambda\neq 1\\ a/(a+b) & \lambda=1\,.\end{cases}\end{cases}$$

While its average return is (since the process can be considered a renewal process as well)

$$\bar{\pi}(-a,b)=\frac{bP\left(S_{T(-a,b)}=b\right)-aP\left(S_{T(-a,b)}=-a\right)}{E\left(T_{-a,b}\right)}\,.$$

In particular, when $\lambda=1$, the price process is a martingale and the long-run average profit will be null with a variance $2ab$ since:

$$E(\tilde{\pi})=\frac{(-ab+ba)}{a+b}=0\,,\quad \text{var}(\tilde{\pi})=2ab\,.$$

This also means that we cannot make money on the average with a worthless asset if the underlying price process is a (martingale) random walk (whether it is a binomial or a trinomial walk). In this circumstance, there is no free gift, an asset we receive that is worth nothing is indeed worth nothing. A risk-averse investor, will thus be better off getting rid of this asset and not sustaining the risk of losing money. For a binomial random walk, with $\lambda\neq 1$ and $r=0$ we have ([47.42], p. 31):

$$P\left(S_{T(-a,b)}=b\right)=\frac{\lambda^a-1}{\lambda^{a+b}-1}\,;$$
$$P\left(S_{T(-a,b)}=-a\right)=\frac{\lambda^{a+b}-\lambda^a}{\lambda^{a+b}-1}\,.$$

And therefore

$$E\left(T_{-a,b}\right)=\left(\frac{\lambda+1}{\lambda-1}\right)\left(\frac{a\left(\lambda^b-1\right)+b\left(\lambda^{-a}-1\right)}{\lambda^b-\lambda^{-a}}\right)\,.$$

The long-run average profit is thus

$$\bar{\pi}(-a,b)=\frac{\left[b\left(\lambda^a-1\right)-a\left(\lambda^{a+b}-\lambda^a\right)\right](\lambda-1)\left(\lambda^b-\lambda^{-a}\right)}{\left[b\left(\lambda^{-a}-1\right)+a\left(\lambda^b-1\right)\right](\lambda+1)\left(\lambda^{a+b}-1\right)}\,.$$

An optimization of the average profit over the parameters (a,b) when the underlying process is a historical process provides then an approach for selling and buying for a risk-prone trader. For a risk-neutral process ($\lambda=1$), the expected profit will be null for all values a and b.

We can extend this example by considering a trader who owns now an asset worth i_0 dollars that he intends to sell at a later date, either at a preventive loss or at a given profit level. Technically, the sell strategy consists of selling at a price $b>i_0$ for a profit of $\kappa=b-i_0$ or at a price of $a<i_0$ for a loss of $\nu=i_0-a<0$ – whichever comes first. The problems we might be concerned with are:

1. What are the optimal parameters (a,b) for an individual investor if the investor uses a risk-adjusted discount rate and at a risk-free discount rate if the underlying process is a risk-neutral process?
2. What is the risk premium of such a strategy?
3. For an averages profit criterion, what are the optimal parameters (a,b) of the trading strategy?

As stated above, the rationality of such strategies are implicit in individual investors' risk aversion, seeking to make a profit by selling at a higher price, and inversely selling at a preventive loss in case prices fall too much, generating potentially a substantial losses.

47.3 Consumption Capital Asset Price Model and Stochastic Discount Factor

Financial asset pricing is essentially based on defining an approach accounting for the time and risk preferences of future payoffs. To do so, we have sought to determine a discounting mechanism that would, appropriately, reflect the current value of uncertain payoffs to be realized at some future time. The risk-neutral asset pricing framework has provided a linear estimation rule based on the risk-free rate. Another approach considers an investor optimizing the expected utility of consumption and investment. This is also coined the consumption capital asset pricing model (CCAPM), also called the stochastic discount factor (SDF) approach [47.20]. This development will be presented through the application of Euler's equation in the calculus of variations applied

to a consumption problem resulting in a pricing formula defined by:

$$p_t = E(\tilde{M}_{t+1}\tilde{x}_{t+1}), \quad \tilde{M}_{t+1} = \frac{1}{1+\tilde{R}_{t+1}},$$

where p_t is the current asset price at time t that we seek to value, $\tilde{x}_t$ is the next-period asset returns, a random variable and $\tilde{M}_t$ is a stochastic discount factor (also called a kernel). We shall show first through a simple two-period model how a pricing formula is derived. Subsequently, we consider a general multi-period problem. It is noteworthy that in this framework the current price equals the current discounted expectation of (only) future returns.

47.3.1 A Simple Two-Period Model

The rationality of the SDF approach can be explained simply by using the following example (subsequently generalized). Say that an investor owns at a certain time t, a certain amount of money s_t, part of which is invested to buy a quantity of stock y at a price p_t, while the residual is consumed. The utility of consumption is assumed to be $u(c_t)$ where $c_t = s_t - yp_t$. A period hence, at time $t+1$, the asset price is a random variable $\tilde{x}_{t+1}$, at which time it is sold and consumed. Thus, the next-period consumption is equal to the period's current income plus the return from the investment, namely $c_{t+1} = s_{t+1} + y\tilde{x}_{t+1}$. Let the discount factor be β, expressing the subjective discount rate of the consumer. Over two periods, the investor's problem consists then of maximizing the two periods' expected utilities of consumption, given by

$$U(c_t, c_{t+1}) = u(c_t) + \beta E_t u(c_{t+1}) \quad \text{or}$$
$$U(c_t, c_{t+1}) = u(s_t - yp_t) + \beta E_t u(s_{t+1} + y\tilde{x}_{t+1}).$$

The optimal quantity to invest (i. e. the number of shares to buy), found by maximizing the expected utility with respect to y, leads to:

$$\begin{aligned}\frac{\partial U}{\partial y} &= -p_t u'(s_t - p_t y) \\ &\quad + \beta E_t\left[\tilde{x}_{t+1}u'(s_{t+1} + \tilde{x}_{t+1}y)\right] \\ &= -p_t u'(c_t) + \beta E_t\left[\tilde{x}_{t+1}u'(c_{t+1})\right] = 0\end{aligned}$$

which yields for an optimum portfolio price:

$$p_t = E_t\left(\beta\frac{u'(c_{t+1})}{u'(c_t)}\tilde{x}_{t+1}\right).$$

If we set $\tilde{M}_{t+1} = \beta\frac{u'(c_{t+1})}{u'(c_t)}$, we obtain the pricing kernel (stochastic discount factor) used above to price the asset. This kernel expresses, as seen in our condition for optimality, the inter-temporal substitution of current and future marginal utilities of consumption. If we choose to write this term as a *discount rate*, then:

$$\tilde{R}_{t+1} = \left(1 - \beta\frac{u'(c_{t+1})}{u'(c_t)}\right) \Big/ \beta\frac{u'(c_{t+1})}{u'(c_t)}.$$

This equation is particularly robust, and has many well-known results in finance expressed as special cases [47.20]. For example, if the utility function is of the logarithmic type, $u(c) = \ln(c)$ then, $u'(c) = 1/c$ and $\tilde{M}_{t+1} = \beta c_t/(c_{t+1})$, or $\tilde{R}_{t+1} = \beta[(1/\beta)c_{t+1} - c_t]/c_t$ and further, $p_t/c_t = \beta E_t\left(\tilde{x}_{t+1}/c_{t+1}\right)$. In other words, if we write $\pi_t = p_t/c_t$; $\tilde{\pi}_{t+1} = \tilde{x}_{t+1}/c_{t+1}$, then we have: $\pi_t = \beta E_t\left(\tilde{\pi}_{t+1}\right)$. Further, if the asset is a risk-less bond, worth 1 dollar at its exercise time a period hence, then $B_0 = E(\tilde{M}_1 B_1)$ or $B_0 = E(\tilde{M}_1)$. Since $B_0 = 1/(1+R_\mathrm{f})$, we obtain of course: $E(\tilde{M}_1) = 1/(1+R_\mathrm{f})$, providing thereby a relationship between the expected value of the kernel and the risk-free discount rate. An additional and particularly interesting case consists of using the linear CAPM model for pricing risky assets. In this case, let the kernel be

$$M_{t+1} = a_t + b_t R_{M,t+1},$$

where $R_{M,t}$ is the rate of return of the market portfolio (a market index for example). For a given stock, whose rate of return is $1 + R_{t+1} = p_{t+1}/p_t$, we have as stated earlier:

$$\begin{aligned}&1 = E\left[M_{t+1}(1+R_{t+1})\right], \quad \text{hence} \\ &E(1+R_{t+1}) = \frac{1}{E(M_{t+1})} - \frac{\mathrm{cov}\,(M_{t+1}, 1+R_{t+1})}{E(M_{t+1})}.\end{aligned}$$

Inserting the linear model for the kernel we have

$$\begin{aligned}&E(1+R_{t+1}) \\ &= (1+R_{\mathrm{f},t})\left[1 - \mathrm{cov}\,(M_{t+1}, 1+R_{t+1})\right] \\ &= (1+R_{\mathrm{f},t+1})\left[1 - \mathrm{cov}\left(a + bR_{M,t+1}, 1+R_{t+1}\right)\right]\end{aligned}$$

which is reduced to

$$\begin{aligned}&E(R_{t+1} - R_{\mathrm{f},t+1}) \\ &= \frac{\mathrm{cov}\left(R_{M,t+1} - R_{\mathrm{f},t+1}, R_{t+1} - R_{\mathrm{f},t+1}\right)}{\mathrm{var}\left(R_{M,t+1} - R_{\mathrm{f},t+1}\right)} \\ &\quad \times E_t\left(R_{M,t+1} - R_{\mathrm{f},t+1}\right).\end{aligned}$$

This can be written in the CAPM standard formulation (see also [47.61–63]):

$$E(R_{t+1} - R_{f,t+1}) = \beta E_t\left(R_{M,t+1} - R_{f,t+1}\right).$$

where the beta parameter is:

$$\beta = \frac{\operatorname{cov}\left(R_{M,t+1} - R_{f,t+1},\, R_{t+1} - R_{f,t+1}\right)}{\operatorname{var}\left(R_{M,t+1} - R_{f,t+1}\right)} .$$

Of course when the returns are normally distributed such calculations are straightforward and can be generalized further. *Stein* [47.64] has shown that, if market returns are some function $f(y)$, $y = R_{M,t+1} - R_{f,t+1}$ and, if the derivative $f'(.)$ exists, then

$$\operatorname{cov}\left[x,\, f(y)\right] = E\left[f'(y)\right] \operatorname{cov}(x,\, y) .$$

And as a result, the beta parameter is

$$\begin{aligned}\beta &= \frac{\operatorname{cov}\left[f(R_{M+1} - R_{f,t+1}),\, R_{t+1} - R_{f,t+1}\right]}{\operatorname{var}\left(R_{M+1} - R_{f,t+1}\right)} \\ &= \frac{E\left[f'(R_{M+1} - R_{f,t+1})\right]}{\operatorname{var}\left(R_{M+1} - R_{f,t+1}\right)} \\ &\quad \times \operatorname{cov}\left[f'(R_{M+1} - R_{f,t+1}),\, R_{t+1} - R_{f,t+1}\right] .\end{aligned}$$

For example, in a stochastic inflation world, *Roll* [47.65] extends the CAPM of Sharpe by setting:

$$E(RP) = R_{\mathrm{f}} E(P) + \beta E\left(R_M P - R_{\mathrm{f}} P\right) ,$$

where P is a stochastic purchasing power with

$$\beta = \frac{\operatorname{cov}\left(RP,\, R_M P\right)}{\operatorname{var}\left(R_M P\right)} .$$

The hypothesis that the kernel is linear may be limiting however. Recent studies have suggested that we use a quadratic measurement of risk with a kernel given by:

$$M_{t+1} = a_t + b_t R_{M,t+1} + c_t R_{M,t+1}^2 .$$

In this case, the skewness of the distribution enters as well in determining the value of the asset. There is ongoing empirical research on this and related topics.

47.3.2 Euler's Equation and the SDF

The CCAPM model, in its inter-temporal framework can be formulated as a problem in the calculus of variations and the SDF determined by applying the Euler condition for optimal consumption utility [47.1]. Explicitly, let an investor maximize the expected utility of consumption over a horizon $[0, T]$:

$$V_t = \max \sum_{j=0}^{T-1} \beta^j u(c_{t+j}) + \beta^T G(S_T) ,$$

where $u(c_{t+j})$ is the utility of consumption c_{t+j} at time $t+j$, T is the final time and $G(S_T)$ expresses the terminal utility of the wealth state at time T. The investor's discount rate is β. At time t, the investor's wealth is given by $S_t = S_{t-1} - q_t c_t + R_t$, where consumption is priced q_t, while returns from investments are R_t. As a result:

$$c_{t+j} = \frac{R_{t+j} - \Delta S_{t+j}}{q_{t+j}}, \quad \Delta S_{t+j} = S_{t+j} - S_{t+j-1} .$$

The investor's utility is therefore:

$$V_t = \max \sum_{j=0}^{T-1} \beta^j u\left(\frac{R_{t+j} - \Delta S_{t+j}}{q_{t+j}}\right) + \beta^T G(S_T) .$$

Application of Euler's equation (the calculus of variations) yields:

$$\frac{\partial V_t}{\partial S_{t+j}} - \Delta\left(\frac{\partial V_t}{\partial \Delta S_{t+j}}\right) = 0 .$$

Since $\partial V_t / \partial S_{t+j} = 0$, $\Delta\left(\partial V_t / \partial \Delta S_{t+j}\right) = 0$ and therefore we have the following *equilibrium* results:

$$\frac{\partial V_t}{\partial \Delta S_{t+j}} = \frac{\beta^j}{q_{t+j}} \frac{\partial u\left(c_{t+j}\right)}{\partial \Delta S_{t+j}} = A \text{ constant} .$$

For two consecutive instants of time ($j = 0$, $j = 1$):

$$\begin{aligned}\frac{\partial V_t}{\partial \Delta S_t} &= \frac{\partial V_t}{\partial \Delta S_{t+1}} \quad \text{and therefore} \\ \frac{1}{q_t} \frac{\partial u\left(c_t\right)}{\partial \Delta S_t} &= \frac{\beta}{q_{t+1}} \frac{\partial u\left(c_{t+1}\right)}{\partial \Delta S_{t+1}} \quad \text{and} \\ \frac{\partial u\left(c_t\right)}{\partial \Delta S_t} &= \beta E\left(\frac{q_t}{q_{t+1}} \frac{\partial u\left(c_{t+1}\right)}{\partial \Delta S_{t+1}}\right) .\end{aligned}$$

In other words, the marginal utility of wealth (savings) equals the discounted inflation-adjusted marginal utilities of consumption. In particular, if wealth is invested in a portfolio of assets such that:

$$\begin{aligned}\Delta S_t &= (N_t - N_{t-1}) p_t = p_t \Delta N_t \quad \text{and} \\ \frac{\partial V_t}{\partial \Delta S_{t+1}} &= p_t \frac{\partial u\left(c_{t+1}\right)}{\partial \Delta N_{t+1}} \quad \text{then} \\ \frac{\partial u\left(c_t\right)}{\partial \Delta N_t} p_{t-1} &= E\left[\beta \frac{q_t}{q_{t+1}} \left(\frac{\partial u\left(c_{t+1}\right)}{\partial \Delta N_{t+1}} p_t\right)\right] ,\end{aligned}$$

which is reduced to the previous condition in two periods, or

$$\begin{aligned}p_{t-1} &= E\left(\beta \frac{q_t}{q_{t+1}} \frac{u'\left(c_{t+1}\right)}{u'\left(c_t\right)} p_t\right) ; \\ u'\left(c_{t+1}\right) &= \frac{\partial u\left(c_{t+1}\right)}{\partial \Delta N_{t+1}} .\end{aligned}$$

We can write this expression in terms of the stochastic factor M_t, expressing again the *consumption impatience*

$$p_{t-1} = E\,(M_t p_t)\,; \quad M_t = \beta \frac{q_t}{q_{t+1}} \frac{u'\,(c_{t+1})}{u'\,(c_t)}\,.$$

Again, if we set $1 + R_t = p_t / p_{t-1}$, this equation can also be written as follows:

$$1 = E\left(M_t \frac{p_t}{p_{t-1}}\right), \quad \text{hence}$$
$$1 = E\,\{M_t(1+R_t)\,|\Phi_t\}\,,$$

which is the standard form of the SDF equation while Φ_t is a filtration at time t. Here too, we see that to price a default-free zero-coupon bond paying one dollar for sure at time 1, then applying the known risk-free discount rate R_f, we have

$$\frac{1}{1+R_\mathrm{f}} = (1)E\,(M_t)\,. \quad \text{And therefore,}$$
$$E\,(M_t) = \frac{1}{1+R_\mathrm{f}} \quad \text{and finally}$$
$$p_{t-1} = \frac{1}{1+R_\mathrm{f}} E_t^*\,(p_t)\,,$$

where E_t^* assumes the role of a modified (subjective) probability distribution. When the utility function is assumed known, some simplifications can be reached. For example, for $u(.) = \ln(.)$, $u'\big(c_t\big) = 1/c_t$ and therefore $v_t = E\big\{\beta(q_t/q_{t+1})v_{t+1}\big\}$, $v_t = p_{t-1}/c_t$.

47.4 Bonds and Fixed-Income Pricing

The financial valuation of assets, real or financial, deals with streams of cash such as dividends, coupon payments, investment in engineering projects etc. which occur in a random manner or not, paid in at deterministic or random times. In some cases, there may be a default in such payments due to delays, lost and partially recuperated payments etc. For example, investing in a portfolio might result in future returns and dividends that are at best defined in terms of random cash flows. Traditionally, a number of techniques were applied to value such cash streams, spanning a broad set of subjective techniques such as: payback, internal rate of return (IRR), cost–benefit analysis (CBA), net present value (NPV) etc. Bonds pricing is often used to value these cash flows. Here we shall see how bonds, whether risk-free, rated or default-prone, are used to value these cash flows. The simplest bond is the zero-coupon risk-free bond paying 1 dollar a year from now. An investor can have an individual valuation of such a payment, say $B_\mathrm{IND} = 1(1+r)^{-1}$, in which case r represents the discount factor that the investor is willing to associate to such a payment. Buying such a bond is an investment in a risk-free payment which cannot earn anything else but the risk-free rate (otherwise there would be arbitrage). Say that the *market price* for such a bond is currently quoted at \$ 0.90. In this case, the discount rate that the market associates to this bond would be:

$$B_\mathrm{IND} = 0.90 = \frac{100}{(1+R_\mathrm{f})} \quad \text{or}$$
$$R_\mathrm{f} = \frac{1.0}{0.90} - 1 = 0.1111\,,$$

where R_f is used to denote the fact that this is a risk-free rate (since the bond payment has no risk). These rates are usually specified by US government bonds when they are assumed to be risk-less (a currency trader might not think this is the case, however). The price of this bond is usually specified by a function $B_\mathrm{f}(t, T)$, which is the price at time t for a bond paying 1 dollar for sure at time T when the going risk-free rate $R_\mathrm{f}(t, T)$ expresses the time structure of interest rates. For a stream of payments, say a project defined by a set of payments and returns in the future, corporate firms may use a discount rate r for the time value of money. In this case, the present value of such a project at the initial time $t = 0$, NPV(0), is written as follows:

$$\mathrm{NPV}(0) = -\sum_{i=0}^{n} \frac{I_i}{(1+r)^i} + \sum_{i=0}^{N} \frac{C_i}{(1+r)^i}\,,$$

where I_i denotes the investment (or costs sustained at time i, while C_i is a certain (risk-free) cash flow generated by the project. If $\mathrm{NPV}(0) = 0$ then the solution of this equation yields the IRR, the corporate entity uses to rank and value investment projects. There are many problems with this valuation however that open an opportunity for arbitrage by investment funds. For example, the investments and return (or the Is and Cs) may be random, potentially involving defaults, payments delays and so on. Further, the discount rate used might not reflect the cost of borrowing of the firm and its risk rating (potentially given by rating firms such as Moody's, Fitch, Standard and Poor, and their like). In addition, the discount rate does not reflect the time at

which these payments occur (the term structure). As a result, such a valuation (pricing) is quite naïve and arbitrage on these firms can be used to provide the same cash flows at a lower price, thereby cashing in the difference. If payments are known for sure, a market-sensitive valuation would use the term structure risk-free discount rate $R_f(0, i)$ for the payment i-periods hence, the value of such a cash stream would be:

$$\mathrm{NPV}_f(0) = -\sum_{i=0}^{n} \frac{I_i}{[1 + R_f(0, i)]^i} + \sum_{i=0}^{n} \frac{C_i}{[1 + R_f(0, i)]^i} .$$

While at any time t, it is given by:

$$\mathrm{NPV}_f(t) = -\sum_{i=t}^{n} \frac{I_i}{[1 + R_f(t, i)]^{i-t}} + \sum_{i=t}^{n} \frac{C_i}{[1 + R_f(t, i)]^{i-t}} .$$

This latter expression can of course be written in terms of zero-coupon risk-free bonds as follows:

$$\mathrm{NPV}_f(t) = -\sum_{i=t}^{n} I_i B_f(t, i) + \sum_{i=t}^{n} C_i B_f(t, i) .$$

If all pure bonds are priced by the market then of course the NPV is determined by the market. In practice however, pure bond prices are available for only a given subset of times and therefore the NPV has to be priced in some other manner. Subsequently, we shall see that this leads to an important technical problem in financial engineering – one of calculating the yield of the bond (or any portfolio).

Next, say that payments are made by a firm rated k, in which case, the project NPV can be written as follows:

$$\mathrm{NPV}_k(0) = -\sum_{i=0}^{n} \frac{I_i}{[1 + R_f(0, i)]^i} + \sum_{i=0}^{N} \frac{\hat{C}_i}{[1 + R_k(0, i)]^i}, \quad \hat{C}_i = E\left(\tilde{C}_i\right),$$

where $R_k(0, i)$ is the discount rate applied for expected receipts $\hat{C}_i$, i periods hence for a firm whose risk notation is k (for example, AAA, BB, B+, C etc.). Note that in the above expression, we have maintained the payments I_i deterministic and therefore they ought to be discounted at the risk-free rate in effect at time $t = 0$ for time i (if this is not the case, then of course, it will be necessary to select the appropriate discount rate as well). Note that $R_k(0, i)$ expresses the k-rated firm's term structure used for discounting its future returns which includes the risk premium $\Delta_k(0, i)$ in the firm's cash flows, or $R_k(0, i) = R_f(0, i) + \Delta_k(0, i)$. For example, say that the firm is currently rated k. The implication of such a rating is that an obligation of the firm to pay in i periods 1 dollar is currently priced by the market at $B_k(0, i)$. As a result, the set of future prospective investment returns of the firm can be priced by:

$$\mathrm{NPV}_k(0, n) = -\sum_{i=0}^{n} I_i B_f(0, i) + \sum_{i=0}^{n} \hat{C}_i B_k(0, i) ,$$

and at time t,

$$\mathrm{NPV}_k(t, n) = -\sum_{i=t}^{n} I_i B_f(t, i) + \sum_{i=t}^{n} \hat{C}_i B_k(t, i) .$$

This NPV includes of course the discount rate that the market applies to the firm's obligations. For fixed and secured payments the firm is obliged to use the risk-free rate, or equivalently it equals a risk-free coupon bond paying one dollar i-periods hence and denoted by $B_f(0, i)$. When we use the same discount rate for certain payments and uncertain (valued at expectation) costs and returns, the traditional approach may overestimate (or underestimate) the net present value of the investment. For example, a firm which is highly rated may be tempted to borrow more money because it is cheaper than say another firm perceived as risky. By the same token, investment in some projects (ports, highways etc.) may be less expensive when they are performed by a government, that can tax its citizen to repay a loan taken to build such a project, than say, a firm who would invest to self-build the project. Of course, it is for these reasons that private investors in national projects require some government assurance and insurance to reduce the risk (and thereby the risk premium) which they have to pay for building such projects.

The approach outlined above can be generalized further and applied to value all kinds of assets; we consider some examples. Again let $\mathrm{NPV}_k(t)$ be the net present value of an investment project at time t when the firm is rated k. Such a firm may however switch to being rated j with probability p_{kj} a period of time (year) later. These probabilities define a Markov chain $\boldsymbol{P} = [p_{kj}]$, usually specified by rating firms (Moody's, Standard and Poor, Fitch etc.). As a result, over two consecutive periods, we

have

$$\mathrm{NPV}_k(t) = -I_t + C_t + B_k(t, t+1) \times \sum_{\ell=1}^{m} p_{k\ell}\mathrm{NPV}_\ell(t+1)$$

and at the final time n, the NPV is given as a function of the rating (risk) state the firm will be in and specified by $\mathrm{NPV}_\ell(n)$. Further, note that due to the potential (or non-)transition of the firm's rating, the price of the bond may be altered over time as well. Explicitly, the price $B_k(t, T)$ of a coupon paying bond $c_{k,t}$ at time t and l_k dollars at maturity when it is rated k equals the expected present value of the bond in the next period, discounted at a rate associated with its rating in the next period. This is given by the following recurrence equation

$$B_k(t, T) = c_{k,t} + \sum_{j=1}^{m} \frac{p_{kj}}{1+R_{jt}} B_j(t+1, T)\,;$$
$$B_k(T, T) = 1_k, \quad k = 1, 2, 3, \ldots m\,.$$

However, note that for the NPV valuation, we used a zero-coupon bond paying one dollar in the next period, and therefore,

$$B_k(t, t+1) = \sum_{j=1}^{m} \frac{p_{kj}}{1+R_{jt}} B_j(t+1, t+1) = \sum_{j=1}^{m} \frac{p_{kj}}{1+R_{jt}} 1_j\,.$$

For example, if the bond pays one dollar in all circumstances, except if it is rated m, in which case it pays nothing, then

$$B_k(t, t+1) = \sum_{j=1}^{m-1} \frac{p_{kj}}{1+R_{jt}} 1 = \sum_{j=1}^{m-1} \frac{p_{kj}}{1+R_{jt}}\,.$$

Now assume that at some future time t we have the option to stop the bond payments at a price of say $-Q_t$. In other words, the actual net present value at time t with an option to stop at this time would be:

$$\mathrm{NPV}_k^{(o)}(t) = \max\left[-Q_t, \mathrm{NPV}_k(t)\right]\,,$$
$$\mathrm{NPV}_k^{(o)}(T) = \mathrm{NPV}_k(T)$$

and Q_t is the cost associated with implementing the option (for example, the cost to the firm of discontinuing a service, etc.). Note that at the final time, the option is worthless if the project has been terminated. A stopping time (at which the option is exercised) occurs thus at time τ when $-Q_t \geq \mathrm{NPV}_k(\tau)$. A number of situations may arise then. For example, for a firm that is down-rated, the cost of borrowing would increase and it might lead it to decide to exercise the option because of its cost in capital. And vice versa, a firm that is up-rated and is trapped in a costly investment might decide to either stop it or refinance it to reduce its cost or have the current cash flow of the project to be more in concordance with its improved rating. The price of such a *real* option can be valued by noting that, if it is exercised at time $t+1$, when the firm is rated j, resulting in a savings of $-Q_{t+1} - \mathrm{NPV}_j(t+1)$, with $(\mathrm{NPV}_j < 0)$, this saving is worth today

$$\mathrm{NPV}_k^{(1)}(t) = B_k(t, t+1) \sum_{\ell=1}^{m} p_{k\ell} \times \max\left(-Q_{t+1} - \mathrm{NPV}_j(t+1), 0\right)$$
$$\mathrm{NPV}_k^{(1)}(\tau) = -Q_\tau - \mathrm{NPV}_j(\tau)\,, \quad \tau \leq T\,.$$

These equations are of course meaningful only when the discount rate associated to a given rating is specified. If this is the case, then of course, our equations are simple to calculate. A potential for arbitrage may thus occur when these discount rates are not appropriately specified. Later on, we shall be concerned with the determination of these rates based on the construction of a bonds portfolio of various ratings. Examples that demonstrate how calculations are performed will also be used.

Finally, it is worth noting that, when a stream of payments are random, given by $\tilde{C}_i$, and subjectively valued by an investor whose utility of money $u(.)$ is known, then we can calculate the certainty equivalent CE_i of the uncertain payment, in which case: $u\left(CE_i\right) = Eu\left(\tilde{C}_i\right)$ and $CE_i = u^{-1}\left[Eu\left(\tilde{C}_i\right)\right]$. The NPV can then be calculated by applying the risk-free rate:

$$\mathrm{NPV}_{\mathrm{f}}(0) = -\sum_{i=0}^{n} \frac{I_i}{[1+R_{\mathrm{f}}(0,i)]^i} + \sum_{i=0}^{n} \frac{u^{-1}\left[Eu\left(\tilde{C}_i\right)\right]}{[1+R_{\mathrm{f}}(0,i)]^i}\,.$$

Unfortunately, this valuation is also subjective for it is based on a utility function which might not be available. Alternatively, a market valuation, can be used when the price of risk is known, or we establish some mechanism for appropriately accounting for the risk implied in an uncertain cash flow. This is done by calculating the yield of a bond. There are numerous techniques, inspired both

theoretically and numerically, that are applied to calculate the yield. Such a problem is the topic of commercial and theoretical research. Nonetheless we shall consider a number of approaches to calculating the yield because of its importance in financial engineering.

47.4.1 Calculating the Yield of a Bond

The yield of a bond is the discount rate y_T applied to holding the bond for T periods. This yield is often difficult to calculate because data pertaining to the term structure of zero-coupon bonds is simply not available, or available only for certain periods. For example, say that we have a bond at time whose exercise price occurs at time t, or $B(0,t) = B(t)$. To each time t, we associate the rate $y(t)$ and therefore the bond price is $B(t) = \exp\left[-y(t)t\right]$. The function $y(t)$ is called the yield curve. Of course, if zero-coupon bonds are price for time $t = 1$, we then have $y(1) = R_f$, which is the current spot rate. However, if there are no zero-coupon bonds for $t = 6$, the yield for such a bond can only be inferred by some numerical or estimation technique. In other words, unless a zero-coupon bond exists for every maturity for which the discount factor is desired, some estimation technique will be needed to produce a discount factor for any *off-maturity* time. Since zero-coupon bonds are available for only some and other maturities, a lack of liquidity may prevent the determination of the true bond yield [47.66] (see also [47.67–69]. The *yield engineering* problem consists then in determining some technique and appropriate sources of information to estimate the yield for all maturities (also called the yield curve). Approaches to this problems are of course varied. *Nelson* and *Siegel* [47.70] for example suggest the following four-parameter equation, which can be estimated numerically by fitting to the appropriate data

$$y(t) = a_0 + (a_1 + a_2)\left(\frac{1-\exp(-a_3 t)}{a_3}\right) - a_2 \exp(-a_3 t) \; ;$$

$y(t)$ is the spot rate while a_0, a_1, a_2, a_3 are the model's parameters (for related studies and alternative models see [47.66, 71–79], www.episolutions.com) suggest however a zero curve solution, which uses a combination of liquid securities, both zero-coupon and coupon-bearing bonds for which prices are readily available, and consisting of an application of bootstrapping techniques to calculate the yield curve. Explicitly, the Wets approach is based on an approximation, and in this sense it shares properties with purely spline methods. It is based upon a Taylor series approximation of the discount function in integral form. Some prevalent methods for computing (extracting) the zeros, curve-fitting procedures, and equating the yield curve to observed data in central banks include, among others: in Canada the use of the Svensson procedure and David Bolder (Bank of Canada), in Finland the Nelson–Siegel procedure, in France the Nelson–Siegel, Svensson procedures, while in Japan and the USA, the banks use smoothing splines etc. (see [47.71–73, 80]). A critical appreciation of the zero-curve approach is provided by [47.81] and [47.80] (essentially based on the structural form of the polynomial used in the episolutions approach). Other approaches span numerical techniques, smoothing techniques, [47.82], (such as least-squares approaches as we shall see later on when introducing rated bonds), kernel smoothing (SDF) techniques etc. [47.83–86]. For example, consider the price $B(t, T-t)$ of a bond at time t whose maturity is at time T. The next-period price of the bond is in fact unknown (depending on numerous factors including random interest rates). Applying the SDF approach, we can state that

$$B(t, T-t) = E_t\left[M_{t+1} B(t+1, T-t-1)\right] ,$$

where M_{t+1} is the pricing kernel. Rearrange this term as follows

$$1 = E_t\left(M_{t+1}\frac{B(t+1, T-t-1)}{B(t, T-t)}\right) , \quad \text{where}$$
$$\frac{B(t+1, T-t-1)}{B(t, T-t)} = 1 + y_{t+1,T}$$

with $y_{t+1,T}$ denoting the yield of the bond whose maturity is at time T, at time $t+1$. As a result,

$$1 = E_t\left[M_{t+1}\left(1 + y_{t+1,T}\right)\right] ,$$
$$E_t\left[M_{t+1}\right] = \frac{1}{1+R_{t,f}} .$$

To calculate the yield some model is needed for both the kernel and of course the yield distributions. Since these variables are both random and dependent an appropriate model has to be constructed on the basis of which an empirical econometric verification can be reached. Alternatively, if information regarding the marginal distributions of the kernel and the returns is available, then we may also construct copulas to represent the statistical covariation effects of both the kernel and the returns. These are problems that require further research however.

47.4.2 Bonds and Risk-Neutral Pricing in Continuous Time

In many situations, we use stochastic models of interest rates to value bonds. Below we shall consider some examples and provide as well some general results for the valuation of such bonds. In practice however, it is extremely difficult to ensure that such models do indeed predict very well the evolution of interest rates and therefore there is a broad range of techniques for calculating the *yields* of various bonds – of both risk denomination and term structures. In continuous time, let $r(t)$ be the known spot interest rate. A risk-free bond paying one dollar at T with a compounded interest rate $r(t)$ is then given by:

$$B(0,t) = \exp\left[\int_0^t r(u)\,\mathrm{d}u\right], \quad B(T,T) = 1\,.$$

The interest rate process may be deterministic or stochastic as stated above. Since bonds depend intimately on the interest rate process, it is not surprising that much effort is devoted to constructing models that can replicate and predict reliably the evolution of interest rates, as one process values the other. There are many interest rate models however, each expressing an economic rationale for the evolution of interest rates. Generally, and mostly for convenience, an interest rates process $\{r(t), t \geq 0\}$ is represented by an Ito stochastic differential equation:

$$\mathrm{d}r = \mu(r,t)\,\mathrm{d}t + \sigma(r,t)\,\mathrm{d}w\,,$$

where μ and σ are the drift and the diffusion function of the process which may or may not be stationary. Various authors consider alternative models in their analysis [47.1, 87, 88]. The Vasicek model in particular provides a straightforward rationality for interest rates movements (also called the Ornstein–Uhlenbeck process). In other words, it states that the rate of change in interest rates fluctuates around a long-run rate α. This fluctuation is subjected to random and normal perturbations of mean zero and variance $\sigma\Delta t$, or

$$\mathrm{d}r = \beta(\alpha - r)\,\mathrm{d}t + \sigma\,\mathrm{d}w\,.$$

Without much difficulty, it can be shown (see also [47.48]) that this equation has a solution expressed in terms of the current interest rates and the model's parameters given by

$$r(\tau) = \alpha + [r(t) - \alpha]\,\mathrm{e}^{-\beta(\tau - t)} + \sigma \int_t^\tau \mathrm{e}^{-\beta[\tau - y]}\,\mathrm{d}w(y)\,.$$

The value of a bond with variable interest rates is thus:

$$\begin{aligned} B(t,\tau) &= E\exp\left[\int_t^\tau r(u)\,\mathrm{d}u\right] \\ &= E\exp\left\{\int_t^\tau \alpha + [r(t) - \alpha]\,\mathrm{e}^{-\beta(u-t)} + \sigma\int_t^u \mathrm{e}^{-\beta[u-y]}\,\mathrm{d}w(y)\,\mathrm{d}u\right\}; \\ B(T,T) &= 1 \end{aligned}$$

with $\mathrm{d}w(y)$ denoting the risk source (a normally distributed random variable of zero mean and variance $\mathrm{d}y$). Interest rates are therefore also normal with a mean and variance (volatility) evolution we can easily compute. In particular note that:

$$\ln B(t,\tau) = \ln\left\{\int_t^\tau \alpha + [r(t) - \alpha]\,\mathrm{e}^{-\beta(u-t)}\,\mathrm{d}u\right\} + \ln E\exp\left[\int_t^\tau \sigma \int_t^u \mathrm{e}^{-\beta[u-y]}\,\mathrm{d}w(y)\,\mathrm{d}u\right]$$

which can be written as a linear function in the current interest rate, or

$$\ln B(t,\tau) = A(t,\tau)r(t) + D(t,\tau)\,.$$

This is a general property called the affine property which, is found in some general Markov processes X in a state space $D \subset \mathbb{R}^d$. Namely, it states that the bond return is linear in the process X, or $R(x) = a_0 + a_1 X$. Explicitly, we have the characteristic function:

$$E\left\{\mathrm{e}^{\mathrm{i}uX(t)}|X(s)\right\} = \exp[(\varphi t - s, u) + \psi(t-s,u)X(s)]\,.$$

The logarithm is of course a linear function with $a_0 = \varphi(t-s,u)$ and $a_1 = \psi(t-s,u)$ deterministic coefficients. *Duffie* et al. [47.89] show that for a time-homogeneous affine process X with a state space of the form $\mathbb{R}_+^n \times \mathbb{R}^{d-n}$, provided the coefficients $\varphi(\cdot)$ and $\psi(\cdot)$

of the characteristic function are differentiable and their derivatives are continuous at 0. The affine process X must a be a jump-diffusion process in that

$$\mathrm{d}X_t = \mu(X_t)\,\mathrm{d}t + \sigma(X_t)\,\mathrm{d}W_t + \mathrm{d}J_t$$

for standard Brownian motion W in $\mathbb{R}^d$ and a pure jump process J, with J affine dependent on X. A related property is of course

$$E_t\left(\mathrm{e}^{\int_t^s -R[x(u)]\,\mathrm{d}u + wX(s)}\right) = \mathrm{e}^{\alpha(s-t)+\beta(s-t)X(t)}\,,$$

where $\alpha(\cdot)$, $\beta(\cdot)$ satisfy a generalized Ricatti ordinary differential equation (with real boundary conditions). To see this property (in a specific case) consider the following example. Let interest rates be given by the following stochastic differential equation

$$\mathrm{d}r = \beta(\alpha - r)\,\mathrm{d}t + \sigma\sqrt{r}\,\mathrm{d}w\,.$$

Application of Ito's differential rule to $B(t,r) = \exp\left[-\int_t^T r(u)\,\mathrm{d}u\right]$ yields

$$\frac{E\,\mathrm{d}\ln B(t,r)}{\mathrm{d}t} = -r - (T-t)\beta(\alpha - r) + \frac{1}{2}(T-t)^2\sigma^2 r\,,$$

which is clearly a linear function of the current interest rate. Elementary mathematical treatment will also show that the mean and the variance of the interest rates are given by

$$E\{r(t)\mid r_0\} = c(t)\left(\frac{4\beta\alpha}{\sigma^2} + \xi\right)\,;$$

$$\mathrm{var}\,\{r(t)\mid r_0\} = c(t)^2\left(\frac{8\beta\alpha}{\sigma^2} + 4\xi\right), \quad \text{where}$$

$$c(t) = \frac{\sigma^2}{4\beta}\left(1 - \mathrm{e}^{-\beta t}\right)\,,$$

$$\xi = \frac{4r_0\beta}{\sigma^2[\exp(\beta t) - 1]}\,.$$

In this case, interest rates are not normal. Nonetheless the Laplace transform can be calculated and applied to price the bond as we have shown it above.

When interest rate models include stochastic volatility, the valuation of bonds is incomplete. Therefore, it is necessary to turn to appropriate mechanisms that can help us to price bonds. For example, denote by $V = \sigma^2(r,t)$, a *stochastic volatility model* consisting of two stochastic differential equations, with two sources of risk (W_1, W_2), which may be correlated or not. An example would be

$$\mathrm{d}r = \mu(r,t)\,\mathrm{d}t + \sqrt{V(r,t)}\,\mathrm{d}W_1\,;$$
$$\mathrm{d}V = \nu(V,r,t)\,\mathrm{d}t + \gamma(V,r)\,\mathrm{d}W_2\,,$$

where the variance V appears in both equations. Due to market incompleteness, there may be an infinite number of prices. A special case provided by *Hull* and *White* [47.90] is reproduced below. Note that the interest rate model is the square-root model we saw earlier. However, since the variance is subject to stochastic variations as well, it is modeled separately as a stochastic differential equation which is *mean–variance* reverting.

$$\frac{\mathrm{d}r}{r} = \mu\,\mathrm{d}t + \sqrt{V}\,\mathrm{d}W_1\,;$$
$$\mathrm{d}V = \alpha(\beta - V)\,\mathrm{d}t + \gamma r V^{\lambda}\,\mathrm{d}W_2\,.$$

In this case, when stock prices increase, volatility increases, while when volatility increases, interest rates (or the underlying asset we are modeling) increases also. These problems will be considered subsequently when we treat incomplete markets.

47.4.3 Term Structure and Interest Rates

If $r(t,T)$ is the interest rate applied at t for a payment at time T, then at $t+1$, the relevant rate for this period T would be $r(t+1,T)$. If these interest rates are not equal, there may be an opportunity for refinancing [47.91]. As a result, the evolution of interest rates for different maturity dates is important. Further, since bonds may have various maturities, the interest rates applied to value these bonds require necessarily that we assess the interest rates term structure. Below, we shall see how the term structure is implicit in bonds valuation. Say that an interest rate model for maturity at T is:

$$\mathrm{d}r(t,T) = \mu(r,T)\,\mathrm{d}t + \sigma(r,T)\,\mathrm{d}W\,.$$

A bond price with the same maturity is therefore a function of such interest rates, leading to:

$$\frac{\mathrm{d}B(t,T)}{B(t,T)} = \alpha(r,t,T)\,\mathrm{d}t + \beta(r,t,T)\,\mathrm{d}W\,.$$

The parameters $\alpha(.)$ and $\beta(.)$ are easily found by application of Ito's lemmas to $B(t,T) = \exp\left[-r(t,T)(T-t)\right]$,

$$\mathrm{d}B(t,T) = \left[\frac{\partial B}{\partial t} + \frac{\partial B}{\partial r}\mu(r,T) + \frac{1}{2}\frac{\partial^2 B}{\partial r^2}\sigma^2(r,T)\right]\mathrm{d}t + \frac{\partial B}{\partial r}\sigma(r,T)\,\mathrm{d}w\,.$$

Equating these two bond price equations, we have:

$$\alpha(r,t,T)B = \left[\frac{\partial B}{\partial t} + \frac{\partial B}{\partial r}\mu(r,T) + \frac{1}{2}\frac{\partial^2 B}{\partial r^2}\sigma^2(r,T)\right];$$
$$\beta(r,t,T)B = \frac{\partial B}{\partial r}\sigma(r,T).$$

Now assume that the risk premium is proportional to their returns standard deviation and let the price of risk be a known function of r and time t:

$$\alpha(r,t,T) = r + \lambda(r,t)\frac{1}{B}\frac{\partial B}{\partial r}.$$

Inserted into the bond equation derived above, this leads to

$$rB + \lambda(r,t)\frac{\partial B}{\partial r} = \left[\frac{\partial B}{\partial t} + \frac{\partial B}{\partial r}\mu(r,T) + \frac{1}{2}\frac{\partial^2 B}{\partial r^2}\sigma^2(r,T)\right]$$

and finally to the partial differential equation:

$$0 = \frac{\partial B}{\partial t} + \frac{\partial B}{\partial r}[\mu(r,T) - \lambda(r,t)] + \frac{1}{2}\frac{\partial^2 B}{\partial r^2}\sigma^2(r,T) - rB; \quad B(r,T,T) = 1.$$

The solution of this equation, although cumbersome, can be determined. For example, if we set the constants $[\mu(r,T) - \lambda(r,t)] = \theta$; $\sigma^2(r,T) = \rho^2$, then the following solution can be verified:

$$B(r,t,T) = \exp\left[-r(T-t) - \frac{1}{2}\theta(T-t)^2 + \frac{1}{6}\rho^2(T-t)^3\right].$$

In general these equations are difficult to solve analytically or numerically and require therefore a certain amount of mathematical and numerical ability. Alternatively, if we set

$$[\mu(r,T) - \lambda(r,t)] = k(\theta - r);\ \sigma^2(r,T) = \rho^2 r.$$

Then we can show that the solution for the bond value is of the affine structure form and therefore given by

$$\ln B(r,t,T) = A(T-t) + rD(T-t).$$

A solution for the function $A(.)$ and $D(.)$ can then be found by substitution.

47.4.4 Default Bonds

There are various models for default-prone bond, falling into one of two categories: structural models and reduced-form models [47.74, 92, 93]. Structural models of default specify a particular value process and assume that default occurs when the value falls below some explicit threshold (for example, default may occur when the debt-to-equity ratio crosses a given threshold). In this sense, default is a *stopping time* defined by the evolution of a representative stochastic process. These models determine both equity and debt prices in a self-consistent manner via arbitrage, or contingent-claims pricing. These models assume often that debt-holders get back a fraction of the face value of the debt, sometimes called the recovery ratio at default. Such an assumption is observed largely in practice with bondholders recovering 20–80% of their investment. This recovery ratio is known a priori, however, in their models. Structural models have a number of additional drawbacks. For example, they cannot incorporate credit-rating changes that occur frequently for default prone (risky) corporate debts. Many corporate bonds undergo credit downgrades by credit-rating agencies before they actually default, and bond prices react to these changes either in anticipation or when they occur. Thus, any valuation model should take into account the uncertainty associated with credit-rating changes as well as the uncertainty surrounding default.

Reduced-form models instead, specify the default process explicitly, interpreting it as an exogenously motivated jump process, usually given as a function of the firm value. This class of models has been investigated for example by *Jarrow* and *Turnbull* [47.92], *Jarrow*, *Lando* and *Turnbull* [47.93, 94], *Duffie* and *Singleton* [47.78], and others. Although these models are useful when fitting default to observed credit spreads, neglecting the underlying value process of the firm renders it less useful when it is necessary to determine credit-spread variations. There are numerous publications regarding default-prone bonds and therefore we only consider some classical and simple examples.

Example 47.3 (structural models): Longstaff–Schwartz [47.95] assume a risk-free interest rate two-factor model with interest rates given by a *Vacicek* [47.96] model. Let V_t and r_t be the time-t values of the firm's assets and the risk-free interest rate, respectively. The dynamics of these two factors is written in terms of the following

equations

$$dV/V = (r-\delta)\,dt + \sigma_1\,dZ_1\,;$$
$$dr = (\alpha - \beta r)\,dt + \sigma_2\,dZ_2\,,$$

where δ, σ_1, α, β and σ_2 are constants, and Z_1 and Z_2, two standard Brownian motion processes with constant correlation coefficient ρ.

In their model, default occurs when the value of the firm declines to a pre-specified boundary (with the par value of the bond – the face amount due on the maturity date – taken as the boundary). As a result, the default boundary is specified exogenously. In the event of default, bondholders recover a constant fraction of the par value of the bond. In the Longstaff–Schwartz model, a risky coupon bond is valued as a simple portfolio of a risky zero-coupon bond whose value for a \$ 1 face value is given by

$$P(V_t\,|F, r_t, T)$$
$$= D(r_t, T)\,[1-(1-w)Q(V_t\,|F, r_t, T)]\,,$$

where $D(.)$ denotes the value of a default-free discount bond given by the *Vacicek* [47.96] model, $Q(.)$ represents the forward default probability while w is the recovery rate.

Example 47.4 (reduced-form models): Failure of structural models to adequately price risky bonds found in the marketplace led to another approach based on reduced-form models of default risk. These make no attempt to define default as an endogenous event (arising from a low level of firm value or cash flow), but rather specify default as an exogenous event and thus do not explicitly incorporate any relationship between leverage and firm value into the model. These models, such as those of *Duffie* and *Singleton* [47.78], *Jarrow* and *Turnbull* [47.92], and *Jarrow*, *Lando* and *Turnbull* [47.93], are based on parameters that can be estimated with readily available data, such as default rates or bond spreads. The model of *Jarrow*, *Lando*, and *Turnbull* ([47.93], for example) assumes that the value of a default-free zero-coupon bond is known at time t. This bond will mature at time T and pay one dollar on maturity. $p(t, T)$ is the value of this bond. If $v_i(t, T)$ denotes the value of a defaultable zero-coupon bond of a firm that currently has credit rating i (for example, AAA) at time t, will mature at time T, and has a promised payoff of \$ 1 at maturity, then Jarrow, Lando, and Turnbull show that:

$$v_i(t, T) = p(t, T)[\phi + (1-\phi)q_i(t, T)]\,,$$

where ϕ is the recovery ratio, the fraction of the face value (\$ 1) that is recovered at time T after default, and $q_i(t, T)$ denotes the probability of a default occurring after T given that the debt has credit rating i as of time t. To arrive at the valuation formula, *Jarrow*, *Lando*, and *Turnbull* [47.93] assume that default is independent of the level of interest rates. However, this assumption is not critical. The independence assumption can be relaxed so that the model of *Jarrow* et al. extended so that the default relaxes the independence assumption and extends the model of Jarrow et al. so that the default probability can depend on the level of interest rates.

47.5 Options

Options are instruments that give the buyer of the option (the long side) the *right to exercise*, for a price, called the *premium*, the delivery of a commodity, a stock, a foreign currency etc. at a given price, called the *strike price*, at *(within)* a given time period, also called the *exercise date*. Such an option is called a *European (American) call* for the buyer. The seller of such an option (the short side), has by contrast the *obligation* to sell the option at the stated strike and exercise date. A *put* option (the long side) provides the option to sell, while for the short seller there is an obligation to buy. There are many types of options however and considerable research on the pricing of options (for example, see [47.24, 32, 97–106]. We shall consider in particular call and put options. Options are traded on many trading floors and mostly, they are defined in a standard manner. Nevertheless, there are also over-the-counter options, which are not traded in specific markets but are used in some contracts to fit specific needs. For example, there are Bermudan and Asian options. The former option provides the right to exercise the option at several specific dates during the option lifetime, while the latter defines the exercise price of the option as an average of the value attained over a certain time interval. Of course, each option, defined in a different way, will lead to alternative valuation formulas. There can be options on real assets, which are not traded but used to define a contract between two parties (real options). The valuation of options has attracted a huge amount of interest and for this reason it

will also be a substantial issue we shall deal within this chapter.

47.5.1 Options Valuation and Martingales

When the underlying price process is a martingale and risk-neutral pricing of financial assets applies, then the price of a cash flow $\tilde{S}_n$ realized at time n is

$$S_0 = \frac{1}{(1+R_f)^n} E^*\left(\tilde{S}_n\right) .$$

Hence the forward price is:

$$V_0 (1+R_f)^n = E^*\left(\tilde{S}_n \,|\Phi_0\right) ,$$

where Φ_0 is a filtration, representing the initial information on the basis of which the expectation is taken (under the risk-neutral distribution where expectation is denoted by $E^*(*)$). If K is the exercise price of a call option for exercise at some time T, then, the price C_t of such an option (as well as a broad variety of other options) under risk-neutral pricing is

$$C_t = \frac{1}{(1+R_f)^{T-t}} E^*\left[\max\left(K - \tilde{S}_T, 0\right)|\Phi_t\right] .$$

A simple example often used is the binomial option model. For simplicity, assume, a stock whose current price is 1 \$ and consider two asset state prices one period hence (H, L), $H > 1$, $L < 1$. Under risk-neutral pricing, then of course $1 = \frac{1}{1+R_f}\left[pH + (1-p)L\right]$, where p is a risk-neutral probability. To determine this probability we construct a replicating portfolio for the call option whose state prices are $(C_H, C_L) = (H-K, 0)$, $H > K$, $L < K$. Let this portfolio consist of the stock and a risk-less zero-coupon bond paying one dollar one period hence and be given initially by $P = a + b$. One period hence, the portfolio state prices are necessarily $(P_H, P_L) = \left[aH + b(1+R_f), aL + b(1+R_f)\right]$. It is a replicating portfolio if $(P_H, P_L) = (C_H, C_L)$. A solution of these replicating asset prices yields both a^* and b^* – the replicating portfolio composition. Since two assets with identical cash flows have the same price, the portfolio price and the call option ought, in complete markets, have the same price and therefore $C = P^* = a^* + b^*$, which provides the desired solution. Since the call option under risk-neutral pricing equals the discounted (at the risk-free rate) value of the call option at its exercise, or:

$$\begin{aligned} C &= \frac{1}{1+R_f}\left[pC_H + (1-p)C_L\right] \\ &= \frac{1}{1+R_f}\left[p\,(H-K)\,,(1-p)\,(0)\right] \end{aligned}$$

we can solve this equation and obtain the risk-neutral probability

$$\begin{aligned} p &= \frac{(1+R_f)\,(1) - L}{H-L} ; \\ q &= 1 - p = \frac{H - (1+R_f)(1)}{H-L} . \end{aligned}$$

This analysis can be repeated for several periods. Explicitly, for an option whose exercise is at time n we obtain by induction

$$\begin{aligned} C &= \frac{1}{(1+R_f)^n} \\ &\quad \times \left[\sum_{j=0}^{n} \binom{n}{j} p^j (1-p)^{n-j} (H^j L^{n-j} x - K)^+\right] , \\ x &= 1. \end{aligned}$$

We can write this expression in still another form

$$\begin{aligned} C_n &= \frac{1}{(1+r)^n} E^*\left[(x_n - K)^+\right], \quad \text{where} \\ P\left(x_n = H^j L^{n-j} x\right) &= \binom{n}{j} p^j (1-p)^{n-j} . \end{aligned}$$

47.5.2 The Black–Scholes Option Formula

In continuous time and continuous state, the pricing of Black–Scholes options are obtained in a similar manner, albeit using stochastic calculus. The traditional approach is based on the replication of the option value by the construction of a portfolio consisting of the underlying asset (the security) and a risk-free bond. Let $S(t)$ be a security-stock price at time t, distributed as a log-normal process and let V be the value of an asset derived from this stock, which we can write by the following function $V = f(S, t)$, assumed to be differentiable with respect to time and the security-stock $S(t)$. For simplicity, let the security price be given by a log-normal process:

$$\frac{\mathrm{d}S}{S} = \alpha\,\mathrm{d}t + \sigma\,\mathrm{d}W, \quad S(0) = S_0 ,$$

where $\left\{W(t), t \geq 0\right\}$, $W(0) = 0$ is a standard Brownian motion. Let P be a replicating portfolio consisting of bonds and investment in the given stock, $P = B + aS$ or $B = P - aS$, in which case the price of a risk-less bond and the price of a portfolio $P - aS$ is necessarily the same. A perfect hedge is thus constructed by setting: $\mathrm{d}B = \mathrm{d}P - a\,\mathrm{d}S$ where $\mathrm{d}B = R_f B\,\mathrm{d}t$. Now, let $V = C = f(S, t)$ be the option price. Setting the replicating portfolio, we have $P = C$ and $\mathrm{d}P = \mathrm{d}C$, which

is used to obtain a partial differential equation of the option price with appropriate boundary conditions and constraints, providing thereby the solution to the Black–Scholes option price. Each of these steps is translated into mathematical manipulations. First, note that:

$$\mathrm{d}B = \mathrm{d}f - a\,\mathrm{d}S = R_\mathrm{f} B\,\mathrm{d}t\,.$$

By an application of Ito's differential rule we obtain the option price:

$$\begin{aligned}\mathrm{d}C &= \mathrm{d}f \\ &= \left(\frac{\partial f}{\partial t} + \alpha S\frac{\partial f}{\partial S} + \frac{\sigma^2 S^2}{2}\frac{\partial^2 f}{\partial S^2}\right)\mathrm{d}t \\ &\quad + \left(\sigma S\frac{\partial f}{\partial S}\right)\mathrm{d}W\end{aligned}$$

and therefore,

$$\begin{aligned}&\left(\frac{\partial f}{\partial t} + \alpha S\frac{\partial f}{\partial S} + \frac{\sigma^2 S^2}{2}\frac{\partial^2 f}{\partial S^2}\right)\mathrm{d}t \\ &\quad + \left(\sigma S\frac{\partial f}{\partial S}\right)\mathrm{d}W - a\,\mathrm{d}S = R_\mathrm{f}(f - aS)\,\mathrm{d}t\,.\end{aligned}$$

Thereby,

$$\begin{aligned}&\left[\frac{\partial f}{\partial t} + \alpha S\frac{\partial f}{\partial S} + \frac{\sigma^2 S^2}{2}\frac{\partial^2 f}{\partial S^2}\right. \\ &\quad \left. - aS\,(\alpha - R_\mathrm{f}) - R_\mathrm{f} f\right]\mathrm{d}t \\ &\quad + \sigma S\left(-a + \frac{\partial f}{\partial S}\right)\mathrm{d}W = 0\,,\end{aligned}$$

or

$$a = \frac{\partial f}{\partial S};\ \left(\frac{\partial f}{\partial t} + R_\mathrm{f} S\frac{\partial f}{\partial S} + \frac{\sigma^2 S^2}{2}\frac{\partial^2 f}{\partial S^2} - R_\mathrm{f} f\right) = 0$$

and finally

$$\begin{aligned}&-\frac{\partial f}{\partial t} = R_\mathrm{f} S\frac{\partial f}{\partial S} + \frac{\sigma^2 S^2}{2}\frac{\partial^2 f}{\partial S^2} - R_\mathrm{f} f;\quad f(0,t) = 0\,, \\ &\forall t \in [0,T]\,,\qquad f(S,T) = \max\,[0,\,S(T) - K]\,.\end{aligned}$$

The boundary conditions are specified by the fact that the option cannot be exercised until the exercise time (unlike an American option, as we shall see below) and therefore it is worthless until that time. At the exercise date T however, it equals $f(S,T) = \max[0,\,S(T) - K]$. The solution was shown by Black and Scholes to be

$$W = f(S,t) = S\Phi(d_1) - K\,\mathrm{e}^{-R_\mathrm{f} t}\Phi(\mathrm{d}_2)\,,$$

where

$$\begin{aligned}&\Phi(y) = (2\pi)^{-1/2}\int_{-\infty}^{y}\mathrm{e}^{-u^2/2}\,\mathrm{d}u\,; \\ &d_1 = \left(\frac{\log(S/K) + (T-t)(R_\mathrm{f} + \sigma^2/2)}{\sigma\sqrt{T-t}}\right)\,; \\ &d_2 = d_1 - \sigma\sqrt{T-t}\,.\end{aligned}$$

This result is remarkably robust and holds under very broad price processes. Further, it can be estimated by simulation very simply. There are many computer programs that compute these option prices as well as their sensitivities. The price of a put option is calculated in a similar manner (see also [47.107, 108]).

47.5.3 Put–Call Parity

The put–call parity relationship establishes a relationship between the price of a put and that of a call. It can be derived by a simple arbitrage argument between two equivalent portfolios, yielding the same payoff regardless of the stock price. Their value must therefore be the same. To do so, construct the following two portfolios at time t:

Time t	Time T
	$S_T < K$
(1) $c + K\,\mathrm{e}^{-R_\mathrm{f}(T-t)}$	K
(2) $p + S_t$	$K = (K - S_T) + S_T$

Time t	Time T
	$S_T > K$
(1) $c + K\,\mathrm{e}^{-R_\mathrm{f}(T-t)}$	$(S_T - K) + K = S_T$
(2) $p + S_t$	S_T

We see that at time T, the two portfolios yield the same payoff $\max(S_T, X)$ which implies the same price at time t. Thus

$$c + K\,\mathrm{e}^{-R_\mathrm{f}(T-t)} = p + S_t\,.$$

If this is not the case then there would be some arbitrage opportunity. In this sense, computing European options prices is simplified, since knowing one leads necessarily to knowing the other.

When we consider dividend-paying options, the put–call parity relationships are slightly altered. Let D denote the present value of the dividend payments during the

lifetime of the option (occurring at the time of its ex-dividend date), then:

$$c > S - D - K\,\mathrm{e}^{-R_\mathrm{f}(T-t)}\,,$$
$$p > D + K\,\mathrm{e}^{-R_\mathrm{f}(T-t)} - S\,.$$

Similarly, for put–call parity in a dividend-paying option, we have the following bounds

$$S - D - K < C - P < S - K\,\mathrm{e}^{-R_\mathrm{f}(T-t)}\,.$$

Put–call parity can be applied similarly between securities denominated in different currencies. For example, let α be the euro/dollar exchange rate (discounted at the dollar risk-free rate) and let $R_{\mathrm{f,E}}$ be the euro-area discount rate. Then, by put–call parity, we have

$$c + \frac{K}{1 + R_{\mathrm{f,E}}} = p + \alpha\,,$$

which can be used as a regression equation to determine the actual exchange rate based on options data on currencies exchange.

47.5.4 American Options – A Put Option

American options, unlike European options, may be exercised prior to the expiration date. The price of such options is formulated in terms of stochastic dynamic programming arguments. As long as the option is *alive* we may either exercise it or maintain it, continuing to hold it. In a continuation region, the value of the option is larger than the value of its exercise and therefore, it is optimal to wait. In the exercise region, it is optimal to exercise the option and cash in the profits. If the time to the option's expiration date is t, then the exercise of the option provides a profit $K - S(t)$. In this latter case, the exercise time is a *stopping time*, and the problem is terminated. Another way to express such a statement using dynamic programming arguments is:

$$f(S,t) = \max\left[K - S(t),\, \mathrm{e}^{-R_\mathrm{f}\,\mathrm{d}t} E f(S + \mathrm{d}S, t + \mathrm{d}t)\right]\,,$$

where $f(S,t)$ is the option price at time t when the underlying stock price is S and one of the two alternatives holds at equality. At the contracted strike time of the option, we have necessarily, $f(S,0) = K - S(0)$. The solution of the option's exercise time is difficult however and has generated a large number of studies seeking to solve the problem analytically or numerically. Noting that the solution is of barrier type, meaning that there is some barrier $X^*(t)$ that separates the exercise and continuation regions, we have

$$\begin{cases} \text{If } K - S(t) \geq X^*(t) & \text{exercise region:} \\ & \text{stopping time} \\ K - S(t) < X^*(t) & \text{continuation region}\,. \end{cases}$$

The solution of the American put problem consists then of selecting the optimal exercise barrier [47.109, 110]. A number of studies have attempted to do so, including [47.111] as well as many other authors. Although the analytical solutions of American put options are hard to reach, there are some problems that have been solved analytically. For most practical problems, numerical and simulation techniques are used.

Explicitly, assume that an American put option derived from a security is exercised at time $\tau < T$ where T is the option exercise period while the option exercise price is K. Let the underlying stock price be a risk-neutral process:

$$\frac{\mathrm{d}S(t)}{S(t)} = R_\mathrm{f}\,\mathrm{d}t + \sigma\,\mathrm{d}W(t),\; S(0) = S_0\,.$$

Under risk-neutral pricing, the value of the option equals the discounted value (at the risk-free rate) at the optimal exercise time $\tau^* < T$, namely:

$$J(S,T) = \max_{\tau \leq T} E_S\,\mathrm{e}^{-R_\mathrm{f}\tau}\,[K - S(\tau), 0]\,.$$

Thus,

$$J(S,t) = \begin{cases} K - S(t) & \text{exercise region: stopping time} \\ \mathrm{e}^{-R_\mathrm{f}\,\mathrm{d}t} E J(S + \mathrm{d}S, t + \mathrm{d}t) & \\ & \text{continuation region}\,. \end{cases}$$

In the continuation region we have explicitly:

$$\begin{aligned} J(S,t) &= \mathrm{e}^{-R_\mathrm{f}\,\mathrm{d}t} E J(S + \mathrm{d}S, t + \mathrm{d}t) \\ &\approx (1 - R_\mathrm{f}\,\mathrm{d}t) \\ &\quad \times E\left[J(S,t) + \frac{\partial J}{\partial t}\,\mathrm{d}t + \frac{\partial J}{\partial S}\,\mathrm{d}S + \frac{1}{2}\frac{\partial^2 J}{\partial S^2}(\mathrm{d}S)^2\right] \end{aligned}$$

which is reduced to the following partial differential equation

$$-\frac{\partial J}{\partial t} = -R_\mathrm{f} J(S,t) + \frac{\partial J}{\partial S} R_\mathrm{f} S + \frac{1}{2}\frac{\partial^2 J}{\partial S^2}\sigma^2 S^2\,,$$

while in the exercise region:

$$J(S,t) = K - S(t)\,.$$

For a perpetual option, note that the option price is not a function of time but of price only and therefore $\frac{\partial J}{\partial t} = 0$ and the option price is given by an ordinary differential equation of second order

$$0 = -R_f J(S) + \frac{dJ}{dS} R_f S + \frac{1}{2} \frac{d^2 J}{dS^2} \sigma^2 S^2 .$$

Assume that an interior solution exists, with an exercise at price S^*, $S(t) \le S^*$, $S^* \le K$. These specify the two boundary conditions required to solve our equation. In the exercise region $J(S^*) = K - S^*$, while for optimal exercise price $\frac{dJ(S)}{dS}\big|_{S=S^*} = -1$. Let the solution be of the type $J(S) = qS^{-\lambda}$. This reduces the differential equation to an equation we solve for $\lambda : \sigma^2 \frac{\lambda(\lambda+1)}{2} - \lambda R_f - R_f = 0$ and $\lambda^* = 2R_f/\sigma^2$. At the exercise boundary S^* however: $J(S^*) = qS^{*-\lambda^*} = K - S^*$; $dJ(S^*)/dS^* = -\lambda^* q S^{*-\lambda^*-1} = -1$. These two equations are solved for q and $S^*[0, 1]$ leading to: $S^* = \lambda^* K/(1+\lambda^*)$ and $q = (\lambda^*)^{\lambda^*} K^{1+\lambda^*}/(1+\lambda^*)^{1+\lambda^*}$ and the option price is thus:

$$J(S) = \left(\frac{(\lambda^*)^{\lambda^*} K^{1+\lambda^*}}{(1+\lambda^*)^{1+\lambda^*}} \right) S^{-\lambda^*} ,$$

$$\lambda^* = \frac{2R_f}{\sigma^2}, \quad S^* = \frac{\lambda^*}{1+\lambda^*} K .$$

Thus the solution of the perpetual American put is explicitly given by:

$$\begin{cases} \text{Sell if} & S \le S^* \\ \text{Hold if} & S > S^* . \end{cases}$$

When the option time is finite, say T, this problem is much more difficult to solve however. Further, for an American call, it is easily demonstrated that it equals in fact the price of the European call.

In discrete time, a similar approach may be applied if risk-neutral pricing can be applied. For example, consider again the binomial option model considered earlier. The stock can assume at time n the following prices: $H^i L^{n-i} x - K, i = 0, 1, 2, \ldots n+1$, where p is the probability of the price increasing (and $1-p$, the probability that it decreases) and x is the initial price (at time $t = 0$). The price of a put option with an option maturity at time n is then: $P_n(i) = \max(K - H^i L^{n-i} x, 0)$. Suppose that at time t the put is exercised, then the profit is $P_t(i)$. Alternatively, say that the option is not sold at t. In this case, by risk-neutral pricing, the price of the option is

$$P^*_{t+1}(i) = \frac{1}{1+R_f} \left[pP_{t+1}(i+1) + (1-p) P_{t+1}(i) \right] .$$

Thus, by the recurrence (Bellman) equation for this problem, we have:

$$P_t(i) = \max \left[K - H^i L^{n-i} x,\ P^*_{t+1}(i) \right]$$

with boundary condition

$$P_n(i) = \max \left(K - H^i L^{n-i} x, 0 \right) ,$$

and a solution can be found by numerical techniques.

47.5.5 Departures from the Black–Scholes Equation

Any departure from the basic assumptions underlying the Black–Scholes model will necessarily alter the Black–Scholes (BS) solution. For example, if volatility is stochastic, if interest rates are stochastic, if stock prices are not log-normal, etc. the solution will not be necessarily a BS solution. For many cases however, it is possible to construct replicating portfolios and thereby remain within the assumptions that markets are complete. Below we shall consider a number of such cases to demonstrate how we might proceed in different manners. These approaches however, are based on a valuation based on risk-neutral pricing (for example, *Hull* [47.32], *Jarrow* and *Rudd* [47.112]).

The BS option price depends, of course, on the assumptions made regarding the underlying price process. Further, it depends essentially on the stock volatility, which cannot be observed directly. For this reason, the relationships between the option price and volatility have been taken to reflect one or the other. In other words, given the options price and other observables (interest rates, strike price, etc.), the implied volatility is that volatility that solves the BS price equation: $\hat{C} = W(.|\sigma_{\text{imp}})$, where $\hat{C}$ is the current option price and $C = W(.|\sigma)$ is the theoretical option price with an implied volatility $\sigma = \sigma_{\text{imp}}$. Importantly, when the volatility is constant then σ_{imp} does not change as a function of T and K and it equals the true historical volatility. However, in practice when we calculate this implied volatility as a function of (T, K), we observe that there are some variations and therefore the BS model cannot be considered as the true market option price. Further, when the underlying price changes, the implied volatility can be a function of time as well and as a result, the implied volatility is a function $\sigma_{\text{imp}}(t)$. When we consider the options price variations as a function of the strike K, we observe a volatility skew which is the well-known volatility smile. Skewness is smaller however for at-the-money options (in which case, the BS model is

a good predictor of option price). The valuation of options in these circumstances is more difficult and there are, commensurably, numerous studies and extensions that calculate option prices. For example, [47.113, 114] consider transaction costs, [47.90, 115–117] consider option prices with stochastic volatility. *Nelson* and *Ramaswamy* [47.118] use discretized approximations and, even in physics, option pricing is considered as an application [47.119]. We consider below some well-known cases.

Option Valuation and Stochastic Volatility

When the underlying process has a stochastic volatility the replication of an option price by a portfolio requires special attention. We may proceed then by finding an additional asset to use (for example, another option with different maturity and strike price). Consider the following stochastic volatility process as an example

$$\begin{aligned} \mathrm{d}p/p &= \alpha\,\mathrm{d}t + \sqrt{V}\,\mathrm{d}w, & p(0) &= p_0 \\ \mathrm{d}V/V &= \mu\,\mathrm{d}t + \xi\,\mathrm{d}z, & V(0) &= v_0\,; \\ E(\mathrm{d}w\,\mathrm{d}z) &= \rho\,\mathrm{d}t\,, \end{aligned}$$

where (w, z) are two Brownian motions with correlation ρ. A call option would in this case be a function of both p and V, as we saw earlier for the BS option model, or $C(t, p, V)$. Application of Ito's lemma yields

$$\begin{aligned} \mathrm{d}C = \Bigg[& \frac{\partial C}{\partial t} + \frac{\partial C}{\partial p}\alpha p + \frac{\partial C}{\partial V}\mu V + \frac{1}{2}\frac{\partial^2 C}{\partial p^2}(\sigma p)^2 \\ & + \frac{1}{2}\frac{\partial^2 C}{\partial V^2}(\xi V)^2 + \frac{\partial^2 C}{\partial p \partial V}(\mu V + \rho\xi\sigma p V)\Bigg]\mathrm{d}t \\ & + \frac{\partial C}{\partial p}(\sigma p\,\mathrm{d}W) + \frac{\partial C}{\partial V}(\xi V\,\mathrm{d}Z)\,. \end{aligned}$$

The first term in the brackets is the deterministic component while the remaining ones are stochastic terms that ought to be nullified by an appropriate portfolio (i. e. hedged) if we are to apply a risk-neutral framework. Since there are two sources of risk, we require two assets in addition to the underlying asset price. For this reason, we construct a replication portfolio by: $X = n_1 p + n_2 C_2 + B$, $B = (X - n_1 p - n_2 C_2)$, where n_1, n_2 are the number of stock shares and another option with different maturity. In this case, proceeding as we have for the BS model, we have $\mathrm{d}C_1 = \mathrm{d}X$ and therefore

$$\begin{aligned} & \mathrm{d}C_1 - n_1\,\mathrm{d}p - n_2\,\mathrm{d}C_2 = rB\,\mathrm{d}t \\ & = r(C_1 - n_1 p - n_2 C_2)\mathrm{d}t \quad \text{or} \\ & (\mathrm{d}C_1 - rC_1\,\mathrm{d}t) - n_1\,(\mathrm{d}p - rp\,\mathrm{d}t) \\ & - n_2\,(\mathrm{d}C_2 - rC_2\,\mathrm{d}t) = 0 \end{aligned}$$

which provides the equations needed to determine a hedging portfolio given by

$$\begin{aligned} & \mathrm{d}\Phi_1 = (\mathrm{d}C_1 - rC_1\,\mathrm{d}t)\,, \quad \text{hence} \quad \Phi_1 = \mathrm{e}^{-rt}C_1\,; \\ & \mathrm{d}\Phi_2 = (\mathrm{d}p - rp\,\mathrm{d}t)\,, \quad \text{hence} \quad \Phi_2 = \mathrm{e}^{-rt}p\,, \\ & \mathrm{d}\Phi_3 = (\mathrm{d}C_2 - rC_2\,\mathrm{d}t)\,, \quad \text{hence} \quad \Phi_2 = \mathrm{e}^{-rt}C_2\,; \\ & \mathrm{d}\Phi_1 = n_1\,\mathrm{d}\Phi_2 + n_2\,\mathrm{d}\Phi_3\,. \end{aligned}$$

As a result,

$$\mathrm{d}\left(\mathrm{e}^{-rt}C_1\right) = n_1\,\mathrm{d}\left(\mathrm{e}^{-rt}p\right) + n_2\,\mathrm{d}\left(\mathrm{e}^{-rt}C_2\right)\,.$$

Further,

$$\begin{aligned} & \frac{\mathrm{d}C_1}{C_1} = \mu_1\,\mathrm{d}t + \sigma_1\,\mathrm{d}W_1, \quad \text{with} \quad \lambda_1 = \frac{(\mu_1 - r)}{\sigma_1}\,, \\ & \text{hence} \quad \frac{\mathrm{d}C_1}{C_1} - r\,\mathrm{d}t = \sigma_1\,(\lambda_1\,\mathrm{d}t + \mathrm{d}W_1) = \sigma_1\,\mathrm{d}\tilde{W}_1 \end{aligned}$$

while $(\lambda_1\,\mathrm{d}t + \mathrm{d}W_1) = \mathrm{d}\tilde{W}_1$, is the risk-neutral measure. If we apply a CAPM risk valuation, we have then:

$$\begin{aligned} \frac{1}{\mathrm{d}t}E\left(\frac{\mathrm{d}C_1}{C_1} - r\right) &= \sigma_1\lambda_1 \\ &= \left[\left(R_p - r\right)\beta_{cp} + (R_V - r)\,\beta_{cV}\right], \end{aligned}$$

where R_p is the stock mean return, $\beta_{cp} = \frac{p}{C_1}\frac{\partial C_1}{\partial p}\beta_p$ is the stock beta, R_V is the volatility drift while $\beta_{cV} = \frac{V}{C_1}\frac{\partial C_1}{\partial V}\beta_V$ is the beta due to volatility. We therefore obtain the following equations:

$$\begin{aligned} & \frac{1}{\mathrm{d}t}E\left(\frac{\mathrm{d}C_1}{C_1}\right) \\ & = r + \left[(\alpha - r)\,\frac{p}{C_1}\frac{\partial C_1}{\partial p}\beta_p + (\mu - r)\,\beta_V\frac{V}{C_1}\frac{\partial C_1}{\partial V}\right]; \\ & R_p = \alpha; \quad R_V = \mu, \quad \lambda_V = (\mu - r)\,V\beta_V\,, \end{aligned}$$

where λ_V is the risk premium associated with the volatility. Thus,

$$\frac{1}{\mathrm{d}t}E\left(\frac{\mathrm{d}C_1}{C_1}\right) = r + \left[(\alpha - r)\,\frac{p}{C_1}\frac{\partial C_1}{\partial p} + \frac{\lambda_V}{C_1}\frac{\partial C_1}{\partial V}\right]$$

which we equate to the option we are to value. Since,

$$\frac{1}{\mathrm{d}t}E\left(\frac{\mathrm{d}C}{C}\right) = r + \left[(\alpha - r)\,\frac{p}{C}\frac{\partial C}{\partial p} + \frac{\lambda_V}{C}\frac{\partial C}{\partial V}\right]$$

and obtain at last:

$$\begin{aligned} & \frac{1}{\mathrm{d}t}E\left(\frac{\mathrm{d}C}{C}\right) \\ & = \frac{1}{\mathrm{d}t}E\left[\frac{\partial C}{C\partial t}\mathrm{d}t + \frac{\partial C}{C\partial p}\mathrm{d}p + \frac{\partial C}{C\partial V}\mathrm{d}V\right. \\ & \quad + \frac{1}{2}\frac{\partial^2 C}{C\partial p^2}(\mathrm{d}p)^2 + \frac{1}{2}\frac{\partial^2 C}{C\partial V^2}(\mathrm{d}V)^2 \\ & \quad \left. + \frac{\partial^2 C}{C\partial p\partial V}(\mathrm{d}p\,\mathrm{d}V)\right] \end{aligned}$$

which leads to a partial differential equation we might be able to solve numerically. Or:

$$E\left[\frac{\partial C}{\partial t}\,\mathrm{d}t+\frac{\partial C}{\partial p}\,\mathrm{d}p+\frac{\partial C}{\partial V}\,\mathrm{d}V+\frac{1}{2}\frac{\partial^2 C}{\partial p^2}\,(\mathrm{d}p)^2 +\frac{1}{2}\frac{\partial^2 C}{\partial V^2}\,(\mathrm{d}V)^2+\frac{\partial^2 C}{\partial p\partial V}\,(\mathrm{d}p\,\mathrm{d}V)\right] =rC+\left[(\alpha-r)\,p\frac{\partial C}{\partial p}+\lambda_V\frac{\partial C}{\partial V}\right]$$

and explicitly,

$$\left[\frac{\partial C}{\partial t}+\frac{\partial C}{\partial p}rp+\frac{\partial C}{\partial V}\,(\mu V-\lambda_V)+\frac{1}{2}\frac{\partial^2 C}{\partial p^2}Vp^2 +\frac{1}{2}\frac{\partial^2 C}{\partial V^2}V^2\xi^2+\frac{\partial^2 C}{\partial p\partial V}pV^{3/2}\xi\rho-rC\right]=0\,,$$

where $\lambda_V=(\mu-r)V\beta_V$, as stated earlier. Of course the boundary constraints are then $C(T,\,p)=\max(p-K,0)$. The analytical treatment of such problems is clearly unlikely however (see also [47.120].

Options and Jump Processes [47.121]

The valuation of an option with a jump price process also involves two sources of risk, the diffusion and the jump. Merton considered such a problem for the following price process:

$$\frac{\mathrm{d}p}{p}=\alpha\,\mathrm{d}t+\sigma\,\mathrm{d}w+K\,\mathrm{d}Q\,,$$

where $\mathrm{d}Q$ is an adapted Poisson process with parameter $q\Delta t$. In other words, $Q(t+\Delta t)-Q(t)$ has a Poisson distribution function with mean $q\Delta t$ or for infinitesimal time intervals

$$\mathrm{d}Q=\begin{cases}1 & \text{w. p.}\quad q\,\mathrm{d}t\\ 0 & \text{w. p.}\quad (1-q)\,\mathrm{d}t\,.\end{cases}$$

Let $F=F(p,t)$ be the option price. When a jump occurs, the new option price is $F[p(1+K)]$. As a result,

$$\mathrm{d}F=\{F[p(1+K)]-F\}\,\mathrm{d}Q$$

when no jump occurs, we have

$$\mathrm{d}F=\frac{\partial F}{\partial t}\,\mathrm{d}t+\frac{\partial F}{\partial p}\,\mathrm{d}p+\frac{1}{2}\frac{\partial^2 F}{\partial p^2}(\mathrm{d}p)^2$$

and explicitly, letting $\tau=T-t$ be the remaining time to the exercise date, we have

$$\mathrm{d}F=\left(-\frac{\partial F}{\partial\tau}+\alpha p\frac{\partial F}{\partial p}+\frac{1}{2}p^2\sigma^2\frac{\partial^2 F}{\partial p^2}\right)\mathrm{d}t +p\sigma\frac{\partial F}{\partial p}\,\mathrm{d}w\,.$$

Combining these two equations, we obtain

$$\mathrm{d}F=a\,\mathrm{d}t+b\,\mathrm{d}w+c\,\mathrm{d}Q\,,$$
$$a=\left(-\frac{\partial F}{\partial\tau}+\alpha p\frac{\partial F}{\partial p}+\frac{1}{2}p^2\sigma^2\frac{\partial^2 F}{\partial p^2}\right);$$
$$b=p\sigma\frac{\partial F}{\partial p};\quad c=F[p(1+K)]-F$$

with

$$E(\mathrm{d}F)=(a+qc)\,\mathrm{d}t\quad\text{since}\quad E(\mathrm{d}Q)=q\,\mathrm{d}t\,.$$

To eliminate the stochastic elements (and thereby the risks implied) in this equation, we shall construct a portfolio consisting of the option and a stock. To eliminate the *Wiener risk*, i.e. the effect of "$\mathrm{d}w$", we let the portfolio Z consist of a future contract whose price is p, for which a proportion v of stock options is sold (which will be calculated such that this risk disappears). In this case, the value of the portfolio is

$$\mathrm{d}Z=p\alpha\,\mathrm{d}t+p\sigma\,\mathrm{d}w+pK\,\mathrm{d}Q -(va\,\mathrm{d}t+vb\,\mathrm{d}w+vc\,\mathrm{d}Q)\,.$$

If we set $v=p\sigma/b$ and insert in the equation above (as done by Black–Scholes), then we will eliminate the Wiener risk since:

$$\mathrm{d}Z=p(\alpha-\sigma a/b)\,\mathrm{d}t+(p\sigma-vb)\,\mathrm{d}w +p(K-\sigma c/b)\,\mathrm{d}Q$$

or

$$\mathrm{d}Z=p(\alpha-\sigma a/b)\,\mathrm{d}t+p(K-\sigma c/b)\,\mathrm{d}Q\,.$$

In this case, if there is no jump, the evolution of the portfolio follows the differential equation

$$\mathrm{d}Z=p(\alpha-\sigma a/b)\,\mathrm{d}t\quad\text{if there is no jump}\,.$$

However, if there is a jump, then the portfolio evolution is

$$\mathrm{d}Z=p(\alpha-\sigma a/b)\,\mathrm{d}t+p(K-\sigma c/b)\,.$$

Since the jump probability equals $q\,\mathrm{d}t$, we obviously have

$$\frac{E(\mathrm{d}Z)}{\mathrm{d}t}=p(\alpha-\sigma a/b)+pq(K-\sigma c/b)\,.$$

There remains a risk in the portfolio due to the jump. To eliminate it we can construct another portfolio using an option F' (with exercise price E') and a future contract such that the terms in $\mathrm{d}Q$ are eliminated as well. Then, constructing a combination of the first (Z) portfolio and the second portfolio (Z'), both sources of uncertainty

will be reduced. Applying the arbitrage argument (stating that there cannot be a return to a risk-less portfolio which is greater than the risk-less rate of return r) we obtain the proper proportions of the risk-less portfolio.

Alternatively, finance theory [and in particular, application of the capital asset pricing model (CAPM)] state that any risky portfolio has a rate of return in a small time interval $\mathrm{d}t$ which is equal the risk-less rate r plus a return premium for the risk assumed, which is proportional to its effect. Thus, using the CAPM we can write

$$E\frac{\mathrm{d}Z}{Z\,\mathrm{d}t} = r + \lambda\frac{p(K-\sigma c/b)}{Z}\,,$$

where λ is assumed to be a constant and expresses the market price for the risk associated with a jump. This equation can be analyzed further, leading to the following partial differential equation which remains to be solved (once the boundary conditions are specified):

$$-\frac{\partial F}{\partial \tau} + \left((\lambda - q)\left\{pK\frac{\partial F}{\partial p} - F[p(1+K)-F]\right\}\right) + \frac{1}{2}\frac{\partial^2 F}{\partial p^2}p^2\sigma^2 - rF = 0$$

with boundary condition

$$F(T) = \max\,[0,\, p(T) - E]\ .$$

Of course, for an American option, it is necessary to specify the right to exercise the option prior to its final exercise date, or

$$F(t) = \max\left[F^*(t),\, p(t) - E\right]\,,$$

where $F^*(t)$ is the value of the option which is not exercised at time t and given by the solution of the equation above. The solution of this equation is of course much more difficult than the Black–Scholes partial differential equation. Additional papers and extensions include for example, [47.122–124] as well as [47.125, 126].

Call Options on Bonds

Options on bonds are popular products traded in many financial markets. To value these options requires both an interest rate model and a term-structure bond price process. The latter is needed to construct the evolution over time of the underlying bond (say a T bond), which confers the right to exercise it at time $S < T$, in other words, the bond value at time S, whose value is given by an S-bond. To do so, we proceed in two steps: first we evaluate the term structure for a T and an S bond and then proceed to determine the value of a T bond at time S, which is used to replace the spot price at time S in the plain option model of Black–Scholes.

First we construct a hedging portfolio consisting of the two maturities S and T bonds ($S < T$). This portfolio will provide a synthetic rate, equated to the spot interest rate so that no arbitrage is possible. We denote by $k(t)$ this synthetic rate. For example, let the interest process

$$\mathrm{d}r = \mu(r,t)\,\mathrm{d}t + \sigma(r,t)\,\mathrm{d}W$$

and construct a portfolio of these two bonds, whose value is V, with:

$$\frac{\mathrm{d}V}{V} = n_S\frac{\mathrm{d}B(t,S)}{B(t,S)} + n_T\frac{\mathrm{d}B(t,T)}{B(t,T)}\,.$$

The T and S bond values are however, given by:

$$\frac{\mathrm{d}B(t,T)}{B(t,T)} = \alpha_T(r,t)\,\mathrm{d}t + \beta_T(r,t)\,\mathrm{d}W\,,$$

where as seen earlier in the previous section, the term structure is

$$\alpha_T(r,t) = \frac{1}{B(t,T)}\left[\frac{\partial B}{\partial t} + \frac{\partial B}{\partial r}\mu(r,T) + \frac{1}{2}\frac{\partial^2 B}{\partial r^2}\sigma^2(r,T)\right];$$
$$\beta_T(r,t) = \frac{1}{B(t,T)}\frac{\partial B}{\partial r}\sigma(r,T)\,.$$

Similarly, for an S-Bond,

$$\frac{\mathrm{d}B(t,S)}{B(t,S)} = \alpha_S(r,t)\,\mathrm{d}t + \beta_S(r,t)\,\mathrm{d}W$$

with

$$\alpha_S(r,t) = \frac{1}{B(t,S)}\left[\frac{\partial B}{\partial t} + \frac{\partial B}{\partial r}\mu(r,S) + \frac{1}{2}\frac{\partial^2 B}{\partial r^2}\sigma^2(r,S)\right];$$
$$\beta_S(r,t) = \frac{1}{B(t,S)}\frac{\partial B}{\partial r}\sigma(r,S)\,.$$

Replacing the terms for the mean rate of growth in the bond value and its diffusion, we have

$$\frac{\mathrm{d}V}{V} = (n_S\alpha_S + n_T\alpha_T)\,\mathrm{d}t + (n_S\beta_S + n_T\beta_T)\,\mathrm{d}W\,.$$

For a risk-less portfolio we require that the portfolio volatility be null. Further, since initially the portfolio was worth only one dollar, we obtain two equations in two unknowns (the portfolio composition), which we can solve

$$\begin{cases} n_S\beta_S + n_T\beta_T = 0 \\ n_S + n_T = 1 \end{cases} \Rightarrow \begin{cases} n_S = \frac{\beta_T}{\beta_T - \beta_S} \\ n_T = -\frac{\beta_S}{\beta_T - \beta_S}\,. \end{cases}$$

The risk-less portfolio thus has a rate of growth which we call the synthetic rate, or

$$\frac{\mathrm{d}V}{V} = \left(\frac{\beta_T\alpha_S - \beta_S\alpha_T}{\beta_T - \beta_S}\right)\mathrm{d}t = k(t)\mathrm{d}t\,.$$

This rate is equated to the spot rate as stated above, providing thereby the following equality:

$$\left(k(t) = \frac{\beta_T\alpha_S - \beta_S\alpha_T}{\beta_T - \beta_S}\right) \Rightarrow k(t) = r(t) \quad \text{or}$$
$$\frac{r(t)-\alpha_S}{\beta_S} = \frac{r(t)-\alpha_T}{\beta_T} = \lambda(t)$$

with $\lambda(t)$ the price of risk per unit volatility. Each bond with maturity T and S has at its exercise time a one dollar denomination, the value of each of these (S and T) bonds is given by

$$0 = \frac{\partial B_T}{\partial t} + \frac{\partial B_T}{\partial r}\left[\mu(r,T) - \lambda\beta_T\right] + \frac{1}{2}\frac{\partial^2 B}{\partial r^2}\beta_T^2 - rB_T\,;$$
$$B(r,T) = 1\,,$$
$$0 = \frac{\partial B_S}{\partial t} + \frac{\partial B_S}{\partial r}\left[\mu(r,S) - \lambda\beta_S\right] + \frac{1}{2}\frac{\partial^2 B}{\partial r^2}\beta_S^2 - rB_S\,;$$
$$B(r,S) = 1\,.$$

Given a solution to these two equations, we define the option value of a call on a T bond with $S < T$ and strike price K, to be:

$$X = \max\left[B(S,T) - K, 0\right]$$

where $B(S,T)$ is the price of the T bond at time S. $B(S,T)$ is of course found by solving for the term structure and then equating $B(r,S,T) = B(S,T)$. To simplify matters, say that the solution (valued at time t) for the T bond is given by $F(t,r,T)$, then at time S, this value is $F(S,r,T)$, to which we equate $B(S,T)$. In other words,

$$X = \max\left[F(S,r,T) - K, 0\right]\,.$$

Now, if the option price is $P(.)$, then as we have seen in the plain vanilla model in the previous chapter, the value of the bond is found by solving for P in the following partial differential equation

$$0 = \frac{\partial P}{\partial t} + \mu(r,t)\frac{\partial P}{\partial r} + \sigma^2\frac{1}{2}\frac{\partial^2 P}{\partial r^2} - rP\,;$$
$$P(S,r) = \max\left[F(S,r,T) - K, 0\right]\,.$$

Although this might be a difficult problem to solve numerically, there are mathematical tools that allow the finding of such solution. A special case of interest consists of using the term structure model in the problem above, also called the affine term structure (ATS) model, which was indicated earlier in the previous section. In this case, we have:

$$F(t,r,T) = \mathrm{e}^{A(t,T) - rD(t,T)}\,,$$

where $A(.)$ and $D(.)$ are calculated by the term structure model while the option valuation model becomes

$$0 = \frac{\partial P}{\partial t} + \mu(r,t)\frac{\partial P}{\partial r} + \sigma^2\frac{1}{2}\frac{\partial^2 P}{\partial r^2} - rP\,;$$
$$P(S,r) = \max\left[\mathrm{e}^{A(S,T) - rD(S,T)} - K, 0\right]\,.$$

Again, these problems are mostly solved by numerical or simulation techniques.

47.6 Incomplete Markets and Implied Risk-Neutral Distributions

Markets are incomplete when we cannot generate any random cash flow by an appropriate portfolio strategy. The market is then deemed *not rich enough*. Technically, this may mean that the number of assets that make up a portfolio is smaller than the number of risk sources plus one. In the Arrow–Debreu framework seen earlier, this corresponds to rank condition $\boldsymbol{D} \equiv M$, providing a unique solution to the linear pricing equation. If markets are not complete or close to it, financial markets cannot uniquely value assets and there may be opportunities for arbitrage. In such circumstances, financial markets may be perceived as too risky, perhaps *chaotic* and therefore profits may be too volatile, the risk premium would then be too high and investment horizons smaller, thereby reducing investments. Finally, contingent claims may have an infinite number of prices (or equivalently an infinite number of martingale measures). As a result, valuation becomes, forcibly, utility based or based on some other mechanism, which is *subjective* rather than based on the market mechanism. *Ross* [47.104] has pointed out that

> *it is a truism that markets are not complete in the obvious sense that there exist contingencies that have no clearly associated market prices, but, it is not always immediately clear how meaningful this is*

for either pricing or efficiency. Some contingencies may have no markets but may be so trivial as to be insurable in the sense that their associated events are small and independent of the rest of the economy, others, may be replicable while not directly traded

Thus, even if markets are incomplete, we may be able to determine some mechanism which will still allow an approach to asset pricing. Of course, this will require the exact sense of the market incompleteness and determine a procedure to complete it. Earlier, we pointed out some sources of incompleteness, but these are not the only ones. It may arise because of lack of liquidity (leading to market-makers bid/ask spreads for which trading micromodels are constructed); it may be due to excessive friction defined in terms of taxes, indivisibility of assets, varying rates for lending and borrowing (such as no short sales and various portfolio constraints); it could be due to transaction costs and to information asymmetries (insider trading, leading to mis-pricing) indicating that one dimension along which markets are clearly incomplete is that of time. Most traded derivatives markets – futures and options – extend only a few years at most in time and, even when they are formally quoted further out, there is generally little or no liquidity in the far contracts. Yet, it is becoming increasingly common in the world of derivatives to be faced with long-run commitments while liquid markets only provide trading opportunities over shorter run horizons. These are by no means the only situations that lead to incomplete markets. Choice – too much or too little of it – may also induce incompleteness. Rationality implies selecting the best alternative but, when there are too many or the search cost is too high, often investors seek "satisficing solutions" (in the sense of Herbert A. Simon). Barry Schwartz in an article in Scientific American (April 2004) points out, for example, that too much choice may induce an ill feeling and therefore to suboptimal decisions. In addition, regrets [47.17, 36, 37, 127–134], search and other costs can also affect investors' rationality (in the sense of finance's fundamental theory). The Financial Times has pointed out that some investment funds seek to capitalize on human frailties to make money. For example: are financial managers human? Are they always rational, mimicking Star Trek's Mr. Spock? Are they devoid of emotions and irrationality? Psychological decision-making processes integrated in economic rationales have raised serious concerns regarding the rationality axioms of decision-making (DM) processes. There are of course, many challenges to reckon with in understanding human behavior. Some of these include: thought processes based on decision making-approaches focusing on the one hand on the big pictures versus compartmentalization; the effects of under- versus overconfidence on decision making; the application of heuristics of various sorts applied in trading and DM processes. These heuristics are usually based on simple rules. In general, the violation of the assumptions made regarding the definition of rational decision makers and decision makers' psychology are very important issues to reckon with when asset prices in incomplete markets are to be defined (some related references include [47.87, 133, 135–143] and [47.144]).

Networks of hedge funds, communicating with each other and often coordinated explicitly and implicitly into speculative activities can lead to market inefficiencies, thus contradicting a basic hypothesis in finance which assumes that agents are price-takers. In networks, information exchange provides a potential for information asymmetries or at least delays in information [47.145, 146]. In this sense, the existence of networks in their broadest and weakest form may also be a symptom of market breakdown. Analysis of competition in the presence of moral hazard and adverse selection emphasizes the substantial differences between trading of contracts and of contingent commodities. The profit associated with the sale of one unit of a (contingent) good depends then only on its price. Further, the profitability of the sale of one contract may also depend on the identity of the buyer. Identity matters either because the buyer has bought other contracts (the exclusivity problem) or because profitability of the sales depends on the buyer's characteristics, which is also known as the screening problem. Do these issues relate to financial intermediation? Probably yes. Thus financial markets theory has to give a key role to informational and power asymmetries to better understand prices and how they differ from the social values of commodities.

In the presence of proportional transaction costs, no perfect replication strategy is in general available. It is necessary then to define other pricing criteria. Some explicit solutions to the multivariate super-replication problem under proportional transaction costs using a utility maximization problem have been suggested, however. The implication of these and related studies are that super-replication prices are highly expensive and are not acceptable for practical purposes.

Quantitative modeling provides also important sources of incompleteness and at the same time seeks to represent such incompleteness. Research in modeling uncertainty and studies that seek to characterize

mathematically randomness, which can be also sources of incompleteness. We use a number of quantitative approaches including: Brownian motion; long-run memory models and chaos-related approaches ([47.147]; heavy (fat) tails (stable) distributions that, unlike the normal distribution, have very large or infinite variance. These approaches underpin some confusion regarding the definition of uncertainty and how it can be structured in a theory of economics and finance. "G-D does not play dice" (Einstein), "Probabilities do not exist" (Bruno de Finetti) etc. are statements that may put some doubt on the commonly used random-walk hypothesis which underlies martingales finance and markets' efficiency (for additional discussion see [47.148, 149]). These topics are both important and provide open-ended avenues for further and empirical research. In particular, issues of long-run memory and chaos (inducing both very large variances and skewness) are important sources of incompleteness that have been studied intensively [47.150–157]. To deal formally with these issues, *Mandelbrot* and co-workers have introduced both a methodology based on fractal stochastic processes and application of Hurst's 1951 R/S (a range to starndard deviation statistic) methodology (for example, see [47.158–168]). Applications to finance include [47.169–178]). A theoretical extension based on the range process and R/S analysis based on the inverse range process can be found in [47.179, 180] as well as [47.181–183] and [47.184]. Finally, continuous stochastic processes to which risk-neutral pricing can be applied may become incomplete when they are discretized for numerical analysis purposes. Below we shall consider a number of pricing problems in incomplete markets to highlight some of the approaches to asset pricing.

47.6.1 Risk and the Valuation of a Rated Bond

Bonds are not always risk-free. Corporations emitting bonds may default, governments can also default in the payment of their debts, etc. For this reason, rating agencies sell their services and rate firms to assure buyers of the risks they assume when buying the bond. For this reason, the pricing of rated bonds is an important aspect of asset pricing. Below we shall show how such bonds may be valued (see also the earlier bond section). Consider first a non-default coupon-bearing rated bond with a payment of one dollar at maturity T. Further, define the bond m-ratings matrix by a Markov chain $[p_{ij}]$ where $0 \le p_{ij} \le 1$, $\sum_{j=1}^{m} p_{ij} = 1$ denotes the probability that a bond rated i in a given year will be rated j the following one. Discount factors are a function of the rating states, thus a bond rated i has a spot yield R_{it}, $R_{it} \le R_{jt}$ for $i < j$ at time t. As a result, a bond rated i at time t and paying a coupon c_{it} at this time has, as we saw earlier, a value given by

$$B_i(t,T) = c_{it} + \sum_{j=1}^{m} \frac{p_{ij}}{1+R_{jt}} B_j(t+1,T)\,;$$
$$B_{i,T} = \ell_i\,, \quad i = 1,2,3,\ldots m\,,$$

where ℓ_i is the nominal value of a bond rated i at maturity. Usually, $\ell_i = 1$, $i = 1,2,\ldots m-1$, and $\ell_m = 0$ where m is the default state, and there is no recovery in case of default. In vector notation, we have

$$\boldsymbol{B_t} = \boldsymbol{c_t} + \boldsymbol{F_t B_{t+1}}; \quad \boldsymbol{B_T} = \boldsymbol{L}\,,$$

where the matrix $\boldsymbol{F_t}$ has entries $[p_{ij}/(1+R_{jt})]$ and $\boldsymbol{L}$ is a diagonal matrix of entries ℓ_i, $i = 1,2,\ldots,m$. For a zero-coupon bond, we have $\boldsymbol{B}_t = \prod_{k=t}^{T} \boldsymbol{F_k}$. By the same token, rated bonds discounts $q_{it} = 1/(1+R_{it})$ are found by solving the matrix equation

$$\begin{pmatrix} q_{1t} \\ q_{2t} \\ \cdots \\ \cdots \\ q_{mt} \end{pmatrix} = \begin{pmatrix} p_{11}B_{1,t+1} & p_{12}B_{2,t+1} & \cdots\ \cdots & p_{1m}B_{m,t+1} \\ p_{21}B_{1,t+1} & p_{22}B_{2,t+1} & & p_{2m}B_{m,t+1} \\ \cdots & & & \\ \cdots & & & \\ p_{m1}B_{1,t+1} & p_{m2}B_{2,t+1} & & p_{mm}B_{m,t+1} \end{pmatrix}^{-1} \times \begin{pmatrix} B_{1,t} - c_{1t} \\ B_{2,t} - c_{2t} \\ \cdots \\ \cdots \\ B_{m,t} - C_{mt} \end{pmatrix},$$

where at maturity T, $B_i(T,T) = \ell_i$. Thus, in matrix notation, we have: $\bar{\boldsymbol{q}}_t = \boldsymbol{\Gamma}_{t+1}^{-1}(\boldsymbol{B_t} - \boldsymbol{c_t})$. Note that, one period prior to maturity, we have: $\bar{\boldsymbol{q}}_{T-1} = \boldsymbol{\Gamma}_T^{-1}(\boldsymbol{B}_{T-1} - \boldsymbol{c}_{T-1})$, where $\boldsymbol{\Gamma}_T$ is a matrix with entries $p_{ij}B_j(T,T) = p_{ij}\ell_j$.

In order to price the rated bond, consider a portfolio of rated bonds consisting of N_i, $i = 1,2,3\ldots,m$ bonds rated i, each providing ℓ_i dollars at maturity. Let the portfolio value at maturity be equal one dollar. Namely,

$$\sum_{i=1}^{m} N_i \ell_i = 1\,.$$

One period (year) prior to maturity, such a portfolio would be worth $\sum_{i=1}^{m} N_i B_i(T-1,T)$ dollars. By the same token, if we denote by $R_{\mathrm{f},T-1}$ the risk-free discount rate for one year, then assuming no arbitrage, one period

prior to maturity, we have:

$$\sum_{i=1}^{m} N_i B_i(T-1,T) = \frac{1}{1+R_{\mathrm{f},T-1}};$$
$$B_i(T-1,T) = c_{it} + \sum_{j=1}^{m} q_{jt} p_{ij} B_j(T,T);$$
$$B_i(T,T) = \ell_i, \quad i = 1, 2 \ldots, m$$

with $q_{jt} = 1/(1+R_{j,t})$ and $R_{j,t}$ is the one-period discount rate applied to a j rated bond. Assuming no arbitrage, such a system of equations will hold for any of the bonds periods and therefore, we can write the following no-arbitrage condition

$$\sum_{i=1}^{m} N_i B_i(T-k,T) = \frac{1}{\left(1+R_{\mathrm{f},T-k}\right)^k}$$
$$k = 0, 12, 3, \ldots, T,$$

where $R_{\mathrm{f},T-k}$, $k = 1, 2, 3, \ldots$, is the risk-free rate term structure which provides a system of $T+1$ equations spanning the bond life. In matrix notation this is given by

$$\boldsymbol{N}\boldsymbol{B}_{\boldsymbol{T}-k} = \frac{1}{\left(1+R_{\mathrm{f},T-k}\right)^k},$$
$$k = 0, 1, 2, \ldots, T; \quad \boldsymbol{N} = (N_1, N_2, \ldots, N_m);$$
$$\boldsymbol{B}_{\boldsymbol{T}-k} = (B_{1,T-k}, B_{2,T-k}, \ldots, B_{m,T-k}).$$

As a result, assuming that the bond maturity is larger than the number of ratings ($T \geq m+1$), the hedging portfolio of rated bonds is found by a solution of the system of linear equations above, leading to the unique solution:

$$\boldsymbol{N}^* = \Im^{-1}\boldsymbol{\Omega},$$

where $\Im$ is the matrix transpose of $[B_{i,T-j+1}]$ and $\boldsymbol{\Omega}$ is a column vector with entries $\left[1/(1+R_{\mathrm{f},T-s})^s\right]$, $s = 0, 1, 2 \ldots m-1$. Explicitly, we have:

$$\begin{pmatrix} N_1 \\ N_2 \\ \ldots \\ \ldots \\ N_m \end{pmatrix} = \begin{pmatrix} B_{1,T} & B_{2,T} & B_{3,T} & \ldots & B_{m,T} \\ B_{1,T-1} & B_{2,T-1} & B_{3,T-1} & \ldots & B_{m,T-1} \\ \ldots & & & & \ldots \\ \ldots & & & & \ldots \\ B_{1,T-m} & B_{2,T-m} & B_{3,T-m} & \ldots & B_{m,T-m} \end{pmatrix}^{-1} \times \begin{pmatrix} 1 \\ 1/(1+R_{\mathrm{f},T-1})^1 \\ \ldots \\ \ldots \\ 1/(1+R_{\mathrm{f},T-m})^m \end{pmatrix}.$$

Thus, a condition for no arbitrage is given by the system of nonlinear equations

$$\Im^{-1}\boldsymbol{\Omega}\boldsymbol{B}_{\boldsymbol{T}-k} = \frac{1}{\left(1+R_{\mathrm{f},T-k}\right)^k}$$
$$k = m, m+1, \ldots, T.$$

For example, for a zero-coupon rated bond and stationary short discounts, we have $\boldsymbol{B}_{t-k} = (\boldsymbol{F})^k$ and therefore, the no-arbitrage condition becomes:

$$\Im^{-1}\boldsymbol{\Omega}\boldsymbol{F}^k = \frac{1}{\left(1+R_{\mathrm{f},T-k}\right)^k} \quad k = m, m+1, \ldots, T$$

where $\boldsymbol{F}$ has entries $q_j p_{ij}$. This system of equations therefore provides $T+1-m$ equations applied to determining the bond ratings short (one-period) discount rates q_j. Our system of equations may be over- or under-identified for determining the ratings discount rates under our no-arbitrage condition, however. Of course, if $T+1-m = m$, we have exactly m additional equations we can use to solving the discount rates uniquely (albeit, these are nonlinear equations and can only be solved numerically).

Otherwise, the rated bond market is incomplete and we must proceed to some approach that can, nevertheless, provide an estimate of the discount rates. We use for convenience a sum of squared deviations from the rated bond arbitrage condition, in which case we minimize the following expression:

$$\min_{0 \leq q_1, q_2, \ldots q_{m-1}, q_m \leq 1} \sum_{k=m}^{T} \left(\Im^{-1}\boldsymbol{\Omega}\boldsymbol{B}_{\boldsymbol{T}-k} - \frac{1}{\left(1+R_{\mathrm{f},T-k}\right)^k} \right)^2.$$

Further additional constraints, reflecting expected and economic rationales of the ratings discounts q_j, might be added, such as:

$$0 \leq q_j \leq 1 \quad \text{and}$$
$$0 \leq q_m \leq q_{m-1} \leq q_{m-2} \leq q_{m-3}, \ldots \leq q_2 \leq q_1 \leq 1.$$

These are typically nonlinear optimization problems however. A simple two-rating example highlights some of the complexities in determining both the hedging portfolio and the ratings discounts provided the risk-free term structure is given. When the bond can default, we have to proceed as shown below.

47.6.2 Valuation of Default-Prone Rated Bonds

Let the first time n, a bond rated initially i, is rated j and let the probability of such an event be $f_{ij}(n)$. This probability equals the probability of not having gone through a j-th rating in prior transitions and be rated j at time n. For transition in one period, this is equal the transition bond rating matrix (S&P or Moody's matrix, as stated earlier), while for a transition in two periods it equals the probability of transition in two periods conditional on not having reached rating j in the first period. In other words, we have:

$$f_{ij}(1) = p_{ij}(1) = p_{ij}; \quad f_{ij}(2) = p_{ij}(2) - f_{ij}(1)p_{jj}$$

and generally, by recursion,

$$f_{ij}(n) = p_{ij}(n) - \sum_{k=1}^{n-1} f_{ij}(k)p_{jj}(n-k)\,.$$

The probability of a bond defaulting (and not defaulting) prior to time n is thus,

$$F_{km}(n-1) = \sum_{j=1}^{n-1} f_{km}(j)\,;$$
$$\bar{F}_{km}(n-1) = 1 - F_{km}(n-1)\,.$$

At present, denote by $\Phi_i(n)$ the probability that the bond is rated i at time n. In vector notation we write $\bar{\Phi}(n)$. Thus given the rating matrix $[\boldsymbol{P}]$, we have:

$$\bar{\Phi}(n) = [\boldsymbol{P}]^{'}\bar{\Phi}(n-1)\,,$$
$$n = 1, 2, 3, \ldots \quad \text{and} \quad \bar{q}(0) \text{ given}\,,$$

where $[\boldsymbol{P}]^{'}$ is the matrix transpose. Thus, at n, $\bar{\Phi}(n) = [\boldsymbol{P}^{'}]^n\bar{\Phi}(0)$. The present value of a coupon payment at time n (given that there was no default at this time) is therefore discounted at the yield $R_{j,n}$, $q_{j,n} = 1/(1+R_{j,n})$ if the bond is rated j. In other words, its present value is

$$\sum_{j=1}^{m-1} c_{j,n}q_{j,n}^n\Phi_{j,n}; \quad \Phi_{j,n} = \sum_{i=1}^{m-1}\Phi_{i,0}p_{ij}^{(n)}\,,$$

where $p_{ij}^{(n)}$ is the ij-th entry of the transposed power matrix $[\boldsymbol{P}^{'}]^n$ and $\Phi_{i,0}$ is the probability that initially the bond is rated i.

When a coupon-bearing default bond rated i at time s defaults at time $s+1$, $T-(s+1)$ periods before maturity with probability $f_{im}(s+1-s)$, we have a value:

$$V_{s,i} = \left(c_{i,T-s} + q_i\ell_{m,T-(s+1)}\right) \text{ w. p. } f_{im}(1)\,.$$

If such an event occurs at time $s+2$, with probability $f_{im}(s+2-s) = f_{im}(2)$, we have:

$$V_{s,i} = \left(c_{i,T-s} + \sum_{k=1}^{m-1} q_k c_{k,T-(s+1)}\Phi_{k,(s+1)-s} + q_i^2\ell_{m,T-(s+2)}\right) \text{ w. p. } f_{im}(2)\,,$$

where $\Phi_{k,1} = \sum_{i=1}^{m-1}\Phi_{i,0}p_{ik}^{(1)}$ and $\Phi_{i,0}$ is a vector whose entries are all zero except at i (since at s we conditioned the bond value to a rating i). By the same token three periods hence and prior to maturity, we have

$$V_{s,i} = \left(c_{i,T-s} + \sum_{k=1}^{m-1} q_k c_{k,T-(s+1)}\Phi_{i,0}p_{ik}^{(1)} + \sum_{k=1}^{m-1} q_k^2 c_{k,T-(s+2)}\Phi_{i,0}p_{ik}^{(2)} + q_i^3\ell_{m,T-(s+3)}\right) \text{ w. p. } f_{im}(3)\,.$$

And generally, for any period prior to maturity,

$$V_{s,i} = \left(c_{i,T-s} + \sum_{\theta=1}^{\tau-1}\sum_{k=1}^{m-1} q_k^{\theta} c_{k,T-(s+\theta)}\Phi_{i,0}p_{ik}^{(\theta)} + q_i^{\tau}\ell_{m,T-(s+\tau)}\right) \text{ w. p. } f_{im}(\tau)\,.$$

In expectation, if the bond defaults prior to its maturity, its expected price at time s,

$$EB_{i,\mathrm{D}}(s,T) = c_{i,T-s} + \sum_{\tau=1}^{T-s}\left(q_i^{\tau}\ell_{m,T-(s+\tau)} + \sum_{\theta=1}^{\tau-1}\sum_{k=1}^{m-1} q_k^{\theta} c_{k,T-(s+\theta)}\Phi_{i,0}p_{ik}^{(\theta)}\right) \times f_{im}(\tau)\,,$$

where $\ell_{m,T-j}$ is a portion of the bond nominal value that the bondholder recuperates when the bond defaults and which is assumed to be a function of the time remaining for the bond to be redeemed. And therefore, the price of

such a bond is:

$$B_{i,\mathrm{ND}}(s,T)=\left(c_{i,T-s}+\sum_{k=1}^{m-1}q_k^{T-s}\ell_k\Phi_{i,0}p_{ik}^{(T-s)}+\sum_{\theta=1}^{T-s-1}\sum_{k=1}^{m-1}q_k^{\theta}c_{k,T-(s+\theta)}\Phi_{i,0}p_{ik}^{(\theta)}\right)\times\left[1-\sum_{u=1}^{T-s}f_{im}(u)\right]$$

where ℓ_i denotes the bond nominal value at redemption when it is rated i. Combining these sums, we obtain the price of a default-prone bond rated i at time s

$$\begin{aligned}B_i(s,T)=c_{i,T-s}+&\left(c_{i,T-s}+\sum_{k=1}^{m-1}q_k^{T-s}\ell_k\Phi_{i,0}p_{ik}^{(T-s)}+\sum_{\theta=1}^{T-s-1}\sum_{k=1}^{m-1}q_k^{\theta}c_{k,T-(s+\theta)}\Phi_{i,0}p_{ik}^{(\theta)}\right)\times\left[1-\sum_{u=1}^{T-s}f_{im}(u)\right]\\&+\sum_{\tau=1}^{T-s}\left(q_i^{\tau}\ell_{m,T-(s+\tau)}+\sum_{\theta=1}^{\tau-1}\sum_{k=1}^{m-1}q_k^{\theta}c_{k,T-(s+\theta)}\Phi_{i,0}p_{ik}^{(\theta)}\right)f_{im}(\tau)\,.\end{aligned}$$

Finally, for a zero-coupon bond, this is reduced to

$$B_i(s,T)=c_{i,T-s}+\left(\sum_{k=1}^{m-1}q_k^{T-s}\ell_k\Phi_{i,0}p_{ik}^{(T-s)}\right)\times\left[1-\sum_{u=1}^{T-s}f_{im}(u)\right]+\sum_{\tau=1}^{T-s}\left(q_i^{\tau}\ell_{m,T-(s+\tau)}\right)f_{im}(\tau)\,.$$

To determine the price (discounts rates) for a default-prone rated bond we can proceed as before by constructing a hedging portfolio consisting of $N_1, N_2, \ldots, N_{m-1}$ shares of bonds rated $i=1,2,\ldots,m-1$. Again, let $R_{\mathrm{f},T-u}$ be the risk-free rate when there are u periods left to maturity. Then, assuming no arbitrage and given the term structure risk-free rate, we have:

$$\sum_{i=1}^{m-1}N_iB_i(s,T)=\frac{1}{\left(1+R_{\mathrm{f},T-s}\right)^s},\quad s=0,1,2,\ldots$$

with $B_i(s,T)$ defined above. Note that the portfolio consists of only $m-1$ rated bonds and therefore, we have in fact $2m-1$ variables to be determined based on the risk-free term structure. Assuming that our system is over- (or under-)determined, we are reduced to solving the following minimum squared deviations problem:

$$\min_{\substack{0\le q_1\le q_2\le\ldots\le q_{m-1}\le 1;\\ N_1,N_2,N_3\ldots,N_{m-1}}}\sum_{s=0}^{T}\left[\sum_{k=1}^{m-1}N_kB_k(s,T)-\frac{1}{\left(1+R_{\mathrm{f},T-s}\right)^s}\right]^2$$

subject to:

$$\begin{aligned}B_i(s,T)=c_{i,T-s}+&\left(c_{i,T-s}+\sum_{k=1}^{m-1}q_k^{T-s}\ell_k\Phi_{i,0}p_{ik}^{(T-s)}+\sum_{\theta=1}^{T-s-1}\sum_{k=1}^{m-1}q_k^{\theta}c_{k,T-(s+\theta)}\Phi_{i,0}p_{ik}^{(\theta)}\right)\times\left[1-\sum_{u=1}^{T-s}f_{im}(u)\right]+\sum_{\tau=1}^{T-s}\left(q_i^{\tau}\ell_{m,T-(s+\tau)}\right.\\&\left.+\sum_{\theta=1}^{\tau-1}\sum_{k=1}^{m-1}q_k^{\theta}c_{k,T-(s+\theta)}\Phi_{i,0}p_{ik}^{(\theta)}\right)f_{im}(\tau)\,.\end{aligned}$$

This is of course a nonlinear optimization problem which can be solved analytically with respect to the hedged portfolio, and use the remaining equations to calculate the ratings discount rates. A solution can be found numerically. Such an analysis is a straightforward exercise however. Below we consider some examples.

Example 47.5 (a two-rated default bond): Consider a two-rated zero-coupon bond and define the transition matrix

$$\boldsymbol{P}=\begin{pmatrix}p & 1-p\\ 0 & 1\end{pmatrix}\quad\text{with}\quad\boldsymbol{P}^n=\begin{pmatrix}p^n & 1-p^n\\ 0 & 1\end{pmatrix}.$$

The probability of being in one of the two states after n periods is $(p^n, 1-p^n)$. Further,

$$\begin{aligned}f_{12}(1)&=1-p\,;\\ f_{12}(2)&=p_2^{(2)}-(1)f_{12}(1)=1-p^2-(1-p)\\&=p(1-p)\,.\end{aligned}$$

Thus, for a non-coupon-paying bond, we have:

$$B_i(s,T) = c_{i,T-s} + q^{T-s}\ell\left[1 - \sum_{u=1}^{T-s} f_{12}(u)\right] + \sum_{\tau=1}^{T-s}\left(q^{\tau}\ell_{m,T-(s+\tau)}\right) f_{12}(\tau)\,.$$

In particular,

$$\begin{aligned}
B_1(T,T) &= \ell\,,\\
B_1(T-1,T) &= q\ell\,[1-f_{12}(1)] + q\ell_{m,0} f_{12}(1)\,,\\
B_1(T-2,T) &= q^2\ell\,[1-f_{12}(1)-f_{12}(2)]\\
&\quad + q\ell_{m,1} f_{12}(\tau) + q^2\ell_{m,0} f_{12}(2)\,,\\
B_1(T-3,T) &= q^3\ell\,[1-f_{12}(1)-f_{12}(2)-f_{12}(3)]\\
&\quad + \left(q\ell_{m,2}\right) f_{12}(1) + q^2\ell_{m,1} f_{12}(2)\\
&\quad + q^3\ell_{m,0} f_{12}(3)\,.
\end{aligned}$$

If we have a two-year bond, then the condition for no arbitrage is

$$\begin{aligned}
NB_1(T,T) &= N\ell = 1 \quad \text{and} \quad N = 1/\ell\,,\\
NB_1(T-1,T) &= \frac{1}{1+R_{\mathrm{f},T-1}} \Rightarrow 1 + R_{1,T-1}\\
&= \frac{1+R_{\mathrm{f},T-1}}{1-\left(1-\ell_{m,0}/\ell\right) f_{12}(1)}\,.
\end{aligned}$$

If we have a two-year bond, then the least quadratic deviation cost rating can be applied. Namely,

$$\min_{0\le q\le 1} \mathbb{Q} = \left[(1/\ell)B\,(T-1,T) - \left(q_{f,T-1}\right)\right]^2 + \left[(1/\ell)B\,(T-2,T) - \left(q_{f,T-2}\right)\right]^2\,.$$

Subject to:

$$\begin{aligned}
B_1(T-1,T) &= q\ell\,[1-f_{12}(1)] + q\ell_{m,0} f_{12}(1),\\
B_1(T-2,T) &= q^2\ell\,[1-f_{12}(1)-f_{12}(2)]\\
&\quad + q\ell_{m,1} f_{12}(\tau) + q^2\ell_{m,0} f_{12}(2)\,.
\end{aligned}$$

Leading to a cubic equation in q that we can solve by the usual methods. Rewriting the quadratic deviation in terms of the discount rate yields:

$$\min_{0\le q\le 1} \left(q\left\{1-f_{12}(1)\left[1-(\ell_{m,0}/\ell)\right]\right\} - \left(q_{f,T-1}\right)\right)^2 + \left\{q^2\left[1-f_{12}(1)-(1-\ell_{m,0}/\ell) f_{12}(2)\right] + q(\ell_{m,1}/\ell) f_{12}(1) - \left(q_{f,T-2}\right)\right\}^2\,.$$

Set

$$\begin{aligned}
a &= \left\{1-f_{12}(1)\left[1-(\ell_{m,0}/\ell)\right]\right\}\,;\\
b &= \left[1-f_{12}(1)-(1-\ell_{m,0}/\ell) f_{12}(2)\right]\,;\\
c &= (\ell_{m,1}/\ell) f_{12}(1)\,.
\end{aligned}$$

Then an optimal q is found by solving the equation

$$2q^3b^2 + 3q^2bc + q\left(a^2 - 2bq_{f,T-2} + c^2\right) - \left(aq_{f,T-1} + cq_{f,T-2}\right) = 0\,.$$

Assume the following parameters,

$$\begin{aligned}
&R_{\mathrm{f},T-1} = 0.07; \quad R_{\mathrm{f},T-1} = 0.08, \quad p = 0.8,\\
&\ell = 1, \quad \ell_{m,0} = 0.6, \quad \ell_{m,1} = 0.4\,.
\end{aligned}$$

In this case, $f_{12}(1) = 1-p = 0.2$ and $f_{12}(2) = p(1-p) = 0.16$. For a one-period bond, we have

$$1 + R_{1,T-1} = \frac{1+0.07}{1-(0.084)} = 1.168$$

and therefore we have a 16.8% discount, $R_{1,T-1} = 0.168$. For a two-period bond, we have instead (using the minimization technique): $a = 0.92$, $b = 0.736$, $c = 0.084$ and therefore,

$$q^3 + 0.171\,129\,q^2 - 0.470\,28\,q - 0.865\,33 = 0\,.$$

Whose solution provides q and therefore $1 + R_{1,T-1}$.

47.6.3 "Engineered" Risk-Neutral Distributions and Risk-Neutral Pricing

When a market is complete, an asset price can be defined as follows:

$$S_t = \mathrm{e}^{-R_{\mathrm{f}}(T-t)} E_t^*\left(S_T\,|\Omega_t\right)\,,$$

where Ω_t is a filtration, meaning that the expectation is calculated on the basis of all the information available up to time t and the probability distribution with respect to which the expectation is taken is a risk-neutral distribution. That is:

$$E_t^*\left(S_T\,|\Omega_t\right) = \int S_T\,\mathrm{d}F_{T|t}\,, \quad T > t$$

where $F_{T|t}$ is the asset risk-neutral distribution at time T based on the data available at time t. If the underlying price process is given by a stochastic process, then $E_t^*\left(S_T\,|\Omega_t\right)$ is the optimal forecast (filter) estimate of the asset price using the distribution $F_{T|t}$. In such circumstances, and if such a distribution exists, then derived assets such as call and put options are also priced by

$$C_t = \mathrm{e}^{-R_{\mathrm{f}}(T-t)} E_t^*\left(C_T\,|\Omega_t\right) = \int_K C_T\,\mathrm{d}F_{T|t}\,\left(S_T\right)\,,$$

$$C_T = \max(S_T - K, 0), \quad T > t\,,$$

$$P_t = \mathrm{e}^{-R_\mathrm{f}(T-t)} E_t^* \left(P_T \,|\Omega_t\right) = \int_0^K P_T \,\mathrm{d}F_{T|t}\,(S_T)\ ,$$

$$P_T = \max(K - S_T, 0), \quad T > t\,.$$

Of course, if the distribution happens to be normal then the assets prices equal the discounted best mean forecast of the future asset price. When this is not the case and markets are incomplete, asset pricing in practice seeks to determine the risk-neutral distribution that allows application of risk-neutral pricing whether markets are in fact complete or incomplete (for an empirical study see [47.185, 186], for example). There are numerous sources of information, and approaches used to *engineer* such a distribution. For example, let there be m derived assets x_t^j and let there be some data points up to time t regarding these assets. In this case, for each time t, the optimal least-square estimate of the risk-neutral distribution is found by minimizing the least squares below by a selection of the appropriate parameters defining the underlying price process:

$$\sum_{i=0}^{t} \left\{ \sum_{j=1}^{m} \left[x_i^j - \mathrm{e}^{-R_\mathrm{f}(T-i)} E_i^* \left(x_T^j \,|\Omega_i \right) \right]^2 + \left[S_i - \mathrm{e}^{-R_\mathrm{f}(T-i)} E_i^* \left(S_T \,|\Omega_i\right) \right]^{\ddot{}2} \right\} .$$

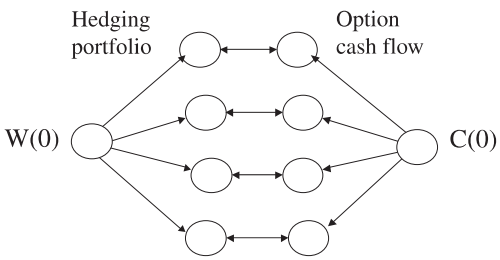
Here x_i^j is an actual observation of asset j taken at time i. If prices are available over several specific time periods (for example, an option for three months, six months and a year), then summing over available time periods we will have:

$$\sum_{i=0}^{t} \left\{ \sum_{\ell=1}^{L} \sum_{j=1}^{m} \left[x_i^j - \mathrm{e}^{-R_\mathrm{f}(T_\ell - i)} E_i^* \left(x_{T_\ell}^j \mid \Omega_i \right) \right]^2 + \sum_{k=i+1} \left[S_i - \mathrm{e}^{-R_\mathrm{f}(k-i)} E_i^* \left(S_k \mid \Omega_i\right) \right]^{\ddot{}2} \right\} .$$

Of course, other techniques can be taken in this spirit, providing thereby the optimal distribution forecast estimate. This is a problem that is over-parameterized however and therefore some assumptions are often made to reduce the number of parameters that define the presumed risk-neutral distribution. Examples and applications are numerous. Some authors assume a general multi-parameter distribution (such as the Burr distribution) for the risk-neutral distribution and calculate the parameters. Others seek the distribution outright while others assume an underlying process and calculate the best fit parameters. Both discrete-time and continuous-time models are used. Other models assume a broader framework such as a stochastic process with or without stochastic volatility with parameters to be estimated based on data availability. Below we shall consider a number of such cases (see also [47.187, 188].

Example 47.6 (mean variance replication hedging): This example consists of constructing a hedging portfolio in an incomplete (stochastic volatility) market by equating *as much as possible* cash flows resulting from a hedging portfolio and option prices. We shall do so while respecting the basic rules of rational expectations and risk-neutral pricing. This implies that at all times the price of the portfolio and the option price are the same. Let $W(t)$ be the portfolio price and $C(t)$ be the option price. At time $t = 0$, we evidently have as well $W(0) = C(0)$, similarly at some future date.

$$\begin{array}{ccc} W(0) & \Leftarrow & \tilde{W}(1) \\ \Downarrow & & \Updownarrow \\ C(0) & & \tilde{C}(1) \end{array}$$



$$\tilde{W}(1) = \tilde{C}(1)$$

However, under risk-neutral pricing we have:

$$C(0) = \frac{1}{1+R_\mathrm{f}} E\tilde{C}(1); \quad W(0) = \frac{1}{1+R_\mathrm{f}} E\tilde{W}(1)$$

$$\text{and} \quad C(0) = W(0) \quad \text{and} \quad E\tilde{W}^2(1) = \tilde{E}C^2(1)\,.$$

These provide three equations only. Since a hedging portfolio can involve a far greater number of parameters, it might be necessary to select an objective to minimize. A number of possibilities are available.

Rubinstein [47.189], as well as *Jackwerth* and *Rubinstein* [47.190] for example, suggested a simple quadratic

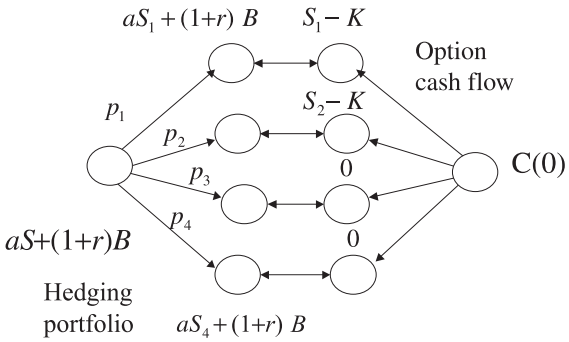
optimization problem by minimizing the quadratic difference of the probabilities associated to the binomial tree. Alternatively, a quadratic objective that leads to the minimization of a hedging portfolio and the option ex-post values of some option contract with risk-neutral pricing leads to:

$$\min_{p_1,\dots p_n} \Phi = E\left(\tilde{W}(1)-\tilde{C}(1)\right)^2 . \quad \text{Subject to:}$$

$$W(0)=C(0) \quad \text{or}$$

$$\frac{1}{1+R_\mathrm{f}}\left[E\tilde{W}(1)\right]=\frac{1}{1+R_\mathrm{f}}\left[E\tilde{C}(1)\right] \quad \text{and}$$

$$E\tilde{W}^2(1)=\tilde{E}C^2(1)$$



Of course the minimizing objective can be simplified further to:

$$\min_{p_1,\dots p_n} \Phi = E\tilde{C}^2(1)-E\tilde{W}(1)\tilde{C}(1) \quad \text{or}$$

$$\min_{p_1,\dots p_n} \Phi = \sum_{i=1}^{n} p_i\left(C_{1i}^2-W_{1i}C_{1i}\right),$$

where W_{1i}, C_{1i} are the hedging portfolio and option outcomes associated with each of the events i, which occur with probability p_i, $i=1,2,\dots n$.

Example 47.7: Define by S_j, $j=1,2,\dots n$ the n states a stock can assume at the time an option can be exercised. We set, $S_0<S_1<S_2<\dots<S_n$ and define the buying and selling prices of the stock by S^a, S^b, respectively. By the same token, define the corresponding observed call option prices C^a, C^b. Let p be the probability of a price increase. Of course, if the ex-post price is S_n, this will correspond to the stock increasing each time period with probability $P_n=(n,n)^\top p^n(1-p)^{n-n}=p^n$. By the same token, the probability of the stock having a price S_j corresponding to the stock increasing j times and decreasing $n-j$ times is given by the binomial probability

$$P_j=\binom{n}{j}p^j(1-p)^{n-j} .$$

As a result, we have under risk-neutral pricing:

$$S=\frac{1}{1+R_\mathrm{f}}\sum_{j=0}^{n}P_jS_j$$

$$=\frac{1}{1+R_\mathrm{f}}\sum_{j=0}^{n}S_j\binom{n}{j}p^j(1-p)^{n-j};$$

$$S^a\le S\le S^b$$

while the call option price is

$$C=\sum_{j=0}^{n}C_j$$

$$=\frac{1}{(1+R_\mathrm{f})^n}\sum_{j=0}^{n}\binom{n}{j}p^j(1-p)^{n-j}$$

$$\times\max(S_j-K,0)$$

with an appropriate constraint on the call option value $C^a\le C\le C^b$. Note that S, C as well as p are the only unknown values so far. While the buy and sell values for stock and options, the strike time n and its price K as well as the discount rate and future prices S_j are given. Our problem at present is to select an objective which will make it possible to obtain risk-neutral probabilities. We can do so by minimizing the quadratic distance between a portfolio of a unit of stock and a bond B. At n, the portfolio is equal $aS_j+(1+R_\mathrm{f})^nB$ if the price is S_j. Of course, initially, the portfolio equals:

$$S=\frac{1}{(1+R_\mathrm{f})^n}\left[a\sum_{j=0}^{n}P_jS_j+(1+R_\mathrm{f})^nB\right] .$$

As a result, the least-squared replicating portfolio is given by:

$$\Phi=\sum_{j=1}^{n}P_j\left[aS_j+(1+R_\mathrm{f})^nB-\max(S_j-K,0)\right]^2$$

which leads to the following optimization problem

$$\min_{1\geq p\geq 0, C, S} \Phi = \sum_{j=1}^{n} \binom{n}{j} p^j (1-p)^{n-j} \times \left[aS_j + (1+R_f)^n B - \max(S_j - K, 0)\right]^2 .$$

Subject to:

$$S = \frac{1}{(1+R_f)^n} \sum_{j=0}^{n} \binom{n}{j} p^j (1-p)^{n-j} S_j ;$$

$$S^a \leq S \leq S^b,$$

$$C = \frac{1}{(1+R_f)^n} \sum_{j=0}^{n} \binom{n}{j} p^j (1-p)^{n-j} \times \max(S_j - K, 0); \quad C^a \leq C \leq C^b ,$$

$$aS + B = C .$$

The numerical solution of this problem is straightforward.

Example 47.8 (fitting continuous risk-neutral distributions): The simplest such model of course consists of using an underlying binomial stock process and using options data (call and put) to estimate the stock process parameters and risk-neutral distribution. Assume that we assume a theoretical mixture price model given by:

$$\frac{dS}{S} = \begin{cases} \alpha_j \, dt + \sigma_j \, dW_j & \pi_j \\ j = 1, 2, \ldots, m & \\ \pi_j \geq 0 & \sum_{j=1}^{m} \pi_j \end{cases} , \quad S(0) = S_0 .$$

The solution of this model in terms of a risk-neutral numeraire is, (as we saw earlier):

$$S(t) = S(0) \sum_{j=1}^{m} \pi_j \, e^{\left(R_f - \frac{\sigma_j^2}{2}\right)t + \sigma_j W_t^*(t)} ,$$

$$W_t^*(t) = W_j(t) + \frac{\alpha_j - R_f}{\sigma_j} t .$$

Let there be call and put options prices given by:

$$C_t = e^{-R_f(T-t)} E_t^* (C_T \,|\Omega_t) ,$$
$$C_T = \max(S_T - K, 0), \quad T > t ,$$
$$P_t = e^{-R_f(T-t)} E_t^* (P_T \,|\Omega_t) ,$$
$$P_T = \max(K - S_T, 0), \quad T > t .$$

A simple least-squares optimization problem that seeks to calculate the underlying process parameters is then:

$$\min_{\alpha_j, \sigma_j, \pi_j} \sum_{i=0}^{t} \left\{ \left[C_i - e^{-R_f(T-i)} E_i^* (C_T \,|\Omega_i) \right]^2 + \left[P_i - e^{-R_f(T-i)} E_i^* (P_T \,|\Omega_i) \right]^2 \right\} ,$$

where

$$C_t = e^{-R_f(T-t)} E_t \left\{ \max \left[S(0) \times \sum_{j=1}^{m} \pi_j \, e^{\left(R_f - \frac{\sigma_j^2}{2}\right)t + \sigma_j W^*(t)} - K, 0 \right] |\Omega_t \right\} ,$$

$$P_t = e^{-R_f(T-t)} E_t \left\{ \max \left[K - S(0) \times \sum_{j=1}^{m} \pi_j \, e^{\left(R_f - \frac{\sigma_j^2}{2}\right)t + \sigma_j W^*(t)}, 0 \right] |\Omega_t \right\} .$$

Of course such problems can be solved by MATLAB or by nonlinear optimization routines. Further refinements can be developed by noting that the stock price must also meet the risk-neutral condition at each time prior to time t. A simple case is obtained when we consider the mixture of two such log-normal models. Such an assumption will imply of course that prices are skewed. Explicitly, assume a mixture of the log-normal distributions

$$f(S_T) = \begin{cases} L(\alpha_1, \beta_1) & \text{w.p. } \theta \\ L(\alpha_2, \beta_2) & \text{w.p. } 1-\theta \end{cases} ;$$

$$\hat{f}(S_T) \sim \theta L(\alpha_1, \beta_1) + (1-\theta) L(\alpha_2, \beta_2) .$$

For such a process we can use the normal mixtures as follows:

$$P(\tilde{R} \leq R) = \theta N\left(\frac{\log R - \mu_1}{\sigma_1}\right) + (1-\theta) N\left(\frac{\log R - \mu_2}{\sigma_2}\right) .$$

Elementary but tedious analysis of the moments can provide an estimate of the variance, the distribution

skewness and its kurtosis, or

$$\begin{aligned}
\text{var} &= \theta_1\sigma_1^2 + \theta_2\sigma_2^2 + \theta_1\theta_2\,(\mu_1-\mu_2)^2\ , \\
\text{Skewness} &= \frac{\theta_1\theta_2\,(\mu_1-\mu_2)}{(\text{var})^{3/2}} \\
&\quad\times\left[3\left(\sigma_1^2-\sigma_2^2\right)+(\theta_2-\theta_1)\,(\mu_1-\mu_2)^2\right], \\
\text{Kurtosis} &= \frac{3\left(\theta_1\sigma_1^4+\theta_2\sigma_2^4\right)}{(\text{var})^2} \\
&\quad+\frac{6\theta_2\theta_1\,(\mu_1-\mu_2)^2\left(\theta_2\sigma_1^1+\theta_1\sigma_2^2\right)}{(\text{var})^2} \\
&\quad+\frac{\theta_2\theta_1\,(\mu_1-\mu_2)^4\left(\theta_1^3+\theta_2^3\right)}{(\text{var})^2}\ .
\end{aligned}$$

These moments of the mixture process indicate the behavior of the underlying risk-neutral distribution, highlighting the *market* intention as it is reflected in these moments (skew to the right or to the left of the uncertainty regarding future asset prices). To estimate the mixture process parameters we may then fit the data to say, call and put data, freely available on the appropriate market. Let:

$\hat{C}_{i,T}$ = European Call option price at $i = 1, \ldots m$;

$\hat{P}_{i,T}$ = European Put option price at $i = 1, 2, \ldots m$

with

$$\hat{C}(S, K_i, T) = \mathrm{e}^{-R_\mathrm{f}T}\int_{K_i}^{\infty}(S_T - K_i)\hat{f}(S_T)\mathrm{d}S_T\ ,$$

$$\hat{P}(S, K_i, T) = \mathrm{e}^{-R_\mathrm{f}T}\int_{0}^{K_i}(K_i - S_T)\hat{f}(S_T)\mathrm{d}S_T\ .$$

Table 47.1 Comparison of the log-normal and bi-log-normal model

Date	Number of observations	Fit (sum of squares)	
		Log-normal	Bi-log-normal
09/06/2002	24	0.121	0.121
10/06/2002	24	0.060	0.060
17/06/2002	26	0.022	0.011
15/06/2002	23	0.070	0.004
10/07/2002	19	0.038	0.008
12/08/2002	16	0.022	0.005
Average	21.7	0.056	0.038

The resulting (data fit) optimization problem is then

$$\min_{\alpha_1,\beta_1;\alpha_2,\beta_2;\theta}\left[\sum_{i=1}^{m}\left(\hat{C}_{i,T}-C_{i,T}\right)^2 + \sum_{j=1}^{m}\left(\hat{P}_{j,T}-P_{j,T}\right)^2\right].$$

Subject to the call and put theoretical price estimates. In other words, introducing the time-dependent prices for the call and put options, we have

$$\min_{\alpha_1,\beta_1;\alpha_2,\beta_2;\theta}\sum_{t=0}^{T}\left[\sum_{i=1}^{m}\left(\hat{C}_{i,t}-C_{i,t}\right)^2 + \sum_{j=1}^{m}\left(\hat{P}_{j,t}-P_{j,t}\right)^2\right].$$

Subject to:

$$C_{it} = \mathrm{e}^{-R_\mathrm{f}(T-t)}\int_{K_i}^{\infty}(S_T - K_i)\hat{f}_t(S_T)\mathrm{d}S_T \quad \text{and}$$

$$\hat{P}_{it} = \mathrm{e}^{-R_\mathrm{f}(T-t)}\int_{0}^{K_i}(K_i - S_T)\hat{f}_t(S_T)\mathrm{d}S_T\ ,$$

where $\hat{f}_t(S_T)$ is given by the underlying multi-parameter mixture log-normal process. *Stein* and *Hecht* (Bank of Israel, Monetary Devision) use instead the following objective, which they have found more stable using data of the Israeli shekel and the American dollar.

$$\min_{\alpha_1,\beta_1;\alpha_2,\beta_2;\theta}\sum_{t=0}^{T}\left[\sum_{i=1}^{m}\left(1-\frac{\hat{C}_{i,t}}{C_{i,t}}\right)^2 + \sum_{j=1}^{m}\left(1-\frac{\hat{P}_{i,t}}{P_{i,t}}\right)^2\right]$$

Using Israeli and US currency data and comparing a log-normal and a bi-log-normal model they show that the bi-log-normal model provides a better fit, as shown in Table 47.1.

For each of these periods, they calculated as well the parameters of the underlying exchange rate process. As a result, they were able to estimate the probability of currency devaluation and that of appreciation of the shekel versus the dollar. Clearly, the result in Table 47.1 point out to a better fit when the bi-lognormal model is used.

Some authors simplify the computation of implied parameters by considering a multi-parameter distribution. In other words, this approach assumes outright that

the risk-neutral distribution can be approximated by a known distribution. For simplicity, assume first a two-parameter (c, ζ) Weibull distribution given by:

$$f(\tau) = \frac{c}{\zeta}\left(\frac{\tau}{\zeta}\right)^{c-1} \mathrm{e}^{-(\tau/\zeta)^c}, \quad \tau \geq 0, \zeta, \quad c > 0;$$
$$F(\tau) = 1 - \mathrm{e}^{-(\tau/\zeta)^c},$$
$$E(\tau) = \zeta \Gamma\left(\frac{1}{c} + 1\right),$$
$$\mathrm{var}(\tau) = \zeta^2\left[\Gamma\left(\frac{2}{c} + 1\right) - \Gamma^2\left(\frac{1}{c} + 1\right)\right].$$

For the call option, calculations are easily applied and we have after some elementary manipulations:

$$\hat{C}_{it} = \mathrm{e}^{-R_\mathrm{f}(T-t)} \int_{K_i}^{\infty} (S_T - K_i) \hat{f}_t(S_T) \mathrm{d}S_T$$
$$= \mathrm{e}^{-R_\mathrm{f}(T-t)} c \int_{K_i}^{\infty} \left(\frac{S_T}{\zeta}\right)^c \mathrm{e}^{-(S_T/\zeta)^c} \mathrm{d}S_T$$
$$- \mathrm{e}^{-R_\mathrm{f}(T-t)} K_i \mathrm{e}^{-(K_i/\zeta)^c}.$$

If we set:

$$\left(\frac{S_T}{\zeta}\right)^c = u, \quad c\left(\frac{1}{\zeta}\right)\left(\frac{S_T}{\zeta}\right)^{c-1} \mathrm{d}S_T = \mathrm{d}u \quad \text{then},$$
$$\hat{C}_{it} = \mathrm{e}^{-R_\mathrm{f}(T-t)} c \int_{\left(\frac{K_i}{\zeta}\right)^c}^{\infty} u \mathrm{e}^{-u} \mathrm{d}S_T$$
$$- \mathrm{e}^{-R_\mathrm{f}(T-t)} K_i \mathrm{e}^{-(K_i/\zeta)^c}.$$

For the put option, we have similarly:

$$\hat{P}_{it} = \mathrm{e}^{-R_\mathrm{f}(T-t)} \int_0^{K_i} (K_i - S_T) \hat{f}_t(S_T) \mathrm{d}S_T$$
$$= \mathrm{e}^{-R_\mathrm{f}(T-t)} K_i \left(1 - \mathrm{e}^{-(K_i/\zeta)^c}\right)$$
$$- \mathrm{e}^{-R_\mathrm{f}(T-t)} \zeta \int_0^{\left(\frac{K_i}{\zeta}\right)^c} u^{\frac{1}{c}} \mathrm{e}^{-u} \mathrm{d}u.$$

Note that:

$$\int_0^{u_i} u^{\frac{1}{c}} \mathrm{e}^{-u} \mathrm{d}u = \gamma\left(1 + \frac{1}{c}, u_i\right) \quad \text{and}$$
$$\int_0^{\left(\frac{K_i}{\zeta}\right)^c} u^{\frac{1}{c}} \mathrm{e}^{-u} \mathrm{d}u = \gamma\left[1 + \frac{1}{c}, \left(\frac{K_i}{\zeta}\right)^c\right]$$

and therefore

$$\hat{P}_{it} = \mathrm{e}^{-R_\mathrm{f}(T-t)} K_i \left(1 - \mathrm{e}^{-(K_i/\zeta)^c}\right)$$
$$- \mathrm{e}^{-R_\mathrm{f}(T-t)} \zeta\gamma\left[1 + \frac{1}{c}, \left(\frac{K_i}{\zeta}\right)^c\right].$$

The underlying price is then

$$\hat{S}_t = \mathrm{e}^{-R_\mathrm{f}(T-t)} E_{\mathrm{RND,W}}(S_T) \quad \text{and}$$
$$\hat{S}_t = \mathrm{e}^{-R_\mathrm{f}(T-t)} \zeta \Gamma\left(\frac{1}{c} + 1\right).$$

We can use other distributions as well. For example, several authors like to use the Burr distribution because it includes as special cases numerous and well-known distributions. In his case, we have

$$F(S_T, T) = 1 - \frac{1}{\left(1 + S_T^c\right)^q}, \; S_T \geq 0, c, q > 1;$$
$$f(S_T, T) = \frac{qcS_T^{c-1}}{\left(1 + S_T^c\right)^{q+1}}$$

or using the following notation

$$f(S_T) = \frac{\alpha\nu S_T^{\alpha-1}}{\left(S_T^\alpha + \delta\right)^{\delta+1}},$$
$$E\left(S_T^m\right) = \frac{1}{\alpha}\delta^{(m+\alpha)/\alpha} B\left(1 + \frac{m}{\alpha}, \delta - \frac{m}{\alpha}\right),$$

which can be used to fit an available data set to the distribution and optimize to obtain parameter estimates. The problem with this technique, however, is that it is mostly appropriate for an estimation of a specific risk-neutral distribution for a specific instant of time rather than to the evolution of the risk-neutral distribution over a stochastic process. Similar considerations are applied when we use the Burr distribution. In this case, for a Burr III distribution we have

$$F_{\mathrm{BR}}(S_T, T) = \left(1 - \frac{1}{1 + (S_T/\beta)^c}\right)^\alpha,$$
$$S_T \geq 0, c > 0, \alpha > 0, \beta > 0$$

while the probability distribution is

$$f(S_T, T) = \frac{c\alpha S_T^{c\alpha-1}\left(S_T^c + \beta^c\right) - c\alpha S_T^{c(\alpha-1)}}{\left(S_T^c + \beta^c\right)^{1+\alpha}}.$$

Then by simply minimizing the sum of squared differences between a model premia conditional upon the parameters of the distribution and the observed option premia, an estimate of the approximate risk-neutral distribution can be obtained (for references see [47.191, 192]).

An alternative approach consists of recovering the risk-neutral distribution associated with an asset based on the information available on its derived products. For example, under risk-neutral pricing, for a vanilla call option with exercise price K and exercise date T, we have by definition:

$$C(K,T) = \mathrm{e}^{-R_f T} \int_K (S-K) f(S)\,\mathrm{d}t\,,$$

where $f(S)$ is the underlying asset risk-neutral density function of the price at its exercise time. Note that:

$$\begin{aligned}
\frac{\partial C(K,T)}{\partial K} &= -\mathrm{e}^{-R_f T} \int_K f(S)\,\mathrm{d}t \\
&= -\mathrm{e}^{-R_f T}\,[1-F(K)]\,, \\
\frac{\partial^2 C(K,T)}{\partial K^2} &= \mathrm{e}^{-R_f T} f(S)\,, \\
f(S) &= \mathrm{e}^{R_f T} \frac{\partial^2 C(K,T)}{\partial K^2}\,,
\end{aligned}$$

where $f(S)$, the RND is explicitly stated above as the second partial derivative of the call option. Of course, although such a relationship may be of theoretical value, it has little use if there is no data that can be used to calculate the underlying risk-neutral distribution. Other approaches and techniques might therefore be needed. This is a broad and difficult area of research which we can consider here only briefly. One approach that may be used is based on the constrained maximization of entropy to determine candidate risk-neutral distributions. This is considered next.

47.6.4 The Maximum-Entropy Approach

When some characteristics, data or other information regarding the risk-neutral distribution are available, it is possible to define its underlying distribution by selecting that distribution which assumes the least, that is the distribution with the greatest variability, given the available information. One approach that allows the definition of such distributions is defined by the maximum-entropy principle.

Entropy is based essentially on a notion of randomness. Its origins are in statistical physics. Boltzmann observed that entropy relates to missing information inasmuch as it pertains to the number of alternatives which remain possible to a physical system after all the macroscopically observable information concerning it has been recorded. In this sense, information can be interpreted as that which changes a system's state of randomness (or equivalently, as that quantity which reduces entropy). For example, for a word, which has k letters assuming zeros and ones, and one two, define a sequence of k letters, $(a_0, a_1, a_2, \ldots, a_k)$,

$$a_i = \begin{cases} 1 \\ 0 \end{cases}$$

for all $i \neq j$, $a_j \neq a_i = 2$ and one j. The total number of configurations (or strings of $k+1$ letters) that can be created is N where, $N = 2^k(k+1)$. The logarithm to the base 2 of this number of configurations is the information I, or $I = \log_2 N$ and in our case, $I = k + \log_2(k+1)$. The larger this number I, the larger the number of possible configurations and therefore the larger the randomness of the word. As a further example, assume an alphabet of G symbols and consider messages consisting of N symbols. Say that the frequency of occurrence of a letter is f_i, i. e., in N symbols the letter G occurs on average $N_i = f_i N$ times. There may then be W different possible messages, where

$$W = \frac{N!}{\prod_{i=1}^{N} N_i!}\,.$$

The uncertainty of an N-symbol message is simply the ability to discern which message is about to be received. Thus,

$$\begin{aligned}
&W = \mathrm{e}^{HN} \quad \text{and} \\
&H = \lim_{N\to\infty} \frac{1}{N} \log(W) = \sum p_i \log\left(1/p_i\right),
\end{aligned}$$

which is also known as Shannon's entropy. If the number of configurations (i. e. W) is reduced, then the *information* increases. To see how the mathematical and statistical properties of entropy may be used in defining the risk-neutral distribution, we shall outline below a number of problems.

Discrimination and divergence

Consider for example two probability distributions given by $[F, G]$, one a theoretical risk-neutral distribution and another empirical expressing observed prices for example. We want to construct a measure that makes it possible to discriminate between these distributions. An attempt may be reached by using the following function we call the discrimination information [47.193]:

$$I(F,G) = \int F(x) \log \frac{F(x)}{G(x)}\,\mathrm{d}x\,.$$

In this case, $I(F, G)$ is a measure of *distance* between the distributions F and G. The larger the measure, the more we can discriminate between these distributions. For example, if $G(.)$ is a uniform distribution, then we have Shannon's measure of information. In this sense, it also provides a measure of departure from the random distribution. Selecting a distribution which has a maximum entropy (given a set of assumptions which are made explicit) is thus equivalent to the principle of insufficient reason proposed by Laplace. Thus, selecting a distribution with the largest entropy will imply a most conservative (risk wise) distribution. By the same token, we have

$$I(G, F) = \int G(x) \log \frac{G(x)}{F(x)} \mathrm{d}x$$

and the *divergence* between these two distributions is defined by

$$\begin{aligned} J(F, G) &= I(F, G) + I(G, F) \\ &= \int [F(x) - G(x)] \log \frac{F(x)}{G(x)} \mathrm{d}x \,, \end{aligned}$$

which provides a *symmetric measure* of distributions' *distance* since $J(F, G) = J(G, F)$.

For a discrete-time distribution (p, q), discrimination and divergence are given by

$$I(p, q) = \sum_{i=1}^{n} p_i \log \frac{p_i}{q_i} \,;$$

$$I(q, p) = \sum_{i=1}^{n} q_i \log \frac{q_i}{p_i}, \sum_{i=1}^{n} p_i = 1 \,,$$

$$\sum_{i=1}^{n} q_i = 1, \quad p_i \geq 0, \quad q_i \geq 0 \,,$$

$$\begin{aligned} J(p, q) &= \sum_{i=1}^{n} p_i \log \frac{p_i}{q_i} + \sum_{i=1}^{n} q_i \log \frac{q_i}{p_i} \\ &= \sum_{i=1}^{n} (p_i - q_i) \log \frac{p_i}{q_i} \,. \end{aligned}$$

For example, say that q_i, $i = 1, 2, 3, \ldots n$ is a known empirical distribution and say that p_i, $i = 1, 2, 3, \ldots n$ is a theoretical distribution given by the geometric distribution: $p_i = (n, i)^{\top} p^i (1 - p)^{n-i}$, whose parameter p we seek to estimate by minimizing the divergence, then the problem is:

$$\begin{aligned} &\min_{0 \leq p \leq 1} J(p, q) \\ &= \sum_{i=1}^{n} \left[\binom{n}{i} p^i (1 - p)^{n-i} - q_i \right] \\ &\quad \times \log \frac{\binom{n}{i} p^i (1 - p)^{n-i}}{q_i} \,, \end{aligned}$$

which can be minimized with respect to the parameter p. This approach can be generalized further to a multi-variable setting. For a bi-variate state discrete distribution, we have similarly:

$$I(p, q) = \sum_{j=1}^{m} \sum_{i=1}^{n} p_{ij} \log \left(\frac{p_{ij}}{q_{ij}} \right) ;$$

$$J(p, q) = \sum_{j=1}^{m} \sum_{i=1}^{n} (p_{ij} - q_{ij}) \log \left(\frac{p_{ij}}{q_{ij}} \right) .$$

On other hand for, for continuous distributions, we also have

$$I(F, G) = \int \int F(x, y) \log \frac{F(x, y)}{G(x, y)} \mathrm{d}x \, \mathrm{d}y$$

as well as the divergence:

$$\begin{aligned} &J(F, G) \\ &= \int \int [F(x, y) - G(x, y)] \log \frac{F(x, y)}{G(x, y)} \mathrm{d}x \, \mathrm{d}y \,. \end{aligned}$$

This distribution may then be used to provide divergence–distance measures between empirically observed and theoretical distributions.

When the underlying process is time-varying, we have for each time period:

$$I(p, q) = \sum_{t=1}^{T} \sum_{i=1}^{n} p_{it} \log \left(\frac{p_{it}}{q_{it}} \right) \quad \text{and}$$

$$J(p, q) = \sum_{t=1}^{T} \sum_{i=1}^{n} (p_{it} - q_{it}) \log \left(\frac{p_{it}}{q_{it}} \right)$$

where, obviously,

$$\sum_{i=1}^{n} p_{it} = 1; \quad \sum_{i=1}^{n} q_{it} = 1; \quad p_{it} \geq 0, q_{it} \geq 0 \,.$$

Moments condition as well as other constraints may also be imposed, providing a *least-divergent* risk-neutral pricing approximation to the empirical (incomplete) distribution considered.

Example 47.9: Assume that a non-negative random security price $\{\theta\}$ has a known mean given by $\hat{\theta}$, the maximum-entropy distribution for a continuous state distribution is given by solution of the following optimization problem:

$$\max H = -\int_0^\infty f(\theta)\log[f(\theta)]\,\mathrm{d}\theta \quad \text{Subject to:}$$

$$\int_0^\infty f(\theta)\mathrm{d}\theta = 1,$$

$$\hat{\theta} = \int_0^\infty \theta f(\theta)\mathrm{d}\theta\,.$$

The solution of this problem, based on the calculus of variations, yields an exponential distribution. In other words,

$$f(\theta) = \frac{1}{\hat{\theta}}\mathrm{e}^{-\theta/\hat{\theta}}, \quad \theta \geq 0\,.$$

When the variance of a distribution is specified as well, it can be shown that the resulting distribution is the normal distribution with specified mean and specified variance. This approach can be applied equally when the probability distribution is discrete, bounded, and multivariate with specified marginal distributions etc. In particular, it is interesting to point out that the maximum entropy of a multivariate distribution with specified mean and known variance–covariance matrix also turns out to be multivariate normal, implying that the normal is the most random distribution that has a specified mean and a specified variance. Evidently, if we also specify leptokurtic parameters, the distribution will not be normal. Potential applications are numerous, for example, let S and V be a stock price and its volatility, each of which is assumed to have observable prices and volatility. If we apply the conditions for a risk-neutral price, we then have:

$$S(t) = \mathrm{e}^{-R_\mathrm{f}(T-t)}E_\mathrm{RN}S(T)$$
$$= \int_0^\infty\int_0 \mathrm{e}^{-R_\mathrm{f}(T-t)}S(T)f(S,V,T)\mathrm{d}V\,\mathrm{d}S\,,$$

where $f(S,V,T)$ is the probability distribution of the stock price with volatility V at time T. Adding data regarding the observed volatility at various times, prices of call and puts derived from this security, a theoretical optimization problem can be constructed that will indicate potential candidate distributions as implied risk-neutral distributions.

Example 47.10: consider the following random volatility process:

$$x_{t+1}^\alpha = x_t^\alpha + z_t; \quad z_t = \begin{cases} +3 & (0.5)(1-q) \\ +1 & (0.5)q \\ -1 & (0.5)q \\ -3 & (0.5)(1-q)\,. \end{cases}$$

A three-stage standard binomial process with probability π leads to

$$x_{t+1}^\alpha = x_t^\alpha + z_t\,;$$
$$z_t = \begin{cases} +3 & 0.5(1-q) \leftrightarrow \pi^3 \\ +1 & 0.5q \leftrightarrow 3\pi^2(1-\pi) \\ -1 & 0.5q \leftrightarrow 3\pi(1-\pi)^2 \\ -3 & 0.5(1-q) \leftrightarrow (1-\pi)^3\,. \end{cases}$$

As a result, we can calculate the probability π by minimizing the divergence J, which is given by by an appropriate choice of π

$$J = \left[\pi^3 - (0.5)(1-q)\right]\log\left(\frac{\pi^3}{0.5(1-q)}\right)$$
$$+\left[3\pi^2(1-\pi) - (0.5)q\right]\log\left(\frac{3\pi^2(1-\pi)}{0.5q}\right)$$
$$+\left[3\pi(1-\pi)^2 - (0.5)q\right]\log\left(\frac{3\pi(1-\pi)^2}{0.5q}\right)$$
$$+\left[(1-\pi)^3 - 0.5(1-q)\right]\log\left(\frac{(1-\pi)^3}{0.5(1-q)}\right)\,.$$

Example 47.11: the problem based on forward and option prices be given by:

$$\max_{f(.)}\int_0^\infty f(S)\ln\left(\frac{1}{f(S)}\right)\mathrm{d}S \quad \text{Subject to:}$$

$$\int_0^\infty f(S)\mathrm{d}S = 1; \quad F(0,T) = \int_0^\infty Sf(S)\mathrm{d}S \quad \text{and}$$

$$C_i(S,K,T) = \mathrm{e}^{-R_\mathrm{f}T}\int_0^\infty c_i(x)f(x)\mathrm{d}x,$$

$$i = 1,2,\ldots m\,,$$

where C_i is the price of the option at time t with payoff at T given by $c_i(x)$. The solution of this problem is

$$f(S) = \frac{1}{\mu} \exp\left[\lambda_0 S + \sum_{i=1}^{m} \lambda_i c_i(S)\right] \quad \text{with}$$

$$\mu = \int_0^\infty \exp\left[\lambda_0 S + \sum_{i=1}^{m} \lambda_i c_i(S)\right] \mathrm{d}S$$

which can be used as a candidate risk-neutral distribution where the parameters are to be determined based on the available data.

Example 47.12 (a maximum-entropy price process): Consider a bivariate probability distribution (or a stochastic price process) $h(x, t)$, $x \in [0, \infty)$, $t \in [a, b]$ the maximum-entropy criterion can be written as an optimization problem, maximizing the entropy as follows:

$$\max H = -\int_0^\infty \int_a^b h(x,t) \log[h(x,t)] \,\mathrm{d}t \,\mathrm{d}x \,,$$

subject to partial information regarding the distribution $h(x, t)$, $x \in [0, \infty)$, $t \in [a, b]$. Say that, at the final time b, the price of a stock is for sure X_b, while initially it is given by X_a. Further, let the average price over the relevant time interval be known and be given by $\bar{X}_{(a,b)}$, this may be translated into the following constraints:

$$h(X_a, a) = 1, \quad h(X_b, b) = 1 \quad \text{and}$$

$$\frac{1}{b-a} \int_a^b \int_0^\infty x h(x,t) \,\mathrm{d}x \,\mathrm{d}t = \bar{X}_{(a,b)}$$

which are to be accounted for in the entropy optimization problem. Of course, we can add additional constraints when more information is available. Thus, the maximum-entropy approach can be used as an *alternative rationality* for the construction of risk-neutral distributions when the burden of explicit hypotheses formulation or the justification of the model at hand is too heavy. Theoretical justifications as well as applications to finance may be found in *Avellaneda* et al. [47.194] (see also [47.195–197]). Below we consider a simple example to highlight some of the practical issues we may have to address when dealing with such problems.

Example 47.13 (engineered bond pricing): consider a Vasicek model of interest rates, fluctuating around a long-run rate α. This fluctuation is subjected to random and normal perturbations of mean zero and variance $\sigma \,\mathrm{d}t$, or.

$$\mathrm{d}r = \beta(\alpha - r)\mathrm{d}t + \sigma \,\mathrm{d}w$$

whose solution at time t when the interest rate is $r(t)$ is, as seen earlier:

$$r(u; t) = \alpha + \mathrm{e}^{-\beta(u-t)}[r(t) - \alpha] + \sigma \int_t^u \mathrm{e}^{-\beta(u-\tau)} \,\mathrm{d}w(\tau) \,.$$

In this theoretical model we might consider the parameters set $\Lambda \equiv (\alpha, \beta, \sigma)$ as determining a number of martingales (or bond prices) that obey the model above, namely bond prices at time $t = 0$ can theoretically equal the following:

$$B_{\mathrm{th}}(0, T; \alpha, \beta, \sigma) = E\left(\mathrm{e}^{\int_0^T r(u;\alpha,\beta,\sigma)\mathrm{d}u}\right) .$$

In this simple case, interest rates have a normal distribution with a mean and variance (volatility) evolution stated above and therefore $\int_0^T r(u,\alpha,\beta,\sigma)\mathrm{d}u$ also has a normal probability distribution with mean and variance give by

$$m[r(0), T] = \alpha T + \left(1 - \mathrm{e}^{-\beta T}\right) \frac{r(0) - \alpha}{\beta} \,,$$

$$v(r(0), T) = v(T) = \frac{\sigma^2}{2\beta^3}\left(4\mathrm{e}^{-\beta T} - \mathrm{e}^{-2\beta T} + 2\beta T - 3\right) .$$

Note that in these equations the variance is independent of the interest rate while the mean is a linear function of the interest, which we write as:

$$m[r(0), T] = \alpha\left(T - \frac{\left(1 - \mathrm{e}^{-\beta T}\right)}{\beta}\right) + r(0)\frac{\left(1 - \mathrm{e}^{-\beta T}\right)}{\beta} \,.$$

This property is called an affine structure as we saw earlier and is of course computationally desirable for it will allow a simpler calculation of the desired martingale. As a result, the theoretical zero-coupon bond price paying

one dollar T periods hence can be written as:

$$
\begin{aligned}
B_{\text{th}}(0, T; \alpha, \beta, \sigma) &= E\left(\mathrm{e}^{\int_0^T r(u,\alpha,\beta,\sigma)\,\mathrm{d}u}\right) \\
&= \mathrm{e}^{-m(r(0),T)+v(T)/2} \\
&= \mathrm{e}^{A(T)-r_0 D(T)}\,, \\
A(T) &= -\alpha\left(T - \frac{\left(1-\mathrm{e}^{-\beta T}\right)}{\beta}\right) \\
&\quad + \frac{\sigma^2}{4\beta^3}\left(4\mathrm{e}^{-\beta T} - \mathrm{e}^{-2\beta T}\right. \\
&\quad \left. + 2\beta T - 3\right)\,, \\
D(T) &= \frac{\left(1-\mathrm{e}^{-\beta T}\right)}{\beta}\,.
\end{aligned}
$$

Assume now that continuous series affine bond values are observed and given by $B_{\text{obs}}(0, T)$ which we write for convenience as $B_{\text{obs}}(0, T) = \mathrm{e}^{-R_T T}$. Without loss of generality we can consider the yield error term given by

$$\Delta_T = R_T - [A(T) - r_0 D(T)]$$

and thus select the parameters (i. e. the martingale) that is closest in some sense to the observed values. For example, a least-squares solution of n observed bond values yields the following optimization problem:

$$\min_{\alpha,\beta,\sigma} \sum_{i=1}^{n} (\Delta_i)^2$$

Alternatively, we can also minimize the divergence between the theoretical and the observed series. For a continuous-time function $B_{\text{obs}}(0, T) = \mathrm{e}^{-R_T T}$, we have

$$
\begin{aligned}
&\min_{\alpha,\beta,\sigma} J(\Upsilon) \\
&= \int_0^{\Upsilon} [B_{\text{th}}(0, u) - B_{\text{obs}}(0, u)] \ln\left(\frac{B_{\text{th}}(0, u)}{B_{\text{obs}}(0, u)}\right) \mathrm{d}u\,.
\end{aligned}
$$

In this case, it is easy to show that, given the continuous-time observed bond function $\left[B_{\text{obs}}(0, u), 0 \le u \le \Upsilon\right]$, the optimal parameters satisfy the following three equalities

$$
\begin{aligned}
&\int_0^{\Upsilon} \left(\frac{\partial \ln B_{\text{th}}(0, u)}{\partial\theta} [B_{\text{obs}}(0, u) - B_{\text{th}}(0, u)]\right) \\
&= \int_0^{\Upsilon} \frac{\partial B_{\text{th}}(0, u)}{\partial\theta} \ln\left(\frac{B_{\text{th}}(0, u)}{B_{\text{obs}}(0, u)}\right) \mathrm{d}u\,,
\end{aligned}
$$

where $\theta = \alpha, \beta, \sigma$. These problems can be solved numerically of course.

When the model has time-varying parameters, the problem we faced above turns out to have an infinity of unknown parameters and therefore the yield-curve estimation problem we considered above might be grossly under-specified. Explicitly, let the interest mode be defined by:

$$\mathrm{d}r(t) = \beta[\alpha(t) - r(t)]\,\mathrm{d}t + \sigma\,\mathrm{d}w$$

The theoretical bond value still has an affine structure and therefore we can write

$$
\begin{aligned}
B_{\text{th}}(t, T; \alpha(t), \beta, \sigma) &= E\left(\mathrm{e}^{\int_0^T r(u,\alpha,\beta,\sigma)\,\mathrm{d}u}\right) \\
&= \mathrm{e}^{A(t,T)-r(t)D(t,T)}\,.
\end{aligned}
$$

The integral interest rate process is still normal with mean and variance leading to

$$
\begin{aligned}
D(t, T) &= \frac{1}{\beta}\left(1 - \mathrm{e}^{-\beta(T-t)}\right)\,, \\
A(t, T) &= \int_t^T \left[\frac{1}{2}\sigma^2 D^2(s, T) - \beta\alpha(s) D(s, T)\right] \mathrm{d}s
\end{aligned}
$$

or

$$
\begin{aligned}
\frac{\mathrm{d}A(t, T)}{\mathrm{d}t} &= \alpha(t)\left(1 - \mathrm{e}^{-\beta(T-t)}\right) \\
&\quad - \frac{\sigma^2}{2\beta^2}\left(1-\mathrm{e}^{-\beta(T-t)}\right)^2\,, \quad A(T, T) = 0
\end{aligned}
$$

in which $\alpha(t)$, β, and σ are unspecified. If we equate this equation to the available bond data we will obviously have far more unknown variables than data points and therefore the yield-curve estimate will depend again on the optimization technique we use to generate the best fit functions $\alpha^*(t)$, β^*, and σ^*. Such problems can be formulated as standard problems in the calculus of variations. For example, if we consider the observed bond prices $B_{\text{obs}}(t, T)$, $t \le T < \infty$, for a specific time T and minimize the squared error, the following problem results

$$
\begin{aligned}
\min_{\alpha(u)} J(\alpha, A) = \int_0^t \Bigg[&\mathrm{e}^{A(u,T)-r(u)\left[\frac{1}{\beta}\left(1-\mathrm{e}^{-\beta(T-u)}\right)\right]} \\
&- B_{\text{obs}}(u, T)\Bigg]^2 \mathrm{d}u,
\end{aligned}
$$

$$\frac{\mathrm{d}A(u,T)}{\mathrm{d}u} = \alpha(u)\left(1-\mathrm{e}^{-\beta(T-u)}\right) - \frac{\sigma^2}{2\beta^2}\left(1-\mathrm{e}^{-\beta(T-u)}\right)^2,$$
$$A(T,T)=0$$

which can be solved by the usual techniques in optimal control. Note that this problem can be written as the linear quadratic optimization problem where we have purposely given greater weight to data observed close to time t, and given less importance to data that are farther away from the current time t, or:

$$\min_{\alpha(u)} = \int_0^t \mathrm{e}^{\upsilon u}\left[A(u,T)-c(u,T)\right]^2 \mathrm{d}u\,,$$
$$\frac{\mathrm{d}A(u,T)}{\mathrm{d}u} = \alpha(u)a(u,T)-b(u,T)\,, \quad A(T,T)=0\,,$$
$$c(u,t) = y_{\mathrm{obs}}(u,T)+r(u)\left[\frac{1}{\beta}\left(1-\mathrm{e}^{-\beta(T-u)}\right)\right],$$
$$a(u,t) = \left(1-\mathrm{e}^{-\beta(T-u)}\right);$$
$$b(u,t) = \frac{\sigma^2}{2\beta^2}\left(1-\mathrm{e}^{-\beta(T-u)}\right)^2.$$

The solution of this problem is a standard optimal control problem which may be either a boundary solution (called bang–bang, bringing the control parameter $\alpha(u)$ to an upper or lower constraint value) or that can be singular (in which case its calculation is found by tests based on a higher-order derivative). Using the deterministic dynamic programming framework, we have an optimal solution given by:

$$-\frac{\partial J}{\partial u} = \min_{\alpha(u)}\left\{\mathrm{e}^{\upsilon u}\left[A(u,T)-c(u,T)\right]^2 + \frac{\partial J}{\partial A}\left[\alpha(u)a(u,T)-b(u,T)\right]\right\}$$

On a singular strip, $\frac{\partial J}{\partial A}=0$ where $a(u,t)\neq 0$ and thus, in order to calculate $\alpha(u)$, we can proceed by a change of variables and transforming the original control problem into a linear quadratic control problem that can be solved by the standard optimal control methods. Explicitly, set:

$$y(u) = \mathrm{e}^{\nu u/2}\left[A(u,T)-c(u,T)\right],$$
$$\frac{\mathrm{d}w(u)}{\mathrm{d}u} = \alpha(u) \quad \text{and}$$
$$z(u) = y(u)-\mathrm{e}^{\nu u/2}a(u,T)w(u).$$

Thus, the problem objective is reduced to

$$\min_{\alpha(u)} = \int_0^t \left[z(u)+e^{\nu u/2}a(u,T)w(u)\right]^2 \mathrm{d}u$$

while the constraint is

$$\frac{\mathrm{d}A(u,T)}{\mathrm{d}u} = \alpha(u)a(u,T)-b(u,T)\,,$$
$$z(u)+\mathrm{e}^{\nu u/2}a(u,T)w(u) = \mathrm{e}^{\nu u/2}\left[A(u,T)-c(u,T)\right];$$
$$\frac{\mathrm{d}w(u)}{\mathrm{d}u} = \alpha(u)\,.$$

After some elementary manipulations, we have

$$\dot{z}(u) = \frac{\upsilon}{2}z(u)-\mathrm{e}^{\nu u/2}\dot{a}(u,T)w(u) - \mathrm{e}^{\nu u/2}\left[b(u,T)-\mathrm{e}^{\nu u/2}\dot{c}(u,T)\right].$$

This defines a linear quadratic cost-control problem

$$\min_{w(u)} = \int_0^t \left[z(u)+\mathrm{e}^{\nu u/2}a(u,T)w(u)\right]^2 \mathrm{d}u\,.$$

Subject to:

$$\frac{\mathrm{d}z(u)}{\mathrm{d}u} = \frac{\upsilon}{2}z(u)-\mathrm{e}^{\nu u/2}\dot{a}(u,T)w(u) - \mathrm{e}^{\nu u/2}\left[b(u,T)-\mathrm{e}^{\nu u/2}\dot{c}(u,T)\right].$$

Inserting the original problem parameters we have:

$$\min_{w(u)} \int_0^t \left[z(u)+\mathrm{e}^{\nu u/2}\left\{1-\mathrm{e}^{-\beta(T-u)}\right\} \times w(u)\right]^2 \mathrm{d}u. \quad \text{Subject to:}$$
$$\frac{\mathrm{d}z(u)}{\mathrm{d}u} = \dot{z}(u) = \frac{\upsilon}{2}z(u)+\beta\,\mathrm{e}^{-\beta(T-u-\nu u/2\beta)}w(u) - \mathrm{e}^{\nu u/2}\left[\frac{\sigma^2}{2\beta^2}\left(1-\mathrm{e}^{-\beta(T-u)}\right)^2 - \mathrm{e}^{\nu u/2}\dot{c}(u,T)\right],$$
$$\frac{\mathrm{d}c(u)}{\mathrm{d}u} = \dot{c}(u,t) = \dot{y}_{\mathrm{obs}}(u,T) + \dot{r}(u)\left[\frac{1}{\beta}\left(1-\mathrm{e}^{-\beta(T-u)}\right)\right] - r(u)\,\mathrm{e}^{-\beta(T-u)},$$

which is a control problem linear in the state and in the control with a quadratic objective. As a result, the solution for the control $w(u)$ is of the linear feedback form

$$w(u) = Q(u) + S(u)z(u) \quad \text{or}$$
$$\alpha(u) = \dot{Q}(u) + S(u)\dot{z}(u) + \dot{S}(u)z(u)\,.$$

Finally, when bond data are available over multiple periods dates T, the optimal control problem we have considered above can be extended by solving

$$\min_{\alpha(u)} \sum_{j=1}^{N_T} \int_0^t e^{\nu u} \left[A(u, T_j) - c(u, T_j)\right]^2 \mathrm{d}u$$

$$\frac{\mathrm{d}A(u, T_j)}{\mathrm{d}u} = \alpha(u)a(u, T_j) - b(u, T_j)\,,$$
$$A(T_j, T_j) = 0$$

and in continuous time:

$$\min_{\alpha(u)} \int_0^\infty \int_0^t \mathrm{e}^{\nu u} \left[A(u, T) - c(u, T)\right]^2 \mathrm{d}T\,\mathrm{d}u\,,$$
$$\frac{\partial A(u, T)}{\partial u} = \alpha(u)a(u, T) - b(u, T)\,,$$
$$A(T, T) = 0\,.$$

The solution of these problems are then essentially numerical problems, however.

48. Statistical Management and Modeling for Demand of Spare Parts

In recent years increased emphasis has been placed on improving decision making in business and government. A key aspect of decision making is being able to predict the circumstances surrounding individual decision situations. Examining the diversity of requirements in planning and decision-making situations, it is clearly stated that no single forecasting methods or narrow set of methods can meet the needs of all decision-making situations. Moreover, these methods are strongly dependent on factors such as data quantity, pattern and accuracy, that reflect their inherent capabilities and adaptability, such as intuitive appeal, simplicity, ease of application and, not least, cost.

Section 48.1 deals with the placement of the demand-forecasting problem as one of biggest challenge in the repair and overhaul industry; after this brief introduction Sect. 48.2 summarizes the most important categories of forecasting methods; Sects. 48.3–48.4 approach the forecast of spare parts firstly as a theoretical construct, although some industrial applications and results are added from field training, as in many other parts of this chapter.

Section 48.5 undertakes the question of optimal stock level for spare parts, with particular regard to low-turnaround-index (LTI) parts conceived and designed for the satisfaction of a specific customer request, by the application of classical Poisson methods of minimal availability and minimum cost; similar considerations are drawn and compared in Sect. 48.6, which deals with models based on the binomial distribution. An innovative extension of binomial models based on the total cost function is discussed in Sect. 48.7. Finally Sect. 48.8 adds the Weibull failure-rate function to the analysis of the LTI spare-parts stock level in a maintenance system with declared wear conditions.

48.1 The Forecast Problem for Spare Parts

Demand forecasting is one of the most crucial issues for inventory management. Forecasts, which form the basis for the planning of inventory levels, are probably the biggest challenge in the repair and overhaul industry.

An example can be seen in the airline industry, where a common problem is the need to forecast short-term demand with the highest possible degree of accuracy. The high cost of modern aircraft and the expense of re-

pairable spares, such as aircraft engines and avionics, contribute significantly to the considerable total investment of many airline operators. These parts, although required with low demand, are critical to operation and their unavailability can lead to excessive downtime costs.

This problem is absolutely relevant in case of intermittent demand. Demand for an item is classified as *intermittent* when it is irregular and sporadic. This type of demand, typical for a large number of spare parts, is very difficult to predict. This complicates efficient management and control of the inventory system, which requires an acceptable balance between inventory costs on one hand and stock-outs on the other. Inventory management models require accurate forecasts in order to achieve this balance.

We can explicitly consider both the pattern and size of demand as it occurs in order to classify demand patterns into four categories [48.1], as follows:

- *intermittent demand*, which appears to be random, with many time periods having no demand,
- *erratic demand*, which is (highly) variable, the erratic nature relating to the size of demand rather than the demand per unit time period,
- *slow moving* (*smooth*) demand, which also occurs at random, with many time periods having no demand. Demand, when it occurs, is for single or very few units,
- *lumpy demand*, which likewise seems random, with many time periods having no demand. Moreover demand, when it occurs, is (highly) variable. The lumpy concept corresponds to an extremely irregular demand, with great differences between each period's requirements and with a large number of periods with zero requirements.

Traditionally the characteristics of intermittent demand are derived from two parameters: the average interdemand interval (ADI) and the coefficient of variation (CV). ADI measures the average number of time periods between two successive demands and CV represents the standard deviation of requirements divided by the average requirement over a number of time periods:

$$\mathrm{CV} = \frac{\sqrt{\frac{\sum_{i=1}^{n}(\varepsilon_{ri}-\varepsilon_{\mathrm{a}})^2}{n}}}{\varepsilon_{\mathrm{a}}}\,, \tag{48.1}$$

where n is the number of periods, and ε_{ri} and ε_{a} are the actual and average demand for spare parts in period i, respectively. The four resulting demand categories are represented graphically in Fig. 48.1.

The categorization scheme suggests different ways of treating the resulting categories according to the following characteristics:

- The condition ADI $\leq x$; $\mathrm{CV}^2 \leq y$ tests for stock-keeping units (SKUs), which are not very intermittent and erratic (i. e. faster moving parts, or parts whose demand pattern does not raise any significant forecasting or inventory control difficulties);
- The condition ADI $> x$; $\mathrm{CV}^2 \leq y$ tests for low-demand patterns with constant, or more generally not highly variable, demand sizes (i. e. not very erratic);
- The condition ADI $> x$; $\mathrm{CV}^2 > y$ tests for items with lumpy demand. Lumpy demand may be defined as a demand with large differences between each period's requirements and with a large number of periods having zero requests;
- Finally, the condition ADI $\leq x$; $\mathrm{CV}^2 > y$ tests for items with erratic (irregular) demand with rather frequent demand occurrences (i. e. not very intermittent).

In all cases, x denotes the cutoff value (ADI = 1.32) for ADI, which measures the average number of time periods between two successive demands, and y denotes the corresponding cutoff value ($\mathrm{CV}^2 = 0.49$) for CV^2, which is equal to the square of the standard deviation of the requirements divided by the average requirement over a number of time periods.

Forecasting systems generally depend on the category of part used. Therefore it is important to have two factors in order to indicate deviation from expected val-

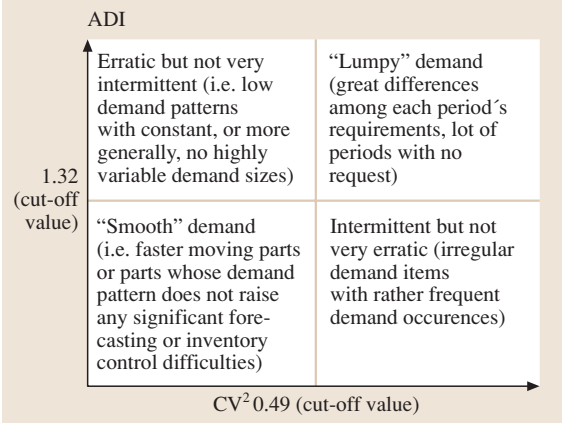

Fig. 48.1 Categorization of demand pattern

Table 48.1 A summary of selected forecasting methods

No.	Method	Abbreviation	Description
1	Additive Winter	AW	Assumes that seasonal effects are of constant size
2	Multiplicative Winter	MW	Assumes that seasonal effects are proportional in size to the local de-seasonalized mean level
3	Seasonal regression model	SRM	Used in time series for modelling data with seasonal effects
4	Component service life (replacement)	MTBR	Estimates of the service-life characteristics of the part (MTBR = mean time between replacement), derived from historical data
5	Croston	Croston	Forecasting in case of low and intermittent demand
6	Single-exponential smoothing	SES	Forecasting in case of low and intermittent demand
7	Exponential weighted moving average	EWMA, Holt	An effective forecasting tool for time series data that exhibits a linear trend
8	Trend-adjusted exponential smoothing	TAES	Forecasting time series data that have a linear trend
9	Weighted moving averages	WMA	A simple variation on the moving average technique that allows for such a weighing to be assigned to the data being averaged
10	Double-exponential smoothing	DES	Forecasting time series data that have a linear trend
11	Adaptive-response-rate single-exponential smoothing	ARRSES	Has an advantage over SES in that it allows the value of α to be modified in a controlled manner as changes in the pattern of data occur
12	Poisson model	POISSON	Models based on the Poisson distribution with the definition of a customer's service level
13	Binomial models	BM	Methods based on the binomial distribution

ues of demand with respect to both demand size and inter-demand interval. The performance of a forecasting method should vary with the level and type of lumpiness. A classification of research on intermittent demand forecasting can be arranged according to Willemain as follows:

1. extension of standard methods [48.2, 3] and variants of the Poisson model [48.4–10];
2. reliability theory and expert systems [48.11];
3. single exponential smoothing, Winter models [48.12–14],
4. Croston's variant of exponential smoothing [48.14–17];
5. bootstrap methods [48.18–21];
6. moving average and variants [48.22, 23];
7. models based on the binomial distribution [48.24–27].

The principle forecasting methods are briefly summarized in Table 48.1.

48.1.1 Exponential Smoothing

Exponential smoothing (ES) methods are widely used time-series methods when reasonably good forecasts are needed over the short term, using historical data to obtain a *smoothed* value for the series. This smoothed value is then extrapolated to become the forecast for the future value of the series. ES methods apply an unequal set of weights that decrease exponentially with time to past data; that is, the more recent the data value, the greater its weighting. In particular, the general form used in computing a forecast by the method of single-exponential smoothing (SES) is given by (48.2), where F_t represents the smoothed estimate, X_t the actual value at time t and α the smoothing constant, which has a value between 0 and 1. SES is best suited to data that exhibits a flat trend.

$$F_{t+1} = \alpha X_t + (1-\alpha) F_t \,. \tag{48.2}$$

When a trend exists, the forecasting technique must consider the trend as well as the series average; ignoring the trend will cause the forecast to underestimate or to overestimate actual demand, depending on whether there is an increasing or decreasing trend. In fact double-exponential smoothing (DES), which is useful when the historic data series are not stationary, applies SES twice and has the general

form:

$$F''_{t+1} = \alpha F_{t+1} + (1-\alpha) F_t \,. \tag{48.3}$$

48.1.2 Croston's Method

A little-known alternative to single-exponential smoothing is Croston's method, which forecasts separately the non-zero demand size and the inter-arrival time between successive demands using SES, with forecasts being updated only after demand occurrences. Let F_t and Y_t be the forecasts of the $(t+1)$th demand size and the inter-arrival time respectively, based on data up to demand t, and let Q_t be the inter-arrival time between two successive non-zero demand. Then Croston's method gives:

$$F_t = (1-\alpha) F_{t-1} + \alpha Y_t \,, \tag{48.4}$$

$$Y_t = (1-\alpha) Y_{t-1} + \alpha Q_t \,. \tag{48.5}$$

The predicted demand at time t is the ratio between F_t and Y_t

$$P_t = F_t / Y_t \,. \tag{48.6}$$

The SES and Croston methods are most frequently used for low and intermittent demand forecasting; in particular Croston's method can be useful with intermittent, erratic and slow-moving demand and its use is significantly superior to ES under intermittent demand conditions, according to the categorization scheme of Fig. 48.1. The straight Holt method, exponentially weighted moving average (EWMA), is also only applicable when there are low levels of lumpiness. The widespread use of the SES and mean time between replacement (MTBR) methods for parts with high variation (lumpy demand) are questionable as they consistently lead to poor forecasting performance, which remains poor as the demand variability increases. The only method that fits lumpy demand quite well is the weighted moving average (WMA) method and its superiority to ES methods has been proved: its use could provide tangible benefits to maintenance service organizations forecasting intermittent demand. By WMA we mean a moving average method in which, to compute the average of the most recent n data points, the more recent observations are typically given more weight than older observations.

48.1.3 Holt–Winter Models

Methods based on Winter's models [additive Winter (AW), multiplicative Winter (MW)] consider the seasonal factor and provide the biggest forecasting error when there is high variation (lumpy demand). While computing Holt–Winter filtering of a given time series, unknown parameters are determined by minimizing the squared prediction error; α, β and γ are the parameters of the Holt–Winter filter for the level, trend and seasonal components, respectively; if β is set to 0, the function will perform exponential smoothing, while if the γ parameter is set to 0, a non-seasonal model is fitted.

The additive Holt–Winter prediction function (for time series with period length p) is

$$\bar{Y}[t+h] = a[t] + h \cdot b[t] + s\,[t+1+(h-1)\,|p|] \tag{48.7}$$

where $a[t]$, $b[t]$ and $s[t]$ are given by

$$a[t] = \alpha(\bar{Y}[t] - s[t-p]) + (1-\alpha)(a[t-1] b[t-1]) \,, \tag{48.8}$$

$$b[t] = \beta(a[t] - a[t-1]) + (1-\beta) b[t-1] \,, \tag{48.9}$$

$$s[t] = \gamma(\bar{Y}[t] - a[t]) + (1-\gamma) s[t-p] \,. \tag{48.10}$$

The multiplicative Holt–Winter prediction function (for time series with period length p) is

$$\bar{Y}[t+h] = (a[t] + hb[t]) s[t+1+(h-1)|p|] \,, \tag{48.11}$$

where $a[t]$, $b[t]$ and $s[t]$ are given by

$$a[t] = \alpha \left(\frac{\bar{Y}[t]}{s[t-p]} \right) + (1-\alpha)(a[t-1] + b[t-1]) \,, \tag{48.12}$$

$$b[t] = \beta(a[t] - a[t-1]) + (1-\beta) b[t-1] \,, \tag{48.13}$$

$$s[t] = \gamma \left(\frac{\bar{Y}[t]}{a[t]} \right) + (1-\gamma) s[t-p] \,. \tag{48.14}$$

The function tries to find the optimal values of α and/or β and/or γ by minimizing the squared one-step prediction error, if they are omitted. For seasonal models starting values for a, b and s are detected by performing a simple decomposition in the trend and seasonal components using moving averages on the first period (a simple linear regression on the trend component is used for the starting level and trend). For level/trend models (no seasonal component) starting values for a and b are $X[2]$ and $X[2] - X[1]$, respectively. For level-only models (ordinary exponential smoothing), the starting value for a is $X[1]$.

In our opinion, although many different classification schemes could be used, the most significant classification divides the major approaches to forecasting into three main categories, as summarized in Table 48.2 [48.28]: judgmental, quantitative and technological. Each category includes several types of methods, many individual techniques and variations. *Judgmental methods* are most commonly used in business and government organizations. Such forecasts are most often made as individual judgments or by committee agreements. Nevertheless quantitative methods are better than judgmental ones in determining spare-part inventory levels and we suggest judgmental methods only in extremis.

The second category – *quantitative methods* – is the type on which the majority of the forecasting literature has focused. There are three subcategories of these methods. *Time-series methods* seek to identify historical patterns (using a time reference) and then forecast using a time-based extrapolation of those patterns. *Explanatory methods* seek to identify the relationships that led to observed outcomes in the past and then forecast by applying those relationships to the future. *Monitoring methods*, which are not yet in widespread use, seek to identify changes in patterns and relationships; they are used primarily to indicate when extrapolation of past patterns or relationship is not appropriate.

The third category – *technological methods* – address long-term issues of a technological, societal, economic or political nature. The four subcategories here are extrapolative (using historical patterns and relationships as a basis for forecasts), analogy-based (using historical and other analogies to make forecasts), expert-based and normative-based (using objectives, goals and desired outcomes as a basis for forecasting, thereby influencing future events).

48.2.1 Characterizing Forecasting Methods

In describing forecasting methods there are seven important factors, which reflect their inherent capabilities and adaptability.

1. *Time horizon* – two aspects of the time horizon relate to individual forecasting methods. First is the span of time in the future for which different forecasting methods are best suited. Generally speaking, qualitative methods of forecasting are used more for longer-term forecasts, whereas quantitative methods are used more for intermediate- and shorter-term situations. The second impor-

tant aspect of the time horizon is the number of periods for which a forecast is desired. Some techniques are appropriate for forecasting only one or two periods in advance; others can be used for several periods. There are also approaches for combining forecasting horizons of different lengths.

2. *Pattern of the data* – underlying the majority of forecasting methods is an assumption about the type of pattern(s) found in the data to be forecast: for example, some data series may contain seasonal as well as trend patterns; others may consist simply of an average value with random fluctuations and still others might be cyclical. Because different forecasting methods vary in their ability to predict different types of patterns, it is important to match the presumed pattern(s) in the data with the appropriate technique.
3. *Cost* – generally three direct elements of costs are involved in the application of a forecasting procedure: development, data preparation and operation. The variation in cost obviously affects the attractiveness of different methods for different situations.
4. *Accuracy* – closely related to the level of detail required in a forecast is the desired accuracy. For some decision situations, plus or minus ±10% may be sufficient, whilst in others a small variation of 2% could spell disaster.
5. *Intuitive appeal, simplicity, ease application* – a general principle in the application of scientific methods to management is that only methods that are deeply understood are used by decision makers over time. This is particularly true in the area of forecasting.
6. *Number of data points required from past history* – some methods produce good results without consistent data from the past, because they are less affected by estimation errors in their input parameters.
7. *Availability of computer software* – it is seldom possible to apply a given quantitative forecasting method unless an appropriate computer program exists. Such software must be user-friendly and well conceived.

48.3 The Applicability of Forecasting Methods to Spare-Parts Demands

Companies have to select in advance an appropriate forecasting method matching their cyclical demand for parts. Particular attention has to be paid to the demand for service-part inventories, which is generally irregular and difficult to predict. A summary of the better forecasting methods, related to the categorization scheme in Fig. 48.1, is presented in Table 48.3.

48.4 Prediction of Aircraft Spare Parts: A Case Study

The technical divisions of airlines are based on total hours flown and on the fleet size. With this data, the purchasing department tries to determine the quantity of stock necessary for a particular operating period. Alternatively, when new types of aircrafts are introduced, the airframe and engine manufacturers normally provide a recommended spares provisioning list, which is based on the projected annual flying hours, and includes forecast usage information for new aircraft. Original equipment manufacturers also provide overhaul manuals for aircraft components that support the assessment of required parts based on reliability information, i. e., on the specified components' operational and life limits. Consequently the forecast of spare parts is practically based on past usage patterns and personal experience.

Before any consideration about lumpiness and aircraft spare-parts forecast a discussion on the selection of the main variables used as the *clock* for spare-parts life evaluation is absolutely necessary. According to Campbell's study on maintenance records of the United State Air Force the demand for spare parts appears to be strongly related to flying hours; but this sometimes does not appear to be the best indicator, e.g., to forecast demand for landing gear, what matters is not how long the aircraft is in the air, but how often it lands, or radar components that work only when the aircraft is on the ground. In conclusion often flying hours are the best clock, but a demonstration of its effectiveness is necessary for each item.

In this study different forecasting methods have been considered; briefly:

1. Additive/Multiplicative Winter (AW/MW) For each forecast the optimal combination of level, trend and seasonal parameters is realized. Available values for each variable (level and trend) are 0.2 and 0.01; the seasonal length used is 12 periods.
2. Seasonal regression model (SRM). A multiplicative model with trend and seasonal components. The seasonal length is 12 periods.
3. Single-exponential smoothing (SES). The statistical software applied (Minitab 14.0©) supports the research of the optimal weight of the smoothing constant. The result is then the best forecast with this method.
4. Double-exponential smoothing (DES). Dynamic estimates are calculated for two components: level and trend; the software supports their optimization. In this case the best forecast with DES is also guaranteed.
5. Moving average (on the generic i-period) [MA(i)]. Moving averages (MAs) are calculated with different

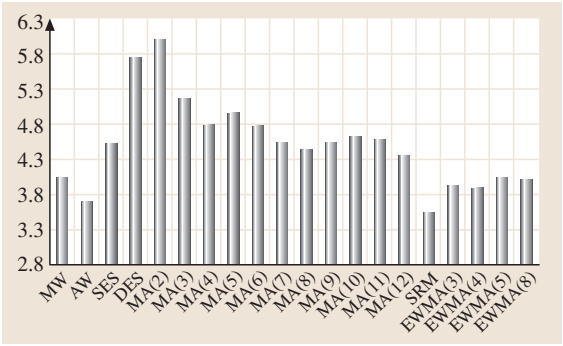

Fig. 48.4 MAD for item z

time horizons (i-period). The notation is MA(i). This analysis employs every period length from 2 to 12.

6. Exponentially weighted moving average [EWMA(i)]. In this case a weight optimization of smoothing coefficient for an MA series has also been realized. EWMA(i) is calculated for $i = 3, 4, 5$ and 8 periods.

Despite their importance in the literature [48.29–31], we do not evaluate and compare methods based on the Poisson approach because they are revealed as inadequate for the prediction of intermittent demand.

The case study deals with more than 3000 different items, with different levels of lumpiness: the Airbus fleet belonging to the Italian national-flag airline. For each component records relate to the daily demand level grouped in monthly interval of item usage, from 1998–2003. In terms of lumpiness these avionic spare parts are classified into five different classes of behavior; for each class a representative item, named a, x, y, z, w for confidentiality, is indicated.

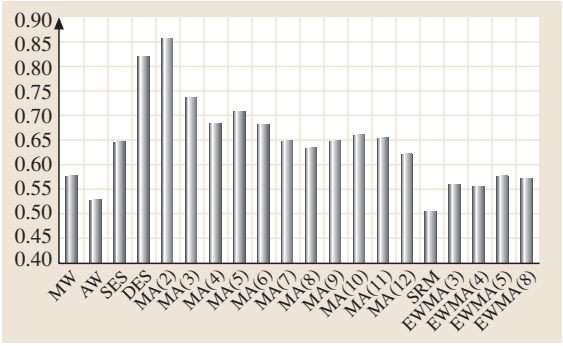

Fig. 48.5 MAD/A for item z

Figure 48.3 presents an exemplifying demand of item z. The five lumpiness levels are reported in Fig. 48.2.

The mean absolute deviation (MAD) of the forecast error is adopted as a performance index

$$\mathrm{MAD} = \frac{\sum_{i=1}^{n} |\varepsilon_{ri} - \varepsilon_{fi}|}{n} , \qquad (48.15)$$

where ε_{fi} is the forecasted demand for period i. Some authors propose the mean absolute percentage error (MAPE) for this comparison, but under lumpy conditions many item demands are zero, and as a consequence MAPE is not defined. For this reason some authors propose a similar index, called MAD/A, also defined when the demand for items is zero:

$$\mathrm{MAD/A} = \frac{\mathrm{MAD}}{\mathrm{AVERAGE}} , \qquad (48.16)$$

where AVERAGE is the average value of the historical demand for the item. The tracking signal (TS), as defined by *Brown* [48.32], is used to check if forecasts are in control or not.

$$\mathrm{TS}_t = \left| \frac{\mathrm{CUSUM}_t}{\mathrm{EMAD}_t} \right| , \qquad (48.17)$$

where $\mathrm{CUSUM}_t = (\varepsilon_{rt} - \varepsilon_{ft}) + \mathrm{CUSUM}_{t-1}$ and $\mathrm{EMAD}_t = \alpha\,|\varepsilon_{rt} - \varepsilon_{ft}| + (1-\alpha)\mathrm{EMAD}_{t-1}$.

Limit values of TS and the optimal α value (0.25) are derived from the approach of Alstrom and Madsen [48.33]. For the items analyzed forecasts are in control from the third year (i. e., their tracking signals respect the limits). The different forecasting methods are compared for all items and in particular for the proposed five components.

Table 48.4 and Figs. 48.4 and 48.5 show, respectively, some brief and full results of MAD and MAD/A for item z. Table 48.5 presents, for each representative item, the list of forecasting methods ordered

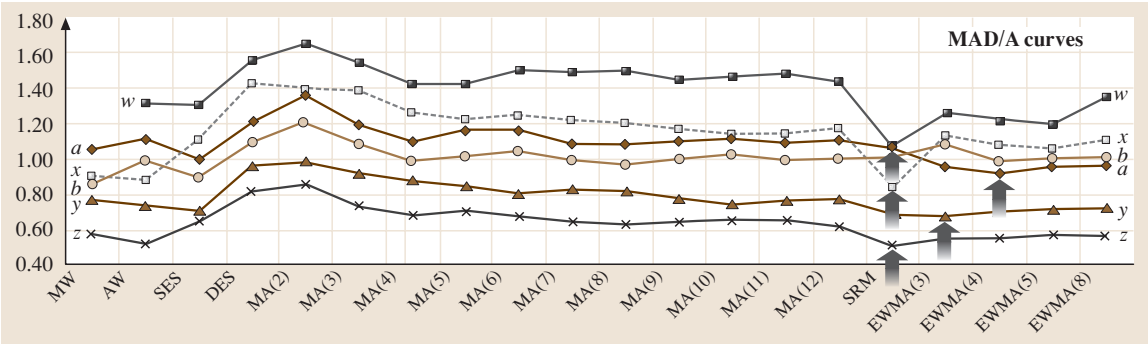

Fig. 48.6 MAD/A data and curves

by decreasing MAD, thus assigning a relative weight related to the ranking position: a simple elaboration of these weights permits a full comparison in terms of total and average scores (MW is not defined for item w, due to its characteristics).

By means of MAD/A it is possible to compare different forecasting methods for different items and their behavior in face of different lumpiness conditions; SRM, EWMA(i) and Winter are the best forecasting methods. This result is not related to the lumpiness level, at least for lumpiness represented by ADI < 3.3 and $CV^2 < 1.8$, which is the typical range for aircraft components. Some interesting observations can be drawn:

- Figure 48.6 clearly attests that item lumpiness is a dominant parameter, whilst the choice of the forecasting method is of secondary relevance; all methods for a slightly lumpy item (e.g. items y and z) generally perform better than the best method for a highly lumpy component (e.g. items x and w). However lumpiness is an independent variable and is not controllable;
- the average value of MAD/A, calculated for all forecasts generated by all methods, is 1.02. The aim of this study is to compare the different forecasting methods, but we can conclude that demand forecasting for lumpy items is very difficult and the results

are not very accurate. Moreover, lumpy demand is often equal to zero or one: all predictions lower than one must be rounded up to one. This phenomenon introduces another source of error;

- for a single component, the average fluctuation (in terms of MAD/A) of the ratio maximum/minimum, among different techniques, is about 1.55 (usually between 1.40 and 1.70); for a single forecasting method, the average fluctuation (in terms of MAD/A) of the ratio maximum/minimum, among different components, is about 2.17 (usually between 1.57 and 2.18). Thus, the demonstrating again the relevance of lumpiness.
- analyzing the effectiveness of a single model, research demonstrates (Tables 48.3 and 48.4) that the seasonal regression model (SRM), the exponentially weighted moving average [EWMA(i)] and the Winter model are the best forecasting methods. It is important to remember that the analyzed items are effectively representative of a population of aircraft spare parts. This result is not related to the lumpiness level, at least for lumpiness represented by ADI < 3.3 and $CV^2 < 1.8$ (the typical range for aircraft components).

In conclusion, intermittent demand for, usually highly priced, service parts is a very critical issue, especially for the prediction of lumpy demand, as is typical for avionic spare parts. In the literature forecasting for lumpy demand has not been investigated deeply, apart from Ghobbar's interesting research, and conflicting results are sometimes recovered. The introduction of the economic question is the final development: it is absolutely necessary to check the impact of stocking costs and out-of-stock components on the forecasting methods; an aircraft operator can incur costs of more than \$30 000 per hour if a plane is on the ground.

48.5 Poisson Models

For builders of high-technology products, such as automatic packaging machines, the supply of spare parts creates a strategic advantage with respect to their competitors, with particular regards to low-turnaround-index (LTI) parts conceived and designed for the satisfaction of a specific customer request. The strategic problem to solve is to determine the minimum number of spare parts required to avoid downtimes of the customer's plants for a specific period, called the covering period, which coincides with the time between two consecutive consignments.

The procedure actually used by a great number of manufacturers, called *recommended parts*, consists of the creation, at the design stage, of different groups of replaceable parts with different covering times for every functional machine group. This methodology is very qualitative and depends strongly on the opinion of the designer; moreover, it does not consider information feedback from customers, and usually overestimates the number of spare parts with respect to the real demands of customers. Even though this avoids plant downtimes, which are absolutely forbidden due to the high costs of production loss, it normally creates excessive and expensive stocks, with undesirably high risks of damage and obsolescence. For LTI items the usual economic batch or safety stock methods are not suitable to forecast the amount of spare parts required. For such a situation a lot of different approaches have been developed in recent years, usually based on the Poisson distribution; of these, conditioning of the stock level to minimal availability or to minimum total cost (Fig. 48.7) are considered the most interesting.

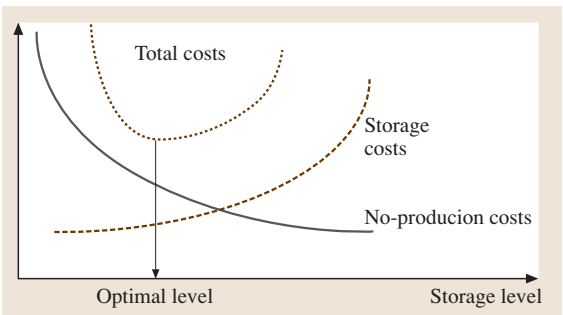

Fig. 48.7 Economic approach

Every study reported in the literature [48.34, 35] assumes that an item's failure time (for spare-parts demand) is exponentially distributed and, as a consequence, the failure rate $\lambda(t)$ is independent of time; this simplifying hypothesis is due to the difficulties in estimating real values of mean time before failure (MTBF). Finally it is important to underline that the quantity of spare parts and its temporal distribution also represent

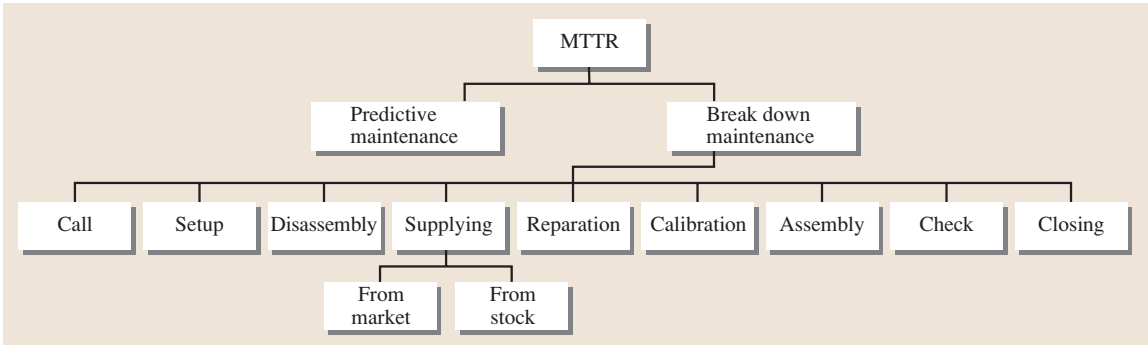

Fig. 48.8 MTTR structure

strategic information during negotiations with customers for the purchase of plants and the quantification of related costs.

48.5.1 Stock Level Conditioned to Minimal Availability

This method firstly needs to calculate the asymptotic availability A by the known formula:

$$A = \frac{\text{MTBF}}{\text{MTBF}+\text{MTTR}} \,. \tag{48.18}$$

The mean time to repair (MTTR) term is derived from different factors, as shown in Fig. 48.8.

Its value depends strongly on the spare part being on consignment, i. e. on hand, or not, and can be calculated by the formula

$$\text{MTTR} = T_1 + \int_0^{T_S} (T_S - T_x) f(T_x) \mathrm{d}T_x = \text{MTTR}(N) \,, \tag{48.19}$$

where T_1 is the amount of time due to factors except supply time (for instance, disassembling), T_S is the supply lead time for unavailable components, N is the number of spare parts available in stock at time zero, T_x is the time interval between the instant when the consumption of the part reaches the value N (empty stock situation) and the consignment of the spare part, and $f(t)$ is the failure density distribution.

It is worth noting that, for increasing N, we get decreasing MTTR, increasing availability A and the falling downtime costs. Secondly the method affords the quantitative definition of the storage cost, which requires the definition of the average number of parts stored during the time of supply T_S. If the warehouse contains N parts at time zero, the probability P_N of N failures in T_S can be described by the Poisson formula

$$P_N = \frac{(\lambda T_S)^N \cdot \mathrm{e}^{(-\lambda T_S)}}{N!} \,. \tag{48.20}$$

In the same way it is possible to calculate the probability of one, two, or N failures.

Let R indicate the cost of each spare part, and s be the stocking cost index per year; the annual stock costs C can be evaluated by the formula $C = Rs[NP_0 + (N-1)P_1 + (N-2)P_2 + \ldots P_{N-1}]$, which can be used in an iterative manner to find the optimum level N that leads to a minimum for the cost C, while allowing the minimum level of availability $A_{\min}(N)$ to guarantee on-time technical requests to be satisfied (for example, safety questions or productivity level)

$$\begin{cases} \min \left\{ C = Rs \left[NP_0 + (N-1)P_1 \right. \right. \\ \qquad \left. \left. + (N-2)P_2 + \cdots + P_{N-1} \right] \right\} \\ \text{subject to } A(N) = \frac{\text{MTBF}}{\text{MTBF}+\text{MTTR}(N)} \geq A_{\min} \,. \end{cases} \tag{48.21}$$

48.5.2 Stock Level Conditioned to Minimum Total Cost

The aim of this method is to determinate the total amount N of replaceable parts that minimizes the total cost function C_{tot} defined by

$$C_{\text{tot}}(N) = C_1 + C_2 \,. \tag{48.22}$$

The warehousing cost term C_1 can be estimated as in (48.21), while for the cost C_2 it is necessary to quantify the probability of stock-out situations. During the time T_S production losses could occur if the number of failures exceeds the number N of parts supplied at the consignment time, assumed to be zero. The cumulative

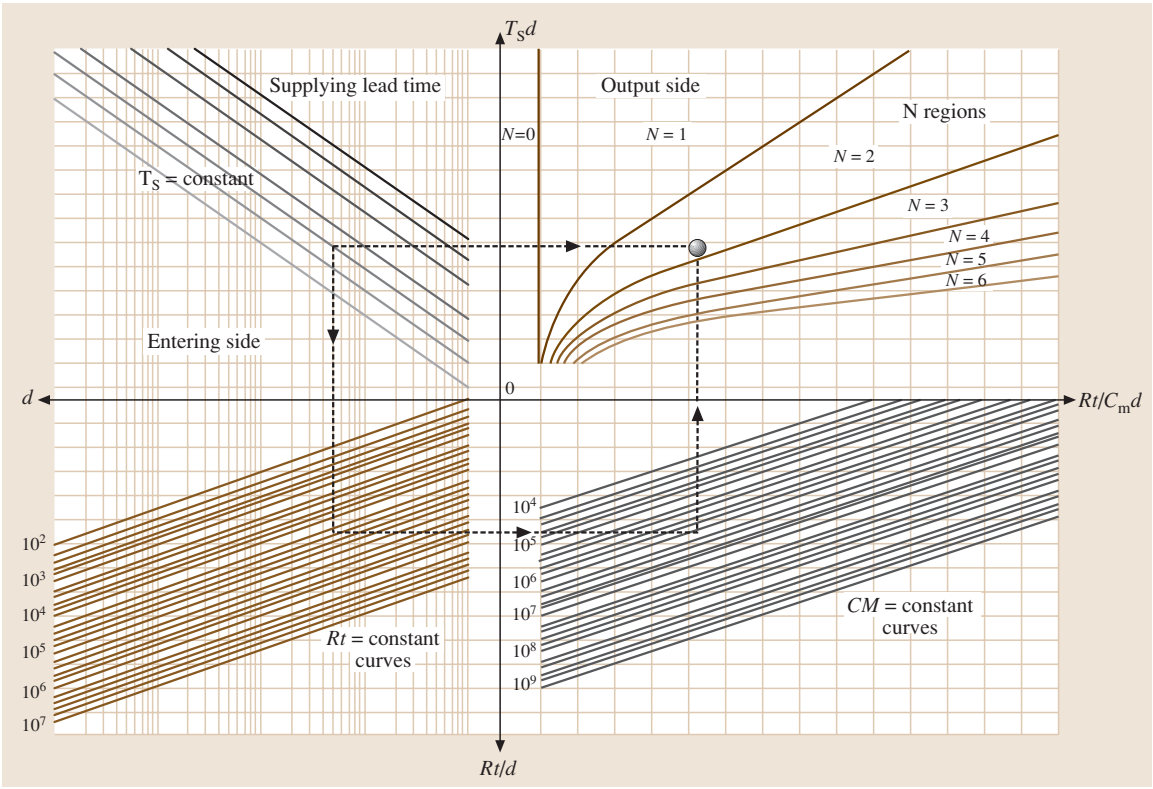

Fig. 48.9 Graphical abacus

probability, calculated by the Poisson distribution, is

$$P = P_{N+1} + P_{N+2} + P_{N+3} + \dots . \tag{48.23}$$

Let d indicate the annual part consumption of a customer and CM the cost corresponding to a loss of production; the term due to stock-out is

$$C_2 = CMdP . \tag{48.24}$$

For a rapid choice it is possible to employ a user-friendly abacus (Fig. 48.9).

48.6 Models Based on the Binomial Distribution

Industrial applications show that methodologies based on the Poisson formula usually overestimate the actual replacement consumption. To overcome this problem we present a new quantitative procedure that, in contrast to the Poisson methods, does not assume that requests for parts are linear over time.

The innovative approach calculates the requirement for components, for a given covering period T, by the addition of two addenda x_1 and x_2: the first is related to the wear damage of the replaceable component and can be deduced from the MTBF value, while the second refers to the randomness of breakdowns and covers the possibility of failures in advance of the average situation. The optimal number of replacements is $N = x_1 + x_2$.

Let n be the number of different employments of a component in several machines owned by the customer and let T be the covering period; x_1 can be expressed by:

$$x_1 = \text{int}\left(\frac{T}{\text{MTBF}}\right) n . \tag{48.25}$$

This average term assumes interesting values only in the presence of high consumption of the component, in par-

Table 48.6 Example of N evaluation for a specific item (code 0X931: pin for fork gear levers)

Input	
MTBF (h)	3945
Positions (n)	26
Confidence level	97%

X_1	0
Tresidual (h)	2300
P (Tresidual)	0.442
X_2	See table
$N = X_1 + X_2$	16

ticular in the rare situations when a LTI part has a lot of applications, indicated by n. Anyway this term x_1 represents scant information; we have to consider the second term, which corresponds to the number of parts needed to obtain the required value of the customer service level (LS) in the residual time T_{residual}, defined as the residue of the ratio between T and MTBF. The customer service level is the probability that the customer finds the parts during the remaining period, and can be fixed separately according to strategic and economic assessments.

The value of x_2 is obtained as follows

$$T_{\text{residual}} = T - \text{int}\left(\frac{T}{\text{MTBF}}\right)\text{MTBF}\,, \tag{48.26}$$

$$p = Q(T_{\text{residual}}) = 1 - \text{e}^{-\left(\frac{T_{\text{residual}}}{\text{MTBF}}\right)}\,, \tag{48.27}$$

where p represents the failure probability during T_{residual}. Using p and the binomial distribution it is easy to calculate the probability that a component (with n applications) requires fewer than x_2 replacements in T_{residual}:

$$P\left[x \le x_2; n; Q(T_{\text{residual}})\right] = \sum_{i=0}^{x_2}\binom{n}{i}(1-p)^{n-i}p^i\,. \tag{48.28}$$

As a consequence it is possible to quantify the confidence level for no stock-outs to compare with the customer satisfaction as

$$\text{LS}(x_2) = 1 - P\left[x \le x_2; n; Q(T_{\text{residual}})\right]\,. \tag{48.29}$$

The main innovative result is that the procedure, in contrast to other methods, does not consider the total requests for spare parts to be linear with time; it tries to set the best moment for supply in order to maximize the customer service level without increasing the average number of spare parts. In fact the new method respects the average consumption through the term x_1 and increases the levels of customer service by planning requirements for spare parts in the residual time through the term x_2.

48.6.1 An Industrial Application

This procedure is successfully running on PC systems in an Italian company that is a leader in manufacturing

of packaging machines. The supply of spare parts creates a strategic advantage over competitors, because the automatic packaging machines usually present a long life cycle and contain a lot of functional groups, often conceived and designed ad hoc. The economic impact of replacement activity is not negligible: it usually amounts to 15% of global business volume. A good forecast of spares parts can surely simplify manufacturer production planning. Before its industrial real-time application the innovative procedure was tested to forecast the consumption of 190 different spare parts indicated by several customers over a 33-month period.

The experimental results of these procedure were evaluated by two performance indexes:

1. percentage of spare parts without stock-out periods,
2. effective utilization of replacements by the customer.

As a first test the new procedure was applied with the restrictive hypothesis of a covering period of one

month: using an LS value of 99.8% the method performed well for 166 replaceable parts and there was very good correlation between predicted and actual customer consumption. This is shown in the comparison in Table 48.6 between actual consumption and the Poisson linear forecast (LS = 90%) for a pin for fork gear levers with 26 applications in the customer's machine park.

88% of the components investigated did not suffer from stock-out in any month; 3% presented less than three months of under-evaluation and 9% had more than three months in stock-out. On the other hand the utilization index showed that 87% of the components had normal, good or optimal customer use: in other words they did not remain in the spare-parts warehouse for more than 15 days before installation (Fig. 48.11).

Moreover, parts with bad forecasts were investigated to understand the reasons, with very encouraging results; errors were usually caused by preventive maintenance operations, machine revisions, changes of suppliers or changes in the application of the component not pointed out by the customer. The effect of the extension of the covering period was analyzed by testing the new method with different values of T. For increasing T we obtain an increasing stock of spare parts but the number of stock breakages strongly decreases: in fact for $T = 1$ month the method performed well for 88% of the parts investigated, and this percentage increased to 90% for $T = 3$ months, 95% for $T = 6$ months and to 98% for $T = 1$ year. Therefore it was possible to study the optimum extension of the covering period, that for the 190 components investigated was found to be equal to three periods (Fig. 48.12).

Some simulations with different values of MTBF show the influence of its approximate evaluation: values of MTBF overestimated by 10% and 20% reduce the performance of the method respectively by 6% and 9% in terms of the percentage of spare parts without stock-out periods (Fig. 48.13).

In spite of this important conclusion, it is important to remember that MTBF values have to be updated, starting from the initial value of $\mathrm{MTBF}_{\mathrm{initial}}$, by feedback information from the customers; the most suitable control parameter is the component quantity Y employed by the customer during the covering period T and the relation (48.30) that gave the best results, as shown in Figs. 48.14 and 48.15:

$$\mathrm{MTBF}_{\mathrm{updated}} = \frac{\mathrm{MTBF}_{\mathrm{initial}}\,(\mathrm{MTBF}_{\mathrm{initial}}) + \frac{nT}{Y}(nT)}{\mathrm{MTBF}_{\mathrm{initial}} + nT}\,, \tag{48.30}$$

where $\mathrm{MTBF}_{\mathrm{updated}}$ is the weighted average of $\mathrm{MTBF}_{\mathrm{initial}}$, and $\frac{nT}{Y}$ (weights in round brackets).

48.7 Extension of the Binomial Model Based on the Total Cost Function

The proposed model required the assumption of a specific spare-part LS defined as the probability of finding the part in case of breakdown. Some simulations with different values of LS show that it is important to assume LS $\leq$ 80% and to reserve LS $\geq$ 90% for particular situations, e.g. customers placed in a distant country or without skilled workers. It is possible to determine the number N of replaceable parts needed and therefore the LS value capable of minimizing a total cost function defined by the sum of costs due to storage and production losses.

48.7.1 Service-Level Optimization: Minimum Total Cost Method

The aim of this paragraph is to determine the requirement N of replaceable parts capable of minimizing a total cost function defined by the sum of production losses costs C_1 and storage costs C_2. During the time T_S production losses could occur if the number of failures exceeds the number N of supplied parts that are available after the consignment at time zero. The corresponding cumulative probability can be calculated by formula:

$$\begin{aligned} P &= P(N+1)+P(N+2)+P(N+3)+\ldots \\ &= 1-\mathrm{LS}(x_2) = 1-\mathrm{LS}(N-x_1)\,, \end{aligned} \tag{48.31}$$

$$\mathrm{LS}(N-x_1) = P[X \leq N-x_1,\ n,\ Q(T_{\mathrm{residual}})]\,. \tag{48.32}$$

If d and CM represent, respectively, the customer annual part consumption and the cost for a production lack, the total cost C_1 due to stock-out is

$$C_1 = CMdP\,. \tag{48.33}$$

The storage cost C_2 requires the definition of the average number of parts stored during the supplying time T_S. Two different situations are possible related to the spare-part MTBF and T_S:

Table 48.7 LS % and minimum cost related to $T_s d$ and $Rt/(C_m d)$– no. of employments $n = 5$

LS % ($n = 5$)	$T_s d$							
$Rt/(C_m d)$	5	4	2	1	0.8	0.2	0.02	0.02
9	0.7	1.8	13.5	37	44.9	81.9	98	99.8
3	6.5	13.1	13.5	37	44.9	81.9	98	99.8
1.5	26.4	40.6	46.8	37	44.9	81.9	98	99.8
0.9	60.5	40.6	46.8	78	44.9	81.9	98	99.8
0.3	89.9	74.3	79.6	78	83.9	81.9	98	99.8
0.1	100	94.9	95.7	95	97.4	81.9	98	99.8
0.03	100	100	99.6	100	97.4	98.6	98	99.8
0.003	100	100	100	100	99.8	99.9	100	99.8
0.0003	100	100	100	100	100	100	100	100

Case a. MTBF $< T_S$; in this case $N = x_1 + x_2 = x_2$ because $x_1 = 0$.

If the warehouse contains N parts at time zero, the probability P_N of N failures in T_S can be calculated using (48.21). Let R indicates the cost of each spare part, and t the annual stocking cost index; the global annual storage cost C can be evaluated by

$$C = Rt \sum_{k=0}^{N} \left[\binom{N}{k} (1-p)^{N-k} p^k \right] (N-k) \,. \quad (48.34)$$

Case b. MTBF $\geq T_S$

In this case the definition of the average number of parts stored during the supply time T_S has to take in account both contributions, in terms of average stock $S(x_1)$ and $S(x_2)$, of x_1 and x_2. LS is connected to x_2, and the minimum real value of N is therefore x_1. We can get the contributions in (48.36) by the previously defined values of x_1 and x_2. The annual stock cost C can be evaluated by

$$C = Rt\,[S(x_1) + S(x_2)] \,, \quad (48.35)$$

which can be used in an iterative process to find the optimum level N according to the minimization of previous cost C.

$$S(x_1) = \frac{1}{2} \left(\frac{x_1 \mathrm{MTBF}}{T_S} \right) ;$$

$$S(x_2) = \frac{x_2 \mathrm{MTBF}}{T_S} + \frac{\sum_{k=0}^{N-x_1} \binom{N-x_1}{k} (1-p)^{N-x_1-k} p^k}{T_S} \times (N - x_1 - k)\,(T_S - \mathrm{MTBF}) \,. \quad (48.36)$$

48.7.2 Simulation and Results

A simulation model has been designed in order to find the optimum value of LS for different values of the parameters. Input data are the MTBF, number of employments n, time for supply T_S, cost of each spare part R, annual stocking cost index t, downtime cost per hour C_m, MTTR, total hours per year of uptimes plus

Table 48.8 LS % and minimum cost related to $T_s d$ and $Rt/(C_m d)$– no. of employments $n = 15$

downtimes H, the customer annual part consumption d. Assuming for instance MTBF = 10 000 h and $n = 5$, the optimum value of LS versus the two variables $(Rt)/(C_m d)$ and $T_S d$ is reported in Tables 48.7 and 48.8 (for $n = 5$ and $n = 15$, respectively). It is worth stating that LS must be close to 100% when $C_m \gg R$, while in the opposite case the optimum LS is a function of $T_S d$, and always tends upwards for decreasing n.

Figure 48.16 shows how to employ the abacus.

Table 48.9 Optimization of T_s for fixed number of spare parts N

Component	$N = x_1 + x_2$	$T_s(d)$	LS(%)

Clamp	4	90	98
Special gasket	5	90	95

48.7.3 An Industrial Application

This case study is related to an important producer of steam boiler systems that actually manufacturing components for internal use and for replacement ordered by customers according to a fixed economic order quantity (EOQ). The application deals with the optimization of the supply time in order to reduce the total management costs of spare parts at the assigned EOQ [48.36]; that is, the aim is to define the time between consignments capable of reducing total costs for the same value of EOQ. Three components (a support grid, the clamp and a special gasket) are considered, with a downtime calculated

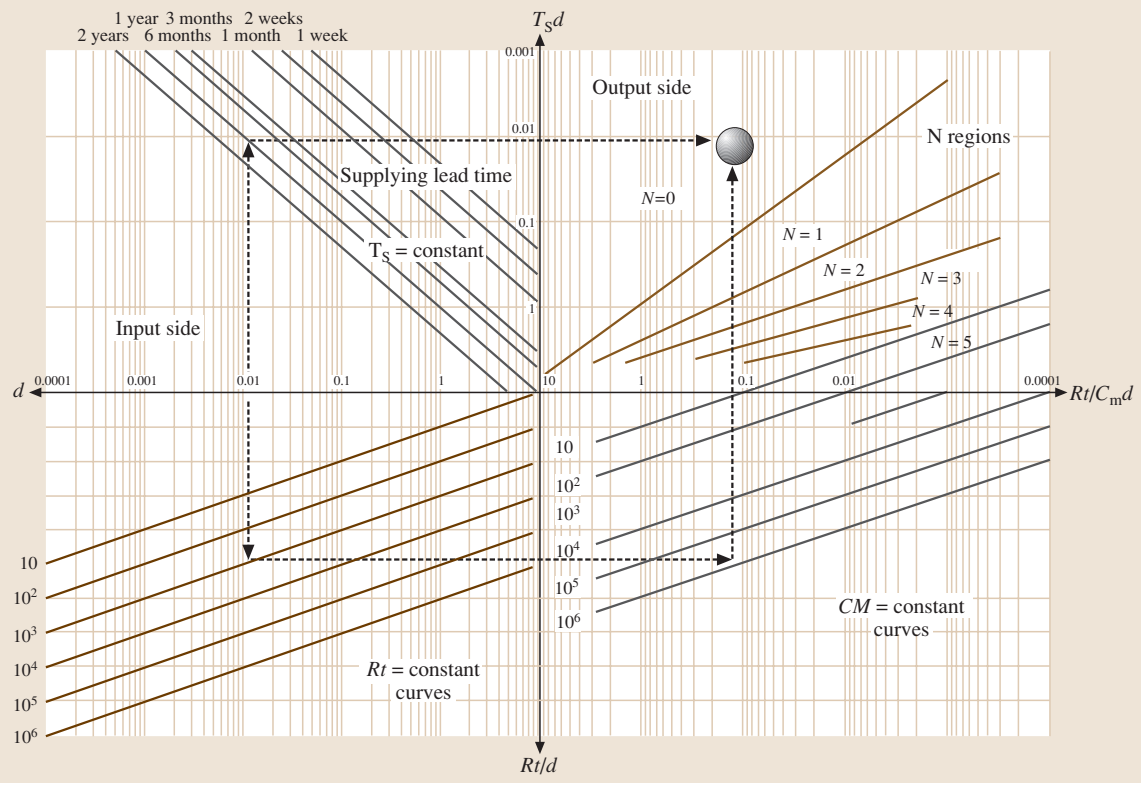

Fig. 48.16 Graphical solution for this methodology

as

$$\text{Downtime} = \text{MTTR} \times dn \,. \tag{48.37}$$

In particular the support grid has $n = 5$ employments, $H = 1760$ total hours per year, $d = 0.5$ annual part consumption [unit/year] on the whole, MTTR = 10 h, MTBF = 8800 h downtime cost per hour $C_m = 1000\,€/h$ and, as a consequence, $CM = C_m\text{MTTR} = 10\,000\,€$ cost for a production stock-out. This component was supplied in fixed EOQ with $N = 3$ elements, at a cost per unit of $R = 100\,€/\text{unit}$ ($R \ll C_m$); the relative risk of damage and obsolescence suggests $t = 0.1$ for the annual stocking cost index. Entering the abacus with these values for N, CM and Rt (Fig. 48.15) we obtain as a result the optimal time for supply $T_S = 400$ d; by means of (48.31) and (48.32) with $N = x_1 + x_2 = 0 + 3$ ($x_1 = 0$ because MTBF $< T_S$) we determine LS $\approx 99\%$; this very high level is due to the low values of t and the rate R/C_m.

The results following the use of the graphical abacus are shown in Table 48.9 for the whole set of components.

The results are summarized in Fig. 48.17 and compared with the output of an existent minimum-cost method based on the Poisson distribution.

48.8 Weibull Extension

This innovative methodology can be extended to the whole lifetime by implementing the Weibull failure-rate function to the stock level of LTI spare parts level in maintenance systems with declared wear conditions. The Weibull distribution is one of the most commonly used lifetime distributions and is flexible in modeling failure-time data, as the corresponding failure-rate function can vary or be assumed to be constant. The literature offers a lot of papers dealing with models for bath-tub-shaped failure rates. For example *Hjorth* [48.37] proposed a three-parameter distribution; *Mudholkar* and *Srivastava* [48.38] introduced an exponential Weibull distribution; *Chen* [48.39] spoke about a two-parameter lifetime distribution with a bath-tub shape or an increasing failure-rate function; *Xie* [48.40] wrote a very interesting paper about a model that can be seen as a generalization of the Weibull distribution and tries to improve the procedure for estimation of the parameters.

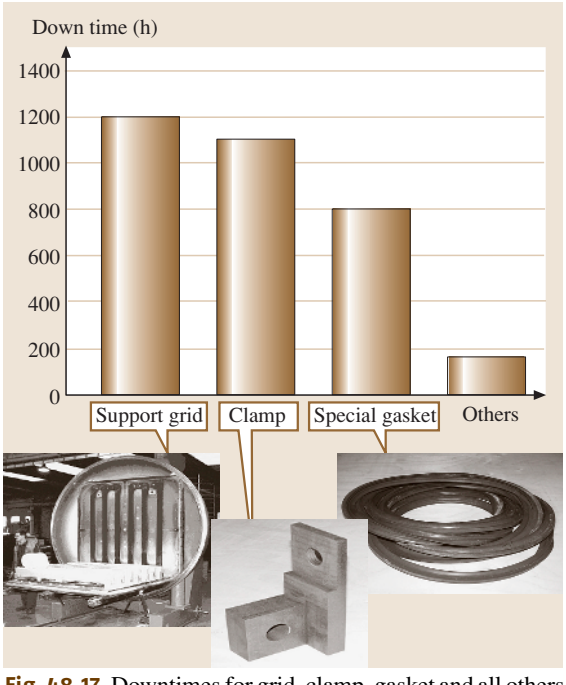

Fig. 48.17 Downtimes for grid, clamp, gasket and all others components (cumulative)

Estimation of the well-known parameters η (scale) and β (shape) in a Weibull distribution can be performed graphically but this is not accurate unless there is a large sample size, which is not always the case for LTI spare parts; anyway we focus our attention to the final zone in the traditional *bath-tub* wear model, and our aim is to understand whether the hypothesis of constant failure rate in our previous works increases the spare-parts costs, in comparison with more sophisticated distributions. For this reason we developed our model using the traditional Weibull distribution, but this could be extended to any of the models mentioned above.

48.8.1 The Extension of the Modified Model Using the Weibull Distribution

Using historical data it is possible to determine the cumulative percentage of component failures related to their lifetime. The graphical approach of Fig. 48.18 permits the definition of the Weibull distribution parameters η (scale parameter) and β (shape parameter). This is possible by Plait transformation (Weibull transformation); starting from the failure rate calculated as in (48.38),

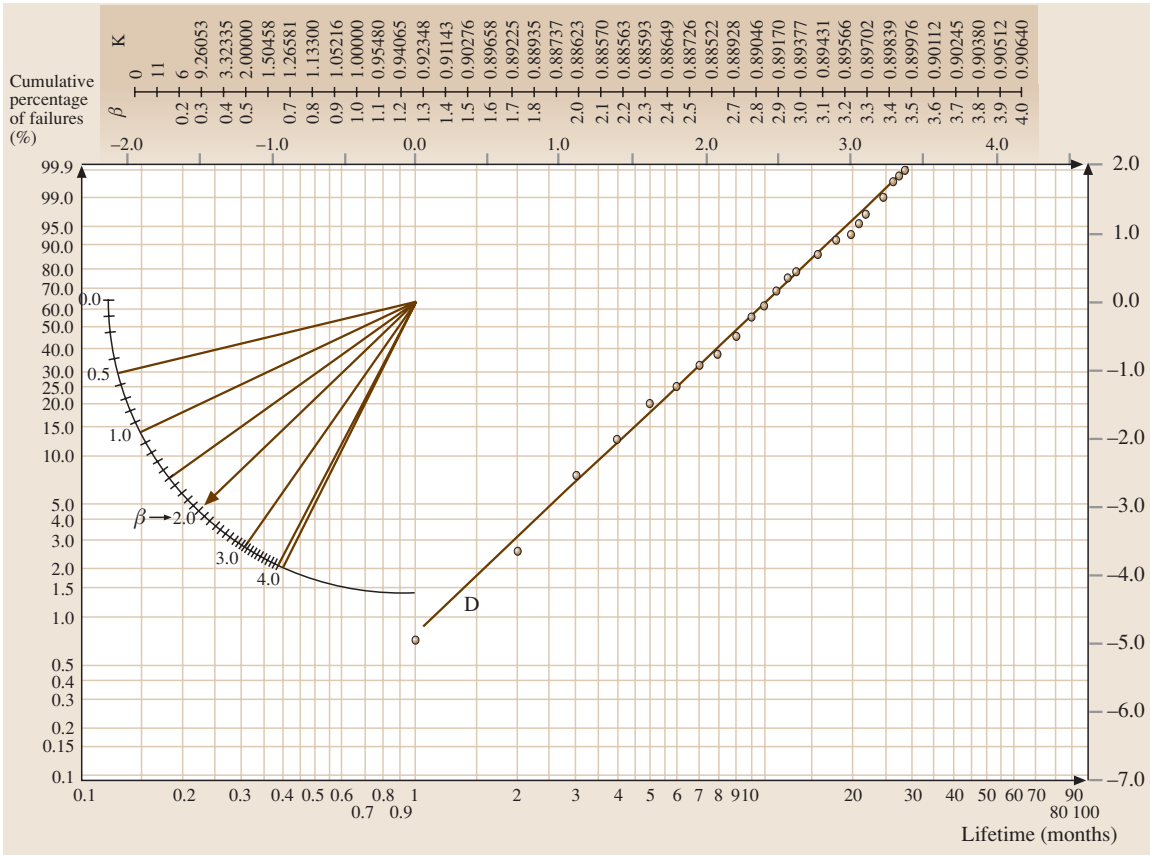

Fig. 48.18 Graphical estimation of the β value

the reliability in (48.39), the cumulative distribution functions in (48.40), and the definition of a normalized parameter x using (48.41), find a linear correlation between the parameter x and the cumulative distribution function (48.42), represented in Fig. 48.18

$$\lambda(t) = \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{t}{\eta}\right)^{\beta} = \frac{\beta}{\eta}\left(\frac{t}{\eta}\right)^{\beta-1} = \frac{\beta}{\eta^{\beta}} t^{\beta-1} , \tag{48.38}$$

$$R(t) = \mathrm{e}^{-\left(\frac{t}{\eta}\right)\beta} , \tag{48.39}$$

$$F(t) = 1 - R(t) = \mathrm{e}^{\left(-\frac{t}{\eta}\right)^{\beta}} , \tag{48.40}$$

$$x = -\frac{t}{\eta} , \tag{48.41}$$

$$\beta \ln(x) = \ln\left[\ln\left(\frac{1}{1-F(x)}\right)\right] . \tag{48.42}$$

The optimal replacement number of LTI spare parts is also given by relation (48.25), whilst the relations (48.27) and (48.28) are modified by the Weibull parameters η and β:

$$p = Q\left(T_{\text{residual}}\right) = 1 - \mathrm{e}^{-\left(\frac{t}{\eta}\right)^{\beta}} , \tag{48.43}$$

$$P\left[x \le x_2; n; Q\left(T_{\text{residual}}\right)\right] = \sum_{i=0}^{x_2} \binom{n}{i} (1-p)^{n-i} p^i . \tag{48.44}$$

It is possible to quantify the no-stock-out confidence level to compare with customer satisfaction as $\mathrm{LS}(x_2) = 1 - P[x \le x_2; n; Q(T_{\text{residual}})]$. As previously stated LS must be close to 100% when $C_{\mathrm{m}} \gg R$, while in the opposite case the optimum LS is a function of $T_{\mathrm{S}}d$; in this case, for fixed MTBF, the optimum LS increases with the number of employments n.

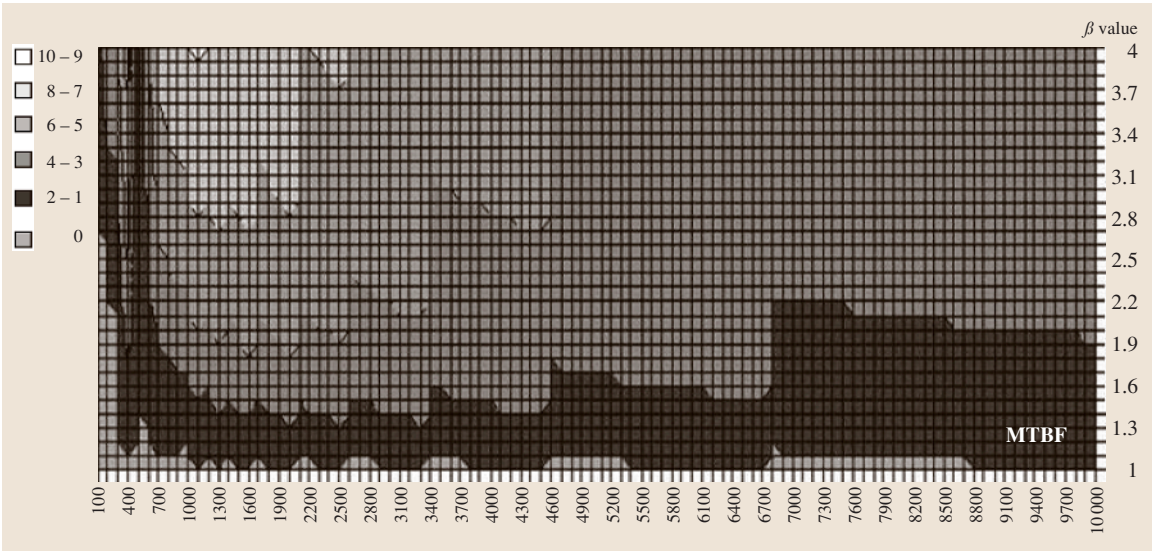

Fig. 48.19 Difference between optimal numbers of replacements calculated by (48.29) or (48.44) with respect to the average life of the component MTBF and β values

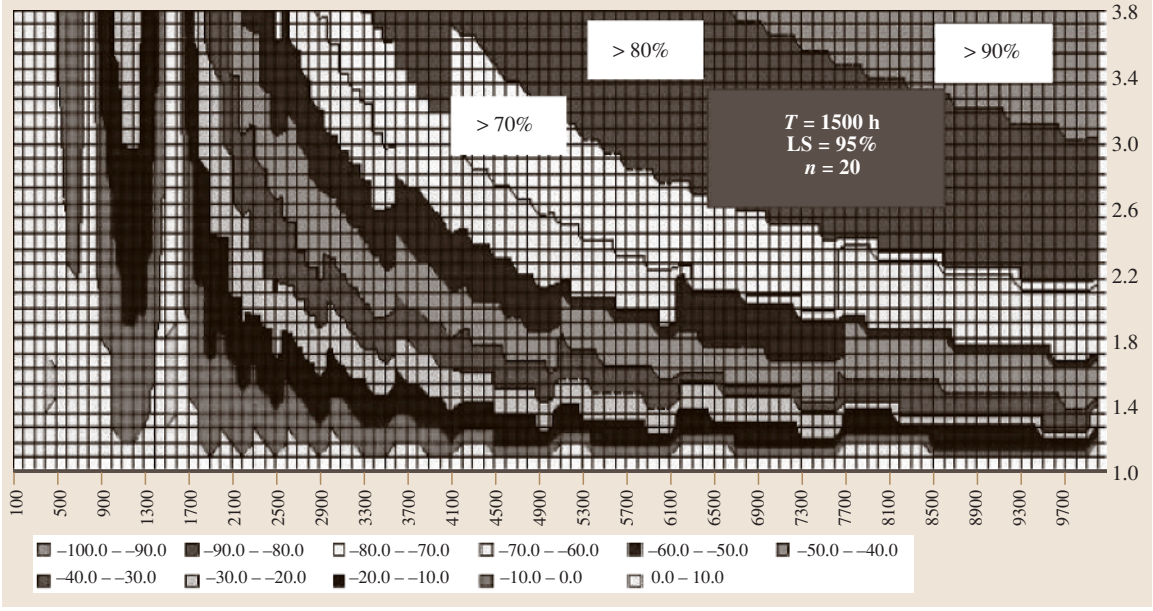

Fig. 48.20 Number of spare parts saved

48.8.2 Simulation and Results

This extended model is compared with previously proposed models for different values of the parameters involved. The relation between the parameters MTBF, T_S and β appears very interesting. In fact the first two parameters are fundamental to finding the quantity x_2, see (48.29) and (48.44), while β indicates the gap from the hypothesis of constant failure rate. The surface of Fig. 48.19 (with T_S equal to 500 h and a customer service level of 95%) relates the difference between optimal replacement numbers calculated

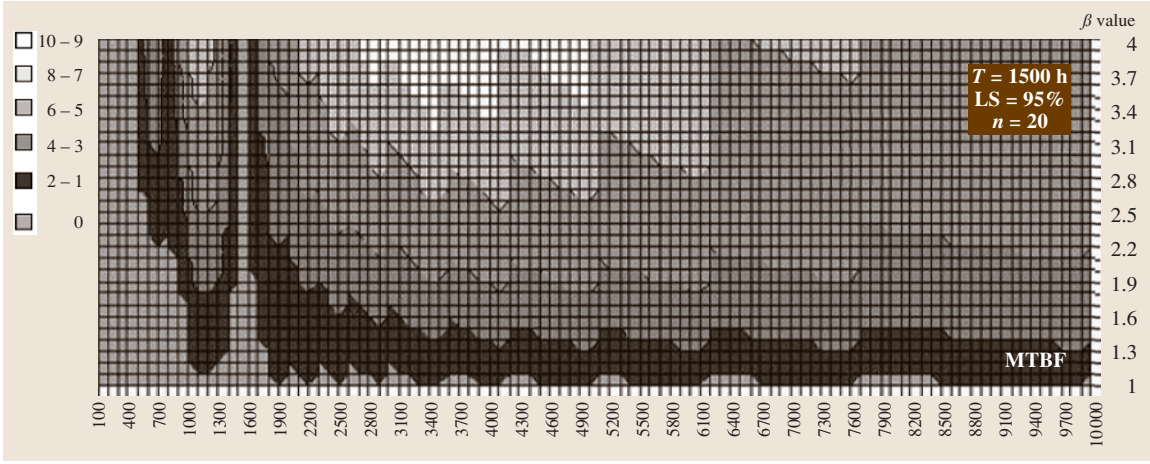

Fig. 48.21 Share of saving with respect to hypothesis of constant failure rate

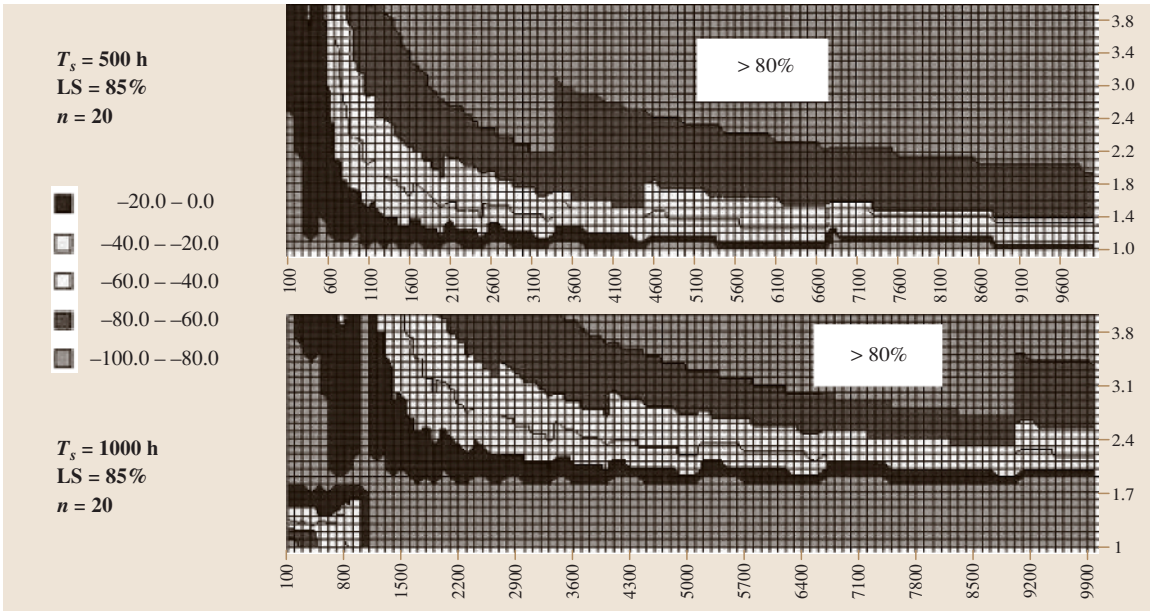

Fig. 48.22 Share of saving with respect to hypothesis of constant failure rate for different parameter values

by (48.29) or (48.44) respectively for given MTBF and β values. For a fixed value of MTBF the saving increases with greater values of β, because the use of the Weibull distribution takes into account that failures are grouped in a specific time region where part breakdowns occur with high probability. The MTBF value of 500 h is very important because it defines T_{residual} equal to zero and so x_2 equals zero for any approach. Values of MTBF lower than 500 h mean that the optimal replacement number is influenced by the quantity x_1, while values grater than 500 h are just defined by the use of quantity x_2 (x_1 being equal to zero). Considering a MTBF range starting from the T_S value for a specific value of β; the saving of spare parts needed decreases with greater values of MTBF, as shown in Fig. 48.23 where two different values of the parameter T_S (500 and 1000 h) are compared. Figure 48.19, as Fig. 48.20, relates the difference between the optimal replacement number calculated by (48.29) and (48.44) for T_S equal to 1500 h.

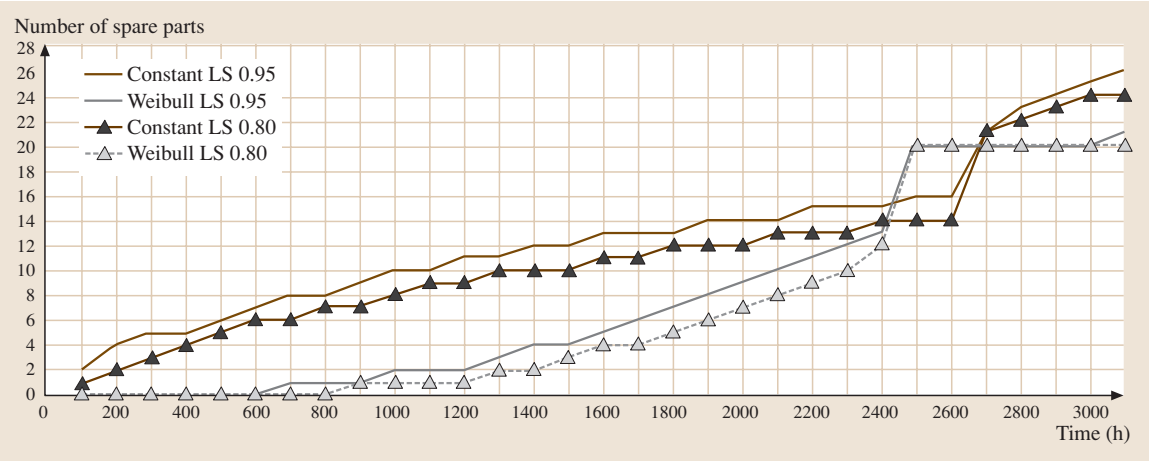

Fig. 48.23 Number of spare parts for component A (number of employments $n = 20$, and $\beta = 4$)

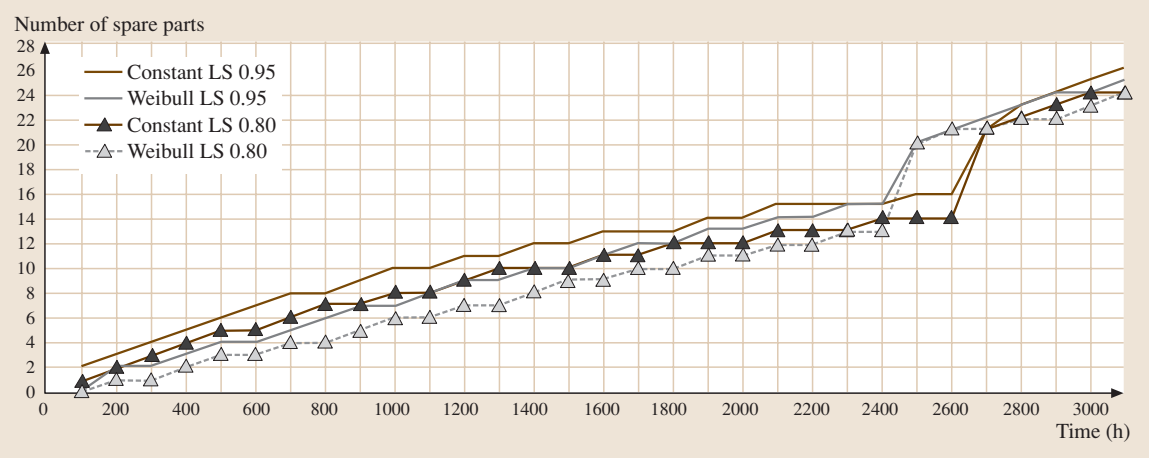

Fig. 48.24 Number of spare parts for component B (number of employments $n = 20$, and $\beta = 1.5$)

Obviously a low frequency of consignments creates a greater requirement for spare parts. Also in this case it is important to notice that methods behave as one when the MTBF is equal to T_S.

48.8.3 Case Study: An Industrial Application

This industrial application deals with an iron metallurgy plant, a European leader in the manufacture of merchant bars. We are interested in production machines characterized by electric iron steel furnaces, rolled sections and the final steps of finishing mills: straightening, cutting to length and packaging.

The extended method was applied with very interesting results, with an average saving of more than 20% in spare parts management. To focus the aim of this study we consider two different components (conic couples), called A and B, that have similar values of MTBF and number of employments n (about 20) but very different values of the parameter β: $\beta = 4$ for part A and $\beta = 1.5$ for part B. The graph in Fig. 48.23 compares the number of spare parts for part A forecasted by methods based on the hypothesis of a time-independent failure rate $\lambda(t)$ or based on the Weibull distribution.

Two different LS values are investigated. It is clear that the use of the Weibull extension reduces the stocks of parts by creating a time delay in the consignments.

The impact will not be significant for values of the β parameter close to one, as stated in Fig. 48.24 for part B, where forecasts are very similar for the methods investigated.

The subject of this study is the evaluation of the spare-parts stock level in maintenance systems in the presence of LTI parts. This paragraph deepens understanding of the fundamental features of a new approach that, in contrast to existing methods, does not consider total spares request to be linear and presents a lower sensitivity to MTBF errors. The proposed model assumes a specific spare-part service level LS defined as the probability of finding the part in case of breakdown: the best values for LS are suggested in Sect. 48.7.1. The aim of the study is to understand whether the hypothesis of a constant failure rate leads to increasing costs or not, compared to more sophisticated distributions. Model extension by the use of the traditional Weibull distribution shows interesting savings in spare parts for values of the β parameter greater than 3 and in the presence of longer times between consignments. The Weibull distribution appears to be a very interesting failure-rate function, but the literature reports some other valid functions; the extended model can easily be extended to any suggested failure-rate function.

49. Arithmetic and Geometric Processes

Section 49.1 introduces two special monotone processes. A stochastic process is an AP (or a GP) if there exists some real number (or some positive real number) such that after some additions (or multiplications) it becomes a renewal process (RP). Either is a stochastically monotonic process and can be used to model a point process, i. e. point events occurring in a haphazard way in time or space, especially with a trend. For example, the events may be failures arising from a deteriorating machine, and such a series of failures is distributed haphazardly along a time continuum.

Sections. 49.2–49.5 discuss estimation procedures for a number K of independent, homogeneous APs (or GPs). More specifically; in Sect. 49.2, Laplace's statistics are recommended for testing whether a process has a trend or K processes have a common trend, and a graphical technique is suggested for testing whether K processes come from a common AP (or GP) as well as having a common trend; in Sect. 49.3, three parameters – the common difference (or ratio), the intercept and the variance of errors – are estimated using simple linear regression techniques; in Sect. 49.4, a statistic is introduced for testing whether K processes come from a common AP (or GP); in Sect. 49.5, the mean and variance of the first average random variable of the AP (or GP) are estimated based on the results derived in Sect. 49.3.

Section 49.6 mentions some simulation studies performed to evaluate various nonparametric estimators and to compare the estimates, obtained from various estimators, of the parameters. Some suggestions for selecting the best estimators under three non-overlapping ranges of the common difference (or ratio) values are made based on the results of the simulation studies.

In Sect. 49.7, ten real data sets are treated as examples to illustrate the fitting of AP, GP, homogeneous Poisson process (HPP) and nonhomogeneous Poisson process (NHPP) models.

In Sect. 49.8, new repair–replacement models are proposed for a deteriorating system, in which the successive operating times of the system form an arithmetico-geometric process (AGP) and are stochastically decreasing, while the successive repair times after failure also constitute an AGP but are stochastically increasing. Two kinds of replacement policy are considered, one based on the working age (a continuous decision variable) of the system and the other determined by the number of failures (a discrete decision variable) of the system. These policies are considered together with the performance measures, namely loss (or its negation, profit), cost, and downtime (or its complement, availability). Applying the well-known results of renewal reward processes, expressions are derived for the long-run expected performance measure per unit total time, and for the long-run expected performance measure per unit operation time, under the two kinds of policy proposed.

In Sect. 49.9, some conclusions of the applicability of an AP and/or a GP based on partial findings of four real case studies are drawn.

Section 49.10 gives five concluding remarks. Finally, the derivations of some key results are outlined in the Appendix, followed by the results of both the APs and GPs summarized in Table 49.6 for easy reference.

Most of the content of this chapter is based on the author's own original works that appeared in *Leung* et al. [49.1–13], while some is extracted from *Lam* et al. [49.14–16].

In this chapter, the procedures are, for the most part, discussed in reliability terminology. Of course, the methods are valid in any area of application (see Examples 1, 5, 6 and 9 in Sect. 49.7), in which case they should be interpreted accordingly.

In the statistical analysis of a series of events, a common method is to model the series using a point process. To start with, it is essential to test whether the data of successive inter-event times, denoted by X_i $(i = 1, 2, \ldots)$, demonstrate a trend. If there is no trend, we may model the data using a stationary point process (i. e. a counting process that has stationary, but not necessarily independent, increments), or using a sequence of independent and identically distributed (i.i.d.) random variables $X \equiv X_i$ for all i. For the latter, we may model the corresponding counts of events in time using a renewal process (RP). In particular, if X is exponentially distributed with a rate parameter λ, we may use a homogeneous Poisson process (HPP) with a constant rate λ to model the data. The HPP is one of the most common stochastic processes for modeling counts of events in time or area/volume. This process is a standard for *randomness*, as the assumptions involved state that events must occur independently and any two non-overlapping intervals of the same size have the same probability of capturing one of the events of interest. However, in practice the data of successive inter-event times usually exhibit a trend. We may model them using a nonstationary model, or using a nonhomogeneous Poisson process (NHPP) in which the rate at time t is a function of t. The NHPP is a popular approach used to model data with a trend. For more details of these methods, see *Cox* and *Lewis* [49.17], and *Ascher* and *Feingold* [49.18].

Most research on the maintenance of a repairable system has made either the perfect or minimal repair assumption. Perfect repair means that, after repair, a failed system is as good as new, i. e. a system's successive operating times constitute an RP, see *Barlow* and *Proschan* [49.19]. For a perfect repair model, if the time needed to repair a system is considered negligible, results of RPs can be applied to resolve the system's maintenance problems, see *Ross* [49.20]; if repair time has to be taken into account and the corresponding consecutive repair times constitute another RP, results of alternating RPs can be applied instead, see *Birolini* [49.21]. However, in practice, this is not always the case. Minimal repair means that a failed system will function, after repair, with the same rate of failure and the same effective age as at the epoch of the last failure. For a minimal repair model, where repair time is assumed negligible, an NHPP in which the rate of occurrence of failures (ROCOF) is monotone can provide at least a good first-order model for a deteriorating system, see *Ascher* and *Feingold* [49.18]. That is, failures constitute an NHPP with a suitable parametric form for ROCOF. If the repair time has to be taken into account, the NHPP approach cannot be used.

The popularity of the power-law process (PLP) is based on two features: firstly, it can model deteriorating or improving systems; secondly, point estimators for the parameters have simple closed-form expressions and hypotheses tests can be undertaken using existing tables. The PLP denoted and given by $r(t) = \lambda\beta t^{\beta-1}$ for $t \geq 0$ and λ, $\beta > 0$ is the most important ROCOF parametric form in an NHPP model. If $\beta > 1$, the ROCOF increases

with time, as often happens with aging machinery. This is one of the two main conditions for a preventive replacement being worth carried out (the other condition is that the average cost c_p of a replacement is much greater than that c_r of a minimal repair). But if $0 < \beta < 1$, the ROCOF decreases with time; hence, the PLP can model reliability growth as well. The HPP, which has constant ROCOF, is a special case of the PLP with $\beta = 1$. *Rigdon* and *Basu* [49.22] gave a detailed discussion of the PLP.

Another two-parameter ROCOF form, widely quoted in the literature, that can also model deterioration and reliability growth is the log-linear process (LLP), in which the ROCOF at time t is modeled as $s(t) = e^{\alpha_0+\alpha_1 t}$ for $t \geq 0$ and $-\infty < \alpha_0, \alpha_1 < \infty$, with $\alpha_1 > 0$ under deterioration. This process is less often used, possibly because it is seldom found to be applicable or mathematically less tractable.

Barlow and *Hunter* [49.23] first introduced the idea of minimal repair and proposed a system which is replaced with a regular period T and undergoes minimal repairs upon failures between the periodic replacements. *Muth* [49.24] then proposed a replacement model in which minimal repairs upon system failures are performed up to age T and the system is replaced at the first failure after T. Later, *Park* [49.25] proposed a modification of the model in which a system undergoes minimal repairs for the first $(N-1)$ failures and is replaced at the Nth failure. *Nakagawa* and *Kowada* [49.26] put the first and third types of policy together and constructed a replacement model in which a system is regularly replaced with a period T or at the Nth failure after its installation, whichever occurs first. The system undergoes only minimal repair upon failures between the periodic replacements. In *Leung* and *Cheng* [49.3], Nakagawa and Kowada's replacement model was employed, and the optimal replacement policy based on minimizing the long-run expected cost per month for each type of engine was determined.

The perfect repair model may be reasonable for a system with one simple unit only, and the minimal repair model seems plausible for systems consisting of many components, each having its own failure mode. In many practical instances, repair activities may not result in such extreme situations but in complicated intermediate ones. *Brown* and *Proschan* [49.27] considered the model of imperfect repair which, with probability p, is a perfect repair or, with probability $1-p$, is a minimal repair. *Kijima* [49.28, 29] studied a more general repair model which includes the imperfect repair model as a special case. For a review of imperfect maintenance models, see *Pham* and *Wang* [49.30], and *Wang* and *Pham* [49.31].

An arithmetic process (AP) or a geometric process (GP), which is a nonstationary model, can be used as an alternative to the NHPP in analyzing data of inter-event times that exhibit a trend. This appears to be a useful model for failure or repair data arising from a single system or a collection of independent, homogeneous systems. Consider the maintenance problems of a repairable system and bear in mind that most repairable systems, like engines and gearboxes, are deteriorative. Two basic characteristics of a deteriorating system are that, because of wear through operation or metal fatigue under stress, the system's successive operating times decrease and so the system's life is finite; and that, because it is more difficult and hence takes more time to rectify accumulated wear, the corresponding consecutive repair times increase until finally the system is beyond repair. Based on this understanding, an AP approach proposed by *Leung* [49.5] or a GP approach proposed by *Lam* [49.14] is considered more relevant, realistic and direct for the modeling of maintenance problems in a deteriorating system. Although all discussions in this chapter are in terms of deteriorating systems, they are also valid for improving systems (see Examples 2, 4 and 10 in Sect. 49.7).

The following main symbols in the text are adopted. For a fixed $k = 1, \ldots, K$,

- $A_{n,k}$ (or $G_{n,k}$) denotes either the operating time after the $(n-1)$th repair for $n = 1, 2, \ldots, N_k$ with $X_0 = 0$, or the repair time after the nth failure for $n = 1, 2, \ldots, N_k$;
- d denotes either a common difference d_a of a decreasing arithmetic process such that $d_a \in \left(0, \frac{\mu_{A_1,k}}{n-1}\right]$ or a common difference d_b of an increasing arithmetic process such that $d_b < 0$;
- r denotes either a common ratio r_a of a decreasing geometric process such that $r_a > 1$ or a common ratio r_b of an increasing geometric process such that $0 < r_b < 1$;
- $\mu_{A_{n,k}}$ (or $\mu_{G_{n,k}}$) is the mean of $A_{n,k}$ (or $G_{n,k}$) for $n = 1, 2, \ldots, N_k$;
- $\sigma^2_{A_{n,k}}$ (or $\sigma^2_{G_{n,k}}$) is the variance of $A_{n,k}$ (or $G_{n,k}$) for $n = 1, 2, \ldots, N_k$;
- $\varepsilon_{A,n,k}$ (or $\varepsilon_{G,n,k}$) is an error term with mean 0 and constant variance denoted by $\sigma^2_{A,\varepsilon}$ (or $\sigma^2_{G,\varepsilon}$).

49.1 Two Special Monotone Processes

The work in this section is substantially based on *Leung* [49.4, 11].

49.1.1 Arithmetic Processes

Suppose that K independent, homogeneous APs are available. A definition of the kth AP for $k = 1, \ldots, K$ is given below.

Definition 49.1
Given a sequence of random variables $A_{1,k}, A_{2,k}, \ldots$, if for some real number d, $\{A_{n,k} + (n-1)d, n = 1, 2, \ldots\}$ forms an RP, then $\{A_{n,k}, n = 1, 2, \ldots\}$ is an AP for $k = 1, \ldots, K$. The constant d is called the common difference of the AP.

Three specializations of an AP are given below.

If $d \in \left(0, \frac{\mu_{A_1}}{n-1}\right]$, where $n = 2, 3, \ldots$ and $k = 1, \ldots, K$; and $\mu_{A_1,k}$ is the mean of the first random variable $A_{1,k}$, then the AP is called a decreasing AP. If $d < 0$, then the AP is called an increasing AP. If $d = 0$, then the AP reduces to an RP.

The upper bound of d in the first specialization can be obtained as follows: by Definition 49.1, the expression for the general term of an AP is given by $A_{n,k} \stackrel{d}{=} A_{1,k} - (n-1)d$. Taking expectations of both sides of this expression, and remembering that $A_{n,k}$ is a nonnegative random variable and hence $\boldsymbol{E}(A_{n,k}) \equiv \mu_{A_n,k} \geq 0$ for $n = 1, 2, \ldots$; we obtain, after transposition, the upper bound of d given by $\frac{\mu_{A_1,k}}{n-1}$ for $n = 2, 3, \ldots$. Clearly, the positive integer n is limited for a decreasing AP. Moreover, if the value of d is close to its upper bound, we will obtain a short sequence of nonnegative random variables. However, such a subtractive process is likely to be useful in a deteriorating system (e.g. an engine or a gearbox), which fails rarely (e.g. two/three times) over its usual span of life (e.g. five years). This implicitly means that the system wears out, between two successive failures, to such an extraordinary extent that the corresponding system's successive operating time decreases dramatically.

Given an AP $\{A_{n,k}, n = 1, 2, \ldots\}$ for $k = 1, \ldots, K$, we have $A_{n,k} \stackrel{d}{=} A_{1,k} - (n-1)d$ by Definition 49.1. Therefore, the means and variances of $A_{n,k}$ can respectively be written as

$$\begin{aligned}\mu_{A_n,k} &\equiv \boldsymbol{E}(A_{n,k}) = \boldsymbol{E}(A_{1,k}) - (n-1)d \\ &\equiv \mu_{A_1,k} - (n-1)d \end{aligned} \tag{49.1}$$

and

$$\begin{aligned}\sigma^2_{A_n,k} &\equiv \boldsymbol{V}(A_{n,k}) = \boldsymbol{V}[A_{1,k} - (n-1)d] = V(A_{1,k}) \\ &\equiv \sigma^2_{A_1,k} \,. \end{aligned} \tag{49.2}$$

Consider K independent, homogeneous APs $\{A_{n,k}, n = 1, \ldots, N_k$ and $k = 1, \ldots, K\}$ together. Without loss of generality, we assume $N_1 \geq N_2 \geq \ldots \geq N_K$. Denote

$$\bar{A}_n \equiv \frac{\sum_{k=1}^{K^*} A_{n,k}}{K^*} \,,$$

$$\mu_{\bar{A}_1} \equiv \frac{\sum_{k=1}^{K} \mu_{A_1,k}}{K} = \frac{\sum_{k=1}^{K^*} \mu_{A_1,k}}{K^*} \,, \quad \text{and}$$

$$\sigma^2_{\bar{A}_1} \equiv \frac{\sum_{k=1}^{K} \sigma^2_{A_1,k}}{K} = \frac{\sum_{k=1}^{K^*} \sigma^2_{A_1,k}}{K^*} \,,$$

where

$$\begin{aligned} K^* &= K && \text{for } n = 1, \ldots, N_K \text{ or,} \\ &= K-1 && \text{for } n = N_K + 1, \ldots, N_{K-1} \text{ or,} \\ &= K-2 && \text{for } n = N_{K-1} + 1, \ldots, N_{K-2} \text{ or,} \\ &\vdots \\ &= 1 && \text{for } n = N_2 + 1, \ldots, N_1 \,. \end{aligned}$$

To clarify the definition of $\bar{A}_n$, let us consider $K = 3$, $N_1 = 5$, $N_2 = 3$, $N_3 = 2$. Then we have

$$\begin{aligned} \bar{A}_1 &= \frac{A_{1,1} + A_{1,2} + A_{1,3}}{3} \,, \\ \bar{A}_2 &= \frac{A_{2,1} + A_{2,2} + A_{2,3}}{3} \,, \\ \bar{A}_3 &= \frac{A_{3,1} + A_{3,2}}{2} \,, \\ \bar{A}_4 &= A_{4,1} \text{ and } \bar{A}_5 = A_{5,1} \,. \end{aligned}$$

Therefore, using (49.1) and (49.2), the means and variances of $\bar{A}_n$ can respectively be written as

$$\begin{aligned}\mu_{\bar{A}_n} &\equiv \boldsymbol{E}(\bar{A}_n) = \frac{\sum_{k=1}^{K^*} E(A_{n,k})}{K^*} \\ &= \frac{\sum_{k=1}^{K^*} E[A_{1,k} - (n-1)d)]}{K^*} \\ &\equiv \frac{\sum_{k=1}^{K^*} \mu_{A_1,k} - K^*(n-1)d}{K^*} = \mu_{\bar{A}_1} - (n-1)d\end{aligned} \tag{49.3}$$

and

$$\begin{aligned}\sigma^2_{\bar{A}_n} &\equiv \boldsymbol{V}(\bar{A}_n) = \frac{\sum_{k=1}^{K^*} V(A_{n,k})}{(K^*)^2} \\ &= \frac{\sum_{k=1}^{K^*} V[A_{1,k} - (n-1)d]}{(K^*)^2} \\ &\equiv \frac{\sum_{k=1}^{K^*} \sigma^2_{A_1,k}}{(K^*)^2} = \frac{\sigma^2_{\bar{A}_1}}{K^*} .\end{aligned} \tag{49.4}$$

49.1.2 Geometric Processes

Suppose that K independent, homogeneous GPs are available. A definition of the kth GP for $k = 1, \ldots, K$ is given below.

Definition 49.2

Given a sequence of random variables $G_{1,k}, G_{2,k}, \ldots$, if for some $r > 0$, $\{r^{(n-1)}G_{n,k}, n = 1, 2, \ldots\}$ forms an RP, then $\{G_{n,k}, n = 1, 2, \ldots\}$ is a GP for $k = 1, \ldots, K$. The constant r is called the common ratio of the GP.

Three specializations of a GP are given below.

If $r > 1$, then the GP is called a decreasing GP. If $0 < r < 1$, then the GP is called an increasing GP. If $r = 1$, then the GP reduces to an RP.

Given a GP $\{G_{n,k}, n = 1, 2, \ldots\}$ for $k = 1, \ldots, K$; we have $G_{n,k} \stackrel{d}{=} \frac{G_{1,k}}{r^{(n-1)}}$ from Definition 49.2. Therefore, the means and variances of $G_{n,k}$ can be written as

$$\mu_{G_n,k} \equiv \boldsymbol{E}(G_{n,k}) = \frac{\boldsymbol{E}(G_{1,k})}{r^{(n-1)}} \equiv \frac{\mu_{G_1,k}}{r^{(n-1)}} \tag{49.5}$$

and

$$\begin{aligned}\sigma^2_{G_n,k} &\equiv \boldsymbol{V}(G_{n,k}) = \boldsymbol{V}\left(\frac{G_{1,k}}{r^{(n-1)}}\right) = \frac{\boldsymbol{V}(G_{1,k})}{r^{2(n-1)}} \\ &\equiv \frac{\sigma^2_{G_1,k}}{r^{2(n-1)}} .\end{aligned} \tag{49.6}$$

Consider K independent, homogeneous GPs $\{G_{n,k}, n = 1, \ldots, N_k \text{ and } k = 1, \ldots, K\}$ together. Without loss of generality, we assume $N_1 \geq N_2 \geq \ldots \geq N_K$. Denote

$$\begin{aligned}\bar{G}_n &\equiv \frac{\sum_{k=1}^{K^*} G_{n,k}}{K^*} , \\ \mu_{\bar{G}_1} &\equiv \frac{\sum_{k=1}^{K} \mu_{G_1,k}}{K} = \frac{\sum_{k=1}^{K^*} \mu_{G_1,k}}{K^*} , \quad \text{and} \\ \sigma^2_{\bar{G}_1} &\equiv \frac{\sum_{k=1}^{K} \sigma^2_{G_1,k}}{K} = \frac{\sum_{k=1}^{K^*} \sigma^2_{G_1,k}}{K^*} ,\end{aligned}$$

where K^* has previously been defined and $\bar{G}_n$ has a similar meaning to $\bar{A}_n$.

Therefore, using (49.5) and (49.6), the means and variances of $\bar{G}_n$ can respectively be written as

$$\begin{aligned}\mu_{\bar{G}_n} &\equiv \boldsymbol{E}(\bar{G}_n) = \frac{\sum_{k=1}^{K^*} \boldsymbol{E}(G_{n,k})}{K^*} = \frac{\sum_{k=1}^{K^*} \boldsymbol{E}\left[\frac{G_{1,k}}{r^{(n-1)}}\right]}{K^*} \\ &\equiv \frac{\sum_{k=1}^{K^*} \frac{\mu_{G_1,k}}{r^{(n-1)}}}{K^*} = \frac{\mu_{\bar{G}_1}}{r^{(n-1)}}\end{aligned} \tag{49.7}$$

and

$$\sigma^2_{\bar{G}_n} \equiv \boldsymbol{V}(\bar{G}_n) = \boldsymbol{V}\left(\frac{\sum_{k=1}^{K^*} G_{n,k}}{K^*}\right) = \frac{\sum_{k=1}^{K^*} V(G_{n,k})}{(K^*)^2} ,$$

as $G_{n,k}$s are independent

$$= \frac{\sum_{k=1}^{K^*} V\left[\frac{G_{1,k}}{r^{(n-1)}}\right]}{(K^*)^2} \equiv \frac{\sum_{k=1}^{K^*} \frac{\sigma^2_{G_1,k}}{r^{2(n-1)}}}{(K^*)^2} = \frac{\sigma^2_{\bar{G}_1}}{r^{2(n-1)}K^*} . \tag{49.8}$$

According to the three specializations of an AP (or a GP), for a deteriorating system, it is reasonable to assume that the successive operating times of the system form a decreasing AP (or GP), whereas the corresponding consecutive repair times constitute an increasing AP

(or GP). However, the replacement times for the system are usually stochastically the same no matter how old the used system is; hence, these will form an RP. This is the motivation behind the introduction of the AP (or GP) approach.

Thus, d, $\mu_{\bar{A}_1}$ and $\sigma^2_{\bar{A}_1}$ (or r, $\mu_{\bar{G}_1}$ and $\sigma^2_{\bar{G}_1}$) are the most important parameters in K APs (or GPs) because the means and variances of the $\bar{A}_n$s (or $\bar{G}_n$s) are completely determined by these three parameters. In view of this fact, in this chapter the procedure is defined for applying the AP (or GP) approach in a reliability context and the functions of estimators are derived for the three fundamental parameters. Now, there are three questions. The first is, given a set of data of successive inter-event times of a point process, how do we test whether this is consistent with an AP (or a GP)? The second question is, if the data do come from a common AP (or GP), how can we estimate the parameters d, $\mu_{\bar{A}_1}$ and $\sigma^2_{\bar{A}_1}$ (or r, $\mu_{\bar{G}_1}$ and $\sigma^2_{\bar{G}_1}$)? The third question is, after fitting an AP (or a GP) model to the data set, how good is the fit?

In this chapter, the statistical inference for K independent, homogeneous APs (or GPs) is investigated and the first two questions are answered using well-known statistical methods. In Sect. 49.3, the parameters d, α_{A} and $\sigma^2_{\mathrm{A},\varepsilon}$ (or r, α_{G} and $\sigma^2_{\mathrm{G},\varepsilon}$) are estimated using simple linear regression techniques. In Sect. 49.5, first $\mu_{\bar{A}_1}$ and $\sigma^2_{\bar{A}_1}$ (or $\mu_{\bar{G}_1}$ and $\sigma^2_{\bar{G}_1}$) are estimated based on the results derived in Sect. 49.3, and then $\mu_{\bar{A}_n}$ and $\sigma^2_{\bar{A}_n}$ (or $\mu_{\bar{G}_n}$ and $\sigma^2_{\bar{G}_n}$) are correspondingly estimated using (49.3) and (49.4) [or (49.7) and (49.8)], respectively.

49.2 Testing for Trends

Much of the work in this section is based on *Leung* [49.4, 11].

49.2.1 Laplace Test

Suppose now that K independent, homogeneous series are available with periods of observation $T_1, T_2, \ldots, T_K$. The numbers of events in the different series are denoted by $N_1, N_2, \ldots, N_K$ and the times of occurrence of events by $Y_{n,1}, Y_{n,2}, \ldots, Y_{n,K}$. Given the data $\{A_{n,k}$ (or $G_{n,k}), n = 1, 2, \ldots$ and $k = 1 \ldots, K\}$ of successive inter-event times of a point process, first of all we need to test whether the $A_{n,k}$s are identically distributed by checking for the existence of a trend. To do this, many techniques discussed in *Ascher* and *Feingold* [49.18] can be used. Laplace's trend test is used for ease of manipulation and interpretation.

Null hypothesis H_0: $A_{n,k}$s (or $G_{n,k}$) are identically distributed.

Alternative hypothesis H_1: $A_{n,k}$s (or $G_{n,k}$) are not identically distributed, i. e. there is a trend.

Laplace's test statistic for a time-truncated data set (i. e. when the data are time truncated, the time of the conclusion of observation is fixed and the number of events is random) is given by

$$L_k = \frac{\sum_{n=1}^{N_k} Y_{n,k} - \frac{N_k T_k}{2}}{\sqrt{\frac{N_k T_k^2}{12}}} \quad \text{for } k = 1, \ldots, K\,, \tag{49.9}$$

where $Y_{1,k}, \ldots, Y_{N_k,k}$, with $Y_{n,k} = \sum_{i=1}^{n} A_{i,k}$ (or $Y_{n,k} = \sum_{i=1}^{n} G_{i,k}$) are the event times for a process observed in $(0, T_k]$, and T_k is the pre-specified time of observation.

Laplace's test statistic for an event-truncated data set (i. e. when the data are event-truncated, the number of events is fixed before observation begins and the time of the conclusion of the observation is random) is given by

$$L_k = \frac{\sum_{n=1}^{N_k-1} Y_{n,k} - \frac{(N_k-1)Y_{N_k,k}}{2}}{\sqrt{\frac{(N_k-1)Y^2_{N_k,k}}{12}}} \quad \text{for } k = 1, \ldots, K\,, \tag{49.10}$$

where $Y_{n,k} = \sum_{i=1}^{n} A_{i,k}$ (or $Y_{n,k} = \sum_{i=1}^{n} G_{i,k}$) is the time of the nth failure for $n = 1, 2, \ldots, N_k$, and N_k is the pre-specified number of events.

L_k is approximately distributed as the standard normal for $N_k \geq 3$, time-truncated data, or $N_k \geq 4$, event-truncated data, at the 5% level of significance, see *Ascher* and *Feingold* [49.18]. If $|L_k| > 1.96$, then H_0 is rejected at the 5% level of significance, i. e. the event data set $\{A_1, A_2, \ldots, A_{N_k}\}$ (or $\{G_1, G_2, \ldots, G_{N_k}\}$) exhibits a trend.

Rigdon and *Basu* [49.22], on p. 259, reach the conclusion that

> *using any model for event times, one clearly indicates the time that data collection started and the time that it ceased. This is necessary so that the appropriate analysis, that is, an analysis based on event-truncated or time-truncated data, can be applied and maximum information can be obtained from the data. For time-truncated data, the time between the last event and the termination of the test contains some information that should not be wasted.*

Suppose, however, that a pooled test is required. It would often be best to take the null hypothesis to be that the series individually follow stationary point processes which possibly differ for different series. We can then make a combined test for trend in the data and this can be done using (49.11) or (49.12), which are given below.

Laplace's test pooled statistic for a time-truncated data set is given by

$$L = \frac{\sum_{k=1}^{K}\sum_{n=1}^{N_k} Y_{n,k} - \frac{1}{2}\sum_{k=1}^{K} N_k T_k}{\sqrt{\frac{\sum_{k=1}^{K} N_k T_k^2}{12}}} \qquad (49.11)$$

and Laplace's test pooled statistic for an event-truncated data set is given by

$$L = \frac{\sum_{k=1}^{K}\sum_{n=1}^{N_k-1} Y_{n,k} - \frac{1}{2}\sum_{k=1}^{K}(N_k-1)Y_{N_k,k}}{\sqrt{\frac{\sum_{k=1}^{K}(N_k-1)Y_{N_k,k}^2}{12}}}\,, \qquad (49.12)$$

which under the null hypothesis has zero mean, unity variance and very nearly a normal distribution.

Note that the series can be tested individually for trend using (49.9) or (49.10); however, it is worth making a combined trend test in the data using (49.11) or (49.12). *Cox* and *Lewis* [49.17], on p. 50, note that there are other ways the separate trend tests could be combined, for example by forming

$$L = \frac{\sum_{k=1}^{K} L_k}{\sqrt{12}} \quad \text{or} \quad L = \sum_{k=1}^{K} L_k^2$$

the former would be tested as a standardized normal variable, the latter as chi-squared with $(K-1)$ degrees of freedom. These tests take no account of the very different numbers of observations in the different series.

49.2.2 Graphical Techniques

Another possible approach is to use simple linear regression techniques.

Arithmetic Processes

To start with, let

$$W_{A,n,k} = A_{n,k} + (n-1)d\,. \qquad (49.13)$$

From Definition 49.1, $W_{A,n,k}$s are i.i.d. and can be written as

$$W_{A,n,k} = \alpha_A + \varepsilon_{A,n,k}\,, \qquad (49.14)$$

where

$$E(W_{A,n,k}) = \alpha_A \qquad (49.15)$$

and $\varepsilon_{A,n,k}$s are also i.i.d. (not necessarily normally distributed if our objective is estimation only, e.g. see *Gujarati* [49.32], p. 281) with

$$E(\varepsilon_{A,n,k}) = E(\varepsilon_{A,n}) = 0, \text{ irrespective of } k \qquad (49.16)$$

and

$$V(\varepsilon_{A,n,k}) = V(\varepsilon_{A,n}) \equiv \sigma^2_{A,\varepsilon_n}\,, \qquad (49.17)$$

irrespective of k and $\sigma^2_{A,\varepsilon_n} = \sigma^2_{A,\varepsilon}$, equal variance irrespective of n.

Combining (49.13) and (49.14) yields

$$A_{n,k} = -d(n-1) + \alpha_A + \varepsilon_{A,n,k} \quad \text{for } n = 1, \ldots, N_k \quad \text{and } k = 1, \ldots, K\,, \qquad (49.18)$$

which is a simple linear regression equation.

Geometric processes

To start with, let

$$W_{\mathrm{G},n,k} = r^{(n-1)} G_{n,k} \tag{49.19}$$

or

$$\ln W_{\mathrm{G},n,k} = (n-1)\ln r + \ln G_{n,k}\,. \tag{49.20}$$

From Definition 49.2, $W_{G,n,k}$s are i.i.d. and can be written as

$$\ln W_{\mathrm{G},n,k} = \alpha_{\mathrm{G}} + \varepsilon_{\mathrm{G},n,k} \tag{49.21}$$

or

$$W_{\mathrm{G},n,k} = \mathrm{e}^{\alpha_{\mathrm{G}}+\varepsilon_{\mathrm{G},n,k}}\,, \tag{49.22}$$

where

$$\mathrm{E}(\ln W_{\mathrm{G},n,k}) = \alpha_{\mathrm{G}} \tag{49.23}$$

and $\varepsilon_{G,n,k}$s are also i.i.d. (not necessarily normally distributed if our objective is estimation only, e.g. see *Gujarati* [49.32], p. 281) with

$$\mathrm{E}(\varepsilon_{\mathrm{G},n,k}) = \mathrm{E}(\varepsilon_{\mathrm{G},n}) = 0,\ \text{irrespective of } k \tag{49.24}$$

and

$$\mathrm{V}(\varepsilon_{\mathrm{G},n,k}) = \mathrm{V}(\varepsilon_{\mathrm{G},n}) \equiv \sigma^2_{\mathrm{G},\varepsilon_n}\,, \tag{49.25}$$

irrespective of k and $\sigma^2_{\mathrm{G},\varepsilon_n} = \sigma^2_{\mathrm{G},\varepsilon}$, equal variance irrespective of n.

Combining (49.20) and (49.21) yields

$$\ln G_{n,k} = -\ln r(n-1) + \alpha_{\mathrm{G}} + \varepsilon_{\mathrm{G},n,k} \quad \text{for } n = 1,\ldots,N_k \quad \text{and } k = 1,\ldots,K\,, \tag{49.26}$$

which is a simple linear regression equation.

According to (49.18) [or (49.26)], we can plot $A_{n,k}$ (or $\ln G_{n,k}$) against $(n-1)$ for $n = 1,\ldots,N_k$ and $k = 1,\ldots,K$ to see whether there is a linear relationship between them. Clearly, this is also useful for testing whether the observations $\{A_{n,k}$ (or $G_{n,k})$, $n = 1,\ldots,N_k$ and $k = 1,\ldots,K\}$ come from a common AP (or GP) as well as whether they share a common trend.

49.3 Estimating the Parameters

The work in this section is substantially based on *Leung* [49.4, 11].

49.3.1 Estimate Parameters d, α_{A} and $\sigma^2_{\mathrm{A},\varepsilon}$ of K APs (or r, α_{G} and $\sigma^2_{\mathrm{G},\varepsilon}$ of K GPs)

We can estimate the parameters d, α_{A} and $\sigma^2_{\mathrm{A},\varepsilon}$ using the simple linear regression method. The least-squares point estimates $\hat{d}$, $\hat{\alpha}_{\mathrm{A}}$ and $\hat{\sigma}^2_{\mathrm{A},\varepsilon}$ of the parameters d, α_{A} and $\sigma^2_{\mathrm{A},\varepsilon}$ are calculated respectively using the following formulae:

$$\hat{d} = \frac{\frac{\left(\sum_{k=1}^{K} N_k^2 - N\right)\left(\sum_{k=1}^{K}\sum_{n=1}^{N_k} A_{n,k}\right)}{2N} - \sum_{k=1}^{K}\sum_{n=1}^{N_k}(n-1)A_{n,k}}{\sum_{k=1}^{K}\frac{(N_k-1)N_k(2N_k-1)}{6} - \frac{\left(\sum_{k=1}^{K} N_k^2 - N\right)^2}{4N}}\,, \tag{49.27}$$

$$\hat{\alpha}_{\mathrm{A}} = \frac{\sum_{k=1}^{K}\sum_{n=1}^{N_k} A_{n,k}}{N} + \frac{\hat{d}\left(\sum_{k=1}^{K} N_k^2 - N\right)}{2N} \tag{49.28}$$

and

$$\hat{\sigma}^2_{\mathrm{A},\varepsilon} = \frac{\sum_{k=1}^{K}\sum_{n=1}^{N_k} A_{n,k}^2 - \frac{\left(\sum_{k=1}^{K}\sum_{n=1}^{N_k} A_{n,k}\right)^2}{N}}{N-2} + \frac{\hat{d}\left(\sum_{k=1}^{K}\sum_{n=1}^{N_k}(n-1)A_{n,k}\right)}{N-2} - \frac{\hat{d}\left(\frac{\left(\sum_{k=1}^{K} N_k^2 - N\right)\left(\sum_{k=1}^{K}\sum_{n=1}^{N_k} A_{n,k}\right)}{2N}\right)}{N-2}\,, \tag{49.29}$$

where

$$N = \sum_{k=1}^{K} N_k\,. \tag{49.30}$$

The derivations of (49.27) to (49.29) are given in the Appendix.

The least-squares point estimates $\hat{r}$, $\hat{\alpha}_{\mathrm{G}}$ and $\hat{\sigma}^2_{\mathrm{G},\varepsilon}$ of the parameters r, α_{G} and $\sigma^2_{\mathrm{G},\varepsilon}$ can be obtained simply

by replacing $\hat{d}$ with $\ln \hat{r}$ and $A_{n,k}$ with $\ln G_{n,k}$ on the right-hand side of (49.27) to (49.29).

49.3.2 Estimating the Parameters of a Single AP (or GP)

When $K = 1$, (49.30) becomes $N = N_1$. Note that

1. for a single AP or GP, we simply use N to represent the number of successive events, and
2. the equations given below are consistent with those derived in *Leung* [49.8] and *Lam* [49.15].

Then (49.27) to (49.29) become

$$\hat{d} = \frac{6(N-1)\sum_{n=1}^{N} A_n - 12\sum_{n=1}^{N}(n-1)A_n}{(N-1)N(N+1)}\,, \tag{49.27.1}$$

$$\hat{\alpha}_{\mathrm{A}} = \frac{2(2N-1)\sum_{n=1}^{N} A_n - 6\sum_{n=1}^{N}(n-1)A_n}{N(N+1)} \tag{49.28.1}$$

and

$$\hat{\sigma}^2_{\mathrm{A},\varepsilon} = \frac{\sum_{n=1}^{N} A_n^2 - \frac{1}{N}\left(\sum_{n=1}^{N} A_n\right)^2}{N-2} - \frac{\hat{d}\left[\frac{(N-1)}{2}\sum_{n=1}^{N} A_n - \sum_{n=1}^{N}(n-1)A_n\right]}{N-2}\,. \tag{49.29.1}$$

For a single GP, $\hat{d}$, $\hat{\alpha}_{\mathrm{A}}$, $\hat{\sigma}^2_{\mathrm{A},\varepsilon}$ and A_n are replaced by $\ln \hat{r}$, $\hat{\alpha}_{\mathrm{G}}$, $\hat{\sigma}^2_{\mathrm{G},\varepsilon}$ and $\ln G_n$ in (49.27.1) to (49.29.1).

49.4 Distinguishing a Renewal Process from an AP (or a GP)

Much of the work in this section is based on *Leung* [49.4, 11]. We test whether the data comes from an RP or AP.

Null hypothesis $\mathbf{H_0}$: $d = 0$

Alternative hypothesis $\mathbf{H_1}$: $d \neq 0$

The t-test statistic is denoted and given by

$$t_{\mathrm{A}} = \frac{-\hat{d}\sqrt{\sum_{k=1}^{K}\frac{(N_k-1)N_k(2N_k-1)}{6} - \frac{\left(\sum_{k=1}^{K} N_k^2 - N\right)^2}{4N}}}{\hat{\sigma}_{\mathrm{A},\varepsilon}}\,, \tag{49.31}$$

where t_{A} is distributed as a Student's t with $(N-2)$ degrees of freedom. If $|t_{\mathrm{A}}|$ is larger than the critical value $t_{N-2,0.025}$, then H_0 is rejected at the 5% level of significance, i. e. the data set $\{A_{n,k},\, n = 1, \ldots, N_k$ and $k = 1, \ldots, K\}$ comes from a common AP. The derivation of (49.31) is given in the Appendix.

To test whether the data comes from an RP or a GP, H_0 becomes $\ln r = 0$ or its equivalence $r = 1$ and H_1 becomes $\ln r \neq 0$ or its equivalence $r \neq 1$, and the t-test statistic is obtained simply by replacing t_{A}, $\hat{d}$ and $\hat{\sigma}^2_{\mathrm{A},\varepsilon}$ with t_{G}, $\ln \hat{r}$ and $\hat{\sigma}^2_{\mathrm{G},\varepsilon}$ in (49.31).

One point worth noting is that, for testing purposes, each $\varepsilon_{\mathrm{A},n,k}$ (or $\varepsilon_{\mathrm{G},n,k}$) is essentially normally distributed, e.g. see *Gujarati* [49.32], p. 282. It is difficult to evaluate the normality assumption for a sample of only 20 observations, and formal test procedures are presented in *Ramsey* and *Ramsey* [49.33].

49.5 Estimating the Means and Variances

The work in this section is substantially based on *Leung* [49.4, 11].

49.5.1 Estimating $\mu_{\bar{A}_1}$ and $\sigma^2_{\bar{A}_1}$ of $\bar{A}_n$s

First, the mean and variance of $\bar{A}_1$ are estimated using the relevant estimators with the formulae given below.

First we denote

$$\bar{W}_{\mathrm{A},n} \equiv \frac{\sum_{k=1}^{K^*} W_{\mathrm{A},n,k}}{K^*} \quad \text{and} \quad \mu_{\bar{A}_1} \equiv \frac{\sum_{k=1}^{K^*} \mu_{A_1,k}}{K^*}\,.$$

From Definition 49.1, $W_{\mathrm{A},n,k}$s are i.i.d., we have

$$\mathrm{E}(\bar{W}_{\mathrm{A},n}) \equiv \frac{\sum_{k=1}^{K^*}\mathrm{E}(W_{\mathrm{A},n,k})}{K^*} = \frac{\sum_{k=1}^{K^*}\mu_{A_1,k}}{K^*} \equiv \mu_{\bar{A}_1}$$

and

$$\mathrm{V}(\bar{W}_{\mathrm{A},n}) \equiv \frac{\sum_{k=1}^{K^*}\mathrm{V}(W_{\mathrm{A},n,k})}{(K^*)^2} = \frac{\sum_{k=1}^{K^*}\sigma^2_{A_1,k}}{(K^*)^2} \equiv \frac{\sigma^2_{\bar{A}_1}}{K^*}\,.$$

From (49.14), (49.15), (49.16) and (49.17), we obtain

$$\mathrm{E}(\bar{W}_{\mathrm{A},n}) \equiv \frac{\sum_{k=1}^{K^*} \mathrm{E}(W_{\mathrm{A},n,k})}{K^*} = \frac{K^*\alpha_{\mathrm{A}}}{K^*} = \alpha_{\mathrm{A}}$$

and

$$\begin{aligned}\mathrm{V}(\bar{W}_{\mathrm{A},n}) &\equiv \frac{\sum_{k=1}^{K^*} \mathrm{V}(W_{\mathrm{A},n,k})}{(K^*)^2} = \frac{\sum_{k=1}^{K^*} \mathrm{V}(\alpha_A + \varepsilon_{\mathrm{A},n,k})}{(K^*)^2} \\ &= \frac{\sum_{k=1}^{K^*} \mathrm{V}(\varepsilon_{\mathrm{A},n,k})}{(K^*)^2} = \frac{\sum_{k=1}^{K^*} \sigma^2_{\mathrm{A},\varepsilon}}{(K^*)^2} \\ &= \frac{K^*\sigma^2_{\mathrm{A},\varepsilon}}{(K^*)^2} = \frac{\sigma^2_{\mathrm{A},\varepsilon}}{K^*} .\end{aligned}$$

Therefore, the first estimators for $\mu_{\bar{A}_1}$ and $\sigma^2_{\bar{A}_1}$ are denoted and given by

$$\hat{\mu}_{\bar{A}_1,1} = \hat{\alpha}_{\mathrm{A}} \tag{49.32}$$

and

$$\hat{\sigma}^2_{\bar{A}_1,1} = \hat{\sigma}^2_{\mathrm{A},\varepsilon} . \tag{49.33}$$

Alternatively, since $W_{\mathrm{A},n,k}$s are i.i.d. with mean $\mu_{W_{\mathrm{A},n,k}} = \mu_{A_1,k}$ and variance $\sigma^2_{W_{\mathrm{A},n,k}} = \sigma^2_{A_1,k}$, it is plausible to estimate $\mu_{\bar{A}_1}$ and $\sigma^2_{\bar{A}_1}$ by the sample mean and sample variance of $\hat{W}_{\mathrm{A},n,k}$s, where $\hat{W}_{\mathrm{A},n,k} = A_{n,k} + (n-1)\hat{d}$. Hence, the second estimators for $\mu_{\bar{A}_1}$ and $\sigma^2_{\bar{A}_1}$ are denoted and given by

$$\begin{aligned}\hat{\mu}_{\bar{A}_1,2} &= \frac{\sum_{k=1}^{K}\sum_{n=1}^{N_k} \hat{W}_{\mathrm{A},n,k}}{N} = \frac{\sum_{k=1}^{K}\sum_{n=1}^{N_k} [A_{n,k} + (n-1)\hat{d}]}{N} \\ &= \frac{\sum_{k=1}^{K}\sum_{n=1}^{N_k} A_{n,k}}{N} + \frac{\hat{d}\left(\sum_{k=1}^{K} N_k^2 - N\right)}{2N}\end{aligned} \tag{49.34}$$

and

$$\begin{aligned}\hat{\sigma}^2_{\bar{A}_1,2} = &\frac{\sum_{k=1}^{K}\sum_{n=1}^{N_k} \left[A_{n,k} + (n-1)\hat{d}\right]^2}{N-1} \\ &- \frac{\left\{\sum_{k=1}^{K}\sum_{n=1}^{N_k} [A_{n,k} + (n-1)\hat{d}]\right\}^2}{N(N-1)} .\end{aligned} \tag{49.35}$$

Notice that the second estimator $\hat{\mu}_{\bar{A}_1,2}$ given by (49.34) is the same as the first estimator $\hat{\mu}_{\bar{A}_1,1}$ given by (49.32) or (49.28).

It is also plausible to obtain the third estimator for $\mu_{\bar{A}_1}$ provided $N_k \cong N_0$ for $k = 1, \ldots, K$ as follows.

Let $S_N = \sum_{k=1}^{K}\sum_{n=1}^{N_k} A_{n,k} = \sum_{k=1}^{K}\sum_{n=1}^{N_k} [A_{1,k} - (n-1)d]$. Then

$$\begin{aligned}\mathrm{E}(S_N) &= \sum_{k=1}^{K} N_k \mathrm{E}(A_{1,k}) - \frac{d\left(\sum_{k=1}^{K} N_k^2 - N\right)}{2} \\ &= \sum_{k=1}^{K} N_k \mu_{A_{1,k}} - \frac{d\left(\sum_{k=1}^{K} N_k^2 - N\right)}{2} .\end{aligned}$$

If $N_k \cong N_0$ for $k = 1, \ldots, K$; then

$$\begin{aligned}\mathrm{E}(S_N) &\cong N_0 \sum_{k=1}^{K} \mu_{A_1,k} - \frac{dK\left(N_0^2 - N_0\right)}{2} \\ &= KN_0\mu_{\bar{A}_1} - \frac{dKN_0(N_0-1)}{2} .\end{aligned}$$

After transposition, we have

$$\mu_{\bar{A}_1} \cong \frac{\mathrm{E}(S_N)}{KN_0} + \frac{d(N_0-1)}{2} .$$

Hence, the third estimator for $\mu_{\bar{A}_1}$, provided $N_k \cong N_0$, for $k = 1, \ldots, K$, is denoted and given by

$$\begin{aligned}\hat{\mu}_{\bar{A}_1,3} &\cong \frac{S_N}{KN_0} + \frac{\hat{d}(N_0-1)}{2} \\ &= \frac{\sum_{k=1}^{K}\sum_{n=1}^{N_0} A_{n,k}}{KN_0} + \frac{\hat{d}(N_0-1)}{2} .\end{aligned} \tag{49.36}$$

In fact, we can deduce (49.36) directly from (49.28) by putting $N_k \cong N_0$ and $N \cong KN_0$. In other words, the third estimator for $\mu_{\bar{A}_1}$ is indeed the first estimator but calculated approximately using (49.36). As a whole, only one estimator for $\mu_{\bar{A}_1}$, namely $\hat{\mu}_{\bar{A}_1,1}$ has been derived so far. It is furthermore plausible to obtain the second (*fourth*) and third (*fifth*) estimators for $\mu_{\bar{A}_1}$, provided $N_k \cong N_0$ for $k = 1, \ldots, K$, as follows.

In view of the fact that $\mathrm{E}(\bar{W}_{\mathrm{A},n}) = \mu_{\bar{A}_1}$, we can write

$$\bar{W}_{\mathrm{A},n} = \mu_{\bar{A}_1}(1 + \delta_{\mathrm{A},n}) . \tag{49.37}$$

1. We have

$$\mathrm{E}\left(\frac{\bar{W}_{\mathrm{A},n}}{\mu_{\bar{A}_1}}\right) = 1 + \mathrm{E}(\delta_{\mathrm{A},n})$$

and so it follows that

$$\mathrm{E}(\delta_{\mathrm{A},n}) = 0\,. \tag{49.38}$$

2. We obtain

$$\mathrm{V}\left(\frac{\bar{W}_{\mathrm{A},n}}{\mu_{\bar{A}_1}}\right) = \mathrm{V}(1+\delta_{\mathrm{A},n})\,,$$

$$\frac{\mathrm{V}(\bar{W}_{\mathrm{A},n})}{\mu^2_{\bar{A}_1}} = \mathrm{V}(\delta_{\mathrm{A},n})$$

and so it follows that

$$\mathrm{V}(\delta_{\mathrm{A},n}) = \frac{\sigma^2_{\bar{A}_1}}{K^*\mu^2_{\bar{A}_1}}\,. \tag{49.39}$$

3. Taking the logarithm of $\bar{W}_{\mathrm{A},n} \equiv \frac{\sum_{k=1}^{K^*} W_{\mathrm{A},n,k}}{K^*}$, using equation (49.14) and the fact that $\varepsilon_{\mathrm{A},n,k} \equiv \varepsilon_{\mathrm{A},n}$, irrespective of k, and taking the logarithm for (49.37), we obtain

$$\ln \bar{W}_{\mathrm{A},n} = \ln\left[\alpha_{\mathrm{A}}\left(1+\frac{\varepsilon_{\mathrm{A},n}}{\alpha_{\mathrm{A}}}\right)\right] = \ln\alpha_{\mathrm{A}} + \ln\left(1+\frac{\varepsilon_{\mathrm{A},n}}{\alpha_{\mathrm{A}}}\right) \tag{49.40}$$

and

$$\ln \bar{W}_{\mathrm{A},n} = \ln\mu_{\bar{A}_1} + \ln(1+\delta_{\mathrm{A},n})\,. \tag{49.41}$$

Taking the expectations of (49.40) and (49.41), equating them, and expanding the logarithm series, we have

$$\begin{aligned}
&\ln\alpha_{\mathrm{A}} + \mathrm{E}\left(\frac{\varepsilon_{\mathrm{A},n}}{\alpha_{\mathrm{A}}} - \frac{\varepsilon^2_{\mathrm{A},n}}{2\alpha^2_{\mathrm{A}}} + \frac{\varepsilon^3_{\mathrm{A},n}}{3\alpha^3_{\mathrm{A}}} - \cdots\right) \\
&= \ln\mu_{\bar{A}_1} + \mathrm{E}\left(\delta_{\mathrm{A},n} - \frac{\delta^2_{\mathrm{A},n}}{2} + \frac{\delta^3_{\mathrm{A},n}}{3} - \cdots\right)\,, \\
&\ln\alpha_{\mathrm{A}} + \frac{1}{\alpha_{\mathrm{A}}}\mathrm{E}(\varepsilon_{\mathrm{A},n}) - \frac{1}{2\alpha^2_{\mathrm{A}}}\mathrm{E}(\varepsilon^2_{\mathrm{A},n}) \\
&\cong \ln\mu_{\bar{A}_1} + \mathrm{E}(\delta_{\mathrm{A},n}) - \frac{1}{2}\mathrm{E}(\delta^2_{\mathrm{A},n})\,, \\
&\ln\alpha_{\mathrm{A}} - \frac{1}{2\alpha^2_{\mathrm{A}}}\mathrm{V}(\varepsilon_{\mathrm{A},n}) \\
&= \ln\mu_{\bar{A}_1} - \frac{1}{2}\mathrm{V}(\delta_{\mathrm{A},n}) \quad \text{by (49.16) and (49.38)} \\
&\ln\alpha_{\mathrm{A}} - \frac{\sigma^2_{\mathrm{A},\varepsilon}}{2\alpha^2_{\mathrm{A}}} \\
&= \ln\mu_{\bar{A}_1} - \frac{\sigma^2_{\bar{A}_1}}{2K^*\mu^2_{\bar{A}_1}} \quad \text{by (49.17) and (49.39);}
\end{aligned}$$

4. $\mu_{\bar{A}_1}$ must satisfy the equation

$$\ln\left(\frac{\mu_{\bar{A}_1}}{\alpha_{\mathrm{A}}}\right) - \frac{1}{2}\left(\frac{\sigma^2_{\bar{A}_1}}{K^*\mu^2_{\bar{A}_1}} - \frac{\sigma^2_{\mathrm{A},\varepsilon}}{\alpha^2_{\mathrm{A}}}\right) = 0\,.$$

5. We can estimate $\mu_{\bar{A}_1}$, provided $N_k \cong N_0$ for $k = 1, \ldots, K$, i. e., $K = K^*$, by $\hat{\mu}_{\bar{A}_1,2}$, which satisfies the equation

$$\ln\left(\frac{\mu_{\bar{A}_1}}{\hat{\alpha}_{\mathrm{A}}}\right) - \frac{1}{2}\left(\frac{\hat{\sigma}^2_{\bar{A}_1,1}}{K\mu^2_{\bar{A}_1}} - \frac{\hat{\sigma}^2_{\mathrm{A},\varepsilon}}{\hat{\alpha}^2_{\mathrm{A}}}\right) = 0 \tag{49.42}$$

or by $\hat{\mu}_{\bar{A}_1,3}$, which satisfies the equation

$$\ln\left(\frac{\mu_{\bar{A}_1}}{\hat{\alpha}_{\mathrm{A}}}\right) - \frac{1}{2}\left(\frac{\hat{\sigma}^2_{\bar{A}_1,2}}{K\mu^2_{\bar{A}_1}} - \frac{\hat{\sigma}^2_{\mathrm{A},\varepsilon}}{\hat{\alpha}^2_{\mathrm{A}}}\right) = 0\,, \tag{49.43}$$

where $\hat{\alpha}_{\mathrm{A}}, \hat{\sigma}^2_{\mathrm{A},\varepsilon}, \hat{\sigma}^2_{\bar{A}_1,1}$ and $\hat{\sigma}^2_{\bar{A}_1,2}$ are given by (49.28), (49.29), (49.33) and (49.35), respectively.

Clearly, if $d = 0$, the parameters $\mu_{\bar{A}_1}$ and $\sigma^2_{\bar{A}_1}$ can be estimated using the sample mean and sample variance, which are given by

$$\hat{\mu}_{A_1,4} = \frac{\sum_{n=1}^{N} A_n}{N} \quad \text{and} \quad \hat{\sigma}^2_{A_1,3} = \frac{\sum_{n=1}^{N}(A_n - \hat{\mu}_{A_1,4})^2}{N-1}\,. \tag{49.44}$$

Secondly, we use (49.3) and (49.4), and let $N_1 \geq N_2 \geq \ldots \geq N_K$, the means and variances of $\bar{A}_n$ for $n = 2, 3, \ldots, N_k$ and $k = 1, \ldots, K$ are estimated using the following formulae:

$$\begin{aligned}
&\hat{\mu}_{\bar{A}_n} = \hat{\mu}_{\bar{A}_1} - (n-1)\hat{d} \quad \text{and} \\
&\hat{\sigma}^2_{\bar{A}_n} = \frac{\hat{\sigma}^2_{\bar{A}_1}}{K^*} \quad \text{for } n = 2, 3, \ldots, N_1\,.
\end{aligned} \tag{49.45}$$

49.5.2 Estimating $\mu_{\bar{G}_1}$ and $\sigma^2_{\bar{G}_1}$ of $\bar{G}_n$s

First, the mean and variance of $\bar{G}_1$ are estimated using the relevant estimators with the formulae given below.

First we denote

$$\bar{W}_{\mathrm{G},n} \equiv \frac{\sum_{k=1}^{K^*} W_{\mathrm{G},n,k}}{K^*}\,.$$

From Definition 49.2, $W_{G,n,k}$s are i.i.d., we have

$$\mathrm{E}(\bar{W}_{\mathrm{G},n}) \equiv \frac{\sum_{k=1}^{K^*} \mathrm{E}(W_{\mathrm{G},n,k})}{K^*} = \frac{\sum_{k=1}^{K^*} \mu_{G_1,k}}{K^*} \equiv \mu_{\bar{G}_1}$$

and

$$\mathrm{V}(\bar{W}_{\mathrm{G},n}) \equiv \frac{\sum_{k=1}^{K^*} \mathrm{V}(W_{\mathrm{G},n,k})}{(K^*)^2} = \frac{\sum_{k=1}^{K^*} \sigma^2_{G_1,k}}{(K^*)^2} \equiv \frac{\sigma^2_{\bar{G}_1}}{K^*} .$$

From (49.22), (49.24) and (49.25), we obtain

$$\begin{aligned}
\mathrm{E}(\bar{W}_{\mathrm{G},n}) &\equiv \frac{\sum_{k=1}^{K^*} \mathrm{E}(W_{\mathrm{G},n,k})}{K^*} = \frac{\sum_{k=1}^{K^*} \mathrm{E}(\mathrm{e}^{\alpha_{\mathrm{G}}+\varepsilon_{\mathrm{G},n,k}})}{K^*} \\
&= \frac{\mathrm{e}^{\alpha_{\mathrm{G}}} \sum_{k=1}^{K^*} \mathrm{E}(\mathrm{e}^{\varepsilon_{\mathrm{G},n,k}})}{K^*} \\
&= \frac{\mathrm{e}^{\alpha_{\mathrm{G}}} \sum_{k=1}^{K^*} \mathrm{E}\left(1+\varepsilon_{\mathrm{G},n,k}+\frac{\varepsilon^2_{\mathrm{G},n,k}}{2!}+\cdots\right)}{K^*} \\
&\cong \frac{\mathrm{e}^{\alpha_{\mathrm{G}}} \sum_{k=1}^{K^*} \left[1+\mathrm{E}(\varepsilon_{\mathrm{G},n,k})+\frac{1}{2}\mathrm{E}(\varepsilon^2_{\mathrm{G},n,k})\right]}{K^*} \\
&= \frac{\mathrm{e}^{\alpha_{\mathrm{G}}} \sum_{k=1}^{K^*} \left[1+\frac{1}{2}\mathrm{V}(\varepsilon_{\mathrm{G},n,k})\right]}{K^*} \\
&= \mathrm{e}^{\alpha_{\mathrm{G}}}\left(1+\frac{\sigma^2_{\mathrm{G},\varepsilon}}{2}\right) .
\end{aligned}$$

From (49.22) and (49.25), we obtain

$$\begin{aligned}
\mathrm{V}(\bar{W}_{\mathrm{G},n}) &\equiv \frac{\sum_{k=1}^{K^*} \mathrm{V}(W_{\mathrm{G},n,k})}{(K^*)^2} = \frac{\sum_{k=1}^{K^*} \mathrm{V}\left(\mathrm{e}^{\alpha_{\mathrm{G}}+\varepsilon_{\mathrm{G},n,k}}\right)}{(K^*)^2} \\
&= \frac{\mathrm{e}^{2\alpha_{\mathrm{G}}} \sum_{k=1}^{K^*} \mathrm{V}\left(\mathrm{e}^{\varepsilon_{\mathrm{G},n,k}}\right)}{(K^*)^2} \\
&= \frac{\mathrm{e}^{2\alpha_{\mathrm{G}}} \sum_{k=1}^{K^*} \mathrm{V}\left(1+\varepsilon_{\mathrm{G},n,k}+\frac{\varepsilon^2_{\mathrm{G},n,k}}{2!}+\cdots\right)}{(K^*)^2} \\
&\cong \frac{\mathrm{e}^{2\alpha_{\mathrm{G}}} \sum_{k=1}^{K^*} \mathrm{V}(1+\varepsilon_{\mathrm{G},n,k})}{(K^*)^2} \\
&= \frac{\mathrm{e}^{2\alpha_{\mathrm{G}}} \sum_{k=1}^{K^*} \mathrm{V}(\varepsilon_{\mathrm{G},n,k})}{(K^*)^2} = \frac{\mathrm{e}^{2\alpha_{\mathrm{G}}}\sigma^2_{\mathrm{G},\varepsilon}}{K^*} .
\end{aligned}$$

Therefore, the first estimators for $\mu_{\bar{G}_1}$ and $\sigma^2_{\bar{G}_1}$ are denoted and given by

$$\hat{\mu}_{\bar{G}_1,1} = \mathrm{e}^{\hat{\alpha}_{\mathrm{G}}}\left(1+\frac{\hat{\sigma}^2_{\mathrm{G},\varepsilon}}{2}\right) \tag{49.46}$$

and

$$\hat{\sigma}^2_{\bar{G}_1,1} = \mathrm{e}^{2\hat{\alpha}_{\mathrm{G}}}\hat{\sigma}^2_{\mathrm{G},\varepsilon} . \tag{49.47}$$

Alternatively, since $W_{\mathrm{G},n,k}$s are i.i.d. with mean $\mu_{W_{\mathrm{G},n,k}} = \mu_{G_1,k}$ and variance $\sigma^2_{W_{\mathrm{G},n,k}} = \sigma^2_{G_1,k}$, it is plausible for us to estimate $\mu_{\bar{G}_1}$ and $\sigma^2_{\bar{G}_1}$ by the sample mean and sample variance of $\hat{W}_{\mathrm{G},n,k}$s, where $\hat{W}_{\mathrm{G},n,k} = \hat{r}^{(n-1)}G_{n,k}$. Hence, the second estimators for $\mu_{\bar{G}_1}$ and $\sigma^2_{\bar{G}_1}$ are denoted and given by

$$\hat{\mu}_{\bar{G}_1,2} = \frac{\sum_{k=1}^{K}\sum_{n=1}^{N_k} \hat{W}_{\mathrm{G},n,k}}{N} = \frac{\sum_{k=1}^{K}\sum_{n=1}^{N_k} (\hat{r}^{(n-1)}G_{n,k})}{N} \tag{49.48}$$

and

$$\hat{\sigma}^2_{\bar{G}_1,2} = \frac{\sum_{k=1}^{K}\sum_{n=1}^{N_k} (\hat{r}^{(n-1)}G_{n,k})^2 - \frac{\left[\sum_{k=1}^{K}\sum_{n=1}^{N_k} (\hat{r}^{(n-1)}G_{n,k})\right]^2}{N}}{N-1} . \tag{49.49}$$

It is also plausible for us to obtain the third estimator for $\mu_{\bar{G}_1}$ provided $N_k \cong N_0$ for $k = 1, \ldots, K$.

Let

$$\begin{aligned}
S_N &= \sum_{k=1}^{K}\sum_{n=1}^{N_k} G_{n,k} = \sum_{k=1}^{K}\sum_{n=1}^{N_k}\left(\frac{G_{1,k}}{r^{(n-1)}}\right) \\
&= \sum_{k=1}^{K} G_{1,k} \sum_{n=1}^{N_k} \frac{1}{r^{(n-1)}} \\
&= \frac{1}{1-r^{-1}} \sum_{k=1}^{K}\left(1-r^{-N_k}\right) G_{1,k} .
\end{aligned}$$

Then

$$\mathrm{E}(S_N) = \frac{1}{1-r^{-1}} \sum_{k=1}^{K}\left(1-r^{-N_k}\right)\mu_{G_1,k} .$$

If $N_k \cong N_0$ for $k = 1, \ldots, K$, then

$$\mathrm{E}(S_N) \cong \frac{K\mu_{\bar{G}_1}\left(1-r^{-N_0}\right)}{1-r^{-1}} .$$

After transposition, we have

$$\mu_{\tilde{G}_1} \cong \frac{\mathrm{E}(S_N)\left(1-r^{-1}\right)}{K(1-r^{-N_0})} .$$

Hence, the third estimator for $\mu_{\tilde{G}_1}$, provided $N_k \cong N_0$, for $k = 1, \ldots, K$, is denoted and given by

$$\hat{\mu}_{\tilde{G}_1,3} \cong \frac{S_N\left(1-\hat{r}^{-1}\right)}{K(1-\hat{r}^{-N_0})} = \frac{\left(1-\hat{r}^{-1}\right)\sum_{k=1}^{K}\sum_{n=1}^{N_0} G_{n,k}}{K(1-\hat{r}^{-N_0})} . \tag{49.50}$$

It is furthermore plausible for us to obtain the fourth and fifth estimators for $\mu_{\tilde{G}_1}$ provided $N_k \cong N_0$ for $k = 1, \ldots, K$, as follows:

Since $\mathrm{E}(\bar{W}_{\mathrm{G},n}) = \mu_{\tilde{G}_1}$, we can write

$$\bar{W}_{\mathrm{G},n} = \mu_{\tilde{G}_1}(1+\delta_{\mathrm{G},n}) . \tag{49.51}$$

1. We have

$$\mathrm{E}\left(\frac{\bar{W}_{\mathrm{G},n}}{\mu_{\tilde{G}_1}}\right) = 1+\mathrm{E}(\delta_{\mathrm{G},n})$$

and so it follows that

$$\mathrm{E}(\delta_{\mathrm{G},n}) = 0 . \tag{49.52}$$

2. We obtain

$$\mathrm{V}\left(\frac{\bar{W}_{\mathrm{G},n}}{\mu_{\tilde{G}_1}}\right) = \mathrm{V}(1+\delta_{\mathrm{G},n}) ,$$

$$\frac{\mathrm{V}(\bar{W}_{\mathrm{G},n})}{\mu^2_{\tilde{G}_1}} = \mathrm{V}(\delta_{\mathrm{G},n})$$

and so it follows that

$$\mathrm{V}(\delta_{\mathrm{G},n}) = \frac{\sigma^2_{\tilde{G}_1}}{K^*\mu^2_{\tilde{G}_1}} . \tag{49.53}$$

3. Taking the logarithm of $\bar{W}_{\mathrm{G},n} \equiv \frac{\sum_{k=1}^{K^*} W_{\mathrm{G},n,k}}{K^*}$, using (49.21) and the fact that $\varepsilon_{\mathrm{G},n,k} \equiv \varepsilon_{\mathrm{G},n}$, irrespective of k, and taking the logarithm of (49.51), we obtain

$$\ln \bar{W}_{\mathrm{G},n} = \alpha_{\mathrm{G}} + \varepsilon_{\mathrm{G},n} \tag{49.54}$$

and

$$\ln \bar{W}_{\mathrm{G},n} = \ln \mu_{\tilde{G}_1} + \ln(1+\delta_{\mathrm{G},n}) \tag{49.55}$$

Taking the expectations of (49.54) and (49.55), equating them, and expanding the logarithm series, we have

$$\alpha_{\mathrm{G}} + \mathrm{E}(\varepsilon_{\mathrm{G},n}) = \ln \mu_{\tilde{G}_1} + \mathrm{E}\left(\delta_{\mathrm{G},n} - \frac{\delta^2_{\mathrm{G},n}}{2} + \frac{\delta^3_{\mathrm{G},n}}{3} - \cdots\right) ,$$

$$\alpha_{\mathrm{G}} \cong \ln \mu_{\tilde{G}_1} + \mathrm{E}(\delta_{\mathrm{G},n}) - \frac{1}{2}\mathrm{E}(\delta^2_{\mathrm{G},n})$$

$$= \ln \mu_{\tilde{G}_1} - \frac{1}{2}\mathrm{V}(\delta_{\mathrm{G},n})$$

$$= \ln \mu_{\tilde{G}_1} - \frac{\sigma^2_{\tilde{G}_1}}{2K^*\mu^2_{\tilde{G}_1}} \quad \text{by (49.53)} .$$

4. $\mu_{\tilde{G}_1}$ must satisfy the equation

$$2K^*(\ln \mu_{\tilde{G}_1} - \alpha_{\mathrm{G}})\mu^2_{\tilde{G}_1} - \sigma^2_{\tilde{G}_1} = 0 .$$

5. We can estimate $\mu_{\tilde{G}_1}$, provided $N_k \cong N_0$ for $k = 1, \ldots, K$, i. e., $K = K^*$, by $\hat{\mu}_{\tilde{G}_1,4}$ which satisfies the equation

$$2K(\ln \mu_{\tilde{G}_1} - \hat{\alpha}_{\mathrm{G}})\mu^2_{\tilde{G}_1} - \hat{\sigma}^2_{\tilde{G}_1,1} = 0 \tag{49.56}$$

or by $\hat{\mu}_{\tilde{G}_1,5}$ which satisfies the equation

$$2K(\ln \mu_{\tilde{G}_1} - \hat{\alpha}_{\mathrm{G}})\mu^2_{\tilde{G}_1} - \hat{\sigma}^2_{\tilde{G}_1,2} = 0 , \tag{49.57}$$

where $\hat{\alpha}_{\mathrm{G}}$, $\hat{\sigma}^2_{\mathrm{G},\varepsilon}$, $\hat{\sigma}^2_{\tilde{G}_1,1}$ and $\hat{\sigma}^2_{\tilde{G}_1,2}$ are given by (49.28), (49.29) (where $\hat{d}$, $A_{n,k}$ are replaced by $\ln \hat{r}$ and $\ln G_{n,k}$), (49.47) and (49.49), respectively.

Clearly, if $\ln r = 0$ or $r = 1$, the parameters $\mu_{\tilde{G}_1}$ and $\sigma^2_{\tilde{G}_1}$ can be estimated using the sample mean and sample variance, which are given by

$$\hat{\mu}_{G_1,6} = \frac{\sum_{n=1}^{N} G_n}{N} \quad \text{and} \quad \hat{\sigma}^2_{G_1,3} = \frac{\sum_{n=1}^{N}(G_n - \hat{\mu}_{G_1,6})^2}{N-1} . \tag{49.58}$$

Secondly, we use (49.7) and (49.8), and let $N_1 \geq N_2 \geq \ldots \geq N_K$, the means and variances of $\bar{G}_n$ for $n = 2, 3, \ldots, N_k$ and $k = 1, \ldots, K$ are estimated using the following formulae:

$$\hat{\mu}_{\bar{G}_n} = \frac{\hat{\mu}_{\tilde{G}_1}}{\hat{r}^{(n-1)}} \quad \text{and} \quad \hat{\sigma}^2_{\bar{G}_n} = \frac{\hat{\sigma}^2_{\tilde{G}_1}}{\hat{r}^{2(n-1)}K^*} \quad \text{for } n = 2, 3, \ldots, N_1 . \tag{49.59}$$

49.5.3 Estimating the Means and Variances of a Single AP or GP

When $K = 1$, (49.30) becomes $N = N_1$. Note again that

1. for a single AP or GP, we simply use N to represent the number of successive events, and
2. the results listed in the next two subsections are consistent with those derived in *Leung* [49.8] and *Lam* [49.15].

A Single AP

First, the mean and variance of A_1 are estimated using the relevant estimators with the formulae given below.

The first estimators for μ_{A_1} and $\sigma^2_{A_1}$ are denoted and given by

$$\hat{\mu}_{A_1,1} = \hat{\alpha}_{\mathrm{A}} \tag{49.32.1}$$

and

$$\hat{\sigma}^2_{A_1,1} = \hat{\sigma}^2_{\mathrm{A},\varepsilon}\,, \tag{49.33.1}$$

where $\hat{\alpha}_{\mathrm{A}}$ and $\hat{\sigma}^2_{\mathrm{A},\varepsilon}$ are given by (49.28.1) and (49.29.1).

The second estimator for $\sigma^2_{A_1}$ is denoted and given by

$$\hat{\sigma}^2_{A_1,2} = \frac{\sum_{n=1}^{N}[A_n+(n-1)\hat{d}]^2 - \frac{\left\{\sum_{n=1}^{N}[A_n+(n-1)\hat{d}]\right\}^2}{N}}{N-1}\,, \tag{49.35.1}$$

where $\hat{d}$ is given by (49.27.1).

The second $\hat{\mu}_{A_1,2}$ and third $\hat{\mu}_{A_1,3}$ estimators for μ_{A_1}, respectively, satisfy the equations

$$\ln\left(\frac{\mu_{A_1}}{\hat{\alpha}_{\mathrm{A}}}\right) - \frac{1}{2}\left(\frac{\hat{\sigma}^2_{A_1,1}}{\mu^2_{A_1}} - \frac{\hat{\sigma}^2_{\mathrm{A},\varepsilon}}{\hat{\alpha}^2_{\mathrm{A}}}\right) = 0 \tag{49.42.1}$$

and

$$\ln\left(\frac{\mu_{A_1}}{\hat{\alpha}_{\mathrm{A}}}\right) - \frac{1}{2}\left(\frac{\hat{\sigma}^2_{A_1,2}}{\mu^2_{A_1}} - \frac{\hat{\sigma}^2_{\mathrm{A},\varepsilon}}{\hat{\alpha}^2_{\mathrm{A}}}\right) = 0\,, \tag{49.43.1}$$

where $\hat{\alpha}_{\mathrm{A}}$, $\hat{\sigma}^2_{\mathrm{A},\varepsilon}$, $\hat{\sigma}^2_{A_1,1}$ and $\hat{\sigma}^2_{A_1,2}$ are given by (49.28.1), (49.29.1), (49.33.1) and (49.35.1), respectively.

Clearly, if $d = 0$, the parameters μ_{A_1} and $\sigma^2_{A_1}$ can be estimated using (49.44).

Secondly, using (49.3) and (49.4), the means and variances of A_n for $n = 2, 3, \ldots, N$ are estimated using the following formulae:

$$\hat{\mu}_{A_n} = \hat{\mu}_{A_1} - (n-1)\hat{d} \quad \text{and} \quad \hat{\sigma}^2_{A_n} = \hat{\sigma}^2_{A_1} \quad \text{for } n = 2, 3, \ldots, N\,. \tag{49.45.1}$$

A Single GP

First, the mean and variance of G_1 are estimated using the relevant estimators with formulae given below.

The first estimators for μ_{G_1} and $\sigma^2_{G_1}$ are denoted and given by

$$\hat{\mu}_{G_1,1} = \mathrm{e}^{\hat{\alpha}_{\mathrm{G}}}\left(1 + \frac{\hat{\sigma}^2_{\mathrm{G},\varepsilon}}{2}\right) \tag{49.46.1}$$

and

$$\hat{\sigma}^2_{G_1,1} = \mathrm{e}^{2\hat{\alpha}_{\mathrm{G}}}\hat{\sigma}^2_{\mathrm{G},\varepsilon}\,, \tag{49.47.1}$$

where $\hat{\alpha}_{\mathrm{G}}$ and $\hat{\sigma}^2_{\mathrm{G},\varepsilon}$ are given by (49.28.1) and (49.29.1) with $\hat{d}$ and A_n replaced by $\ln \hat{r}$ and $\ln G_n$.

The second estimators for μ_{G_1} and $\sigma^2_{G_1}$ are denoted and given by

$$\hat{\mu}_{G_1,2} = \frac{\sum_{n=1}^{N}\hat{r}^{(n-1)}G_n}{N} \tag{49.48.1}$$

and

$$\hat{\sigma}^2_{G_1,2} = \frac{\sum_{n=1}^{N}\left(\hat{r}^{(n-1)}G_n\right)^2 - \frac{\left(\sum_{n=1}^{N}\hat{r}^{(n-1)}G_n\right)^2}{N}}{N-1}\,, \tag{49.49.1}$$

where $\hat{r}$ is given by (49.27.1) with A_n replaced by $\ln G_n$.

The third estimator for μ_{G_1} is denoted and given by

$$\hat{\mu}_{G_1,3} = \frac{\left(1-\hat{r}^{-1}\right)\sum_{n=1}^{N}G_n}{1-\hat{r}^{-N}}\,. \tag{49.50.1}$$

The fourth $\hat{\mu}_{G_1,4}$ and fifth $\hat{\mu}_{G_1,5}$ estimators for μ_{G_1} respectively satisfy the equations

$$2(\ln\mu_{G_1} - \hat{\alpha}_{\mathrm{G}})\mu^2_{G_1} - \hat{\sigma}^2_{G_1,1} = 0 \tag{49.56.1}$$

and

$$2(\ln\mu_{G_1} - \hat{\alpha}_{\mathrm{G}})\mu^2_{G_1} - \hat{\sigma}^2_{G_1,2} = 0\,, \tag{49.57.1}$$

where $\hat{\sigma}^2_{G_1,1}$ and $\hat{\sigma}^2_{G_1,2}$ are given by (49.47.1) and (49.49.1).

Clearly, if $r = 1$, the parameters μ_{G_1} and $\sigma^2_{G_1}$ can be estimated using (49.58).

Secondly, using (49.7) and (49.8), the means and variances of A_n for $n = 2, 3, \ldots, N$ are estimated using the following formulae:

$$\hat{\mu}_{G_n} = \frac{\hat{\mu}_{G_1}}{\hat{r}^{(n-1)}} \quad \text{and} \quad \hat{\sigma}^2_{G_n} = \frac{\hat{\sigma}^2_{G_1}}{\hat{r}^{2(n-1)}} \quad \text{for } n = 2, 3, \ldots, N . \tag{49.59.1}$$

49.6 Comparison of Estimators Using Simulation

Much of the work in this section is based on *Leung* [49.7], and *Leung* and *Lai* [49.13].

49.6.1 A Single AP or GP

Some simulation studies were performed to evaluate various estimators given in Sect. 49.5.3 and to compare the different estimates of μ_{A_1} and $\sigma^2_{A_1}$ (or μ_{G_1} and $\sigma^2_{G_1}$).

For each realization $\{A_n, n = 1, \ldots, 20\}$, the estimates $\hat{\mu}_{A_1,i}, i = 1, 2, 3, 4$ are ranked using three criteria. First, if our objective is to estimate the value of μ_{A_1}, we can compute the deviation ϕ of $\hat{\mu}_{A_1,i}$ from μ_{A_1}, i. e. $\phi = \left|\hat{\mu}_{A_1,i} - \mu_{A_1}\right|$. Secondly, if our objective is to fit A_ns values only, we can calculate the mean square error (MSE) between the fitted values $\hat{A}_{n,i} = \hat{\mu}_{A_1,i} - (n-1)\hat{d}$s and observations A_ns, i. e. $\text{MSE} = \sum_{n=1}^{N} \left(\hat{A}_{n,i} - A_n\right)^2 / N$. Thirdly, if our objective is to estimate μ_{A_1} as well as fitting values of A_ns, then we can use $\Phi = \phi + \sqrt{\text{MSE}}$. Moreover, the estimates $\hat{\sigma}^2_{A_1,1}$ and $\hat{\sigma}^2_{A_1,2}$ can be compared by their standard deviations (s.d.) from $\sigma^2_{A_1}$. The recommended estimators based on the simulation studies are summarized in Table 49.1 (for more details, see *Leung* et al. [49.7]).

Similarly, for each realization $\{G_n, n = 1, \ldots, 101\}$, the estimates $\hat{\mu}_{G_1,i}, i = 1, 2, 3, 4, 5, 6$ are ranked using the aforementioned three criteria, and the estimates $\hat{\sigma}^2_{G_1,1}$ and $\hat{\sigma}^2_{G_1,2}$ can be compared by their s.d. from $\sigma^2_{G_1}$. The recommended estimators based on the simulation studies are summarized in Table 49.2 (for more details, see *Lam* [49.15]).

49.6.2 *K* Independent, Homogeneous APs or GPs

Some simulation studies were also performed to evaluate various estimators given in Sect. 49.5.1 (or Sect. 49.5.2) and to compare the different estimates of $\mu_{\bar{A}_1}$ and $\sigma^2_{\bar{A}_1}$ (or $\mu_{\bar{G}_1}$ and $\sigma^2_{\bar{G}_1}$).

For each realization $\{A_{n,k}, n = 1, \ldots, 20$ and $k = 1, \ldots, 10\}$ (or $\{G_{n,k}, n = 1, \ldots, 101$ and $k = 1, \ldots, 10\}$), the estimates $\hat{\mu}_{\bar{A}_1,i}$, $i = 1, 2, 3, 4$ (or $\hat{\mu}_{\bar{G}_1,i}, i = 1, 2, 3, 4, 5, 6$) are ranked using the first criterion, namely the deviation ϕ of $\hat{\mu}_{\theta,i}$ from μ_θ, i. e. $\phi = \left|\hat{\mu}_{\theta,i} - \mu_\theta\right|$, and the estimates $\hat{\sigma}^2_{\theta,1}$ and $\hat{\sigma}^2_{\theta,2}$

Table 49.1 Recommended estimators for μ_{A_1} and $\sigma^2_{A_1}$

can be compared by their s.d. from σ^2_θ, where $\theta =$ either $\bar{A}_1$ or $\bar{G}_1$. The recommended estimators based on the simulation studies are summarized in Table 49.3 (for more details, see *Leung* and *Lai* [49.13]).

49.6.3 Comparison Between Averages of Estimates and Pooled Estimates

Having obtained the estimates $\hat{d}$, $\hat{\mu}_{A_1}$ and $\hat{\sigma}^2_{A_1}$ (or $\hat{r}$, $\hat{\mu}_{G_1}$ and $\hat{\sigma}^2_{G_1}$) using the relevant estimators suggested in Table 49.1 (or Table 49.2), of the parameters d, μ_{A_1} and $\sigma^2_{A_1}$ (or r, μ_{G_1} and $\sigma^2_{G_1}$) of a single system, we can compute the averages of the respective estimates for a collection of homogeneous systems and then use these averages to estimate $\hat{\mu}_{A_n}$ and $\hat{\sigma}^2_{A_n}$ (or $\hat{\mu}_{G_n}$ and $\hat{\sigma}^2_{G_n}$). *Leung* and *Lai* [49.13] drew the conclusion that, in any cases, the pooled estimates obtained using the pooled estimators for APs or GPs suggested in Table 49.3 are better than the respective averages of estimates.

49.7 Real Data Analysis

Lam et al. [49.16] presented ten examples, each analyzing a real data set using four models:

1. the GP model with a nonparametric method,
2. the HPP model,
3. the NHPP model with PLP and
4. the NHPP model with LLP.

Example 1 examines 190 data of the intervals in days between successive coal-mining disasters in Great Britain, which have been used by a number of researchers to illustrate various techniques that can be applied to point processes; see, for example, *Cox* and *Lewis* [49.17], pp. 42–43. The data set can be found in *Hand* et al. [49.34], p. 155 or *Andrews* and *Herzberz* [49.35], pp. 51–56, in which the data are recorded in more detail.

Examples 2–4 study 29, 30 and 27 data of the intervals in operating hours between successive failures of air-conditioning equipment in aircrafts 3, 6 and 7. The 13 data sets tabulate on p. 6 of *Cox* and *Lewis* [49.17], and the data sets being examined are the largest three.

Example 5 investigates 257 failure times of a computer in unspecified units. The data are given in *Cox* and *Lewis* ([49.17], p. 11).

Example 6 examines 245 arrival times of patients at an intensive care unit in a hospital. The data are given in *Cox* and *Lewis* ([49.17], p. 14 and pp. 254–255).

Examples 7 and 8 study 71 and 56 data of the arrival times to unscheduled overhauls for the no. 3 and no. 4 main propulsion diesel engines for two submarines. The two data sets tabulate on pp. 75–76 of *Ascher* and *Feingold* [49.18].

Example 9 investigates the times that 41 successive vehicles traveling northwards along the M1 motorway in England passed a fixed point near junction 13 in Bedfordshire on Saturday 23 March 1985. The data are given in *Hand* et al. ([49.34], p. 3).

Example 10 examines 136 failure times [in central processing unit (CPU) seconds, measured in terms of execution time] of a real-time command-and-control software system. The data are given in *Hand* et al. ([49.34], p. 10–11).

Lam et al. [49.16] concluded that, on average, the GP model is the best model for fitting these ten real data sets among the four models based on the MSE criterion (as defined in Sect. 49.5.1). This is the reason why the GP model can be applied to the maintenance problems.

Furthermore, *Lam* and *Chan* [49.36] applied the GP model to fit the three real data sets in Examples 1, 7 and 8 using a parametric method with one of the log-normal, exponential, gamma and Weibull distributions. The numerical results also conclude that all three data sets can be well fitted by the GP model based on the MSE criterion.

The author is currently investigating the following:

1. The ten data sets are analyzed using the AP model with a nonparametric method and the numerical results are compared with those in *Lam* et al. [49.16].
2. The data sets in Examples 2–4 (or even the 13 data sets) and the data sets in Examples 7 and 8 are respectively pooled together to estimate the parameters using the methods suggested in Sects. 49.2–49.5 for AP and GP, and the methods used in *Leung* and *Cheng* [49.3] for HPP and NHPP. The numerical results are also compared with those in *Lam* et al. [49.16] plus those obtained using the AP model.

49.8 Optimal Replacement Policies Determined Using Arithmetico-Geometric Processes

The work in this section is substantially based on *Leung* [49.5].

49.8.1 Arithmetico-Geometric Processes

A definition of an AGP is given below.

Definition 49.3

Given a sequence of random variables $H_1, H_2, \ldots$, if for some real number d and some $r > 0$, $\{[H_n + (n-1)d]r^{(n-1)}, n = 1, 2, \ldots\}$ forms an RP, then $\{H_n,\ n = 1, 2, \ldots\}$ is an AGP. The two parameters d and r are called the common difference and the common ratio of the AGP respectively.

Three specializations of an AGP are given below.

If $r > 1$ and $d \in \left(0, \frac{\mu_{H_1}}{(n-1)r^{(n-1)}}\right]$, where $n = 2, 3, \ldots$ and μ_{H_1} is the mean of the first random variable H_1, then the AGP is called a decreasing AGP. If $d < 0$ and $0 < r < 1$, then the AGP is called an increasing AGP. If $d = 0$ and $r = 1$, then the AGP reduces to an RP.

Two immediate remarks concerning the characteristics of an AGP are as follows:

1. An AGP is the name given to a series in which the general term is the product of the general term of an AP and of a GP; we take this term to be, in general,
$$H_n = \frac{H_1}{r^{(n-1)}} - (n-1)d\ .$$
2. It is evident that, if we put $r = 1$ but d $\neq 0$, or $d = 0$ but $r \neq 1$ into the above expression, the process obtained becomes an AP, or a GP. Hence, an AGP extends and generalizes an AP or a GP.

Therefore, for a deteriorating system, it is reasonable to assume that the successive operating times of the system form a decreasing AGP, whereas the corresponding consecutive repair times constitute an increasing AGP. However, the replacement times for the system are usually stochastically the same no matter how old the used system is; hence, they will form an RP. This is the motivation behind the introduction of the AGP approach.

49.8.2 Model

Before deriving new repair–replacement models, the following assumptions are stated.

1. At the beginning, a new system is used.
2. Whenever the system fails, it can be repaired. Let X_n be the survival time after the $(n-1)$th repair, then a sequence $\{X_n, n = 1, 2, \ldots\}$ forms a decreasing AGP with parameters $d_a > 0$ and $r_a > 1$ such that $\mu_{X_1}/(n-1)r_a^{(n-1)} \geq d_a$, where $\mathrm{E}(X_1) \equiv \mu_{X_1} > 0$.
3. Let Y_n be the repair time after the nth failure, then a sequence $\{Y_n, n = 1, 2, \ldots\}$ forms an increasing AGP with parameters $d_b < 0$ and $0 < r_b < 1$, and $\mathrm{E}(Y_1) \equiv \mu_{Y_1} \geq 0$. $\mu_{Y_1} = 0$ means that the repair time is negligible.
4. A sequence $\{X_n, n = 1, 2, \ldots\}$ and a sequence $\{Y_n, n = 1, 2, \ldots\}$ are independent.
5. An average operating cost rate is c_o, an average repair cost rate is c_f, and an average revenue rate of a working system is w.
6. The system may be replaced at some time by a new and identical one. An average replacement cost rate under policy T or N is c_{RT} or c_{RN}, respectively, and an average replacement downtime under policy T or N is u_{RT} or u_{RN}, respectively. Two kinds of replacement policy are considered in this model.
   a) A replacement policy T is a policy in which we replace the system whenever the working age of the system reaches T, a continuous decision variable, see *Barlow* and *Proschan* [49.19]. The working age T of a system at time t is the

cumulative survival time by time t, i. e.

$$T = \begin{cases} t - V_n, U_n + V_n \le t < U_{n+1} + V_n \\ U_{n+1}, U_{n+1} + V_n \le t < U_{n+1} + V_{n+1} \end{cases}, \quad (49.60)$$

where $U_n = \sum_{i=1}^{n} X_i$, $V_n = \sum_{i=1}^{n} Y_i$ and $U_0 = 0$, $V_0 = 0$.

b) A replacement policy N is a policy in which we replace the system at the time of Nth failure since the last replacement, a discrete decision variable, see *Nakagawa* [49.37].

Under replacement policy T or N, the problem is to determine an optimal replacement policy T^* or N^*, respectively, such that the long-run expected loss per unit total time or per unit operation time is minimized.

49.8.3 The Long-Run Expected Loss Rate

Let T_n be the time between the $(n-1)$th replacement and the nth replacement with $T_0 = 0$, then $\{T_n, n = 1, 2, \dots\}$ forms an RP. Applying known results from renewal theory (see e.g. *Ross* [49.20], pp. 51–54), the long-run expected loss per unit time is obtained by

$$l(T) \text{ or } l(N) = \frac{\text{E(loss incurred in a cycle)}}{\text{E(length of a cycle)}}, \quad (49.61)$$

where the loss is defined as the total cost minus total revenue, and a cycle is the time between two consecutive replacements.

Under the replacement policy T, denote the length of a cycle by W, then

$$W = T + V_n \quad \text{and}$$
$$U_n < T \le U_{n+1} \quad \text{for } n = 0, 1, \dots . \quad (49.62)$$

From Definition 49.3 and Assumption 3, it follows that $\mathrm{E}(Y_n) = \frac{\mu_{Y_1}}{r_b^{(n-1)}} - (n-1)d_b$. Then

$$\mathrm{E}(W) = \mathrm{E}\left(T + \sum_{j=1}^{n} Y_j\right) = \mathrm{E}\left[T + \sum_{j=1}^{\infty} Y_j I(n \ge j)\right],$$

where I is the indicator random variable defined as

$$I(n \ge j) = \begin{cases} 1 & \text{if } n \ge j \\ 0 & \text{if } n < j \end{cases}.$$

Since $n \ge j \Leftrightarrow U_j \le T$, we have

$$\begin{aligned} \mathrm{E}(W) &= \mathrm{E}\left[T + \sum_{j=1}^{\infty} Y_j I(U_j \le T)\right] \\ &= \mathrm{E}(T) + \sum_{j=1}^{\infty} \mathrm{E}(Y_j)\mathrm{E}[I(U_j \le T)] \\ &\quad \text{as } Y_j \text{ and } U_j \text{ are independent} \\ &= T + \sum_{j=1}^{\infty}\left[\frac{\mu_{Y_1}}{r_b^{(j-1)}} - (j-1)d_b\right] \\ &\quad \times [1 \times \Pr(U_j \le T) + 0 \times \Pr(U_j > T)] \\ &= T + \sum_{j=1}^{\infty}\left[\frac{\mu_{Y_1}}{r_b^{(j-1)}} - (j-1)d_b\right] F_j(T), \end{aligned}$$

where F_j is the cumulative distribution function of U_j.

Thus, from (49.61) the long-run expected loss per unit total time $l(T)$ under policy T is given by

$$l(T) = \frac{(c_o - w)T + c_{RT}u_{RT}}{T + \sum_{j=1}^{\infty}\left[\frac{\mu_{Y_1}}{r_b^{(j-1)}} - (j-1)d_b\right]F_j(T) + u_{RT}} + \frac{c_f\left\{\sum_{j=1}^{\infty}\left[\frac{\mu_{Y_1}}{r_b^{(j-1)}} - (j-1)d_b\right]F_j(T)\right\}}{T + \sum_{j=1}^{\infty}\left[\frac{\mu_{Y_1}}{r_b^{(j-1)}} - (j-1)d_b\right]F_j(T) + u_{RT}} \quad (49.63)$$

and also from (49.61) the long-run expected loss per unit total time $l(N)$ under policy N is given by

$$l(N) = \left\{(c_o - w)\sum_{j=1}^{N}\left[\frac{\mu_{X_1}}{r_a^{(j-1)}} - (j-1)d_a\right] + c_f\sum_{j=1}^{N-1}\left[\frac{\mu_{Y_1}}{r_b^{(j-1)}} - (j-1)d_b\right] + c_{RN}u_{RN}\right\} \Big/ \left\{\sum_{j=1}^{N}\left[\frac{\mu_{X_1}}{r_a^{(j-1)}} - (j-1)d_a\right] + \sum_{j=1}^{N-1}\left[\frac{\mu_{Y_1}}{r_b^{(j-1)}} - (j-1)d_b\right] + u_{RN}\right\}. \quad (49.64)$$

Further, from (49.61) the long-run expected loss per unit operation time $l_{\mathrm{op}}(T)$ under policy T or $l_{\mathrm{op}}(N)$ under policy N is respectively given by

$$l_{\mathrm{op}}(T) = \frac{(c_{\mathrm{o}} - w)T + c_{RT}u_{RT}}{T} + \frac{c_{\mathrm{f}}\left\{\sum_{j=1}^{\infty}\left[\frac{\mu_{Y_1}}{r_{\mathrm{b}}^{(j-1)}} - (j-1)d_{\mathrm{b}}\right]F_j(T)\right\}}{T} \tag{49.65}$$

or

$$l_{\mathrm{op}}(N) = \frac{(c_{\mathrm{o}} - w)\sum_{j=1}^{N}\left[\frac{\mu_{X_1}}{r_{\mathrm{a}}^{(j-1)}} - (j-1)d_{\mathrm{a}}\right]}{\sum_{j=1}^{N}\left[\frac{\mu_{X_1}}{r_{\mathrm{a}}^{(j-1)}} - (j-1)d_{\mathrm{a}}\right]} + \frac{c_{\mathrm{f}}\sum_{j=1}^{N-1}\left[\frac{\mu_{Y_1}}{r_{\mathrm{b}}^{(j-1)}} - (j-1)d_{\mathrm{b}}\right] + c_{RN}u_{RN}}{\sum_{j=1}^{N}\left[\frac{\mu_{X_1}}{r_{\mathrm{a}}^{(j-1)}} - (j-1)d_{\mathrm{a}}\right]}. \tag{49.66}$$

To simplify the optimization tasks, first operating cost is excluded ($c_{\mathrm{o}} = 0$) because this belongs to the account of production (rather than maintenance) costs; secondly, without loss of generality, w can be set equal to HK$ 1 because money can be measured in an arbitrary scale (c_{f}, C_{RT}, and C_{RN} are on the same scale of Hong Kong dollars). Hence, putting $c_{\mathrm{o}} = 0$ and $w = 1$ into (49.63) to (49.66) and then adding unity to the right-hand side of (49.63) to (49.66), we obtain the simplified versions of $l(T)$ and $l(N)$, and $l_{\mathrm{op}}(T)$ and $l_{\mathrm{op}}(N)$ namely

$$l_1(T) = \frac{(c_{\mathrm{f}} + 1)\left\{\sum_{j=1}^{\infty}\left[\frac{\mu_{Y_1}}{r_{\mathrm{b}}^{(j-1)}} - (j-1)d_{\mathrm{b}}\right]F_j(T)\right\}}{T + \sum_{j=1}^{\infty}\left[\frac{\mu_{Y_1}}{r_{\mathrm{b}}^{(j-1)}} - (j-1)d_{\mathrm{b}}\right]F_j(T) + u_{RT}} + \frac{(c_{RT} + 1)u_{RT}}{T + \sum_{j=1}^{\infty}\left[\frac{\mu_{Y_1}}{r_{\mathrm{b}}^{(j-1)}} - (j-1)d_{\mathrm{b}}\right]F_j(T) + u_{RT}} \tag{49.67}$$

and

$$l_1(N) = \left\{(c_{\mathrm{f}} + 1)\sum_{j=1}^{N-1}\left[\frac{\mu_{Y_1}}{r_{\mathrm{b}}^{(j-1)}} - (j-1)d_{\mathrm{b}}\right] + (c_{RN} + 1)u_{RN}\right\} \Bigg/ \left\{\sum_{j=1}^{N}\left[\frac{\mu_{X_1}}{r_{\mathrm{a}}^{(j-1)}} - (j-1)d_{\mathrm{a}}\right] + \sum_{j=1}^{N-1}\left[\frac{\mu_{Y_1}}{r_{\mathrm{b}}^{(j-1)}} - (j-1)d_{\mathrm{b}}\right] + u_{RN}\right\}, \tag{49.68}$$

$$l_{\mathrm{op1}}(T) = \frac{c_{\mathrm{f}}\left\{\sum_{j=1}^{\infty}\left[\frac{\mu_{Y_1}}{r_{\mathrm{b}}^{(j-1)}} - (j-1)d_{\mathrm{b}}\right]F_j(T)\right\}}{T} + \frac{c_{RT}u_{RT}}{T} \tag{49.69}$$

and

$$l_{\mathrm{op1}}(N) = \frac{c_{\mathrm{f}}\sum_{j=1}^{N-1}\left[\frac{\mu_{Y_1}}{r_{\mathrm{b}}^{(j-1)}} - (j-1)d_{\mathrm{b}}\right] + c_{RN}u_{RN}}{\sum_{j=1}^{N}\left[\frac{\mu_{X_1}}{r_{\mathrm{a}}^{(j-1)}} - (j-1)d_{\mathrm{a}}\right]}, \tag{49.70}$$

respectively.

Finally, the optimal replacement policy, denoted in general by T^* or N^*, can be determined by minimizing $l(T)$, $l_{\mathrm{op}}(T)$, $l(N)$ or $l_{\mathrm{op}}(N)$ [or alternatively $l_1(T)$, $l_{\mathrm{op1}}(T)$, $l_1(N)$ or $l_{\mathrm{op1}}(N)$], respectively. Furthermore, the minimization procedure can be achieved using analytical or numerical methods.

In practice, we prefer to adopt the optimal policy N^* rather than use the optimal policy T^*, because of the much simpler form of $l(N)$, $l_{\mathrm{op}}(N)$, $l_1(N)$, and $l_{\mathrm{op1}}(N)$. Moreover, under some mild conditions, *Lam* [49.38] has proved that the optimal policy N^* is better than any policy T; in particular, it is better than the optimal policy T^*.

Note that the replacement policy that minimizes l or l_{op} also maximizes p or p_{op} because the long-run expected profit p or p_{op} per unit total time or per unit operation time is equal to the negation of the long-run expected loss l or l_{op} per unit total time or per unit operation time, respectively. The expressions for l and l_{g} include the performance measure of cost or downtime as a special case.

The expressions for c and c_{op}, the long-run expected cost per unit total time and per unit operation time, are

obtained by substituting $w = 0$ or $w = c_o = 0$ into the expressions for l and l_{op}, respectively.

The expressions for u and u_{op}, the long-run expected downtime per unit total time and per unit operation time, are obtained by substituting $w = c_o = 0$, $c_f = c_{RT} = c_{RN} = 1$ into the expressions for l and l_{op} respectively. Also, availability $= (1-u)\times 100\%$ or availability $= (1-u_{op})\times 100\%$.

49.9 Some Conclusions on the Applicability of an AP and/or a GP

As concluded in the last paragraph before Sect. 49.1 AP and/or a GP approach is considered to be relevant, realistic and direct to the modeling of deteriorating system maintenance problems. If a decreasing GP (or an increasing AP) does not fit the system's successive operating times (or repair times), a decreasing AP (or an increasing GP) may be attempted instead. Equation (49.64) with $d_b = 0$, $r_a = 1$ then becomes

$$l_{A,G}(N) = \left\{(c_o - w)\left\{\frac{N}{2}\left[2\mu_{X_1} - (N-1)d_a\right]\right\} + c_f\mu_{Y_1}\sum_{j=1}^{N-1}\frac{1}{r_b^{(j-1)}} + c_{RN}u_{RN}\right\} \Bigg/ \left\{\frac{N}{2}\left[2\mu_{X_1} - (N-1)d_a\right] + \mu_{Y_1}\sum_{j=1}^{N-1}\frac{1}{r_b^{(j-1)}} + u_{RN}\right\} \tag{49.71}$$

which is one of the four replacement models using an AP or a GP or both. This means that there are altogether four options to resolve a replacement problem when using model (49.64).

The reliability findings for the 6LXB type of engine analyzed using GPs (*Leung* and *Lee* [49.1]) and APs (*Leung* and *Kwok* [49.6]) are summarized in Table 49.4.

The reliability findings for the Benz type of gearbox analyzed using GPs (*Leung* and *Fong* [49.2]) and APs (*Leung* and *Lai* [49.10]) are summarized in Table 49.5.

In Table 49.5, the parameter $\hat{d}_b$ or $\hat{r}_b$ is larger than zero or unity for the Benz gearbox. $\hat{d}_b > 0$ or $\hat{r}_b > 1$ indicates that the repair times of the gearboxes decrease and will tend towards zero. The reasons for this phenomenon are:

1. The Kowloon Motor Bus (KMB) Company Limited spends a lot of time on the following when a gearbox first fails (see *Leemis* [49.39], p. 148)
   a) Diagnosis time: time used for fault finding, including adjustment of test equipment, carrying out checks, interpretation of information gained, verification of the conclusions drawn and deciding corrective action.
   b) Logistic time: time used in waiting for spare parts, test gears, additional tools and manpower to be transported to the system.
   c) Administrative time: time used in the allocation of repair tasks, manpower changeover due to

Table 49.4 Estimated values of common difference and ratio, and means for the 6LXB engine

Survival times	$\hat{\mu}_{X_1}$(y)	$\hat{\mu}_{X_2}$(y)	$\hat{\mu}_{X_3}$(y)	$\hat{\mu}_{X_4}$(y)

Survival times	$\hat{\mu}_{X_1}$(y)	$\hat{\mu}_{X_2}$(y)	$\hat{\mu}_{X_3}$(y)	$\hat{\mu}_{X_4}$(y)
AP with $\hat{d}_a = 0.97$ y	3.05	2.08	1.11	0.14
GP with $\hat{r}_a = 2.004$	1.969	0.9825	0.4903	0.2447
Repair times	$\hat{\mu}_{Y_1}$(d)	$\hat{\mu}_{Y_2}$(d)	$\hat{\mu}_{Y_3}$(d)	$\hat{\mu}_{Y_4}$(d)
AP with $\hat{d}_b = 34.07$ d	85.46	51.39	17.32	–
GP with $\hat{r}_b = 2.096$	37.25	17.77	8.479	4.045

demarcation arrangements, official breaks, disputes, etc.
2. KMB gains repair experience from the first failure, which is used to improve their time management, so repair time decreases.
3. When a gearbox is taken out of a bus, there is no follow-up tracing of the gearbox and hence we are unable to find exact consecutive repair times.

The optimal replacement policy based on minimum cost is to replace the engine or gearbox after the second or third failure using the AP or GP approach. Notice that theoretically it is replaced after the ninth failure of the engine or gearbox using the GP approach; this is possible since a decreasing GP converges to zero (but a decreasing AP produces negative values, which are nonexistent in a reliability context).

Based on the four real case studies, we observe that both approaches are applicable in solving reliability problems. As to which one is more appropriate to a given set of reliability data, some criteria have to be established. Once we have criteria comparing the results using the AP and GP approaches, we can separately compare the findings obtained in *Leung* and *Lee* [49.1] with those in *Leung* and *Kwok* [49.6], and *Leung* and *Fong* [49.2] with *Leung* and *Lai* [49.10].

49.10 Concluding Remarks

There follow five notes concerning the application of the models given in the previous sections.

The first note concerns the third question: after fitting an AP (or a GP) model to the data set, how good is the fit?

Estimation of parameters is properly only a precursor to further analysis. The techniques outlined in Sects. 49.2– 49.5 may be extended to provide a basis for confidence bounds, tests for comparing different sets of event counts, and so on. *Lam* et al. [49.16] obtained the asymptotic distributions of the nonparametric estimators of r, μ_{G_1} and $\sigma^2_{G_1}$. By a parametric approach, *Lam* and *Chan* [49.36] also obtained the estimators of r, μ_{G_1} and $\sigma^2_{G_1}$ and their asymptotic distributions.

Scarf [49.40], on p. 498, has recommended that, if the assumptions of a simple AP or GP model are not

Table 49.6 Summary of useful results of both AP and GP processes

APs equation given by	GPs equation given by
$\hat{d}$ (49.27) or (49.27.1)	$\ln \hat{r}$ (49.27) or (49.27.1) with $A_{n,k}$ replaced by $\ln G_{n,k}$
$\hat{\alpha}_{\mathrm{A}}$ (49.28) or (49.28.1)	$\hat{\alpha}_{\mathrm{G}}$ (49.28) or (49.28.1) with $A_{n,k}$ replaced by $\ln G_{n,k}$
$\hat{\sigma}_{\mathrm{A},\varepsilon}$ (49.29) or (49.29.1)	$\hat{\sigma}_{\mathrm{G},\varepsilon}$ (49.29) or (49.29.1) with $A_{n,k}$ replaced by $\ln G_{n,k}$
t_{A} (49.31)	t_{G} (49.31) with $A_{n,k}$ replaced by $\ln G_{n,k}$
For $d \neq 0$	**For $r \neq 1$**
$\hat{\mu}_{\bar{A}_1,1}$ (49.32) or (49.32.1)	$\hat{\mu}_{\bar{G}_1,1}$ (49.46) or (49.46.1)
–	$\hat{\mu}_{\bar{G}_1,2}$ (49.48) or (49.48.1)
–	$\hat{\mu}_{\bar{G}_1,3}$ (49.50) or (49.50.1)
$\hat{\mu}_{\bar{A}_1,2}$ (49.42) or (49.42.1)	$\hat{\mu}_{\bar{G}_1,4}$ (49.56) or (49.56.1)
$\hat{\mu}_{\bar{A}_1,3}$ (49.43) or (49.43.1)	$\hat{\mu}_{\bar{G}_1,5}$ (49.57) or (49.57.1)
$\hat{\sigma}^2_{\bar{A}_1,1}$ (49.33) or (49.33.1)	$\hat{\sigma}^2_{\bar{G}_1,1}$ (49.47) or (49.47.1)
$\hat{\sigma}^2_{\bar{A}_1,2}$ (49.35) or (49.35.1)	$\hat{\sigma}^2_{\bar{G}_1,2}$ (49.48) or (49.48.1)
For $d = 0$	**For $r = 1$**
$\hat{\mu}_{A_1,4}, \hat{\sigma}^2_{A_1,3}$ (49.44)	$\hat{\mu}_{G_1,6}, \hat{\sigma}^2_{G_1,3}$ (49.58)
$\hat{\mu}_{\bar{A}_n}, \hat{\sigma}^2_{\bar{A}_n}$ (49.45) or (49.45.1)	$\hat{\mu}_{\bar{G}_n}, \hat{\sigma}^2_{\bar{G}_n}$ (49.59) or (49.59.1)
Replacement model	**Replacement model**
$l_{\mathrm{A}}(T)$ (49.72)	$l_{\mathrm{G}}(T)$ (49.74)
$l_{\mathrm{A}}(N)$ (49.73)	$l_{\mathrm{G}}(N)$ (49.75)

valid, and in practice this is usually so, then there are two possible routes:

1. extend the model with extra parameters, here d and r, making greater demands on the available data;
2. use the simple model to obtain a crude approximation to the optimum policy.

The second note relates to route 1. The author is focusing his efforts on developing a procedure of statistical inference for an AGP, since fitting a model to failure and/or repair data is preliminary to the utilization of an optimization model, from which an optimal maintenance policy based on minimizing loss, cost or downtime may be found. Naturally, the development of such a procedure involves much more mathematics than that for a GP by *Lam* [49.15] or for an AP by *Leung* [49.8]. Once the procedure is warranted, two parallel case studies using an AGP approach for the same set of real maintenance data of engines and gearboxes will be carried out and then findings will be compared with those obtained in *Leung* et al. [49.1, 4, 5, 10]; these case studies will be presented in two future papers.

The third note relates to route 2. Estimation of parameters is also a precursor to practical use of an optimization model. Two AP models used in resolving replacement problems are obtained by putting $r_b = 1$ in (49.63) and $r_a = r_b = 1$ in (49.64), namely the long-run expected loss per unit total time under policy T, which is given by

$$l_A(T) = \frac{(c_o - w)T + c_{RT}u_{RT}}{T + \sum_{j=1}^{\infty}[\mu_{Y_1} - (j-1)d_b]F_j(T) + u_{RT}} + \frac{c_f\left\{\sum_{j=1}^{\infty}[\mu_{Y_1} - (j-1)d_b]F_j(T)\right\}}{T + \sum_{j=1}^{\infty}[\mu_{Y_1} - (j-1)d_b]F_j(T) + u_{RT}} \tag{49.72}$$

and the long-run expected loss per unit total time $l_A(N)$ under policy N, which is given by

$$l_A(N) = \left\{(c_o - w)\left\{\frac{N}{2}\left[2\mu_{X_1} - (N-1)d_a\right]\right\} + c_f\left\{\frac{N-1}{2}\left[2\mu_{Y_1} - (N-2)d_b\right]\right\} + c_{RN}u_{RN}\right\} \Big/ \left\{\frac{N}{2}\left[2\mu_{X_1} - (N-1)d_a\right] + \frac{N-1}{2}\left[2\mu_{Y_1} - (N-2)d_b\right] + u_{RN}\right\}. \tag{49.73}$$

Correspondingly, two GP models obtained by *Lam* [49.14] by putting $d_b = 0$ in (49.63) and $d_a = d_b = 0$ in (49.64) are given by

$$l_G(T) = \frac{(c_o - w)T + c_f\mu_{Y_1}\sum_{j=1}^{\infty}\frac{F_j(T)}{r_b^{(j-1)}} + c_{RT}u_{RT}}{T + \mu_{Y_1}\sum_{j=1}^{\infty}\frac{F_j(T)}{r_b^{(j-1)}} + u_{RT}} \tag{49.74}$$

and

$$l_G(N) = \frac{(c_o - w)\mu_{X_1}\sum_{j=1}^{N}\frac{1}{r_a^{(j-1)}}}{\mu_{X_1}\sum_{j=1}^{N}\frac{1}{r_a^{(j-1)}} + \mu_{Y_1}\sum_{j=1}^{N-1}\frac{1}{r_b^{(j-1)}} + u_{RN}} + \frac{c_f\mu_{Y_1}\sum_{j=1}^{N-1}\frac{1}{r_b^{(j-1)}} + c_{RN}u_{RN}}{\mu_{X_1}\sum_{j=1}^{N}\frac{1}{r_a^{(j-1)}} + \mu_{Y_1}\sum_{j=1}^{N-1}\frac{1}{r_b^{(j-1)}} + u_{RN}}, \tag{49.75}$$

where F_j is the cumulative distribution function of $\sum_{i=1}^{j} X_i$; μ_{X_1} is the mean operating time after installation; μ_{Y_1} is the mean repair time after the first failure; d_a (or r_a) and d_b (or r_b) are the common differences (or ratios) corresponding to the failure and repair processes of a system, respectively; c_o is the average operating cost rate; c_f is the average repair cost rate; c_{RT} (or c_{RN}) is the average replacement cost rate under policy T (or N); u_{RT} (or u_{RN}) is the average replacement downtime under policy T (or N); and w is the average revenue rate of a working system.

Notice that model (49.72) (or (49.74)) only depends on the AP (or GP) through the parameters d_b (or r_b) and μ_{Y_1}, and model (49.73) (or (49.75)) only on d_b (or r_b) and μ_{Y_1} plus d_a (or r_a) and μ_{X_1}. When $K > 1$, μ_{X_1} and μ_{Y_1} are replaced by $\mu_{\bar{X}_1}$ and $\mu_{\bar{Y}_1}$. In practice, model (49.73) or (49.75) is adopted because of its much simpler form. Moreover, under some mild conditions, *Lam* [49.38] has proved that the optimal policy N^* is better than the optimal policy T^*. Note that, under the same conditions, *Zhang* [49.41] has showed that

the optimal bivariate replacement policy $(T, N)^*$ is better than N^*, which in turn is better than T^* (see also *Leung* [49.12]).

The fourth note is that an AP, GP or AGP approach has not incorporated the dependency of data on maintenance actions. If a GP model is appropriate, then the dependency of data upon maintenance actions should be modeled, i. e. the common ratios r_a and r_b of two distinct GPs are two functions of some preventive maintenance (PM) policy, where the subscripts 'a' and 'b' correspond to the failure and repair processes of a system respectively. *Leung* [49.9] established one type of the relationships between the common ratios r_a and r_b and a nonperiodic PM policy.

The fifth note is that a GP model has been widely used in maintenance problems of one-component systems, and two-component series, parallel and standby systems; see *Lam* [49.42], *Lam* and *Zhang* [49.43, 44], and *Zhang* [49.45] for details. *Lam* et al. [49.46] proved that the monotone process model for the multi-state system is equivalent to a GP model for a two-state one-component system by showing that two systems will have the same long-run expected loss per unit total time and the same optimal policy N^*. Furthermore, *Lam* [49.15], *Lam* and *Chan* [49.36], and *Lam* et al. [49.16] also applied the GP to the analysis of data from a series of events. *Lam* [49.47] gave a brief review and more references for the GP. For more properties and applications of GP, see *Lam* et al. [49.16, 48, 49] and *Zhang* et al. [49.50–53]. Finally, the author considers that almost all variants of GP formulation are also valid for AP or AGP.

49.A Appendix

To determine the line of best fit to the N paired-observations, we minimize the sum of squared errors $(S_{\varepsilon\varepsilon})$ given by

$$\begin{aligned} S_{\varepsilon\varepsilon} &= \sum_{k=1}^{K}\sum_{n=1}^{N_k}(y_{n,k}-\hat{y})^2 \\ &= \sum_{k=1}^{K}\sum_{n=1}^{N_k}(y_{n,k}-\hat{\beta}_0-\hat{\beta}_1 x_{n,k})^2 \,. \end{aligned} \tag{49.A1}$$

Denote

$$N = \sum_{k=1}^{K} N_k \,, \tag{49.30}$$

$$\bar{x} = \frac{\sum_{k=1}^{K}\sum_{n=1}^{N_k} x_{n,k}}{N} \quad \text{and} \quad \bar{y} = \frac{\sum_{k=1}^{K}\sum_{n=1}^{N_k} y_{n,k}}{N} \,, \tag{49.A2}$$

$$\begin{aligned} S_{xx} &= \sum_{k=1}^{K}\sum_{n=1}^{N_k} x_{n,k}^2 - N\bar{x}^2 \,, \\ S_{yy} &= \sum_{k=1}^{K}\sum_{n=1}^{N_k} y_{n,k}^2 - N\bar{y}^2 \quad \text{and} \\ S_{xy} &= \sum_{k=1}^{K}\sum_{n=1}^{N_k} x_{n,k}y_{n,k} - N\bar{x}\bar{y} \,. \end{aligned} \tag{49.A3}$$

Differentiating (49.A1) with respect to $\hat{\beta}_0$ and $\hat{\beta}_1$, setting them equal to zero and solving the associated equations simultaneously, we obtain

$$\hat{\beta}_0 = \frac{\sum_{k=1}^{K}\sum_{n=1}^{N_k} y_{n,k} - \hat{\beta}_1 \sum_{k=1}^{K}\sum_{n=1}^{N_k} x_{n,k}}{N} = \bar{y} - \hat{\beta}_1\bar{x} \tag{49.A4}$$

and

$$\hat{\beta}_1 = \frac{\sum_{k=1}^{K}\sum_{n=1}^{N_k} x_{n,k}y_{n,k} - \bar{y}\sum_{k=1}^{K}\sum_{n=1}^{N_k} x_{n,k}}{\sum_{k=1}^{K}\sum_{n=1}^{N_k} x_{n,k}^2 - \bar{x}\sum_{k=1}^{K}\sum_{n=1}^{N_k} x_{n,k}} = \frac{S_{xy}}{S_{xx}} \,. \tag{49.A5}$$

Substituting (49.A4) and (49.A5) into (49.A1), and after some manipulation, we obtain

$$S_{\varepsilon\varepsilon} = S_{yy} - \hat{\beta}_1 S_{xy} \,. \tag{49.A6}$$

It can be shown that

$$\hat{\sigma}_\varepsilon^2 = \frac{S_{\varepsilon\varepsilon}}{N-2} \,, \tag{49.A7}$$

usually called the mean squared error (MSE), provides a good estimator for σ_ε^2, and that

$$t = \frac{\hat{\beta}_1 - \beta_{1,0}}{\hat{\sigma}_\varepsilon/\sqrt{S_{xx}}} \,, \tag{49.A8}$$

a Student's t distribution with $(N-2)$ degrees of freedom. This statistic is used to test a hypothesis that β_1 equals some particular numerical value, say $\beta_{1,0}$.

Now, putting $y = A_{n,k}$ or $\ln G_{n,k}$, $x_{n,k} = n-1$, $\beta_0 = \alpha_A$ or α_G, $\beta_1 = -d$ or $-\ln r$, $\beta_{1,0} = 0$, $\hat{\sigma}_{\varepsilon}^2 = \hat{\sigma}_{A,\varepsilon}^2$ or $\hat{\sigma}_{G,\varepsilon}^2$, $t = t_A$ or t_G, and using (49.A2) through (49.A8), we obtain (49.27) to (49.29) and (49.31) accordingly. The final forms require the following

$$\bar{x} = \frac{\sum_{k=1}^{K}\sum_{n=1}^{N_k}(n-1)}{N} = \frac{\sum_{k=1}^{K}N_k(N_k-1)}{2N} = \frac{\sum_{k=1}^{K}N_k^2 - N}{2N}$$

and

$$S_{xx} = \sum_{k=1}^{K}\sum_{n=1}^{N_k}(n-1)^2 - N\bar{x}^2 = \sum_{k=1}^{K}\frac{(N_k-1)N_k(2N_k-1)}{6} - N\bar{x}^2 .$$

Note that there are three and two estimators for $\mu_{\bar{A}_1}$ and $\sigma_{\bar{A}_1}^2$, respectively, when $d \neq 0$, but five and two estimators for $\mu_{\bar{G}_1}$ and $\sigma_{\bar{G}_1}^2$, respectively, when $r \neq 1$.

50. Six Sigma

The first part of this chapter describes what Six Sigma is, why we need Six Sigma, and how to implement Six Sigma in practice. A typical business structure for Six Sigma implementation is introduced, and potential failure modes of Six Sigma are also discussed. The second part describes the core methodology of Six Sigma, which consists of five phases, i. e., define, measure, analyze, improve, and control (DMAIC). Specific operational steps in each phase are described in sequence. Key tools to support the DMAIC process including both statistical tools and management tools are also presented. The third part highlights a specific Six Sigma technique for product development and service design, design for Six Sigma (DFSS), which is different from DMAIC. DFSS also has five phases: define, measure, analyze, design and verify (DMADV), spread over product development. Each phase is described and the corresponding key tools to support each phase are presented.

In the forth part, a real case study on printed circuit board (PCB) improvement is used to demonstrate the application of Six Sigma. The company and process background is provided. The DMAIC approach is specifically followed and key supporting tools are illustrated accordingly. At the end, the financial benefit of this case is realized through the reduction of cost of poor quality (COPQ).

Finally, last part is given over to a discussion of future prospects and conclusions.

Since the early 1990s, Six Sigma swept the business world, driving an unprecedented emphasis on greater manufacturing and service quality. Six Sigma is one of the few quality initiatives that actually originated from industrial practice. Six Sigma was originally devised as a measure of quality that strives for near perfection. It has developed into a disciplined, data-driven, customer-focused approach to reduce defects and bring about substantial financial growth. Although most Six Sigma efforts were focused on manufacturing operations in the early years, the Six Sigma approach has now been more widely used in non-manufacturing industrial sectors such as finance, insurance, health care, and telecommunications. Users include American Express, American International Group (AIG), Bank of America, Citibank, J.P. Morgan, Chase, Merrill Lynch, Vanguard, etc. These companies have actually seen larger business impacts and cost savings than those in manufacturing.

50.0.1 What is Six Sigma?

Motorola first introduced the Six Sigma program in the late 1980s with the aim of increasing profitability by reducing defects. General Electric (GE) followed the approach at their manufacturing sites and later at their financial service divisions. After that, Six Sigma was thought to be applicable to all processes and transactions within GE. Six Sigma has now evolved from a quality

Table 50.1 Final yield for different sigma levels in multistage processes

Average sigma level	1	2	3	4	5	6
Final yield for 10 stages	0.0%	2.5%	50.1%	94.0%	99.8%	100.0%
Final yield for 100 stages	0.0%	0.0%	0.1%	53.6%	97.7%	100.0%
Final yield for 1000 stages	0.0%	0.0%	0.0%	0.2%	79.2%	99.7%

improvement program to an overall business strategy executive system and business-results-oriented program, which seems more *total* than total quality management (TQM). We will describe the basic definition of Six Sigma in this section and will elaborate its systematic methodology and business structure in later sections.

Six Sigma is both a business improvement strategy and a methodology to measure process performance. It is used to increase profits by eliminating defects, waste, and variability and to find the causes of mistakes in products, processes and services to increase yields. In Six Sigma, focus on the customer is the top priority. Performance standards are based on actual customer input, so that process effectiveness can be measured and customer satisfaction can be predicted.

In terms of business process improvement, variation reduction is the key since variation signals fluctuation in the process output and is often a major source of poor quality. Variation is present in all processes and every aspect of work. Unintended variation reduces process performance and decreases customer satisfaction. Because of the existence of variation, producing high-quality products and services in the modern industrial environment is a tough task.

Therefore, Six Sigma aims particularly at reducing variation. The word *sigma* or the symbol "σ" is used in statistical notation to represent the standard deviation in a population. The standard deviation is also used as a general measure of variation in any kind of product or process. With six standard deviations between the process mean and the customer's specification limit, we arrive at 3.4 defects per million opportunities (DPMO); that is, a 99.9997 percent yield. Before the Six Sigma technique was introduced, a three-sigma level of variation was regarded as being fairly good quality performance. Three sigma may be acceptable for a product or process having only a single or a few stages. It is not good enough for many products that are the result of hundreds of thousands of stages, such as automobiles and computers.

For example, if a production process is made up of ten stages where the yield of each stage is as high as 90%, the probability of producing a satisfactory product in the first run would be $0.9^{10} = 35\%$. This indicates that about 65% of the products are defective. If a production process is made up of 100 stages, the probability of producing a satisfactory product under the three-sigma program could be as low as 0.1%, as shown in Table 50.1. The Six Sigma regime, however, allows only 3.4 defects for every million opportunities, which ensures a quality product even if the process involves a large number of stages (Table 50.1). Part of the reason for using such a strict requirement in quality management is actually to accommodate the common multistage processes in modern industrial practice.

50.0.2 Why Six Sigma?

The successful implementation of Six Sigma can result in benefits in the areas of cost reduction, increased profit, increased market share and enhanced business competitiveness, mainly by the reduction of the cost of poor quality (COPQ).

COPQ usually includes appraisal costs, internal failure costs, and external failure costs. Appraisal and inspection costs are often incurred, for example, in checking finished goods before they leave the factory, inspecting purchased equipment/supplies, proofreading financial and legal documents, reviewing charges prior to billing, etc. Internal failure costs are those for repairing, replacing, or discarding work in progress or completed work before the delivery of the product to the customer. External failure costs are those that directly affect the customer and are the most expensive to correct, including tangible remedial costs and the intangible costs associated with losing dissatisfied customers.

COPQ cannot be underestimated. In manufacturing industries, COPQ sometimes reaches 15% of total sales (source: Six Sigma Academy). In service industries, the situation is even more serious. COPQ may account for as much as 50% of total costs.

However, these COPQ could be saved with the use of Six Sigma. General Electric has estimated savings of 2 billion US dollars during the first five years of Six Sigma implementation, and Allied Signal has estimated savings of 1.1 billion US dollars in two years. Indeed, thousands of companies around the world have enjoyed the breakthrough benefits of Six Sigma.

For example, Legend Computers in China reported in 2002 savings of $20 million dollars during the first year of implementation. In the same year, the International Bank of Asia in Hong Kong reported savings of 1.4% of total costs during the first year of Six Sigma implementation.

50.0.3 Six Sigma Implementation

Six Sigma implementation is usually a top-down approach, i. e., from the strong commitment of top management. As most Six Sigma projects span several departments, organizational barriers could not be removed without leadership commitment to Six Sigma. Strong commitment, leadership and strategic involvement have proven to be key factors for Six Sigma's success. Secondly, as Six Sigma requires a long-term mentality, it needs to be positioned first as a strategic initiative and then be linked to operational goal. It is important to tie the Six Sigma implementation to corporate goals, such as increased profits through lower costs and higher loyalty, for example. Also, effective internal communication is another key issue for the success of Six Sigma implementation.

In the following, a typical business structure for Six Sigma implementation is introduced. Several potential failure modes and practical considerations of Six Sigma implementation are also discussed.

Training and Belt Structure

The deployment of Six Sigma in a company usually starts with education. Without the necessary training, people are not able to bring about Six Sigma breakthrough improvements. Six Sigma establishes well-defined and structural roles and responsibilities for a project team, and team members are given formal training according to their roles to help the team work effectively. A Six Sigma team is usually organized in a belt structure (as in martial arts) as follows.

At the top of the belt structure is the Six Sigma executive. The Six Sigma executive could be a council that consists of top managers who have the vision and make strategic decisions for a company. They are responsible for establishing the roles and structures of Six Sigma projects. They also need to make decisions on project selection and resources allocations. A progress review is conducted periodically to monitor projects.

Champions are the senior managers who supervise Six Sigma projects. They report directly to the Six Sigma executive and represent the team to the executive. They also need to seek resources and to learn the focus of the business from the Executive. In addition, champions meet black belts and green belts periodically to review the progress and coach the team.

Master black belts work with the champions to ensure that Six Sigma objectives and targets are set. Meanwhile, they are the statistical problem-solving experts in a company. Their responsibilities include determining plans, providing technical expertise, training and coaching black and green belts.

Black belts, as on-site Six Sigma experts, usually possess the technical background needed to help green belts and the other team members to understand the project and apply appropriate statistical techniques. Their roles are to provide formal training to local personnel in new strategies and tools, provide one-on-one support to local personnel, pass on new strategies and tools in the form of training, workshops, case studies, local symposia, etc., and find application opportunities for breakthrough strategies and tools, both internal and external (i. e., to the suppliers and customers).

Green belts, on the other hand, execute Six Sigma in their specific area as a part of their overall job. They may assist black belts in completing sections of their projects and apply their learning to their daily performance of their jobs.

According to the Six Sigma Academy, black belts are able to save companies approximately US$230 000 per project and can complete four to six projects per year. The American Society for Quality (ASQ) has been certifying Six Sigma black belts (SSBB) internationally in recent years. Up to the middle of 2002 there were around 200 ASQ-certified black belts in the US and only 11 ASQ-certified black belts outside the US. Among them, there was only one in the greater China area (Table 50.2).

Six Sigma Failures (Sick Sigma)

Although Six Sigma is a powerful approach, it can lead to failure when some critical issues are neglected. How-

Table 50.2 Number of Six Sigma black belts certified by the American Society for Quality (ASQ) internationally (ASQ record up to April, 2002)

Indonesia	1	United Kingdom	1
India	5	Hong Kong	1
Japan	1	Mainland China	0
Australia	1	Taiwan	0
Brazil	1	Singapore	0

ever, as more companies have implemented Six Sigma since the 1990s, the factors that have led to failure have been identified and summarized. According to *Snee* and *Hoerl* [50.1], project selection and management support are usually the two main sources of failure.

The failure modes in project selection usually include projects not tied to financial results, poorly defined project scopes, metrics, and goals, projects lasting more than six months, the wrong people assigned to projects, project teams that are too large, and infrequent team meetings. On the other hand, the failure modes in management support may include black belts with little time to work on projects, poor or infrequent management reviews, poor support from finance, information technology (IT), human resource (HR), etc., and poor communication of initiatives and progress [50.1].

Especially, for a Six Sigma program to sustain without failure, recognition and reward systems are the key. If recognition and reward systems are lacking or remain unchanged, the program cannot last. Necessary practices include establishing and using selection and promotion criteria and developing corresponding performance management and reward systems. GE's approach, which links 40% of management bonus to Six Sigma, may be too aggressive, but a company must adequately compensate those high-performing members.

Note that the use of statistical methods is not on the list of major failure modes. With recent advances in information technology, computing and sensing technology, the use of advanced statistical methods has become handy via commercial software packages (such as MINITAB, JMP, etc.). Therefore, the use of statistical tools is no longer a bottleneck in Six Sigma implementation.

Moreover, various industry types and company natures are also not an excuse for Six Sigma failure. Six Sigma has been successfully applied to many processes outside of manufacturing, regardless of the company size or nature of the industry. In particular, transactional processes, such as software coding, billing, customer support, etc., often contain variation or excessive cycle time and can be optimized by applying Six Sigma. For example, HR managers may apply it to reduce the cycle time for hiring employees, and regional sales may apply it to improve forecast reliability, pricing strategies or variations.

50.1 The DMAIC Methodology

50.1.1 Introduction

The development of Six Sigma is evolutionary, not revolutionary, and it integrates many useful quality management tools. Thus, it is not surprising to find overlaps between the Six Sigma, TQM, lean, and ISO approaches. The core methodology of Six Sigma is driven by close understanding of customers' needs and the disciplined use of facts, data and statistical analysis, which consists of five phases, i. e., define, measure, analyze, improve, and control (DMAIC).

In the define phase, the specific problem is identified, and the project goals and deliverables are defined. In the measure phase, the critical-to-quality (CTQ) characteristics are identified and the measurement system is reviewed. The nature and properties of the data collection have to be understood thoroughly to ensure the quality of the data. In the analyze phase, both quantitative (i. e., statistical) methods and qualitative (i. e., management) tools are used to isolate the key information that is important to explaining defects. In the improve phase, the key factors that cause the problem should be discovered. In the control phase, the key factors and processes are controlled and monitored continuously to ensure that the improvement is sustainable and the problem will not occur again. A detailed case study on the implementation of the DMAIC methodology in printed circuit board manufacturing can be found in *Tong* et al. [50.2]. The paper "Six Sigma approach to reducing fall hazards among cargo handlers working on top of cargo containers: a case study" by *Ng* et al. [50.3, 4] is another case study using DMAIC that focuses on a non-manufacturing case.

50.1.2 The DMAIC Process

More specifically, we implement the DMAIC methodology in detailed steps in sequence to shift our focus from the output performance (i. e., y) to the root causes (i. e., the x). Based on these steps, we transfer a practical problem into a statistical problem (e.g., mapping x and y), find out a statistical solution for that [e.g., solving $y = f(x)$] and then transform the statistical solution into a practical solution. Each step is described in the following, and the corresponding key tools will be further explained in a later section.

Phase 1: Define (D)

This phase defines the Six Sigma project, which includes a problem statement, the objectives of the project, the expected benefits, the team structure and the project time line. At the end of this phase, we should have a clear operational definition of the project metrics for the final evaluation. In this phase, the main tasks are to identify who the customer is, select the project area, define the goal, scope and resources of the project, form a Six Sigma project team, define the team members' responsibilities, and estimate the profit and cost for this project to ensure the value of the project. Key tools in this phase include the project charter; business process mapping; suppliers, inputs, process, outputs and customer (SIPOC); etc.

Phase 2: Measure (M)

By taking steps in the measure phase, we have a clear understanding of the performance of the current process and, only after knowing where we are now, can we determine where we should be in the future. Three implementation steps in this phase are to select the critical-to-quality (CTQ) measures, determine deliverables, and quantify the measurability of y.

Select the Critical to Quality (CTQ) Measures. In this step, we will identify the external CTQ from the customer's point of view (i. e., the big Y) that will be improved, and then link that with the internal CTQ (i. e., the small y), which is a quantitative measure in the company and will be the focus of the project. Key tools in this step include customer needs mapping (CNM), quality function deployment (QFD), failure modes and effects analysis (FMEA), etc.

Deliverables. We will establish a performance standard and develop a data collection plan for the internal CTQ y in this step. If the measure of y from the previous step is attributal, what is the definition of a defect? If the data are continuous, what are the lower and upper specifications for defectiveness? Key tools used in this step include process mapping and yield calculation.

Quantify Measurability. We validate the measurement system on y to ensure the measurement results are accurate for the following analysis. We may need to improve the measurement system before continuing. Key tools include measurement system analysis (MSA), gage repeatability and reproducibility (R&R) study.

Phase 3: Analyze (A)

After we identify the y in the process, we need to determine the x (root causes), which may impact on the performance of the y. In the analyze phase, we use various management and statistical tools to discover the x for future improvements. Three implementation steps in this phase are to establish the baseline, determine the improvement plan, and identify the sources of variation.

Establish the Baseline. We will establish the process capability for the current process to understand where we are now. We need to collect the current process data, use graphical tools to analyze the data, and calculate the process capability indices, the defect per million opportunities (DPMO), and the sigma level (Z). Key tools include: histograms, process capability indices (PCI), etc.

Determine Improvement Plan. We quantify the goals for the improvement to make the aim of the project clear, and we may determine if the goal is significantly different from today's performance (i. e., the baseline) through hypothesis testing. Key tools include benchmarking, hypothesis testing, t-test, analysis of variations (ANOVA), etc.

Identify Variation Sources. We list all the potential factors (x) that may influence the performance of y. Regression analysis may be conducted, where applicable, to identify potential x. Key tools include brainstorming, cause-and-effect diagram, regression analysis, etc.

Phase 4: Improve (I)

As the root causes for variation are obtained, it becomes possible for us to fix these root causes. In the improve phase, the way that we can achieve a better process needs to be found, where the design of experiments (DOE) is a key technique to help us quantify the relation between the ys and xs, and to improve the process by finding the optimal setting of xs for each y. In this phase, we follow three implementation steps: screen potential sources of variation, discover variable relationships, and formulate the implementation plan.

Screen Potential Sources of Variation. We determine the few vital xs from the many trivial xs in this step. DOE is a key tool for factor screening. Both full factorial and fractional factorial experiments can be used. If necessary, historical data can be used with care, and a similar model or simulation may be used as well.

Discover Variable Relationships. We develop the transfer function $[y = f(x)]$ linking the y to the vital xs. Based on this, we then determine and confirm the optimal settings for the vital few xs. DOE is a key tool for characterization and optimization as well. Various DOE techniques, such as the response surface method (RSM), robust design and the Taguchi method, can be applied in this step. Other than that, simulation or surveys can also be used to find the relationship.

Formulate Implementation Plan. In this step, if a new process or process steps have been put in place, show the new process map. For the new process, indicate the new in-process measurements and associated specifications. If there is not a new process, indicate any new measurements put in place. We list how the changes to the xs will be implemented and how much flexibility is available in the settings of each x. Key tools in this step include tolerance design, main effects plots, interaction plots.

Phase 5: Control (C)

After determining how to fix the process, we want the improvement for the process to be sustainable. The control phase is set up to ensure sustainable improvement and to deploy measurement tools to confirm that the process is in control. It is also critical to realize the financial benefits and develop a transfer plan in this phase. Three implementation steps include validating the implementation plan, controlling the inputs and monitoring the outputs, and finally sustaining the change.

Validate the Implementation Plan. To determine how well the xs can be controlled, we will validate the measurement system on the xs, and we may need to improve measurement system before continuing. We will also report new sigma levels and new DPMO levels at this step. Key tools include gage R&R, ANOVA, etc.

Control Inputs and Monitor Outputs. We determine how each vital xs can be controlled (e.g., attribute control chart, variable control chart, mistake-proofing, etc.) and set up a monitoring plan for the y and xs in this step. Key tools include statistical process control (SPC), attribute control charts, variable control charts, Poka–Yoke (mistake-proofing), etc.

Sustain the Change. The objective of this step is to ensure that changes last after the improvement strategy has been implemented. Process control plans need to be developed and implemented for each x. We will also verify the financial gains that can be achieved and if this project is translatable to any other regions, lines, sites, processes, etc. Key tools in the final step include out-of-control plans, mistake-proofing, audit strategy, etc.

50.1.3 Key Tools to Support the DMAIC Process

This section presents the key tools to support the DMAIC process. Only a few key tools can be covered in this section and each method is outlined briefly with the basic ideas and mechanisms. The books and papers cited in this section give more details.

Business Process Mapping (SIPOC Diagrams)

Purpose. SIPOC stands for suppliers, inputs, process, outputs and customer. SIPOC diagrams are graphical tools to identify all relevant elements of a business process and map the process flow before the project begins. They are usually used in the define phase.

Definitions.

Supplier: Whoever produces, provides, or furnishes the products or services for the input of the process, either an internal or an external supplier.

Inputs: Material, resources and data required to execute the process.

Process: A collection of activities that take one or more kinds of input and creates output that is of value to the customer.

Outputs: The tangible products or services that result from the process.

Customer: Whoever receives the outputs of the process, either an internal customer or an external customer.

How to do it.

Step 1. Clear statement of CTQ and the process.
Step 2. Clear statement of start/end point.
Step 3. Identify major customers, suppliers, outputs, and inputs.
Step 4. Identify the five to seven major process steps using brainstorming and storyboarding.
Step 5. Decide what step to map in detail.
Step 6. Complete detailed map.

Quality Function Deployment (QFD)

QFD is a systematic approach to prioritize and translate customer requirements (i. e., external CTQ) into appro-

priate company requirements (i. e., internal CTQ) at each stage from product development to operations to sales and marketing to distribution. This method is usually used in the measure phase. It is also useful in design for Six Sigma (DFSS) and will be introduced in more detail in the DFSS section.

Failure Modes and Effects Analysis (FMEA)

Purpose. FMEA is a tool to reduce the risk of failures. It is also a tool to identify and prioritize CTQ at the measure phase.

Definitions.

Severity: the assessment of how severe a failure mode is. The severity usually scales from 1–10. Scale 1 means a minor failure mode that may not be noticed, and 10 means a very serious failure that may affect safe operations.

Occurrence: The likelihood that a specific cause will result in the failure mode, which scales from 1–10 with 10 being the highest likelihood.

Detection: The assessment of the ability to identify the failure mode. A 1–10 scale is often used with 10 being the lowest detectability.

RPN: The risk priority number (RPN) is the output of a FMEA. RPN = Severity × Occurrence × Detection.

How to do it [50.4].

Step 1: Identify the products, services, or processes.
Step 2: Identify the potential failure that would arise in the target process.
Step 3: Identify the causes of the effects and their likelihood of occurrence.
Step 4: Identify the current controls for detecting each failure mode and the ability of the organization to detect each failure mode.
Step 5: Calculate the RPN by multiplying the values of severity, potential causes, and detection.
Step 6: Identify the action for reducing or eliminating the RPN for each failure mode.

Measurement System Analysis (MSA)

Purpose. A statistical evaluation of the measurement system must be undertaken to ensure effective analysis of any subsequent data generated for a given process/product characteristic. MSA is usually used in the measure and control phases to validate the measurement system for the y and xs.

Definitions.

Gage R&R: is a tool to study the variation in the measurement arising from the measurement device and the people taking the measurement.

Repeatability: The variability that reflects the basic, inherent precision of the gage itself.

Reproducibility: The variability due to different operators using the gage (or different time, different environments) [50.5].

How to do it.

Step 1: Collect the data. Generally two to three operators, 10 units to measure, and each unit is measured 2–3 times by each operator.
Step 2: Perform the calculations to obtain %R&R [50.5].
Step 3: Analyze the results. A rule of thumb is that:

- %R&R < 10%: measurement system is acceptable.
- %R&R between 10–30%: measurement system may be acceptable. We will make decisions based on the classification of the characteristics, hard applications, customer inputs, and the sigma level of the process.
- %R&R > 30%: measurement system is not acceptable. We should improve the measurement system by finding problems and removing root causes.

Process Capability Analysis

Purpose. Process capability analysis is a statistical technique to quantify process variability, analyze this variability relative to customer requirements or specifications, and assist in reducing the variability [50.5]. It is used in the analyze phase.

Definitions.

Cp: Process/product capability index, is the relationship of the process/product variation to the upper and lower specification limits. It is related to the potential process capability and not a measure of how centered the data are.

Cpk: It compares process variability with the specification's width and location. It takes into account that the sample mean may be shifted from the target. Since both the mean shift and the variability of the characteristics are considered, Cpk

is better related to the capability of the current process.

How to do it. The detailed calculation and analysis is given by *Montgomery* [50.5].

Cause–Effect Diagram (Fishbone Diagram)

Purpose. This is a graphical brainstorming tool to explore the potential causes (i. e., xs) that result in a significant effect on y. It is usually used in the analyze phase.

How to do it.

Step 1: Define clearly the effect or analyzed symptom (y) for which the possible causes (xs) must be identified.
Step 2: Place the effect or symptom (y) being explained on the right of a sheet of paper.
Step 3: Use brainstorming or a rational step-by-step approach to identify the possible causes.
Step 4: Each of the major areas of possible causes should be connected with the central spine by a line.
Step 5: Add possible causes (xs) for each main area.
Step 6: Check for completeness.

Design of Experiments (DOE)

Purpose. DOE is a major tool in the improve phase. It is used for screening the few, vital xs, characterizing the relationship between y and xs, and optimizing the setting of the vital xs.

Definitions.

Factor: An independent variable (i. e., xs) whose state can be varied.
Level of a factor: The state of the factor.
Full factorial experiments: Discover the factor effects and relationship between y and xs by running all the combinations of factor levels.
Fractional factorial experiments: An economical approach to discovering the factor effects and to screening the vital few xs by running only part of the combinations of factor levels.
Response surface methodology (RSM): A DOE technique that is useful for modeling and optimization in which a response of interest y is influenced by several factors xs and the objective is to optimize this response. This method will be discussed more in the DFSS section.

How to do it [50.6, 7].

Step 1: State the problem.
Step 2: Choose the response variable (y).
Step 3: Choose the factors (xs) and their levels and ranges.
Step 4: Determine the experimental plan (i. e., the design matrix).

1. To screen the xs to obtain the few, vital xs, we often use factorial experiments. In such cases, if the number of runs is moderate and we have enough time and resources, we may conduct a full factorial experiment; if the number of runs is large or time and resources are limited, we may consider a fractional factorial experiment.
2. To obtain the optimal response, we may conduct RSM, which is usually conducted after variable screening.

Step 5: Run the experiments under the prescribed conditions and collect the response data.
Step 6: Analyze the data collected using main effect plots, interaction plots, ANOVA, etc.
Step 7: Conclude the experiment and make recommendations. A confirmation run or a follow-up DOE is usually needed.

Statistical Process Control (SPC)

Purpose. SPC is a major tool in the control phase. It is used to control and monitor the stability and capability of the few, vital xs for CTQ.

How to do it. This method will be discussed in more detail in the DFSS section. For a general introduction to SPC, see *Montgomery* [50.5]. For recent advances in SPC, the reader may refer to http://qlab.ielm.ust.hk and references therein.

50.2 Design for Six Sigma

The success of Six Sigma's DMAIC methodology has generated enormous interest in the business world. One of the basic ideas is to measure existing defective processes quantitatively and then to improve them. Compared with this defect-correction methodology, design for Six Sigma (DFSS) is a proactive methodology, which focuses on the new product/service development to prevent quality defects from appearing instead of solving problems when they happen in existing processes.

DFSS is a disciplined and statistical approach to product and service design that ensures that new designs can meet customer requirements at launch. The objective of DFSS is to eliminate and reduce the design vulnerabilities in both the conceptual and operational phases by employing scientific tools and statistical methods.

Unlike the DMAIC methodology, the phases of DFSS are not universally defined. There are many methodologies, such as Woodford's identify, design, optimize, validate (IDOV), El-haik's identify, characterize, optimize, verify (ICOV), Tennant's define, customer concept, design, and implement (DCCDI), and so on. All these approaches share common themes, objectives, and tools. In this section, we refer to above methodologies, especially General Electric's DFSS approach called define, measure, analyze, design and verify (DMADV):

Define the project goals and customer requirements.
Measure and determine customer needs and specifications.
Analyze the options of conceptual solutions to meet customer needs.
Design the product/service to meet customer needs.
Verify the design performance and ability to meet customer needs.

50.2.1 Why DFSS?

Proactive versus Retroactive

During the product/service design process, conceiving, evaluating and selecting good design solutions are difficult tasks with enormous consequences. Usually organizations operate in two modes: *proactive*, that is, conceiving feasible and healthy conceptual solutions the first time; and *retroactive*, that is, an after-the-fact practice that drives design in a design–test–fix–retest cycle and creates what is broadly known as the *fire-fighting* mode of design. If a company follows this practice, it suffers from high development costs, longer times to market, lower quality levels, and marginal competitive edge [50.8].

Compared to retroactive approaches such as DMAIC, which apply performance improvement in the later stages of the product/service life cycle, DFSS shifts the attention to improving performance in the front-end design stages. That is, the focus is on problem prevention instead of problem solving. This action is motivated by the fact that the design decisions made during the early stages of the product/service life cycle have the largest impact on both total cost and quality of the system. It is often claimed that up to 80% of the total cost is committed in the concept development stage. Also, at least 80% of the design quality is committed in the early design stages. According to a study of the design community [50.8], at the early design stage, the impact (influence) of design activity is much higher than a later stage, while the correction cost in the early stage is much lower.

Experience Dependency versus Scientific and Systematic Methodology

Currently, most design methods are empirical in nature, while the work of the design community is often based on experience. This experience-based tradition often leads to unnecessary variation and is difficult for project manager to control. As a result, vulnerabilities are introduced into the new design that makes it impossible for the product/service to achieve Six Sigma performance. This is another motivation for devising DFSS as a scientific and systematic design method to address such needs.

50.2.2 Design for Six Sigma: The DMADV Process

Generally speaking, DFSS has five phases spread over product development. They are called: define, measure, analyze, design and verify (DMADV).

Phase 1: Define (D)

The process of product/service design begins when there is a need (internal or external), which can be a problem to be solved or a new invention. In this phase, design objectives, scope and available resources should be simply and clearly defined in the design project charter as the key deliverables.

Phase 2: Measure (M)

In particular, the voice of customer (VOC) is the critical input in customer-oriented design. Based on VOC, the internal CTQ measures (critical to quality or critical to satisfaction, i. e., the y), such as cost, performance, reliability, aesthetics and serviceability, need to be identified quantitatively and to be prioritized according to their importance to customers. This kind of information can help to define the function requirements in a later phase.

Phase 3: Analyze (A)

In this phase, the CTQs will be decomposed into measurable and solution-free functional requirements (FRs). Then, a number of conceptual-level design alternatives should be produced by the design team for the FRs, considering cost, physical properties, the difficulties to operate/manufacture and maintenance, etc. Through summarizing the design requirements and conceptual-level design alternatives, an overall set that contains high-potential and feasible solutions can be produced to help the design team to decide on the best solution considering the original design charter including the performance, the constraint of cost and available resources.

Phase 4: Design (D)

Once the design team fixes the selection of the conceptual solutions, they need to decompose the FRs into design parameters (DPs). At the same time, they need to consider the potential risk to achieve CTQs when they create detailed designs to the level of design parameters. Then, optimization tools will be used to get optimal values for the design parameters. In DFSS, optimization can be reached statistically, and by using statistical tools, the transfer functions can be generated to mathematically represent the relationships between the input and output of a product or a service process. Then, the design team can rely on the transfer function to optimize the design solutions so that the product/service can achieve a target performance and be insensitive to uncontrollable factors (noise factors), such as the environment and production case-to-case variation.

Phase 5: Verify (V)

In this phase, the design team makes a model formed by the simulation of a service process or a physical prototype that is the first working version of the product. Based on these few prototypes, the design team evaluates and tests the whole design to predict if the future product's performance can meet the design charter and how to improve the solution when failure occurs.

50.2.3 Key Tools to Support the DMADV Process

Below is a summary of the key tools used to support the DMADV process.

Voice of Customer (VOC)

Purpose. Define customer needs/requirements for the new product/service design or existing product/service redesign.

Input. Market segment defined – who the customers are and their environment.

Output. Detailed customer requirements.

How to do it [50.9].

Step 1: Define market segments – to understand who the customers are and where to go to gather their needs.
Step 2: Identify objective for interviews of customer – to learn what of their needs are new, unique, and difficult (NUD).
Step 3: Select customer groups within the target market segments.
Step 4: Decide on the customer visit team – divide into three roles: leader, subordinate interviewer that helps adding balance and diversity in the discussion, and statement writer that writes down the VOC needs statement.

1. Create an interview guide based on objectives – to get customers' responses that are rich in description of needs.
2. Listen, probe, and observe customers by asking stimulating questions and open-ended statements to gather the VOC. Image data can be gathered by actual observation of customers' responses to existing products or services.

Kawakita Jiro (KJ) Method [50.10]

Purpose. Structure and rank the customer requirements.

Input. The detailed VOC.

Output. Organized customer requirements.

How to do it [50.11].

Step 1: Write down customer descriptions as *statements of customer requirements* on a POST-IT note and put them on the wall.
Step 2: Group the similar customer requirements together.
Step 3: Review the customer requirements statements and throw out redundant ones.
Step 4: Write a summary to express the general idea for each group. For those that do not relate to anything else, label it as *independent*.
Step 5: Vote for the most important groups and rank the top three groups and assign some relationships. If a group supports another group in a positive manner, we add an arrow pointing from the supporting group to the supported group. If the relationship is contradictory, we add a line pointing between the two groups with blocks on the end.
Step 6: Look at each detailed customer requirement and highlight the new, unique, or difficult ones.
Step 7: Ask customers to rank (on a scale of 1–10) the strength of importance for each requirement.

The result of these ranked and structured customer requirements will flow into the QFD process.

Quality Function Deployment (QFD): the houses of quality [50.12]

QFD is a methodology that establishes *bridges* between qualitative, high-level customer needs/requirements and the quantitative engineering terms that are critical to fulfilling these high-level needs. By following QFD, relationships can be explored among customer requirements, CTQ measures, function requirements (FRs), design parameters (DPs) and process variables (PVs). And the priorities of each CTQ, FR, DP and PV can be quantitatively calculated.

Generally, the QFD methodology is deployed through a four-phase sequence.

Phase 1 – critical-to-satisfaction planning (HOQ1)
Phase 2 – functional requirements planning (HOQ2)
Phase 3 – design parameters planning (HOQ3)
Phase 4 – process variable planning (HOQ4)

In this chapter, HOQ1 will be introduced in detail as an example.

Input. Structured and ranked new, unique and difficult (NUD) VOC from the KJ diagram.

Key Output. The priorities of each CTQ.

How to do it [50.8].

Step 1: Convert NUD VOC ("WHATs") into a list of CTQs ("HOWs") in terms of the engineering perspective to support customer requirements along the roof of the house. There may be more then one CTQ to achieve each customer requirement.
Step 2: Quantify the relationship between each customer requirement to each CTQ on a $1-3-9$ scale ($9 =$ strong fulfillment, $3 =$ moderate fulfillment, $1 =$ weak fulfillment, or $0 =$ no relationship). These values help to identify which CTQs are critical and which are not.
Step 3: Identify the correlation between each pair of CTQ to address the cooperative and conflicting relationships among CTQs to develop the design to be as cooperative as possible.
Step 4: Conduct a competitive assessment with a main competitor. The comparison with the key competitor on each customer requirement is on a 1–5 scale, with five being high.
Step 5: Prioritize customer requirements. These priorities include importance to customer from the KJ method, improvement factor, and absolute weight. Customer requirements with low completive assessments and high importance are candidates for improvement, which will be assigned improvement factors on a 1–5 scale, with five being the most essential target to improve. The absolute weight can then be calculated by multiplying the customer importance and the improvement factor.
Step 6: Priority CTQs. The CTQs are prioritized by determining absolute weight and relative weight. The absolute weight is calculated by the sum of the products of the relationship between customer requirements and CTQs and the importance to the customer. The relative weight is the sum of the products of the relationship between customer requirements and CTQs and customer requirement absolute weights. The relative and absolute weights are evaluated to prioritize and select CTQs for improvement.

Furthermore, the design team can apply the same method for identifying the relationship among CTQs, functional requirements, design parameters and process variables.

The Pugh Concept Evaluation and Selection Process [50.13]

The Pugh concept evaluation is a solution-iterative selection process. The method alternates between generation and selection activities. The *generation* activity can be enriched by the TRIZ (theory of inventive problem solving, [50.14]) methodology to generate conceptual solutions for each functional requirement. The *selection* activity can use a scoring matrix called the *Pugh matrix* or the *criteria-based matrix* to evaluate the concepts.

Input. Functional requirements and conceptual solutions to achieve corresponding FRs.

Output. The conceptual solutions, which are selected and ready to go forward into the design phase.

How to do it [50.15].

Step 1: Define concept selection criteria from a clear and complete set of requirements.
Step 2: Define a best-in-class benchmarked datum concept.
Step 3: Provide candidate concepts to evaluate against the datum.
Step 4: Evaluate each concept against the datum using (+)s, (−)s, and (*S*)s to rank the fulfillment of the concept selection criteria.

(+) means the concept is better than the benchmarked datum concept;
(−) means the concept is worse than the benchmarked datum concept;
(*S*) means the concept is the same with the benchmarked datum concept.

Step 5: Refine criteria as necessary during the first cycle of evaluation.
Step 6: Analyze the results from the first cycle of evaluation: the sum of (+)s, (−)s, and (*S*)s.
Step 7: Identify weakness in concepts that can be turned into (+)s.
Step 8: Create hybrid *super-concepts* by integrating the strengths of similar concepts to remove (−)s and (*S*)s.
Step 9: Select a new datum based on the scoring that suggests a superior concept after the first cycle of evaluation.
Step 10: Add any new concepts that have been developed.
Step 11: Repeat the evaluation process through the second cycle.
Step 12: The superior concept is selected and ready to go forward into the development or design phase.

Design Failure Modes and Effects Analysis [50.16]

DFMEA is applied to define qualitatively and rank quantitatively the failure modes and effects for new products and service processes across all the phases of DMADV. In particular, the design team can use DFMEA in a design concept for potential failure modes so it can address them early in the design. Usually DFMEA is conducted on the superior concept, which is chosen from all the candidate concepts in the Pugh concept-selection process.

Input. Superior concept architectures, functional requirements, the physical form, etc.

Output. Causes of failure and corrective action.

How to do it [50.8].

Step 1: Develop a block diagram of the design element or function being analyzed (at system, subsystem, subassembly, or component level).
Step 2: Determine the ways in which each design element or function can fail (failure modes).
Step 3: Determine the effects of the failure on the customer(s) for each failure mode associated with the element or function.
Step 4: Identify potential causes of each failure mode.
Step 5: List the current design controls for each cause or failure mode.
Step 6: Assign severity, occurrence, and detection ratings to each cause.
Step 7: Calculate risk priority numbers (RPN) for each cause.
Step 8: Apply tools and best practices to reduce the sensitivity to root causes of failure or eliminate root causes of failure and recalculate RPNs.
Step 9: Document causes of failure and corrective action results qualitatively and quantitatively.

Response Surface methods [50.6,17]

Purpose. Optimize the system performance in the *design* phase by constructing a statistical model and response surface map that represents the relationship between the response and the critical design parameters. If the design parameters are quantitative and there are only a few of them, RSM is an effective tool for modeling and optimization.

Input. Critical design parameters.

Output. Surface map and equations that determine the level of the factors.

How to do it [50.18].

Step 1: Choose a CTQ response to be studied by experimentation.
Step 2: Determine the critical parameter to be modified with the experiments. Focus on the significant factors that affect the response.
Step 3: Select the measurement system used to analyze the parameters.
Step 4: Create the transfer function from the experimental data. The transfer function is a mathematical description of the behavior of the system that can be used to create surface plots and optimize the system's performance.
Step 5: Plot the response surface maps to observe the system behavior.
Step 6: Final output: a surface map and an equation that is used to determine the level of the factors. Sensitivity of the factors can also be analyzed.

Inferential Statistics

Inferential statistics are often employed in the *verification* phase.

Purpose. Identify and control variation in the critical responses.

Input. The new product/service's performance data.

Output. The decision on which factors have an effect on the design's response.

Hypotheses and risk: There are null hypothesis and alternate hypothesis. Once we have data, we can determine whether we should accept or reject the null hypothesis, by calculating a test statistic.

The t-test: Used to compare two samples, or one sample with a standard. The null hypothesis is that the means are equal and the difference between the two population means is zero.

Analysis of variance (ANOVA): We use ANOVA when there are more than two samples to compare. ANOVA is used to test whether the means of many samples differ.

H. Statistical Process Control [50.5]

Purpose. Monitor the critical response of the new product/service in the *verify* phase to assess stability and predictability and detect important changes.

Input. The new product/service's performance data.

Output. Assessment of the new product/service's stability, predictability, sigma level and capability for commercialization readiness.

Main considerations. Sample size considerations – sample size should be large enough to provide good sensitivity in detecting out-of-control conditions

Sampling frequency – sampling should be frequent enough to ensure opportunities for process control and improvement.

Concepts. A production/service process that is operating with only chance causes (common causes) of variation present is said to be *in statistical control*. A process is out of control if there exists assignable causes (special causes) that are not part of the chance cause pattern such as improperly adjusted or controlled machines, operator errors, or defective raw material [50.5]. An SPC chart is used to distinguish these two types of causes by upper and lower control limits (UCL and LCL). As long as all the sample points plot within the control limits, the process is assumed to be in statistical control. If a charting point is out of the control limits, this implies that there is evidence that the process is out of control. We then should investigate the assignable causes and take corrective actions.

We can use SPC charts to determine if a new product/service's CTQ measure is in control. If it is, the product/service may move to the mass-production phase.

How to do it [50.5].

Step 1: Select the environment in which the data will be collected.
Step 2: Select the responses and parameters that will be monitored.
Step 3: Select the measurement systems used to acquire the data.
Step 4: Run the system in the prescribed environment

and acquire the data.

Step 5: Plot the data using the appropriate type of SPC chart.

Step 6: Assess the plots for stability and predictability.

Step 7: Calculate the estimates of sigma level and process capability.

50.3 Six Sigma Case Study

In this section, a case study on printed circuit board (PCB) improvement by the author is used to demonstrate the application of Six Sigma, which is digested from *Tong* et al. [50.2] where a more detailed report of this case may be found. This study was conducted in reference to the DMAIC approach, and the objective is to improve the sigma level for a series of products called PSSD in the screening process.

50.3.1 Process Background

This case study was conducted in an electronic company, which is located in an industrial park in southern China. The company manufactures multilayer PCBs by using the surface-mount technology (SMT), which is a technique for placing surface-mount devices (SMDs) on the surface of a PCB. SMDs are micro-miniature leaded or leadless electronic components that are soldered directly to the pads on the surface of the PCB. The major manufacturing processes in the company are solder screen, component placement, and solder reflow. As any defect in any of the solder joints can lead to the failure of the circuit, the screening process is regarded as the most critical process in PCB manufacturing.

The screening process is a manufacturing process that transfers solder paste onto the solder pad of a PCB. The application method for solder paste is printing, and the printing technique used is off-contact printing, in which there is a snap-off distance between a stencil and a PCB. The type of screening machine used to manufacture PSSD products is semiautomatic. During a printing process, two PCBs are placed side-by-side on the holder of a screening machine. The solder paste is then placed onto a stencil manually before printing. The front/back blade makes a line contact with the stencil and a close contact with the given amount of solder paste. The solder paste is then rolled in front of the front/back blade. In this way, solder paste is pressed against the stencil and transferred onto the solder pad through the stencil openings. More detailed operation of a screening process is described in *Tong* et al. [50.2].

50.3.2 Define Phase

In this case, we specifically focus on the improvement of the sigma level of the PCB screening process. In the screening process, the solder paste volume (height) transferred onto the PCB is the most important factor that needs to be controlled carefully. This is because too little solder paste can cause open circuits and too much solder paste can cause bridging between solder pads in the subsequent processes. As a result, the solder paste height on the solder pads is identified as a critical-to-quality (CTQ) characteristic (i. e., the y) that needs to be controlled in a very precise way by the company. According to that, a project team is formed and a project charter is constructed.

50.3.3 Measure Phase

To control the screening process, the project team in the company has asked operators to measure the solder paste height for the PSSD product on five different points on a PCB. The solder paste height on the five points is measured by using the Cyberoptics Cybersentry system every four hours. The gage repeatability and reproducibility (R&R) of the measurement system was verified before the study on the solder paste height is conducted. The gage R&R results ensured that the data from the current measurement system are accurate enough for the following analysis.

50.3.4 Analyze Phase

Currently, six semiautomatic screening machines are used to manufacture the PSSD product. Therefore, the data on solder paste height of these six machines was collected from the company, and the process capability analysis was conducted for these screening machines in order to analyze the current printing performance. According to the analytical results, the process capability in machine number 12 was not satisfactory because the capability index Cp was only 1.021, which was smaller than 1.33 (the four-sigma level). Moreover, another capability index Cpk was 0.387. This showed that

the screening process was off-center. Based on the process capability study, we concluded that there exist both a high variance and a mean shift in the solder paste process. Therefore, we list all the potential factors (xs) that may cause this through brainstorming and constructing a cause and effect diagram.

50.3.5 Improve Phase

In the analysis of the current printing performance, the result showed that the screening process capability of machine number 12 was not satisfactory. After brainstorming with the mechanical engineers in the company, the designed experiments were decided to conduct on machine number 12 in order to determine the optimal settings of all the input factors (xs) in the screening process. In this phase, DOE was used as a core statistical tool for the sigma level improvement.

In the initial experiments, several possible factors that might have influence the printing performance were taken into account. These experiments were used to screen out new factors that have influence on the printing performance. These significant factors would then be included together with the already-known significant factors (solder paste viscosity, speed of squeegee, and pressure of squeegee) in the further experiments. The aim of the further experiments was to determine the standard settings of all the significant factors (i. e., the few, vital xs). By using these optimal settings in the screening process, the printing performance could be improved. As a result, the sigma level can also be enhanced significantly. The detailed DOE setting, analysis, and result can be found in *Tong* et al. [50.2].

50.3.6 Control Phase

To sustain the improvement of the sigma level in the screening process, control plans for all the important xs were proposed to the company. For example, both the CTQ y and the vital xs should be monitored by SPC charts over time, so that the solder paste height variation and the sigma level can be controlled and sustained continuously. Also, the financial benefits through the reduction of COPQ were calculated.

The comparison of the printing performance before and after the project was reported in *Tong* et al. [50.2]. After using the optimal settings, the sigma level of the screening process can be improved from 1.162 to 5.924. This shows that a nearly six-sigma performance can be achieved. According to *Harry* and *Schroeder* [50.19], the level of defects per million opportunities (DPMO) would reduce to near 3.4 and the COPQ would be less than one percent of the sales. As a result, after the Six Sigma practice, the COPQ of the process for this company has been significantly reduced.

50.4 Conclusion

As Six Sigma is evolving over time, the advantages and benefits of other business-excellence approaches can still be learned and utilized in future Six Sigma programs. According to *Hahn* [50.20], combining other tools or methodologies and the Six Sigma methodology may be a future trend. For example, combining lean tools with the Six Sigma methodology has become popular during the last few years. And there are expected to be more combinations in the future.

Recently, Six Sigma efforts have been pushed to both the external suppliers and external customers along a supply chain, which has resulted in even larger overall business impacts and cost savings. I have also observed an increasing trend outside the US, where more and more companies in Asia and Europe, including small-to-medium-sized enterprizes, have implemented various stages of Six Sigma deployment and discovered its far-reaching benefits.

51. Multivariate Modeling with Copulas and Engineering Applications

This chapter reviews multivariate modeling with copulas and provides novel applications in engineering. A copula separates the dependence structure of a multivariate distribution from its marginal distributions. Properties and statistical inferences of copula-based multivariate models are discussed in detail. Applications in engineering are illustrated via examples of bivariate process control and degradation analysis, using existing data in the literature. A software package has been developed to promote the development and application of copula-based methods.

Section 51.1 introduces the concept of copulas and its connection to multivariate distributions. The most important result about copulas is Sklar's theorem, which shows that any continuous multivariate distribution has a canonical representation by a unique copula and all its marginal distributions. A general algorithm to simulate random vectors from a copula is also presented.

Section 51.2 introduces two commonly used classes of copulas: elliptical copulas and Archimedean copulas. Simulation algorithms are also presented.

Section 51.3 presents the maximum-likelihood inference of copula-based multivariate distributions given the data. Three likelihood approaches are introduced. The exact maximum-likelihood approach estimates the marginal and copula parameters simultaneously by maximizing the exact parametric likelihood. The inference functions for margins approach is a two-step approach, which estimates the marginal parameters separately for each margin in a first step, and then estimates the copula parameters given the the marginal parameters.

The canonical maximum-likelihood approach is for copula parameters only, using uniform pseudo-observations obtained from transforming all the margins by their empirical distribution functions.

Section 51.4 presents two novel engineering applications. The first example is a bivariate process-control problem, where the marginal normality seems appropriate but joint normality is suspicious. A Clayton copula provides a better fit to the data than a normal copula. Through simulation, the upper control limit of Hotelling's T^2 chart based on normality is shown to be misleading when the true copula is a Clayton copula. The second example is a degradation analysis, where all the margins are skewed and heavy-tailed. A multivariate gamma distribution with normal copula fits the data much better than a multivariate normal distribution.

Section 51.5 concludes and points to references about other aspects of copula-based multivariate modeling that are not discussed in this chapter.

An open-source software package for the R project has been developed to promote copula-related methodology development and applications. An introduction to the package and illustrations are provided in the Appendix.

Multivariate methods are needed wherever independence cannot be assumed among the variables under investigation. Multivariate data are encountered in real life much more often than univariate data. This is especially true nowadays with the rapid growth of data-acquisition technology. For example, a quality-control engineer may have simultaneous surveillance of several related quality characteristics or process variables; a reliability analyst may measure the amount of degradation for a certain product repeatedly over time. Because of the dependence among the multiple quality characteristics and repeated measurements, univariate methods are invalid or inefficient. Multivariate methods that can account for the multivariate dependence are needed.

Classic multivariate statistical methods are based on the multivariate normal distribution. Under multivariate normality, an elegant set of multivariate techniques, such as principle-component analysis and factor analysis, has become standard tools and been successful in a variety of application fields. These methods have become so popular that they are often applied without a careful check about whether multivariate normality can reasonably be assumed.

In many applications, the multivariate normal assumption may be inappropriate or too strong to be made. Non-normality can occur in different ways. First, the marginal distribution of some variables may not be normal. For instance, in the degradation analysis in Sect. 51.5, the error rates of magnetic-optic disks at all time points are skewed and heavy-tailed, and hence cannot be adequately modeled by normal distributions. Second, even if all the marginal distributions are normal, jointly these variables may not be multivariate normal. For instance, in the bivariate process-control problem in Sect. 51.5, marginal normality seems appropriate but joint normality is suspicious. In both examples, multivariate distributions that are more flexible than the multivariate normal distribution are needed.

Non-normal multivariate distributions constructed from copulas have proved very useful in recent years in many applications. A copula is a multivariate distribution function whose marginals are all uniform over the unit interval. It is well known that any continuous random variable can be transformed to a uniform random variable over the unit interval by its probability integral transformation. Therefore, a copula can be used to *couple* different margins together and construct new multivariate distributions. This method separates a multivariate distribution into two components, all the marginals and a copula, providing a very flexible framework in multivariate modeling. Comprehensive book references on this subject are *Nelsen* [51.1] and *Joe* [51.2]. For widely accessible introductions, see, for example, *Genest* and *MacKay* [51.3] and *Fisher* [51.4].

Copula-based models have gained much attention in various fields. Actuaries have used copulas when modeling dependent mortality and losses [51.5–7]. Financial and risk analysts have used copulas in asset allocation, credit scoring, default risk modeling, derivative pricing, and risk management [51.8–10]. Biostatisticians have used copulas when modeling correlated event times and competing risks [51.11, 12]. The aim of this chapter is to provide a review of multivariate modeling with copulas and to show that it can be extensively used in engineering applications.

The chapter is organized as follows. Section 51.1 presents the formal definition of copulas and the construction of multivariate distribution with copulas. Section 51.2 presents details about two commonly used classes of copulas: elliptical copulas and Archimedean copulas. Section 51.3 presents likelihood-based statistical inferences for copula-based multivariate modeling. Section 51.4 presents two engineering applications: multivariate process control and degradation analysis. Section 51.5 concludes and suggests future research directions. An open-source software package `copula` [51.13] for the `R` project [51.14] has been developed by the author. A brief introduction to the package and illustrations are presented in the Appendix.

51.1 Copulas and Multivariate Distributions

51.1.1 Copulas

Consider a random vector $(U_1, \ldots, U_p)^\top$, where each margin U_i, $i = 1, \ldots, p$, is a uniform random variable over the unit interval. Suppose the joint cumulative distribution function (CDF) of $(U_1, \ldots, U_p)^\top$ is

$$C(u_1, \ldots, u_p) = \Pr(U_1 \le u_1, \ldots, U_p \le u_p) . \quad (51.1)$$

Then, the function C is called a p-dimensional copula. As *Embrechts* et al. [51.9] noted, this definition of a copula masks some of the problems when construct-

ing copulas using other techniques, by not explicitly specifying what properties a function must have to be a multivariate distribution function; for a more rigorous definition, see for example *Nelsen* [51.1]. However, this definition is operational and very intuitive. For example, one immediately obtains with this definition that, for any p-dimensional copula C, $p \geq 3$, each $k \leq p$ margin of C is a k-dimensional copula and that independence leads to a product copula

$$\Pi_p(u_1, \ldots, u_p) = \prod_{i=1}^{p} u_i \,. \tag{51.2}$$

Every continuous multivariate distribution function defines a copula. Consider a continuous random vector $(X_1, \ldots, X_p)^\top$ with joint CDF $F(x_1, \ldots, x_p)$. Let F_i, $i = 1, \ldots, p$, be the marginal CDF of X_i. Then, $U_i = F_i(X_i)$ is a uniform random variable over the unit interval. One can define a copula C as

$$C(u_1, \ldots, u_p) = F\left\{F_1^{-1}(u_1), \ldots, F_p^{-1}(u_p)\right\} \,. \tag{51.3}$$

The elliptical copulas in Sect. 51.2.1 are constructed this way. Another important class of copulas, Archimedean copulas, is constructed differently (Sect. 51.2.2).

A copula (51.1) can be used to construct multivariate distributions with arbitrary margins. Suppose that it is desired that the i-th margin X_i has marginal CDF G_i. A multivariate distribution function G can be defined via a copula C as

$$G(x_1, \ldots, x_p) = C\{G_1(x_1), \ldots, G_p(x_p)\} \,. \tag{51.4}$$

This multivariate distribution will have the desired marginal distributions.

Clearly, there is a close connection between copulas and multivariate distributions. It is natural to investigate the converse of (51.4). That is, for a given multivariate distribution function G, does there always exist a copula C such that (51.4) holds? If so, is this C unique? These problems are solved rigorously by *Sklar*'s [51.15] theorem in the next section.

51.1.2 Copulas to Multivariate Distributions

Sklar's theorem is the most important result about copulas. The bivariate version of the theorem was established by *Sklar* [51.15] almost half a century ago in the probability metrics literature. The proof in the general p-dimensional case is more involved and can be found in *Sklar* [51.16]. A formal statement of the theorem is as follows [51.1].

Theorem 51.1

Let F be a p-dimensional distribution function with margins $F_1, \ldots, F_p$. Then there exists a p-dimensional copula C such that, for all x in the domain of F,

$$F(x_1, \ldots, x_p) = C\{F_1(x_1), \ldots, F_p(x_p)\} \,. \tag{51.5}$$

If $F_1, \ldots, F_p$ are all continuous, the C is unique; otherwise, C is uniquely determined on $\mathrm{Ran}F_1 \times \cdots \times \mathrm{Ran}F_p$, where $\mathrm{Ran}H$ is the range of H. Conversely, if C is a p-dimensional copula and $F_1, \ldots, F_p$ are distribution functions, then the function F defined by (51.5) is a p-dimensional distribution function with marginal distributions $F_1, \ldots, F_p$.

Sklar's theorem ensures that a continuous multivariate distribution can be separated into two components, univariate margins and multivariate dependence, where the dependence structure is represented by a copula. The dependence structure of a multivariate distribution can be analyzed separately from its margins. It is sufficient to study the dependence structure of a multivariate distribution by focusing on its copula.

The probability density function (PDF) of the CDF F in (51.5) can be found from the PDF of C and $F_1, \ldots, F_p$. The PDF c of the copula C in (51.1) is

$$c(u_1, \ldots, u_p) = \frac{\partial^p C(u_1, \ldots, u_p)}{\partial u_1 \ldots \partial u_p} \,. \tag{51.6}$$

When the density c is known, the density f of the multivariate distribution F in (51.5) is

$$f(x_1, \ldots, x_p) = c\left\{F_1(x_1), \ldots, F_p(x_p)\right\} \prod_{i=1}^{p} f_i(x_i) \,, \tag{51.7}$$

where f_i is the density function of the distribution F_i. Expression (51.7) is called the canonical representation of a multivariate PDF. It will be used to construct likelihood for observed data.

51.1.3 Concordance Measures

The copula of two random variables completely determines any dependence measures that are scale-invariant, that is, measures that remain unchanged under monotonically increasing transformations of the random variables. The construction of the multivariate distribution (51.5) implies that the copula function C is invariant

under monotonically increasing transformations of its margins. Therefore, scale-invariant dependence measures can be expressed in terms of the copulas of the random variables.

Concordance measures of dependence are based on a form of dependence known as concordance. The most widely used concordance measures are Kendall's tau and Spearman's rho. Both of them can be defined by introducing a concordance function between two continuous random vectors (X_1, X_2) and (X_1', X_2') with possibly different joint distributions G and H, but with common margins F_1 and F_2. This concordance function Q is defined as

$$Q = \Pr\left\{(X_1 - X_1')(X_2 - X_2') > 0\right\} - \Pr\left\{(X_1 - X_1')(X_2 - X_2') < 0\right\}, \quad (51.8)$$

which is the difference between the probability of concordance and dis-concordance of (X_1, X_2) and (X_1', X_2'). It can be shown that

$$Q = Q(C_G, C_H) = 4\int_0^1\int_0^1 C_G(u, v)\,\mathrm{d}C_H(u, v) - 1, \quad (51.9)$$

where C_G and C_H are the copulas of G and H, respectively.

For a bivariate random vector (X_1, X_2) with copula C, Kendall's tau is defined as $Q(C, C)$, interpreted as the difference between the probability of concordance and dis-concordance of two independent and identically distributed observations. Therefore, we have

$$\tau = 4\int_0^1\int_0^1 C(u_1, u_2)\,\mathrm{d}C(u_1, u_2) - 1, \quad (51.10)$$

where the range of τ can be shown to be $[-1, 1]$. Spearman's rho, on the other hand, is defined as $3Q(C, \Pi)$, where Π is the product copula obtained under independence. That is,

$$\rho = 12\int_0^1\int_0^1 u_1 u_2\,\mathrm{d}C(u_1, u_2) - 3. \quad (51.11)$$

The constant 3 scales this measure into the range of $[-1, 1]$ (see for example *Nelson* [51.1] p.129). Spearman's rho is proportional to the difference between the probability of concordance and dis-concordance of two vectors: both have the same margins, but one has copula C while the other has the product copula Π. It is straightforward to show that Spearman's rho equals Pearson's product-moment correlation coefficient for the probability-integral-transformed variables $U_1 = F_1(X)$ and $U_2 = F_2(Y)$:

$$\rho = 12E(U_1U_2) - 3 = \frac{E(U_1U_2) - 1/4}{1/12} = \frac{E(U_1U_2) - E(U_1)E(U_2)}{\sqrt{\mathrm{Var}(U_1)\mathrm{Var}(U_2)}}. \quad (51.12)$$

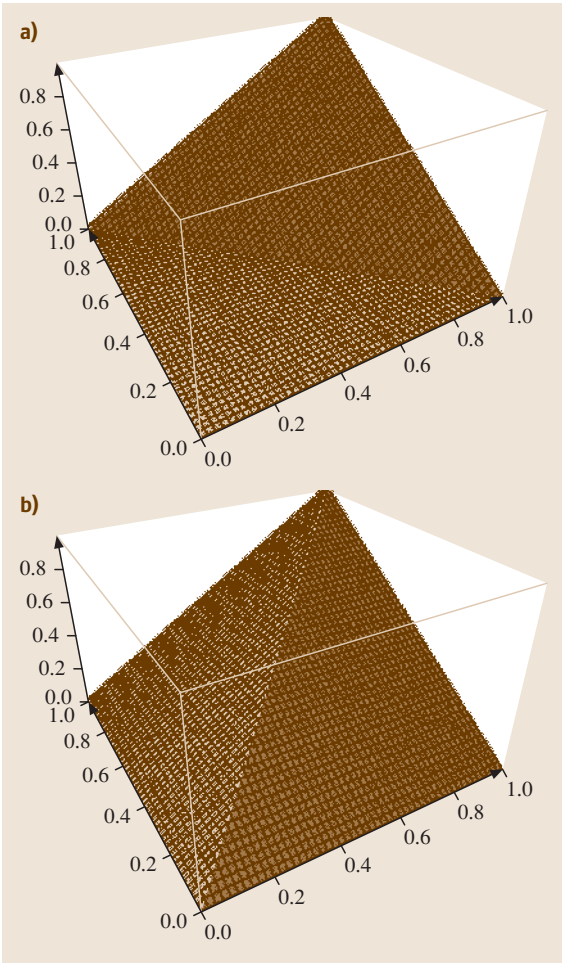

Fig. 51.1a,b Perspective plots of the Fréchet–Hoeffding bounds. **(a)** lower bound; **(b)** upper bound

There are other dependence measures based on copulas. For example, tail dependence is a very important measure when studying the dependence between extreme events. Details can be found in *Joe* [51.2].

51.1.4 Fréchet–Hoeffding Bounds

Important bounds are defined for copulas and multivariate distributions. These bounds are called the Fréchet–Hoeffding bounds, named after the pioneering work of Fréchet and Hoeffding, who independently published their work on this in 1935 and 1940, respectively [51.17]. Define the functions M_p and W_p on $[0,1]^p$ as follows:

$$M_p(u_1,\dots,u_p) = \min(u_1,\dots,u_p),$$
$$W_p(u_1,\dots,u_p) = \max(u_1+\cdots+u_p-n+1,0)\,.$$

Then for every copula C,

$$W_p(u_1,\dots,u_p) \le C(u_1,\dots,u_p) \le M_p(u_1,\dots,u_p)\,. \tag{51.13}$$

These bounds are general bounds, regardless of whether the margins are continuous or not. The function M_p is always a p-dimensional copula for $p \ge 2$. The function W_p fails to be a copula for $p \ge 2$, but it is the best possible lower bound since, for any $u = (u_1,\dots,u_p) \in [0,1]^p$, there exists a copula C (which depends on u) such that $C(u) = W_p(u)$. In the bivariate case, these bounds correspond to perfect negative dependence and perfect positive dependence, respectively. Within a given family of copulas, they may or may not be attained (see for example [51.1] Table 4.1). Figure 51.1 shows the perspective plots of the Fréchet–Hoeffding bounds copulas and the product copula.

Intuitively, perfect dependence should lead to extremes of concordance measures. It can be shown that, for continuous random vector (X_1, X_2) with copula C, $\tau = -1$ (or $\rho = -1$) is equivalent to $C = W_2$ and $\tau = 1$ (or $\rho = 1$) is equivalent to $C = M_2$; see *Embrechts* et al. [51.18] for a proof.

51.1.5 Simulation

Random-number generation from a copula is very important in statistical practice. Consider the p-dimensional copula in (51.1). Let $C_k(u_1,\dots,u_k) = C(u_1,\dots,u_k,1,\dots,1)$ for $k = 2,\dots,p-1$. The conditional CDF of U_k given $U_1 = u_1,\dots,U_{k-1} = u_{k-1}$ is

$$C_k(u_k|u_1,\dots,u_{k-1}) = \frac{\dfrac{\partial^{k-1}C_k(u_1,\dots,u_k)}{\partial u_1\dots\partial u_{k-1}}}{\dfrac{\partial^{k-1}C_{k-1}(u_1,\dots,u_{k-1})}{\partial u_1\dots\partial u_{k-1}}}\,. \tag{51.14}$$

Algorithm (51.1) is a general algorithm to generate a realization $(u_1,\dots,u_p)$ from C via a sequence of conditioning. When the expression for $C_k(\cdot|u_1,\dots,u_{k-1})$ is available, a root-finding routine is generally needed in generating u_k using the inverse CDF method. With realizations from C, one can easily generate realizations from the multivariate distribution (51.4) by applying the inverse CDF method at each margin.

Algorithm 51.1
Generating a random vector from a copula

1. Generate u_1 from a uniform over $[0,1]$.
2. For $k = 2,\dots,p$, generate u_k from $C_k(\cdot|u_1,\dots,u_{k-1})$.

51.2 Some Commonly Used Copulas

We introduce two commonly used copula classes in this section: elliptical copulas and Archimedean copulas. A third class of copulas, extreme-value copulas, is very useful in multivariate extreme-value theory but is omitted here to limit the scope of this chapter; more details about extreme-value copulas can be found in *Joe* [51.2].

51.2.1 Elliptical Copulas

Elliptical copulas are copulas of elliptical distributions. A multivariate elliptical distribution of random vector $(X_1,\dots,X_p)$ centered at zero has density of the form $\phi(t) = \psi(t^\top \Sigma t)$, where $t \in R^p$ and Σ is a $p \times p$ dispersion matrix, which can be parameterized such that $\Sigma_{ij} = \mathrm{Cov}(X_i, X_j)$ [51.19]. Let R_{ij} and τ_{ij} be Pearson's linear correlation coefficient and Kendall's tau between X_i and X_j, respectively. For an elliptical distribution, they are connected through

$$\tau_{ij} = \frac{2}{\pi}\arcsin(R_{ij})\,. \tag{51.15}$$

This relationship makes elliptical copulas very attractive in applications since the similarity between Kendall's tau matrix and the correlation matrix can offer a wide range of dependence structures. Tractable properties similar to those of multivariate normal distributions are another

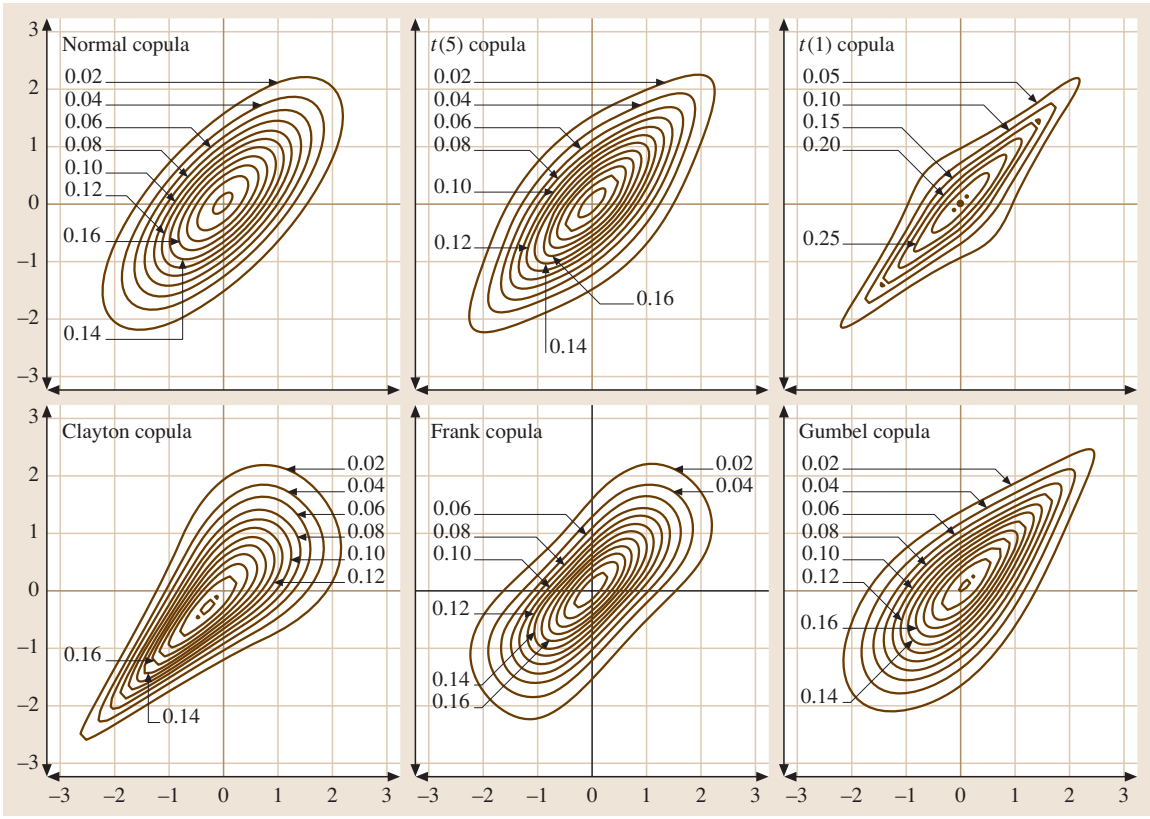

Fig. 51.2 Contours of bivariate distributions with the same marginals but different copulas. Both marginal distributions are standard normal

attractive feature of elliptical copulas. The most popular elliptical distributions are multivariate normal and multivariate t, providing two popular copulas: normal copulas and t copulas.

The normal copula has been widely used in financial applications for its tractable calculus [51.8,20]. Consider the joint CDF Φ_Σ of a multivariate normal distribution with correlation matrix Σ. Let Φ be the CDF of a standard normal variable. A normal copula with dispersion matrix Σ is defined as

$$C(u_1, \ldots, u_p; \Sigma) = \Phi_\Sigma\left[\Phi^{-1}(u_1), \ldots, \Phi^{-1}(u_p)\right] . \quad (51.16)$$

The functions Φ, Φ^{-1} and Φ_Σ are available in any reasonably good statistical softwares, which makes their application widely accessible.

The t copula can be constructed similarly [51.21]. Consider the joint CDF $T_{\Sigma,\nu}$ of the standardized multivariate Student's t distribution with correlation matrix Σ and ν degrees of freedom. Let F_{t_ν} be the CDF of the univariate t distribution with ν degrees of freedom. A t copula with dispersion matrix Σ and degrees-of-freedom parameter ν is defined as

$$C(u_1, \ldots, u_p; \Sigma, \nu) = T_{\Sigma,\nu}\left[F_{t_\nu}^{-1}(u_1), \ldots, F_{t_\nu}^{-1}(u_p)\right] . \quad (51.17)$$

These copulas can be used to construct multivariate distributions using (51.5). Note that a normal copula with normal margins is the same as a multivariate normal distribution. However, a t copula with t margins is not necessarily a multivariate t distribution. A multivariate t distribution must have the same degrees of freedom at all the margins. In contrast, a t copula with t margins can have different degrees of freedom at different margins. It offers a lot more flexibility in modeling multivariate heavy-tailed data.

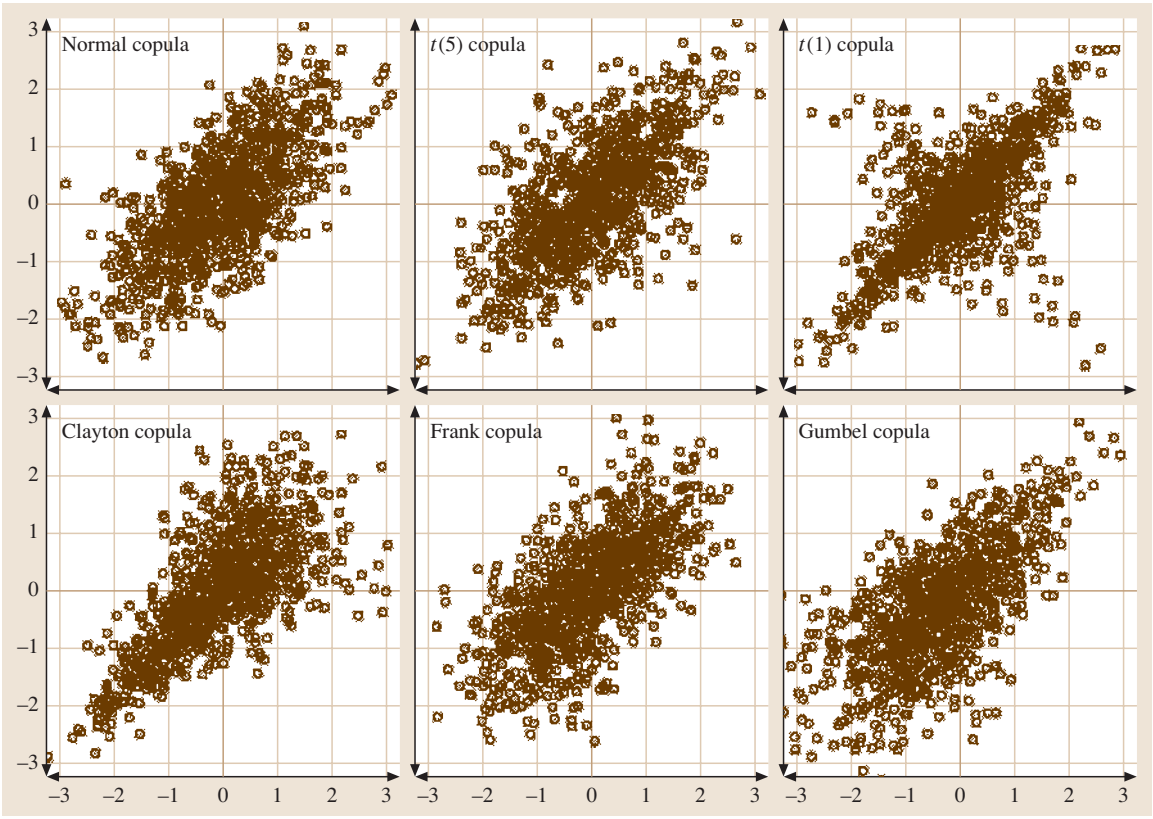

Fig. 51.3 1000 random points from bivariate distributions with the same marginals but different copulas. Both marginal distributions are standard normal

Figure 51.2 shows the density contours of bivariate distributions with the same margins but different copulas. These distributions all have standard normal as both margins, and their values of Kendall's tau are all 0.5. The three plots in the first row of Fig. 51.2 are for a normal copula, t copula with five degrees of freedom, and t copula with one degree of freedom (or Cauchy copula). These densities are computed with (51.7). Note that a normal copula can be viewed as a t copula with infinite degrees of freedom. Figure 51.2 illustrates that the dependence in the tails gets stronger as the number of degrees of freedom decreases.

Simulation from normal copulas and t copulas are straightforward if random-number generators for multivariate normal and t distributions are available. In `R`, the package `mvtnorm` [51.22] provides CDF, PDF and random-number generation for multivariate normal and multivariate t distributions. These facilities are used in the implementation of the package `copula` [51.13].

Figure 51.3 shows 1000 points from the corresponding bivariate distributions in Fig. 51.2.

51.2.2 Archimedean Copulas

Archimedean copulas are constructed via a completely different route without referring to distribution functions or random variables. A key component in this way of construction is a complete monotonic function. A function $g(t)$ is completely monotonic on an interval J if it is continuous there and has derivatives of all orders which alternate in sign, that is,

$$(-1)^k \frac{\mathrm{d}}{\mathrm{d}t^k}\varphi(t) \geq 0, \quad k = 1, 2, \cdots, \tag{51.18}$$

for all t in the interior of J. Let φ be a continuous strictly decreasing function form $[0, 1]$ to $[0, \infty]$ such that $\varphi(0) = \infty$ and $\varphi(1) = 0$, and let φ^{-1} be the inverse of φ. A function defined by

$$C(u_1, \ldots, u_p) = \varphi^{-1}\left[\varphi(u_1) + \cdots + \varphi(u_p)\right] \tag{51.19}$$

Table 51.1 Some one-parameter (α) Archimedean copulas

Family	Generator $\varphi(t)$	Frailty distribution	Laplace transformation of frailty $\mathcal{L}(s) = \varphi^{-1}(s)$
Clayton	$t^{-\alpha} - 1$	Gamma	$(1+s)^{-1/\alpha}$
Frank	$\ln \frac{e^{\alpha t}-1}{e^{\alpha}-1}$	Log series	$\alpha^{-1} \ln [1 + e^{s}(e^{\alpha} - 1)]$
Gumbel	$(-\ln t)^{\alpha}$	Positive stable	$\exp(-s^{1/\alpha})$

is a p-dimensional copula for all $p \geq 2$ if and only if φ^{-1} is completely monotonic over $[0, \infty)$; (see for example [51.1]). The copula C in (51.19) is called an Archimedean copula. The name Archimedean for these copulas comes from a property of the unit cube and copula C which is an analog of the Archimedean axiom for positive real numbers (see [51.1] p. 98 for more details). The function φ is called the generator of the copula. A generator uniquely (up to a scalar multiple) determines an Archimedean copula.

In the bivariate case, an Archimedean copula may be obtained with weaker conditions on the generator φ and its pseudo-inverse $\varphi^{[-1]}$:

$$C(u_1, u_2) = \max \left\{ \varphi^{[-1]} \left[\varphi(u_1) + \varphi(u_2) \right], 0 \right\} , \tag{51.20}$$

where the generator φ is a function with two continuous derivatives such that $\varphi(1) = 0$, $\varphi'(u) < 0$, and $\varphi''(u) > 0$ for all $u \in [0, 1]$, and $\varphi^{[-1]}$ is the pseudo-inverse of φ defined as

$$\varphi^{[-1]}(v) = \begin{cases} \varphi^{-1}(v) & 0 \leq v \leq \varphi(0) , \\ 0 & \varphi(0) \leq v \leq \infty . \end{cases}$$

The generator φ is called a strict generator if $\varphi(0) = \infty$, in which case $\varphi^{[-1]} = \varphi$. *Genest* and *McKay* [51.3] give proofs for some basic properties of bivariate copulas.

The generator φ plays an important role in the properties of an Archimedean copulas. It can be shown that Kendall's tau for an Archimedean copula with generator φ is

$$\tau = 4 \int_0^1 \int_0^1 \frac{\varphi(v)}{\varphi'(v)} \, \mathrm{d}v + 1 . \tag{51.21}$$

This relationship can be used to construct estimating equations that equate the sample Kendall's tau to the theoretical value from the assumed parametric copula family.

Due to the exchangeable structure in (51.19), the associations among all the variables are exchangeable too. As a consequence, an Archimedean copula cannot accommodate negative association unless $p = 2$. For Archimedean copulas with positive associations, there is a mixture representation due to *Marshall* and *Olkin* [51.23]. Suppose that, conditional on a positive latent random variable called the frailty, γ, the distribution of U_i is $F_i(U_i|\gamma) = U_i^{\gamma}$, $i = 1, \ldots, p$, and $U_1, \ldots, U_p$ are independent. Then the copula C of $U_1, \ldots, U_p$ is

$$C(u_1, \ldots, u_p) = E \left(\prod_{i=1}^{p} u_i^{\gamma} \right) , \tag{51.22}$$

where the expectation is taken with respect to the distribution of γ, F_{γ}. Recall that the Laplace transform of γ is

$$\mathcal{L}(s) = E\gamma(\mathrm{e}^{-s\gamma}) = \int_0^{\infty} \mathrm{e}^{-sx} \, \mathrm{d}F_{\gamma}(x) .$$

The Laplace transform has a well-defined inverse $\mathcal{L}^{-1}$. *Marshall* and *Olkin* [51.23] show that the copula in (51.22) is

$$C(u_1, \ldots, u_p) = \mathcal{L} \left[\mathcal{L}^{-1}(u_1) + \cdots + \mathcal{L}^{-1}(u_p) \right] . \tag{51.23}$$

This result suggests that an Archimedean copula can be constructed using the inverse of a Laplace transform as the generator.

Table 51.1 summarizes three commonly used one-parameter Archimedean copulas. A comprehensive list of one-parameter bivariate Archimedean copulas and their properties can be found in Table 4.1 of *Nelson* [51.1]. The three copulas in Table 51.1 all have inverse transforms of some positive random variables as their generators. The Clayton copula was introduced by *Clayton* [51.24] when modeling correlated survival times with a gamma frailty. The Frank copula first appeared in *Frank* [51.25]. It can be shown that the inverse of its generator is the Laplace transform of a log series random variables defined on positive integers. The Gumbel copula can be traced back to *Gumbel* [51.26]. *Hougaard* [51.27] uses a positive stable random variable to derive the multivariate distribution based on a Gumbel copula.

Density contours of bivariate distributions constructed from these three Archimedean copulas are presented in the second row of Fig. 51.2. Both margins of these distributions are still standard normals. The parameters of these copulas are chosen such that the value of Kendall's tau is 0.5. The density of an Archimedean copula can be found by differentiating the copula as in (51.6). When the dimension p is high, the differentiation procedure can be tedious. Symbolic calculus softwares can be used for this purpose. The package `copula` uses the simple symbolic derivative facility in `R` combined with some programming to construct PDF expressions for copulas given the generator function and its inverse function. From Fig. 51.2, one observes that the Frank copula has symmetric dependence. The dependence of the distribution based on the Clayton copula is stronger in the lower-left region than in the upper-right region. In contrast, the dependence of the distribution based on the Gumbel copula is stronger in the upper-right region than in the lower-left region.

Simulation from a general Archimedean can be done using the general Algorithm (51.1) in Sect. 51.2. When the inverse of the generator is known to be the Laplace transform of some positive random variable, an algorithm based on (51.23) is summarized in Algorithm (51.2) [51.6]. This algorithm is very easy to implement, given that a random-number generator of the frailty is available. Gamma-variable generator is available in most softwares. Algorithms for generating positive stable and log series variables can be found in *Chambers* et al. [51.28] and *Kemp* [51.29], respectively. For the bivariate case, the general algorithm (51.1) can be simplified, avoiding numerical root-finding. These algorithms have been implemented in the package `copula` [51.13]. The lower panel of Fig. 51.3 shows 1000 random points generated from the corresponding bivariate distributions with Archimedean copulas in Fig. 51.2.

Algorithm 51.2

tbp Generating a random vector from an Archimedean copula with a known frailty distribution

1. Generate a latent variable γ whose Laplace transformation $\mathcal{L}$ is the inverse generator function φ^{-1}.
2. Generate independent uniform observations $v_1, \ldots, v_p$, $i = 1, \ldots, p$.
3. Output $u_i = \mathcal{L}(-\gamma^{-1} \log v_i)$, $i = 1, \ldots, p$.

51.3 Statistical Inference

This section presents the maximum-likelihood (ML) estimation for multivariate distributions constructed from copulas. Other methods, such as moment methods and nonparametric methods, are less developed for copula-based models and hence omitted.

Suppose that we observe a random sample of size n from a multivariate distribution (51.5):

$$(X_{i1}, \ldots, X_{ip})^\top, \qquad i = 1, \ldots, n\,.$$

The parameter of interest is $\theta = (\beta^\top, \alpha^\top)^\top$, where β is the marginal parameter vector for the marginal distributions $F_i, i = 1, \ldots, p$, and α is the association parameter vector for the copula C. Regression models for the marginal variables can be incorporated easily by assuming that the residuals follow a multivariate distribution (51.5).

51.3.1 Exact Maximum Likelihood

The exact log-likelihood $l(\theta)$ of the parameter vector θ can be expressed from (51.7):

$$l(\theta) = \sum_{i=1}^{n} \log c\left[F_1(X_{i1}; \beta), \ldots, F_p(X_{ip}; \beta); \alpha\right] + \sum_{i=1}^{n}\sum_{j=1}^{p} \log f_i(X_{ij}; \beta)\,. \tag{51.24}$$

The ML estimator of θ is

$$\hat{\theta}_{\mathrm{ML}} = \arg\max_{\theta \in \Theta} l(\theta)\,,$$

where Θ is the parameter space.

Under the usual regularity conditions for the asymptotic ML theory, the ML estimator $\hat{\theta}_{\mathrm{ML}}$ is consistent and asymptotically efficient, with limiting distribution

$$\sqrt{n}(\hat{\theta}_{\mathrm{ML}} - \theta_0) \to N\left[0, I^{-1}(\theta_0)\right]\,,$$

where θ_0 is the true parameter value and I is the Fisher information matrix. The asymptotic variance matrix $I^{-1}(\theta_0)$ can be estimated consistently by an empirical variance matrix of the influence functions evaluated at $\hat{\theta}_{\mathrm{ML}}$.

To carry out the ML estimation, one feeds the log-likelihood function $l(\theta)$ to an optimization routine. The asymptotic variance matrix can be obtained from the inverse of an estimated Fisher information matrix, which is the negative Hessian matrix of $l(\theta)$. In R, one constructs the likelihood function using copula densities supplied in the `copula` package, and uses `optim` to maximize it.

The maximization of $l(\theta)$ in (51.24) may be a difficult task, especially when the dimension is high and/or the number of parameters is large. The separation of the margins and copula in (51.24) suggests that one may estimate the marginal parameters and association parameters in two steps, leading to the method in the next subsection.

51.3.2 Inference Functions for Margins (IFM)

The IFM estimation method was proposed by *Joe* and *Xu* [51.30]. This method estimates the marginal parameters β in a first step by

$$\hat{\beta} = \arg\max_{\beta} \sum_{i=1}^{n} \sum_{j=1}^{p} \log f_i(X_{ij}; \beta) \,, \tag{51.25}$$

and then estimates the association parameters α given $\hat{\beta}$ by

$$\hat{\alpha} = \arg\max_{\alpha} \sum_{i=1}^{n} \log c \times \Big[F_1(X_{i1}; \hat{\beta}), \ldots, F_p(X_{ip}; \hat{\beta}); \alpha \Big] \,. \tag{51.26}$$

When each marginal distribution F_i has its own parameters β_i so that $\beta = (\beta_1^\top, \ldots, \beta_p^\top)^\top$, the first step consists of an ML estimation for each margin $j = 1, \ldots, p$:

$$\hat{\beta}_j = \arg\max_{\beta_j} \sum_{i=1}^{n} \log f(X_{ij}; \beta_j) \,. \tag{51.27}$$

In this case, each maximization task has a very small number of parameters, greatly reducing the computational difficulty. This approach is called the two-stage parametric ML method by *Shih* and *Louis* [51.31] in a censored data setting.

The IFM estimator from (51.25) and (51.26), $\hat{\theta}_{\mathrm{IFM}}$, is in general different from the ML estimate $\hat{\theta}_{\mathrm{ML}}$. The limiting distribution of $\hat{\theta}_{\mathrm{IFM}}$ is

$$\sqrt{n}(\hat{\theta}_{\mathrm{IFM}} - \theta_0) \to N\Big[0, G^{-1}(\theta_0)\Big] \,,$$

where G is the Godambe information matrix [51.32]. This matrix has a sandwich form like the usual robust estimation with estimating functions. Detailed expressions can be found in *Joe* [51.2].

Compared to the ML estimator, the IFM estimator has advantages in numerical computations and is asymptotically efficient. Even in finite samples, it is highly efficient relative to the exact ML estimator [51.2]. The IFM estimate can be used as a starting value in an exact ML estimation.

51.3.3 Canonical Maximum Likelihood (CML)

When the association is of explicit interest, the parameter α can be estimated with the CML method without specifying the marginal distribution. This approach uses the empirical CDF of each marginal distribution to transform the observations $(X_{i1}, \ldots, X_{ip})^\top$ into pseudo-observations with uniform margins $(U_{i1}, \ldots, U_{ip})^\top$ and then estimates α as

$$\hat{\alpha}_{\mathrm{CML}} = \arg\max_{\alpha} \sum_{i=1}^{n} \log c(U_{i1}, \ldots, U_{ip}; \alpha) \,. \tag{51.28}$$

The CML estimator $\hat{\alpha}_{\mathrm{CML}}$ is consistent, asymptotically normal, and fully efficient at independence [51.31, 33].

51.4 Engineering Applications

Two engineering applications of copulas are considered in this section: multivariate process control and degradation analysis. An important third application is the modeling of multivariate failure times, which may be censored. We focus on complete-data applications in this chapter. In the example of multivariate process control, marginal normality seems appropriate but joint normality is suspicious. In the example of degradation analysis, the margins are right-skewed and have long tails. We use a gamma distribution for each margin and a normal copula for the association.

51.4.1 Multivariate Process Control

In quality management, multiple process characteristics necessitate a multivariate method for process

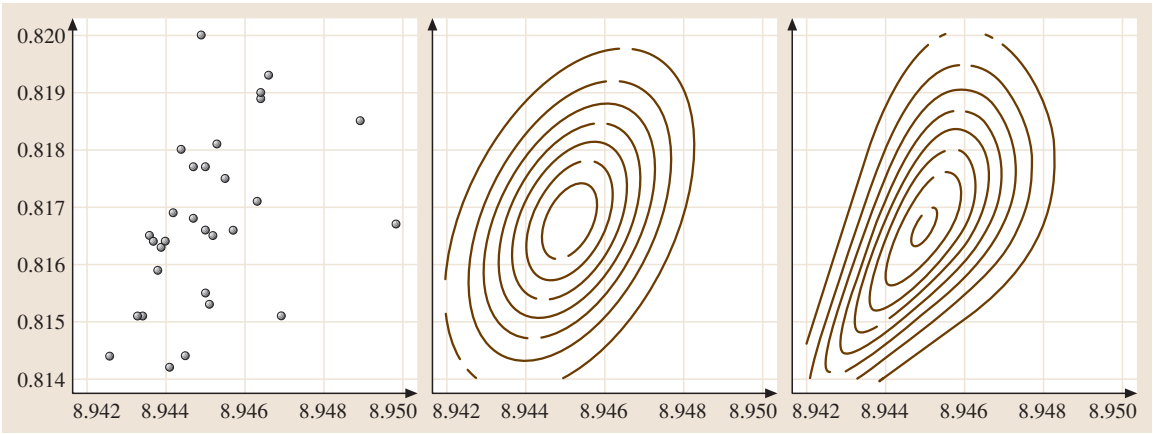

Fig. 51.4 Bivariate process characteristics and parametric fits. *Left*: scatter plot of the data; *center*: contours of bivariate normal fit; *right*: contours of bivariate fit with normal margins and Clayton copula

control. There are three major control charts used in practice: Hotelling's T^2, multivariate cumulative sum (MCUSUM), and multivariate exponentially weighted moving average (MEWMA); see *Lowry* and *Montgomery* [51.34] for a review. The most popular multivariate control chart is the T^2 chart, which has a long history since *Hotelling* [51.35]. *Mason* and *Young* [51.36] give details on how to use it in industrial applications. This method assumes that the multiple characteristics under surveillance are jointly normally distributed. The control limit of the chart is based on the sampling distribution of the statistic T^2, which can be shown to have an F distribution. When the multivariate normal assumption does not hold, due to either univariate or multivariate non-normality, the T^2 control chart based on multivariate normality can be inaccurate and misleading.

Copula-based multivariate distributions open a new avenue for the statistical methods of multivariate process control. The parametric form of the multivariate distribution can be determined from a large amount of historical in-control data. Given a sample of observations when the process is in-control, one can estimate the parameters and propose a statistic that measures the deviation from the target. The exact distribution of this statistic is generally unknown, and the control limit needs to be obtained from bootstrap; see for example *Liu* and *Tang* [51.37].

As an illustration, consider the example of bivariate process control in *Lu* and *Rudy* [51.38]. The data consists of 30 pairs of bivariate measurements from an exhaust manifold used on a Chrysler 5.21 engine in a given model year. They were collected from a machine capability study performed on the machine builder's floor. The sample correlation coefficient is 0.44. The left panel of Fig. 51.4 shows the scatter plot of the 30 observations. The assumption of normality for each margin seems fine from the normal Q–Q plots (not shown). However, the joint distribution may not be a bivariate normal. The scatter plot suggests that the association may be stronger in the lower end than in the higher end of the data. This nonsymmetric association cannot be captured by a symmetric copula, such as those elliptical copula and Frank copula in Fig. 51.2. A better fit of the data may be obtained from a Clayton copula, which allows the bivariate dependence to be stronger in the left tail than in the right tail. The center panel of Fig. 51.4 shows the contours of the ML bivariate normal fit. The right panel of Fig. 51.4 shows the contours of the ML bivariate fit with normal margins and the Clayton copula. The maximized log-likelihood of the two models are 307.64 and 309.87, respectively. A formal test of the difference, which is beyond the scope of this chapter, can be done by comparing non-nested models without knowing the true model based on Kullback–Leibler information [51.39].

The T^2 control chart of *Lu* and *Rudy* [51.38] is a phase II chart for single observations to detect any departure of the underlying process from the standard values. Suppose that we observe a random sample of p-dimensional multivariate observations with sample size m. Let $\bar{X}_m$ and S_m be the sample mean vector and sample covariance matrix, respectively. For a future p-dimensional multivariate observation X, the T^2 is defined as

$$T^2 = (X - \bar{X}_m)^\top S_m^{-1} (X - \bar{X}) \,. \tag{51.29}$$

Table 51.2 Comparison of T^2 percentiles when the true copula is normal and when the true copula is Clayton with various Kendall's τ. The percentiles under Clayton copulas are obtained from 100 000 simulations

Percentiles	Normal copula	Clayton copula			
		$\tau = 0.2$	$\tau = 0.4$	$\tau = 0.6$	$\tau = 0.8$
90%	5.357	5.373	5.416	5.590	5.868
95%	7.150	7.253	7.468	8.061	9.396
99%	11.672	12.220	13.080	15.764	23.526
99.73%	15.754	16.821	18.611	24.173	41.123

Under joint normality, it can be shown that the exact distribution of

$$\frac{m^2 - mp}{p(m+1)(m-1)} T^2$$

is F with degrees of freedom p and $m-p$. The exact upper control limit (UCL) for T^2 with level α is then

$$\mathrm{UCL}_\alpha = \frac{p(m+1)(m-1)}{m^2 - mp} F_{1-\alpha;\,p,m-p}\,, \qquad (51.30)$$

where $F_{1-\alpha;\,p,m-p}$ is the $100(1-\alpha)$ percentile of an F distribution with p and $m-p$ degrees of freedom. In this example, $m = 30$, $p = 2$. The exact upper control limit for T^2 with level α is then

$$\begin{aligned}\mathrm{UCL}_\alpha &= 2(30+1)(30-1)/[30^2 - 2(30)]F_{1-\alpha;2,28} \\ &= 2.14 F_{1-\alpha;2,28}\,.\end{aligned}$$

With $\alpha = 0.9973$, the control limit UCL = 15.75.

When the true copula is a Clayton copula but is misspecified as a normal copula, the control limit in (51.30) can be inaccurate and hence misleading. By comparing the contours of a normal copula model with those of a Clayton copula model in Fig. 51.2, one can conjecture that, if the true copula is a Clayton copula, then $\Pr(T^2 > \mathrm{UCL}_\alpha)$ will be greater than its nominal level α, because the bivariate density with the Clayton copula is more concentrated on the lower-left part of the plot than the bivariate normal density. In other words, in order to maintain the control level α, one needs to increase the UCL of the T^2 chart. This difference obviously depends on the sample size m and the association parameter of the true Clayton copula. For a given sample size m and a Kendall's τ value, which determines the association strength of a Clayton copula, the control limit of T^2 can be obtained by simulation. Table 51.2 compares the 90%, 95%, 99%, and 99.73% percentiles of T^2 when the true copula is normal and when the true copula is Clayton. The percentiles under Clayton copulas are obtained from 100 000 simulations. The true Clayton copulas are parameterized to give Kendall's τ values 0.2, 0.4, 0.6, and 0.8. From Table 51.2, one observes that the simulated percentiles of T^2 are greater than those based on the F distribution under the normal assumption. The control region based on the normal assumption is smaller than expected, which will result in investigating the process more often than necessary when the process is actually in control. The difference increases with the strength of the association.

This example illustrates that a non-normal joint distribution may have an important influence on the control limit of the widely used T^2 chart, even when both the margins are normals. The T^2 statistic still measures the deviance from the target, but its distribution is unknown under the non-normal model. A comprehensive investigation of multivariate process control using copula is a future research direction.

51.4.2 Degradation Analysis

Performance degradation data has repeated measures over time for each test unit (see for example *Meeker* and *Escobar* [51.40] Chap. 13). These repeated measures on the same unit are correlated. There is a voluminous statistical literature on the analysis of repeated mea-

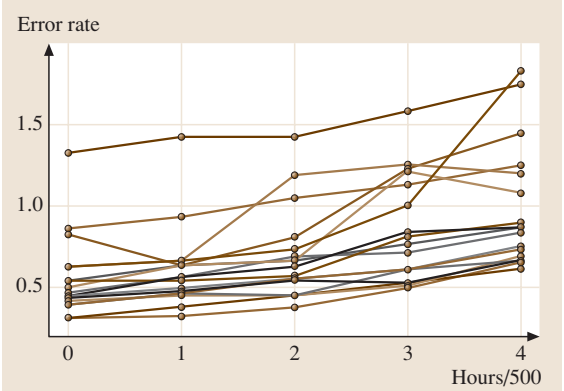

Fig. 51.5 Error rates ($\times 10^5$) of 16 magneto-optic data-storage disks measured every 500 h

Table 51.3 IFM fit for all the margins using normal and gamma distributions, both parameterized by mean and standard deviation. Presented results are log-likelihood (Loglik), estimated mean, and estimated standard deviation (StdDev) for each margin under each model

Time in units of 500 h	Normal margins			Gamma margins		
	Loglik	Mean	StdDev	Loglik	Mean	StdDev
0	−0.484	0.565	0.062	2.568	0.565	0.054
1	−0.526	0.617	0.063	2.538	0.617	0.054
2	−2.271	0.709	0.070	−0.125	0.709	0.064
3	−4.441	0.870	0.080	−3.269	0.870	0.078
4	−6.996	1.012	0.094	−5.205	1.012	0.087

surements (see, for example, *Davis* [51.41]. Analysis of such data has been implemented in popular statistical softwares, for example, `PROC MIXED` of the SAS system [51.42] and the `nlme` package [51.43] for `R` and `Splus`. Continuous response variables are generally assumed to be normally distributed and a multivariate normal distribution is used in likelihood-based approaches. The following example shows that a multivariate gamma distribution with normal copula can provide a much better fit to the data than a multivariate normal distribution.

Degradation data on block error rates of 16 magneto-optic data storage disks are collected every 500 h for 2000 h at 80 °C and 85% relative humidity [51.44]. Figure 51.5 shows these error rates at all five time points. A degradation analysis often needs to fit a curve for the degradation trend in order to allow predictions at unobserved time points. Before choosing a curve to fit, we first carry out exploratory data analysis using the two-step IFM method to look into parametric modeling for each margin and copula separately.

Separate parametric fits for each margin is the first step of the IFM approach in Sect. 51.4. Two parametric models for each margin are used: normal and gamma. To make the parameters comparable across models, the gamma distribution is parameterized by its mean μ and standard deviation σ, giving a density function of

$$f(x;\mu,\sigma)=\frac{1}{\Gamma(\alpha)\beta^{\alpha}}x^{\alpha-1}e^{-\frac{x}{\beta}}\,, \tag{51.31}$$

where $\alpha=\mu^2/\sigma^2$ and $\beta=\sigma^2/\mu$. Table 51.3 summarizes the separate parametric fits for each margins using normal and gamma distributions. For all the margins, the gamma distribution fit yields higher log-likelihood than the normal distribution fit. The estimated mean from both models are the same for the first three digits after the decimal point. The estimated standard deviation is noticeably lower in the gamma model, especially at earlier time points where the data are more skewed and heavier-tailed. These estimates are consistent with the descriptive statistics of each time point, suggesting that the mean error rate is increasing over time, and their standard errors is increasing with the mean level.

Given the parametric fit for each margins, we can explore copula fitting in the second step of IFM. Due to the small number of observations, we choose single-parameter normal copulas with three dispersion structures: AR(1), exchangeable, and Toeplitz. In particular, with $p=5$, the dispersion matrices with parameter ρ under these structures are, respectively,

$$\begin{pmatrix} 1 & \rho & \rho^2 & \rho^3 & \rho^4 \\ \rho & 1 & \rho & \rho^2 & \rho^3 \\ \rho^2 & \rho & 1 & \rho^2 & \rho^2 \\ \rho^3 & \rho^2 & \rho & 1 & \rho \\ \rho^4 & \rho^3 & \rho^2 & \rho & 1 \end{pmatrix}, \quad \begin{pmatrix} 1 & \rho & \rho & \rho & \rho \\ \rho & 1 & \rho & \rho & \rho \\ \rho & \rho & 1 & \rho & \rho \\ \rho & \rho & \rho & 1 & \rho \\ \rho & \rho & \rho & \rho & 1 \end{pmatrix}, \text{ and}$$

$$\begin{pmatrix} 1 & \rho & & & \\ \rho & 1 & \rho & & \\ & \rho & 1 & \rho & \\ & & \rho & 1 & \rho \\ & & & \rho & 1 \end{pmatrix}. \tag{51.32}$$

Table 51.4 summarizes the log-likelihood and the estimated association parameter ρ for the given estimated margins in Table 51.3. Note that the log-likelihood values are not comparable across models with different margins because the data being used in the estimation are different. They are comparable when the modeled margins are the same. For both normal margins and gamma margins, the AR(1) structure gives the highest log-likelihood value. The estimated parameter is about 0.9, indicating high dependence among repeated measurements.

Table 51.4 also presents the normal copulas estimation using the CML method. No parametric distribution is assumed for each margin. The empirical distribution is used to transform the observations of each margin

Table 51.4 IFM and CML fit for single-parameter normal copulas with dispersion structures: AR(1), exchangeable, and Toeplitz

Dispersion structure	IFM fit				CML fit	
	Normal margins		Gamma margins		Empirical margins	
	Loglik	$\hat{\rho}$	Loglik	$\hat{\rho}$	Loglik	$\hat{\rho}$
AR(1)	39.954	0.917	66.350	0.892	10.380	0.964
Exchangeable	38.618	0.868	62.627	0.791	9.791	0.942
Toeplitz	23.335	0.544	39.975	0.540	5.957	0.568

into uniform variables in [0, 1], which are then used in (51.28). The CML fit also shows that the AR(1) structure gives the highest log-likelihood and that the within-disk dependence is high. Based on these exploratory analysis, the AR(1) structure is used for the dispersion matrix of normal copula in an exact ML analysis.

We now present the exact ML estimation of a degradation model. For the sake of simplicity, we use a linear function of time to model the mean $\mu(t)$ and a linear function of $\mu(t)$ to model the logarithm of the standard deviation $\sigma(t)$. That is,

$$\mu(t) = \phi_0 + \phi_1 t, \tag{51.33}$$

$$\log \sigma(t) = \psi_0 + \psi_1 [\mu(t) - 1.0] , \tag{51.34}$$

where ϕ_0, ϕ_1, ψ_0, and ψ_1 are parameters, and the function of $\log \sigma(t)$ is centered at 1.0 for easier prediction of the variance at higher error rates. Two parametric models are considered for the repeated error rates: (1) multivariate normal and (2) multivariate gamma via a normal copula. Note that the two models both use the normal copula. The marginal distributions of the two models at time t are both parameterized by mean $\mu(t)$ and standard deviation $\sigma(t)$ for comparison purpose. A similar parameterization was used in *Lambert* and *Vandenhende* [51.45] and *Frees* and *Wang* [51.7].

Table 51.5 summarizes the maximum-likelihood estimate of the parameters and their standard errors for both models. These estimates for both marginal parameters and the copula parameter are virtually the same or very close to each other. However, the standard errors of these estimates are noticeably smaller in the multivariate gamma model. The maximized log-likelihood from the gamma model is much higher than that from the normal model. Given that both models have the same number of parameters, the multivariate gamma distribution fits the data much better.

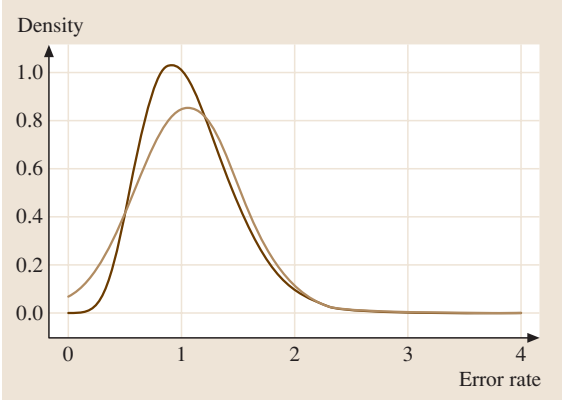

Fig. 51.6 Predictive density of disk error rate at 2500 h. The *dark line* is from the gamma model; the *gray line* is from the normal model

The difference between the two models can also be illustrated by their predictive density of the error rate at 2500 h. Figure 51.6 presents the densities of the error rate at 2500 h using the estimated mean $\mu(2500)$ and

Table 51.5 Maximum-likelihood results for the disk error-rate data. Parameter estimates, standard errors and log-likelihood are provided for both the multivariate normal model and the multivariate gamma model with a normal copula. The second entry of each cell is the corresponding standard error

Model	Marginal parameters				Copula parameter	Loglik
	Mean		StdDev.			
	ϕ_0	ϕ_1	ψ_0	ψ_1	ρ	
Normal	0.564	0.099	−0.849	1.439	0.899	34.719
	0.057	0.019	0.262	0.557	0.034	
Gamma	0.564	0.101	−0.986	1.383	0.900	48.863
	0.051	0.015	0.185	0.442	0.033	

$\sigma(2500)$ obtained with $\hat{\phi}_0$, $\hat{\phi}_1$, $\hat{\psi}_0$, and $\hat{\psi}_1$. The normal model gives mean 1.058 and standard deviation 0.465, while the gamma model gives mean 1.070 and standard deviation 0.411. Although the mean values are close, the gamma model gives a small standard deviation and captures the skewness and long tail of the data.

51.5 Conclusion

This chapter reviews multivariate modeling with copulas and provides novel applications in engineering. Multivariate distribution construction using copulas and their statistical inferences are discussed in detail. Engineering applications are illustrated via examples of bivariate process control and degradation analysis, using existing data in the literature. Copulas offer a flexible modeling strategy that separates the dependence structure from the marginal distributions. Multivariate distributions via copula apply to a much wider range of multivariate scenarios than the traditionally assumed multivariate normal distribution. A publicly available R package has been developed to promote the research on copulas and their applications.

Some important topics about copulas are not discussed in this chapter. The survival function is of great concern in failure-time data analysis. Similarly to (51.5), a multivariate survival function can be constructed via a copula with

$$S(x_1, \ldots, x_p) = C[S_1(x_1), \ldots, S_p(x_p)] ,$$

where S is the joint survival function and $S_i(t) = 1 - F(t)$ is the i-th marginal survival function, $i = 1, \ldots, p$. In this setting C is called a survival copula. Censoring presents an extra difficulty for multivariate failure-time data analysis. *Georges* et al. [51.46] gives an excellent review on multivariate survival modeling with copulas. This chapter has focused on parametric copula models. Standard inferences of the maximum-likelihood method can be applied under the usual regularity conditions. However, which copula to choose and how well it fits the data are important practical problems. Diagnostic tools, particularly graphical tools, can be very useful. There are not many works in this direction; some recent ones are *Wang* and *Wells* [51.11] and *Fermanian* [51.47].

Copulas have had a long history in the probability literature [51.17]. Recent development and application in insurance, finance and biomedical research have been successful. With this chapter, it is hoped to encourage engineering researchers and practitioners to stimulate more advancement on copulas and seek more applications.

51.A Appendix

51.A.1 The R Package Copula

Overview

Software implementation is very important in promoting the development and application of copula-based approaches. Unfortunately, there are few software packages available for copula-based modeling. One exception is the `finmetrics` module [51.48] of `Splus` [51.49]. For an array of commonly used copulas, the `finmetrics` module provides functions to evaluate their CDF and PDF, generate random numbers from them, and fit them for given data. However, these functionalities are limited because only bivariate copulas are implemented. Furthermore, the software is commercial. It is desirable to have an open-source platform for the development of copula methods and applications.

R is a free software environment for statistical computing and graphics [51.14]. It runs on all platforms, including Unix/Linux, Windows, and MacOS. Cutting-edge statistical developments are easily incorporated into R by the mechanism of contributed packages with quality assurance [51.50]. It provides excellent graphics and interfaces easily with lower-level compiled code such as C/C++ or FORTRAN. An active developer–user interaction is available through the R-help mailing list. Therefore, it is a natural choice to write an R package for copulas.

The package `copula` [51.13] is designed using the object-oriented feature of the S language [51.51]. It is publicly available at the Comprehensive R Archive Network [CRAN, `http://www.r-project.org`]. S4 classes are created for elliptical copulas and Archimedean copulas with arbitrary dimension; the extreme-value copula class is still to be implemented at the time of writing. For each copula family, methods of density, distribution, and random-number generator are implemented. For visualization, methods of contour and perspective plots are provided for bivariate copulas.

More facilities, such as extreme-value copulas, association measures and tail dependence measures, will be included in future releases of the package.

Illustration

The package `copula` depends on the contributed packages `mvtnorm`, `scatterplot3d`, and `sn`, taking advantages of the existing facilities in these packages that are relevant. The package needs to be loaded before using:

```
> library(copula)
```

The package is well documented following the requirement of the `R` project [51.50]. A list of help topics can be obtained from:

```
> library(help = copula)
```

We illustrate the features of the package from the following aspects by examples.

Constructing copula objects. An object of class `normalCopula` can be created by

```
> mycop1 <- ellipCopula(family =
"normal", param = c(0.707, 0.5,
0.2), dim = 3, dispstr = "un").
```

The created object `mycop1` is of class `normalCopula`, which inherits `ellipCopula` and `copula`. It has dimension three, with an `unstructured` dispersion matrix

$$\begin{pmatrix} 1.000 & 0.707 & 0.500 \\ 0.707 & 1.000 & 0.200 \\ 0.500 & 0.200 & 1.000 \end{pmatrix}.$$

An object of class `tCopula` can be created similarly, with an extra argument for the degrees of freedom, `df`:

```
> mycop2 <- ellipCopula(family =
"t", param = c(0.9, 0.5, 0.2),
df = 5, dim = 3, dispstr = "un")
```

Examples of objects of Archimedean copulas can be created by:

```
> mycop3 <- archmCopula(family =
"clayton", param = 2, dim = 3)
> mycop4 <- archmCopula(family =
"frank", param = 5.736, dim = 3)
> mycop5 <- archmCopula(family =
"gumbel", param = 2, dim = 3)
```

Constructing Multivariate Distribution via Copulas. An object of multivariate distributions via copulas can be constructed by specifying the copula and its marginal distributions. For example:

```
> mymvd1 <- mvdc(copula =
normalCopula(0.5, dim = 2),
margins = c("norm", "gamma"),
paramMargins = list(list(mean = 0,
sd = 2), list(shape = 2, rate = 2)))
```

The created object `mymvd1` is of class `mvdc`. It is a bivariate distribution constructed via a normal copula. One of the marginal distributions is normal with mean 0 and standard deviation 2. The other marginal distribution is gamma with shape 2 and rate 2.

Density, Distribution, and Simulation. The density and distribution of an object of `copula` class are obtained through the generic method functions `dcopula` and `pcopula`. These functions for an object of the `mvdc` class are obtained through the method functions `dmvdc` and `pmvdc`. The density method `dmvdc` for an `mvdc` object can be used to construct the likelihood for a given dataset.

For Archimedean copulas, obtaining the density function by differentiating the copula can be tedious. The `copula` package provides expressions for the PDF from symbolic calculations. The following code returns the CDF and PDF expressions of a Clayton copula with parameter α:

```
> mycop3@exprdist$cdf
(1 + (u1^(-alpha) - 1 + u2^(-alpha) -
1 + u3^(-alpha) - 1))^(-1/alpha)

> mycop3@exprdist$pdf
(1 + (u1^(-alpha) - 1 + u2^(-alpha) -
1 + u3^(-alpha) - 1))^((((-1/alpha)
- 1) - 1) - 1) * ((((-1/alpha) - 1)
- 1) * (u3^((-alpha) - 1) * (-alpha)))
* (((-1/alpha) - 1) * (u2^((-alpha)
- 1) * (-alpha))) * ((-1/alpha)
* (u1^((-alpha) - 1) * (-alpha)))
```

These can be exported into other programming languages with little or minor modification.

The methods `rcopula` and `rmvdc` generate random numbers from a `copula` or `mvdc` object. The following code generates five observations from `mymvd1` and evaluates the density and distribution at these points:

```
> n <- 5
> x <- rmvdc(mymvd1, n)
> x
          [,1]       [,2]
[1,] -2.7465647 0.6404319
[2,] -1.2674922 0.2707347
[3,] -1.8268522 0.4869647
[4,] 0.2742349 1.1763891
[5,] 2.5947601 1.6410892
```

```
> cbind(dmvdc(mymvd1, x), pmvdc
(mymvd1, x))
           [,1]       [,2]
[1,] 0.06250414 0.06282100
[2,] 0.14514281 0.06221677
[3,] 0.13501126 0.09548434
[4,] 0.10241486 0.45210057
[5,] 0.03698266 0.78582431
```

Bivariate Contour and Perspective Plot.
The `contour` and `persp` methods are implemented for the `copula` and `mvdc` classes. The following code examples draw the contours and perspective plot of the CDF for a bivariate t copula with correlation $\rho = 0.707$:

```
> contour(tCopula(0.707), pcopula)
> persp(tCopula(0.707), pcopula)
```

To draw these plots for an `mvdc` object, the ranges of the margins need to be specified:

```
> persp(mymvd1, dmvdc, xlim =
c(-4, 4), ylim = c(0, 3))
> contour(mymvd1, dmvdc, xlim =
c(-4, 4), ylim = c(0, 3))
```

52. Queuing Theory Applications to Communication Systems: Control of Traffic Flows and Load Balancing

With the tremendous increase in traffic on modern communication systems, such as the World Wide Web, it has made it imperative that users of these systems have some understanding not only of how they are fabricated but also how packets, which traverse the links, are scheduled to their hosts in an efficient and reliable manner. In this chapter, we investigate the role that modern queueing theory plays in achieving this aim. We also provide up-to-date and in-depth knowledge of how queueing techniques have been applied to areas such as prioritizing traffic flows, load balancing and congestion control on the modern internet system.

The Introduction gives a synopsis of the key topics of application covered in this chapter, i. e. congestion control using finite buffer queueing models, load balancing and how reliable transmission is achieved using various transmission control protocols.

In Sect. 52.1, we provide a brief review of the key concepts of queueing theory, including a discussion of the performance metrics, scheduling algorithms and traffic variables underlying simple queues. A discussion of the continuous-time Markov chain is also presented, linking it with the lack of memory property of the exponential random variable and with simple Markovian queues.

A class of queues, known as multiple-priority dual queues (MPDQ), is introduced and analyzed in Sect. 52.2. This type of queues consists of a dual queue and incorporates differentiated classes of customers in order to improve their quality of service. Firstly, MPDQs are simulated under different scenarios and their performance compared using a variety of performance metrics. Secondly, a full analysis of MPDQs is then given using continuous-time Markov chain. Finally, we show how the expected waiting times of different classes of customers are derived for a MPDQ.

Section 52.3 describes current approaches to assigning tasks to a distributed system. It highlights the limitations of many task-assignment policies, especially when task sizes have a heavy-tailed distribution. For these so called heavy-tailed workloads, several size-based load distribution policies are shown to perform much better than classical policies. Amongst these, the policies based on prioritizing traffic flows are shown to perform best of all.

Section 52.4 gives a detailed account of how the balance between maximizing throughput and congestion control is achieved in modern communication networks. This is mainly accomplished through the use of transmission control protocols and selective dropping of packets. It will be demonstrated that queueing theory is extensively applied in this area to model the phenomena of reliable transmission and congestion control.

The final section concludes with a brief discussion of further work in this area, an area which is growing at a rapid rate both in complexity and level of sophistication.

Queues, wherever they arise, are unfortunately an intrinsic part of human existence. We queue for items that are essential in our daily life as well as in situations that some would regard as an annoyance, although they are necessary, such as having to wait at a traffic intersection. On another level, modern communication systems, such as the internet, are under continuous strain in a world where it is not only demand for information that is increasing, but its speed of delivery. Given that some of this information has to be delivered over vast distances, is of varying sizes and is in competition for bandwidth with other traffic in the network, it has become essential in modern communication that traffic congestion be controlled, losses minimized and inefficient operations eradicated.

It has long been recognized that the problem of long delays suffered in many of our daily activities might be solved if one could model queues in all their manifestations. As a result, queueing theory was developed in the early part of the last century using tools and techniques from the well-established fields of probability and statistics to provide a systematic and general approach to understanding queueing phenomena. The earliest queueing applications are to problems of telephone congestion (pioneered by researchers such as *Erlang* [52.1] and *Palm* [52.2]). Subsequently, the subject was further developed and enriched with significant breakthroughs by researchers such as F. Pollaczek, A. Y. Khinchine, D. G. Kendall, D. R. Cox, J. R. Jackson, F. P. Kelly and many others. Queueing theory has been used to model many physical systems that involve delays, and currently, an important application is in modeling computer systems and communication networks.

This chapter considers the application of queueing theory to two critical issues of concern in modern communication systems, namely the problems of traffic flow control and load balancing, especially as they pertain to modern internet traffic. We begin in Sect. 52.1 with a brief review of basic queueing theory and then proceed to discuss the key topics of this paper in Sects. 52.2–52.4. The next three subsections provide a brief synopsis of these topics.

52.0.1 Congestion Control Using Finite-Buffer Queueing Models

Various scheduling algorithms have been introduced with the aim of improving quality of service (QoS) to customers. A wide variety of scheduling methods that aim to reduce congestion in communication systems have been studied. Many differentiate customers through marking and dropping processes (e.g. [52.3,4]). Others use time-marking and derivatives of this to allocate a degree of fairness in service, such as self-clocked fair queueing (SCFQ) and credit-based fair queueing (CBFQ) (e.g. [52.5,6]). A dual -queue length threshold (DQLT) [52.7] was used to divide real-time and non-real-time traffic to separate queues. Weighted round-robin (WRR) was looked at in [52.8].

In [52.9], a dual-queue (DQ) scheme was proposed to give better QoS to most customers at the expense of a few, rather than give poor QoS fairly to all customers. The dual-queue control scheme has two queues with finite space: namely the primary queue, which feeds into the service center, and the secondary queue, which acts as a waiting room when the primary queue is full (refer to Fig. 52.1). Upon arrival, a customer finding the primary

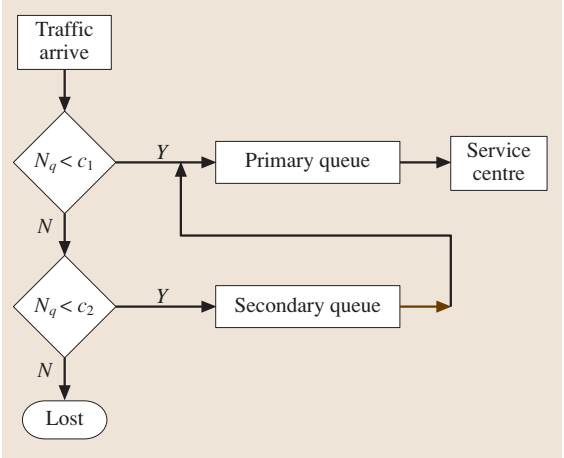

Fig. 52.1 The dual queue; N_q is the queue size, c_1 (c_2) is the primary (secondary) queue's buffer size

queue full waits in the secondary queue, if there is room. When a space becomes vacant in the primary queue, the customer at the front of the secondary queue joins the end of the primary queue. *Hayes* et al. [52.9] analyzed the delay characteristics of the dual queue against standard schemes such as first-come first-served (FCFS) and a modified deficit round-robin (DRR) technique [52.10], and demonstrated distinct advantages using the dual-queueing scheme. This work was extended to a wireless local area network [52.11] where minor modifications were made to the DQ and it was shown to outperform standard round-robin scheduling.

The multiple-priority dual queues (MPDQ), introduced in [52.12], builds upon this DQ scheme. The MPDQ introduces different classes into this scheme with the aim of providing better service to high-class customers without completely penalizing low-class ones. This is possible, not only because of the priority placed on customers' services, but also due to the MPDQ's partitioned queue structure. The MPDQ is especially relevant in the internet engineering task force (IETF) integrated services processes or differentiated services architecture. The MPDQ scheduling discipline provides a simple and effective mechanism for scheduling in these types of architecture.

52.0.2 Task Assignment Policy for Load Balancing

The usage of a *cluster* of commodity computers has become more prevalent in recent times. Such clusters are popular due to their scalable and cost-effective nature – often providing more computing resources at a significantly lower cost than traditional mainframes or supercomputers. They also provide other benefits, such as redundancy and increased reliability. The applications of such systems include supercomputing clusters and web-page serving for high-profile and high-volume websites, among other applications.

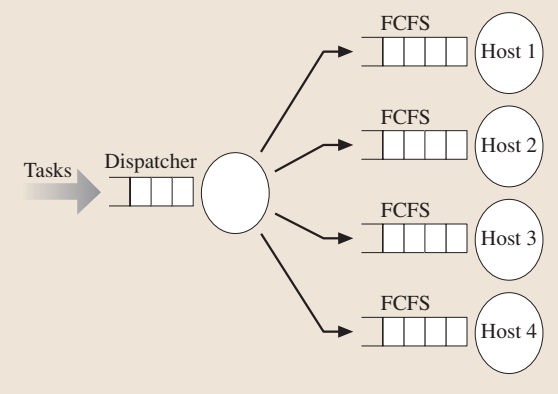

Fig. 52.2 Distributed server model

Figure 52.2 illustrates a common cluster configuration. Tasks, or *jobs* arrive at a central dispatcher, and are dispatched to hosts according to a *task assignment policy*. When a task arrives at the dispatcher, it is placed in a queue, waiting to be serviced in FCFS order.

The decision regarding which task assignment policy to utilize can significantly affect the perceived performance and server throughput. A poorly chosen policy could assign tasks to already overloaded servers, while leaving other servers idle, thus drastically reducing the performance of the distributed system. One major aim of a task assignment policy is to distribute tasks such that all available system resources are utilized and the load on the system is balanced. However, the ideal choice of task assignment policy is still an open question in many contexts.

The cluster configuration depicted in Fig. 52.2 is well suited to analysis via queuing theory. Equipped with some basic knowledge about our system of interest, such as the arrival and service distributions, we can easily obtain the expected performance metrics of the system. With these metrics, we can evaluate the performance of different task assignment policies, and make an informed judgment regarding which policy is best to employ.

52.0.3 Modeling TCP Traffic

The transmission control protocol (TCP) is a protocol that is widely used on the internet to provide reliable end-to-end connections. Reliability is achieved by verifying that each packet that enters the network is received correctly at the other end through the use of a return packet called an acknowledgment (ACK). It also provides congestion control, which attempts to prevent congestion collapse. Congestion collapse would occur if the amount of traffic entering the network greatly exceeded the capacity of the network. Congestion controls allows the amount of traffic entering the network to be controlled at the source.

The TCP congestion control mechanism uses a sliding window called a *congestion window* to control the rate at which packets are transmitted into the network. A congestion window has a size W measured in packets (actually its size is in bytes but it is simpler to think in terms of packets). This window is a segment of a larger buffer which starts at slot x and finishes at slot $x + W$. For example, a window of size $W = 3$ packets in a buffer

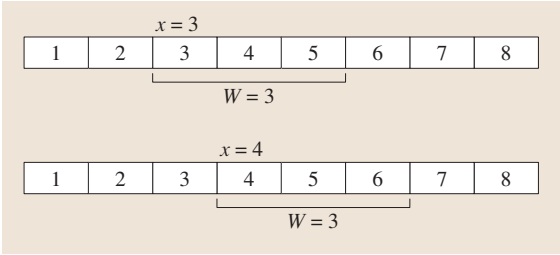

Fig. 52.3 Congestion window

of size eight slots could span slots either 1–3, 2–4, 3–5 and so on. Any packet within this window can be transmitted immediately into the network. When a packet is acknowledged by the receiving end, the window can slide across one place, allowing the next packet within the segment to be transmitted. For example if the window spans slot 3–5 then the window can slide to 4–6 and the packet can be transmitted in slot 6 when an ACK for packet 3 arrives (Fig. 52.3). This window size limits the maximum number of packets that can be in the network at any point in time.

The window size W changes over time as acknowledgements are received or lost. Queueing theory provides the ideal tool for analyzing the flow of packets within a network with TCP control, measuring its throughput and losses as packets are sent through a communication network.

52.1 Brief Review of Queueing Theory

The primary objective of queueing theory is to provide a systematic method of formulating, analyzing and predicting the behavior of queues. For example, customers waiting to be served at a store's checkout counter, cars waiting at an intersection controlled by traffic signals, telephone calls waiting to be answered and client request for an internet connection are a few of the countless phenomena that can be analyzed using standard queueing theory. The amount of literature devoted to queues and related problems is large and continues to grow at an exponential rate, especially since the advent of the World Wide Web. Published in 1961, the classic text on queueing theory, *Saaty* [52.13], has a list of over 900 papers in its bibliography. Since then, there have been many good texts on a broad range of queueing models, among which the following is a very short list of titles cited for their excellent coverage of key concepts and relevant examples: *Asmussen* [52.14], *Allen* [52.15], *Gross* and *Harris* [52.16], *Jaiswal* [52.17], *Kelly* [52.18] and *Kleinrock* [52.19, 20].

The basic queue is portrayed in Fig. 52.4. *Customers* arrive to the service facility from the environment and queue for service if there is someone ahead being serviced. After a length of time waiting, the customer is finally served, after which he departs from the queue. In this chapter, customers arrive as *single* units and not in *batches* or in *bulks*. Also, in the context of communication systems, the term *packets* will often be used interchangeably with *customers*. Each packet will be assumed to have a fixed uniform size; although in many systems packet sizes do vary, this does not affect the overall results unduly.

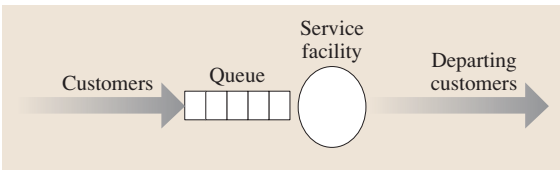

Fig. 52.4 The basic queue

The representation in Fig. 52.4 leaves out much of the internal working of the service facility, neither does it describes how customers arrive into the system. Mathematically, the process can be described more precisely in the following way. Customers arrive from an *input source* requiring service. The n-th customer C_n arrives at time T_n, $n = 1, 2, \ldots$, where $0 < T_1 < T_2 < \ldots$. The inter-arrival times $\tau_n = T_{n+1} - T_n$, $n = 1, 2, \ldots$ are usually assumed to form a *renewal process*, i. e. they are independent and identically distributed random variables. Customer C_n requires a service time of duration s_n and these service times for different customers are also independent and identically distributed random variables. In addition, the processes $(\tau_n)_{n\geq 1}$ and $(s_n)_{n\geq 1}$ are also assumed to be statistically independent of each other.

52.1.1 Queue Characteristics

The characteristics that determine a basic queues are

- A: arrival pattern of customers;
- B: service pattern of customers;
- C: the number of servers;

- D: system capacity or buffer size;
- E: service discipline.

The representation of a queue using the notation $(A/B/C/D)$ with D often omitted is due to David Kendall and is known as Kendall's notation.

Arrival Pattern

This is the distribution of the renewal sequence $(\tau_n)_{n\geq 1}$. Some common distributions are

$$\text{Exponential M:}$$
$$f(t) = \lambda\, e^{-\lambda t}\,,\ t \geq 0\,,\ \lambda > 0\,.$$
$$\text{Deterministic } D$$
$$\text{Erlangian with } k \text{ stages}$$
$$E_k : f_k(t) = \frac{\lambda(\lambda t)^{k-1}\, e^{-\lambda t}}{(k-1)!}\,,\ t \geq 0\,, k = 1, 2, \ldots\,.$$

If the exact distribution is unspecified, $A = GI$ for *general and independent*. Note that the symbol M in the case of the exponential distribution stands for Markov due to the fact that certain stochastic processes in queues, where either the inter-arrival distribution or service distribution are exponentially distributed, have the Markov property (cf. Sect. 52.1.4). Markovian queues are analytically more tractable than other general types of queues. We note also that arrivals to a queue could occur in bulks with the size of each bulk fixed or distributed as a random variable. Bulk and related queues are extensively covered in the book by *Chaudhry* and *Templeton* [52.21].

Service Pattern

This is the distribution of the sequence $(s_n)_{n\geq 1}$. In the internet system, the distribution is also called the *task size distribution* since it refers to the distribution of the sizes of files that are requested by random arrivals of requests to the internet. The most common distributions are the same ones given for the arrival pattern. However, for many communication systems such as the World Wide Web, so called heavy-tailed distributions are more appropriate for file sizes than the exponential distribution (cf. Sect. 52.2). Similar to the arrival pattern, service could also be implemented in bulk, i. e. instead of customers being served as single units, they are served in bulks of fixed or arbitrary sizes.

System Capacity

Traditional queueing theory assumes there is no limit on the number of customers allowed into the service facility. Obviously this is an approximation of what occurs in reality where there *is a limit* to the number allowed into *any* system. In communication networks for example, buffer sizes associated with links between service nodes are finite and packets arriving to a saturated link are *dropped*. This dropping of packets is very commonly employed in modern active queue management (cf. Sect. 52.4).

Number of Servers

The service facility is manned by one, or often by more than one, server who provide service to customers. In communication networks where there are no visible servers, the servers are replaced by the notion of *bandwidth*, which refers to the portion of a transmission link (in megabytes/second, MBps) that a class of packets is allocated. The larger the bandwidth allocated, the faster these packets will traverse the link.

Service Disciplines

Customers are selected for service by a variety of rules called *service disciplines* or *scheduling algorithms*. The most common service discipline is *first-come first-served* (FCFS) where the customer who arrives first is served first. However, many other types of scheduling algorithms are used in modern communication such as last-in first-out (LIFO), SIRO (service in random order) and prioritized service. A *priority queue discipline* is one where the servers specify certain rules for serving customers according to their classes [52.17]. This is usually implemented with *preemption* and *non-preemption*.

Preemption: A preemptive priority scheme is where a customer of a higher class interrupts and ejects a lower-classed customer from service. Three types of preemptive schemes are available: *preemptive–resume, preemptive repeat–identical* and *preemptive repeat–different*. The preemptive–resume scheme allows preempted customers to continue service from their initial point of interruption. The other two named schemes require customers to start again after preemption. The repeat–identical scheme allows the customer to begin again with the full amount of service time required, whereas the repeat–different scheme gives a random service time which does not take into account the time lost. Customers of the same class are served on a FCFS basis.

Non-preemption: The non-preemptive scheme is where a customer of a higher class must wait for a lower-classed customer to complete service if the latter was found to be in service upon the arrival of the higher-class customer.

One of the key objectives of this chapter is to highlight how different service disciplines have been used in communication systems and to compare their performance. We remark that the most mathematically

tractable system is the system $(M/M/c/K)$ with *FCFS* scheduling. Queueing systems with either $A = M$ and $B = GI$ or $A = GI$ and $B = M$ can be analyzed by the method of embedded Markov chains [52.22]. For more general systems, analytical results are often difficult or impossible to obtain. Such systems are conveniently solved using simulation techniques.

52.1.2 Performance Metrics and Traffic Variables

Most queueing models of communication systems assume that the prevailing conditions and constraints on the underlying processes are such that an *equilibrium steady state* is reached and one is dealing with a stationary situation. The analyses can then dispense with the time factor t. This situation will occur if the underlying process is *ergodic*, i. e. aperiodic, recurrent and non-null [52.19], and the system has been in operation for a long time.

The following is a glossary of some performance and traffic variables associated with the simple queue:

- λ : mean arrival rate of customers to the queue. This is usually assumed to be a constant, although it is generally a function of time t when the arrival process is nonstationary.
- μ : mean service rate of customers. This has the same qualification as for λ.
- ρ : traffic intensity. Defined by $\rho = \frac{\lambda}{p\mu}$ for a single class of customer arriving to a queue manned by p servers.
- L_q : the number of customers in the queue in the equilibrium state.
- L_s : the number of customers in the system in the equilibrium state, i. e. which also includes the customers being served.
- W_q : waiting time of each customer in the queue in the equilibrium state.
- W_s : waiting time of each customer in the system in the equilibrium state. In communication systems, W_s is also referred to as the *flow time*. Note that $E(W_s) = E(W_q) + E(X)$, where X is the service time of each customer and $E(\cdot)$ is the expected value operator.
- S : slowdown, defined by $S = W_q/X$. The expected slowdown, $E(S) = E(W_q)E(X^{-1})$ is an important metric in communication systems and measures the expected waiting time of each packet relative to its service requirement. This provides a fairer assessment of the delay suffered by a packet in a queueing system than the waiting time.

The following very useful results, known as Little's formulae, were established as a *folk theorem* for many years until they were shown to be valid by *Little* [52.23]:

$$E(L_q) = \lambda E(W_q)\,,$$
$$E(L_s) = \lambda E(W_s)\,. \tag{52.1}$$

For queues with finite capacity, λ in (52.1) is replaced by the *effective arrival rate* $\lambda_{\text{eff}} = \lambda \times [1 - \Pr(\text{queue full})]$.

52.1.3 The Poisson Process and the Exponential Distribution

Consider the arrival point process $(T_n)_{n\geq 1}$ and let $N(t)$ be defined as follows:

$$N(t) = \#\{n : T_n \in [0, t)\}$$

i. e. the number of arrivals that occur in the time interval $[0, t)$.

Definition 52.1

The point process $N(t)$ is a stationary Poisson process with rate $\lambda > 0$ if it has the following properties:

a) for any sequence of time points $0 = t_0 < t_1 < t_2 \ldots < t_n$, the process increments $N(t_1) - N(t_0)$, $N(t_2) - N(t_1)$, $\ldots$, $N(t_n) - N(t_0)$ are independent random variables;
b) for $s \geq 0$ and $t \geq 0$, the random variable $N(t+s) - N(t)$ has the Poisson distribution

$$P(N(t+s) - N(t) = j) = \frac{(\lambda s)^j \, e^{-\lambda s}}{j!}\,.$$

There is a close relationship between the exponential random variable and the Poisson process. Suppose the renewal sequence $(\tau_n)_{n\geq 1}$ has an exponential distribution with rate λ, i. e.

$$f(t) = \lambda e^{-\lambda t}\,,\ t \geq 0\,.$$

It can easily be shown that T_k has an Erlang distribution with k stages, i. e.

$$f_k(t) = \frac{\lambda(\lambda t)^{k-1} e^{-\lambda t}}{(k-1)!}\,,\ t \geq 0\,.$$

Therefore,

$$\Pr(T_k \leq t) = 1 - \sum_{j=0}^{k-1} \frac{e^{-\lambda t}(\lambda t)^j}{j!} \tag{52.2}$$

and, on using the obvious identity

$$\Pr(T_k \le t) = \Pr(N(t) \ge k) \tag{52.3}$$

we obtain

$$\begin{aligned}\Pr(N(t) = k) &= \Pr[N(t) \ge k] - \Pr[N(t) \ge k+1] \\ &= \Pr(T_k \le k) - \Pr(T_{k+1} \le t) \\ &= \frac{(\lambda t)^k \, \mathrm{e}^{-\lambda t}}{k!}\end{aligned}$$

after applying (52.2). Therefore a renewal sequence with an exponential distribution is a Poisson process. The converse also holds by applying (52.3) and assuming $N(t)$ is a Poisson process.

The Lack of Memory Property of the Exponential Random Variable

Amongst continuous random variables, the exponential random variable has the distinction of possessing the *lack of memory property* (for discrete random variables, the geometric random variable has that property). This property makes analysis of Markovian queues tractable.

The lack of memory property for X states that for any $t > 0$ and $s > 0$,

$$\Pr(X > t+s | X > t) = P(X > s) \, . \tag{52.4}$$

The exponential random variable clearly satisfies (52.4). Therefore, if the time X between consecutive occurrences of a Poisson process has already exceeded t, the chance that it will exceed $s+t$ does not depend on t. Thus the Poisson process *forgets* how long it has been waiting. From (52.4), we also have the following identity

$$\begin{aligned}\Pr(T > t + \Delta t | T > t) &= \mathrm{e}^{-\lambda \Delta t} \\ &= 1 - \lambda \Delta t + o(\Delta t) \, , \end{aligned} \tag{52.5}$$

which implies

$$\begin{aligned}\Pr(T \le t + \Delta t | T > t) &= 1 - \mathrm{e}^{-\lambda \Delta t} \\ &= \lambda \Delta t + o(\Delta t) \, , \end{aligned} \tag{52.6}$$

where $\Delta t \ll t$. Note that (52.5) is the probability of no events within the time interval $(t \, , t + \Delta t)$ given that the time from the last event to the next exceeded t, and (52.6) is the probability of an event within the time interval $(t \, , t + \Delta t)$ given that the time from the last event to the next exceeded t. Therefore, the probability of at least two events within $(t \, , t + \Delta t)$ is

$$1 - [1 - \lambda \Delta t + o(\Delta t)] - [\lambda \Delta t + o(\Delta t)] = o(\Delta t) \, , \tag{52.7}$$

i. e. in a small interval $(t \, , t + \Delta t)$, the Poisson process can increase by at most one occurrence with a non-negligible probability.

52.1.4 Continuous-Time Markov Chain (CTMC)

The theory of Markov process is fundamental in queueing theory and in other branches of applied probability. A comprehensive and authoritative account of the theory can be found in [52.24]. For our purpose, only some rudimentary knowledge of the theory is required and the results here will be presented without proofs.

Definition 52.2

A stochastic process X_t, $t \ge 0$, taking values in a discrete set S, which we may take as the set of non-negative integers, is a standard CTMC if, for any $n = 0, 1, \ldots$ and $t_0 < t_1 < t_2 < \ldots < t_n < t$ and values $i_0, i_1, \ldots, i_n$ and $j \in S$, the following identity holds:

$$\begin{aligned}&\Pr(X_t = j | X_{t_n} = i_n \, , X_{t_{n-1}} = i_{n-1} \, , \ldots \, , X_{t_1} \\ &\quad = i_1 \, , X_{t_0} = i_0) = \Pr(X_t = j | X_{t_n} = i_n) \, . \end{aligned} \tag{52.8}$$

A CTMC is said to be *stationary* if, for all $(i, j) \in S \times S$, the one-step transition probability $\Pr(X_{t+h} = j | X_h = i)$ is independent of h and we denote this probability by $p_{ij}(t)$. One-step transition probabilities for stationary CTMC satisfy:

1. $p_{ij}(t) \ge 0$ for all $(i, j) \in S \times S$ and $t \ge 0$.
2. $\sum_{j \in S} p_{ij}(t) = 1$ for all $i \in S$ and $t \ge 0$.
3. $$\lim_{t \to 0+} p_{ij}(t) = \begin{cases} 1 & \text{if } i = j \\ 0 & \text{if } i \ne j \end{cases} \, .$$
4. (Chapman–Kolmogorov equation)
$$p_{ij}(t+s) = \sum_{k \in S} p_{ik}(t) p_{kj}(s) \, .$$

Theorem 52.1

Let X_t, $t \ge 0$, be a stationary CTMC with transition probability functions $p_{ij}(t)$, $(i, j) \in S \times S$. Then the following (right) derivatives at $t = 0$ exist:

$$\lim_{t \to 0+} \frac{[p_{ii}(t) - 1]}{t} = -q_i$$

$$\text{and} \quad \lim_{t \to 0+} \frac{p_{ij}(t)}{t} = q_{ij} (i \ne j) \, .$$

The parameters q_{ij} and q_i are the *infinitesimal rates* of the CTMC. We note that $0 \le q_i \le \infty$. State i is an *absorbing* state if $q_i = 0$, and it is an *instantaneous* state if $q_i = \infty$. However, q_{ij}, $j \ne i$ is always finite.

Definition 52.3
The matrix $\boldsymbol{A} = (a_{ij})$ where

$$a_{ij} = \begin{cases} -q_i & \text{if } i = j \\ q_{ij} & \text{if } i \ne j \end{cases} \tag{52.9}$$

is called the *infinitesimal generator matrix* $\mathbf{A}$ of the CTMC X_t.

Definition 52.4
A CTMC process is *conservative* if

$$\sum_{j \ne i} q_{ij} = q_i < \infty \text{ for all } i \in S\,. \tag{52.10}$$

The sample path of a conservative CTMC can be described fairly succinctly. If the process is in state i, it remains there for a random time T_i which is exponentially distributed with cumulative distribution

$$\Pr(T_i \le t) = 1 - \mathrm{e}^{-q_i t}\,. \tag{52.11}$$

This is because, by the Markov property (52.8), the probability that the process next jumps to another state depends only on the last recorded state and not on how long it has been in that state. Hence, this lack of memory implies that T_i is an exponential random variable. Furthermore, given that the process is in state i, it next jumps to state $j \ne i$ with probability

$$P_{ij} = \frac{q_{ij}}{q_i}\,. \tag{52.12}$$

Therefore, by considering all situations that could occur, it follows that when $i \ne j$

$$p_{ij}(t) = \sum_{k \ne i} \frac{q_{ik}}{q_i} \int_0^t q_i\, \mathrm{e}^{-q_i s}\, p_{kj}(t-s)\,\mathrm{d}s \tag{52.13}$$

and when $i = j$

$$p_{ii}(t) = \mathrm{e}^{-q_i t} + \sum_{k \ne i} \frac{q_{ik}}{q_i} \int_0^t q_i\, \mathrm{e}^{-q_i s}\, p_{kj}(t-s)\,\mathrm{d}s\,. \tag{52.14}$$

Theorem 52.2
A conservative CTMC satisfies the following system of differential equations called the *forward equations*:

$$p'_{ij}(t) = \sum_{k \ne j} p_{ik}(t) q_{kj} - p_{ij}(t) q_j,\ (i, j) \in S \times S\,. \tag{52.15}$$

If we define the matrix $\boldsymbol{P}(t) = [p_{ij}(t)]$, (52.15) may be concisely expressed as

$$\boldsymbol{P}'(t) = \boldsymbol{P}(t)\boldsymbol{A}\,. \tag{52.16}$$

Let the state distribution of a CTMC X_t be denoted by $\pi(t) = [\pi_i(t)]$, where $\pi_i(t) = \Pr[X(t) = i]$, $i \in S$. Since

$$\pi(t) = \pi(0)\boldsymbol{P}(t)$$

we obtain from (52.16) the equation

$$\pi'(t) = \pi(t)\boldsymbol{A} \tag{52.17}$$

by pre-multiplying both sides of (52.16) with $\pi(0)$.

If the CTMC is ergodic, i. e. aperiodic, recurrent and non-null [52.19], the limit

$$\lim_{t \to \infty} \pi(t) = \bar{\pi}$$

exists and the rate of convergence is exponentially fast [52.24]; $\bar{\pi}$ is known as the *steady-state* or *equilibrium* distribution of the CTMC. Using (52.17), the steady-state distribution is obtained by solving the following system of equations called the *balance equations*:

$$\bar{\pi}\boldsymbol{A} = \boldsymbol{0}\,. \tag{52.18}$$

Birth–Death Processes

A *birth–death process* is a stationary conservative CTMC with state space S, the set of non-negative integers, for which the infinitesimal rates are given by

$$\begin{aligned} q_{n,n+1} &= \lambda_n\,, \\ q_{n,n-1} &= \mu_n\,, \\ q_n &= \lambda_n + \mu_n\,, \\ \text{and } q_{ij} &= 0\,,\ |i-j| \ge 2\,. \end{aligned}$$

A birth and death process can only move to adjacent states, with rates depending only on the state it has moved from (refer to Fig. 52.5). This CTMC is used to model queues where the renewal sequences $(\tau_n)_{n \ge 1}$ and $(s_n)_{n \ge 1}$ are exponential random variables. More

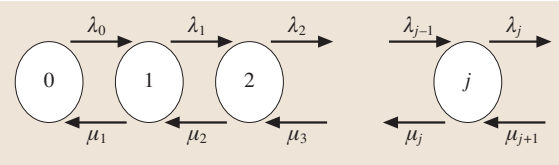

Fig. 52.5 Rate diagram of a birth–death process

specifically, the queueing processes $N_s(t)$ and $N_q(t)$ are birth–death CTMC since they can increase or decrease by 1 with an arrival to or departure from the queueing system, respectively.

From (52.17), the forward equations of the birth–death process take the form

$$\begin{aligned}\pi_0'(t) &= \mu_1\pi_1(t) - \lambda_0\pi_0(t)\,,\\ \pi_j'(t) &= \lambda_{j-1}\pi_{j-1}(t) - (\mu_j+\lambda_j)\pi_j(t)\\ &\quad + \mu_{j+1}\pi_{j+1}(t)\,,\ j\geq 1\,.\end{aligned} \tag{52.19}$$

The solution of (52.19) can be obtained through some ingenious arguments (see e.g. Chap. 4 in [52.13]) but it is much simpler to solve the corresponding balance equations (52.18) for the steady-state distribution $\bar{\pi} = (\pi_0\,,\pi_1\,,\ldots\,,\pi_j\,,\ldots)$, which are:

$$\begin{aligned}\lambda_0\pi_0 &= \mu_1\pi_1\,,\\ (\mu_j+\lambda_j)\pi_j &= \lambda_{j-1}\pi_{j-1} + \mu_{j+1}\pi_{j+1}\,,\ j\geq 1\,.\end{aligned} \tag{52.20}$$

If

$$\sum_{j=0}^{\infty}\frac{\lambda_j\lambda_{j-1}\ldots\lambda_0}{\mu_j\mu_{j-1}\ldots\mu_1} < \infty$$

then (52.20) admits the solution

$$\pi_j = \frac{\lambda_j\lambda_{j-1}\ldots\lambda_0}{\mu_j\mu_{j-1}\ldots\mu_1}\pi_0\,, \tag{52.21}$$

where

$$\pi_0 = \left(1+\sum_{j=0}^{\infty}\frac{\lambda_j\lambda_{j-1}\ldots\lambda_0}{\mu_j\mu_{j-1}\ldots\mu_1}\right)^{-1}\,. \tag{52.22}$$

In the next section, we apply the birth–death process to a very simple queueing model. This is done mainly to illustrate the calculations using the equations displayed in this section as well as to prepare the reader for an analogous but more involved analysis when we come to discuss the MPDQ.

Finite-Buffer Markov Queue (*M*/*M*/*c*/*K*)

This is a very old queueing model with application to telephony and is also commonly used to model other communication systems. Here, it is assumed that the facility can accommodate K customers, including the ones in service, and that once the service facility is full, new arrivals are not allowed in, i. e. they are *lost*. Arrivals to the system are generated according to a Poisson process with rate λ and service time is exponentially distributed with rate μ. There are c servers (or *lines*) where $c \leq K$. From the description of the model, it follows that

$$\lambda_j = \begin{cases}\lambda & \text{for } 0\leq j < K\\ 0 & \text{for } j\geq K\end{cases} \tag{52.23}$$

and

$$\mu_j = \begin{cases}j\mu & \text{for } 0\leq j < c\\ c\mu & \text{for } c\leq j\leq K\,.\end{cases} \tag{52.24}$$

Therefore, (52.21) and (52.22) give

$$\pi_j = \begin{cases}\pi_0\frac{(\rho c)^j}{j!} & \text{for } 0\leq j < c\\ \pi_0\frac{\rho^j c^c}{c!} & \text{for } c\leq j\leq K\,,\end{cases} \tag{52.25}$$

where $\rho = \frac{\lambda}{c\mu}$. Furthermore, applying (52.22), we obtain

$$\pi_0 = \begin{cases}\left(\sum_{j=0}^{c-1}\frac{(c\rho)^j}{j!} + \frac{(c\rho)^c(1-\rho^{K-c+1})}{c!(1-\rho)}\right)^{-1} & \text{if } \rho\neq c\\ \left(\sum_{j=0}^{c-1}\frac{(c\rho)^j}{j!} + \frac{(c\rho)^c(K-c+1)}{c!}\right)^{-1} & \text{if } \rho = c\,.\end{cases} \tag{52.26}$$

Note that π_K is the probability that a customer will be lost (or a packet *dropped*). The steady-state distribution can be used to obtain performance metrics such as:

$$E(L_s) = \sum_{j=1}^{K} j\pi_j$$

$$\text{and } E(L_q) = \sum_{j=c+1}^{K}(c-j)\pi_j$$

whence $E(W_s)$ and $E(W_q)$ are easily derived using the Little formulae (52.1) with λ_{eff} replacing λ.

52.2 Multiple-Priority Dual Queue (MPDQ)

The dual queue with finite buffer is illustrated in Fig. 52.1. We let c_1 be the capacity of the primary queue and c_2 be the capacity of the secondary queue. We assume arrivals belong to k differentiated classes of customers. All arrivals follow an independent Poisson process with rate λ_i and service times are independently exponentially distributed with rate μ_i for $i = 1, 2, \ldots, k$. Unlike the standard dual-queue analysis, we will be incorporating *class-based* service disciplines within the dual-queue model. This means that the favored (high) class of customers will jump to the head of the line before any other class of customers *within the same* queue. Therefore a lower-class customer in the primary queue cannot be ejected to the secondary queue even in the presence of higher-classed customers within the secondary queue. This differs from a single queue in that all high-class customers *in the system* are moved to the head of the queue, whereas in a dual queue, all the high-class customers *within each queue* are moved to the head of the line. A full primary queue blocks any entry from the secondary queue, hence there is an opportunity for lower-class customers to leave the system first, even in the presence of higher-class ones.

In the next section, we compare performances between single (SQ) and dual-queueing models based mainly on waiting-time analysis through simulations using the preemptive and non-preemptive service disciplines (preMPDQ and npMPDQ, respectively). We then give an overview of the analytical solutions when there are only two classes of customers in a subsequent section.

52.2.1 Simulating the MPDQ

The four scheduling disciplines used here in both the single- and dual-queue simulations are FCFS, LIFO, lowest class first (LCF) and highest class first (HCF). LCF and HCF are the two priority disciplines used in the MPDQ. In HCF (and the description is similar for LCF as the two disciplines are symmetrical), a higher-class customer jumps to the head of the queue, behind any already present customers of the same or higher class, and, in turn, is in front of any lower-class customer. As we will see from the simulation results, having both queues under the HCF regime in a dual queue is an effective form of traffic congestion control. The partitioning of a single queue and restricting entry into the primary queue, when it is full, allows lower-class customers to leave the system, even in the presence of other higher-class customers in the system. This is perceived as *fairness* to lower-class customers, as they can exit the system in the presence of higher-class customers but could be deemed as *unfair* to the latter. However, this can only occur when the primary queue is full, so higher-class customers are not disadvantaged all the time.

All simulations on the MPDQ were conducted using the Arena simulation software package [52.25], a flexible windows-based program suitable for a vast array of statistical analysis with dedicated queueing subroutines. In constructing the Arena model, two algorithms (for the preemptive and non-preemptive cases) were designed for the MPDQ. The single-queue schemes were also designed so that various regimes could be compared. Although our simulations dealt only with two classes of customers, which we label class 1 and class 2, all algorithms are simple to extend to multiple classes ($k \geq 3$) of customers. In communication systems, class 1 would refer to high-priority traffics such as web and voice traffic, and class 2 would refer to low-priority traffics such as file transfer protocol (FTP) and hypertext transfer protocol (HTTP).

Results of Simulation Experiments

All customers are considered to be of uniform length. For all models the first-class customer is considered the most infrequent arrival and longest in service. The ra-

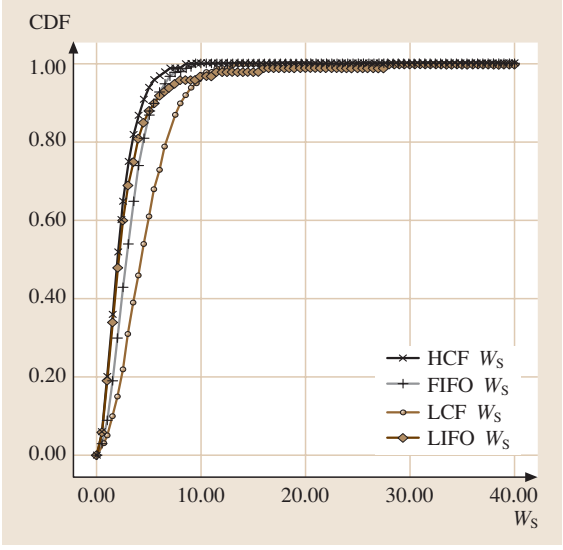

Fig. 52.6 Cumulative distribution functions (CDF) of waiting times for different scheduling disciplines

tionale is that first-class traffic will in many cases be the more demanding on system resources and can be seen as either the most or least valuable, depending upon the type of queueing discipline. Examples of high-class high-demand traffic include video-conference links, streaming audio or streaming video. As more classes are introduced, the performance differences between them may not be as apparent as when there are fewer classes.

The first analysis was to determine whether the HCF regime was superior to the LIFO, FCFS and LCF scheduling disciplines. Our first series of simulations involved the preemptive MPDQ model, the simplest of the two service regimes to simulate. We found that, as traffic intensity increased, the waiting time in the system was markedly lower under a HCF regime for class 1 customers. An example of this is seen in Fig. 52.6, for the parameters $\lambda_1 = 1, \lambda_2 = 2, \mu_1 = 1, \mu_2 = 2, c_1 = c_2 = 4$, the HCF has a lower probability of waiting in the system for class 1 customers in comparison to the other disciplines.

Loss probabilities were also examined. We found marginal differences between the regimes with respect to each class, and little difference in class-based loss. With no appreciable increase in loss by prioritizing traffic, and significant advantages in waiting time, the HCF discipline was chosen as the superior scheduling regime. Further simulations with non-preemptive models continue to confirm that HCF outperformed other scheduling regimes.

The next objective was to explore the differences between the non-preemptive and preemptive service disciplines. The results here provide a framework for communication providers in determining how service disciplines contribute to loss and delay, and how modeling, through simulation, can assist in reducing traffic congestion. We expect class 2 customers to be disadvantaged (in terms of expected waiting time) under the preemptive regime over class 1 (frequent ejection means longer waits) with the reverse situation under the non-preemptive regime. The results certainly show this to be true and Fig. 52.7 clearly demonstrates this.

What improvement does the npMPDQ offer over the non-preemptive single queue (SQ)? We compare the two by considering the non-preemptive dual queue with $c_1 = c_2 = 10$ and the SQ with capacity $c_1 + c_2 = 20$ with a view to measuring its performance under different traffic intensities, achieved through varying the mean arrival rate of class 2 customers. The graphs in Fig. 52.8 are based on a fixed class 1 mean arrival rate, and fixed mean service rates, being $\lambda_1 = 0.2$, and $\mu_1 = \mu_2 = 1$ respectively. We have varied the values of λ_2 from 0.25 to 20. This gives us scope to consider the performance of the system when the traffic intensity is low ($\rho = 0.45$) to when it is well beyond saturation.

From Fig. 52.8, we see that, in periods of low traffic intensity ($\lambda_2 < 1$), there is very little difference in the ratio of class 1 to class 2 customers in the npMPDQ and SQ models. However, for high traffic in-

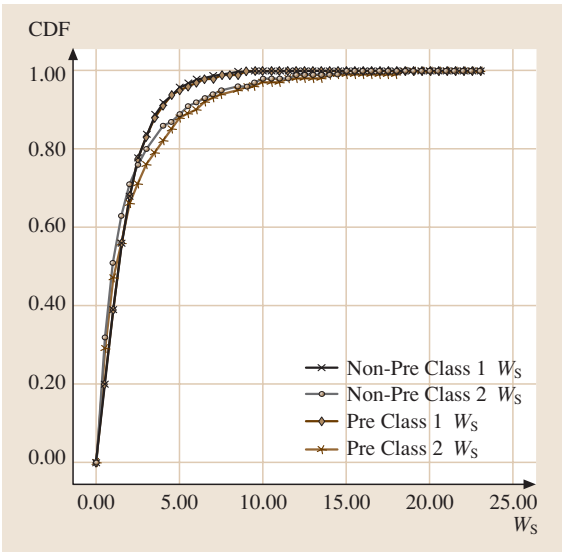

Fig. 52.7 Cumulative distribution functions (CDF) of waiting times for preemptive and non-preemptive service disciplines

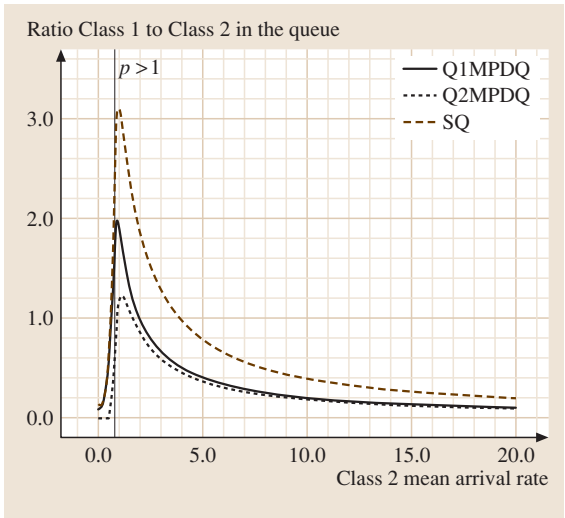

Fig. 52.8 Ratio of class 1 to class 2 customers

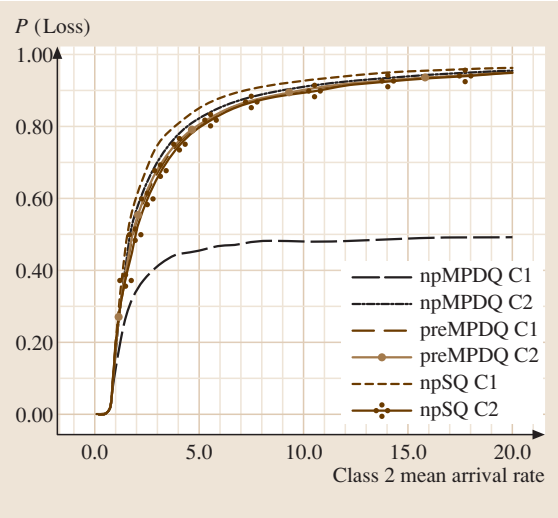

Fig. 52.9 Probability of loss

tensity ($\lambda_2 > 1$) and for both primary and secondary queues, the graphs of the MPDQ models peak and then decline much faster than the SQ model. Note also that, as traffic intensity increases, the distributions of the two classes in both queues appear to stabilize.

Finally we look at the probability of a loss. In Fig. 52.9, we note that class 1 non-preemptive MPDQ customers do best using this measure compared to all the others. The loss probability tapers off significantly for class 1 customers compared to both the SQ and preMPDQ. This does come at the expense of class 2 customers. However, the loss probability for class 2 is still superior to that of the class 1 SQ.

52.2.2 Solving the MPDQ Analytically

In this section, we give a brief summary of the work that has been undertaken in solving the MPDQ for its stationary distribution, and the derivation of the expected waiting times for both classes of customers ([52.12] and [52.26] respectively). We will assume the HCF discipline with class 1 customers designated as the high class. Furthermore, we will only consider the preMPDQ case here, the corresponding results for the npMPDQ case can be obtained from [52.27].

The State Space of the MPDQ and its Infinitesimal Generator

In order to solve the balance equations, which describe the movements by customers between and within the dual queues, it is necessary to define the state space S of the system and the infinitesimal generator matrix A containing the transition rates between states.

State space. The space S can be partitioned into two disjoint sets, $S = S_1 \cup S_2$, corresponding to the case when the secondary queue is empty and when it is not empty, respectively. Here,

$$S_1 = \{(i, j) : 0 \le i + j \le c_1\} ,$$

where i is the number of customers of class 1, and j is the number of customers of class 2. Similarly,

$$S_2 = \{(i, i', j') : 0 \le i' + j' \le c_2, i = 0, 1, \ldots , c_1\} ,$$

where i' is the number of customers of class 1 and j' is the number customers of class 2 in the secondary queue. Note that the number of class 2 customers in the primary queue is simply $c_1 - i$ in this case.

The states of the system can be labeled using S_1 and S_2 above according to the following lexicographical scheme:

$$\boldsymbol{i} = \{(i, 0) , (i, 1) , \ldots , (i, c_1 - i)\}$$
$$\boldsymbol{i0} = \{(i, 0, 1) (i, 0, 2) , \ldots , (i, 0, c_2)\}$$

and for $j = 1, 2, \ldots , c_2$

$$\boldsymbol{ij} = \{(i, j, 0) , (i, j, 1) , \ldots , (i, j, c_2 - j)\}$$

$i = 0, 1, 2, \ldots , c_1$.

The steady-state distribution vector $\overline{\pi}$ is thereby constructed so that its components are ordered using the above labeling scheme:

$$\overline{\pi}^t = \left(\overline{\pi}^t_{\mathbf{0}}, \overline{\pi}^t_{\mathbf{0,0}}, \ldots , \overline{\pi}^t_{\mathbf{0},\mathbf{c_2}}, \overline{\pi}^t_{\mathbf{1}}, \overline{\pi}^t_{\mathbf{1,0}}, \ldots , \overline{\pi}^t_{\mathbf{1},\mathbf{c_2}}, \ldots , \overline{\pi}^t_{\mathbf{c_1}}, \overline{\pi}^t_{\mathbf{c_1},\mathbf{0}}, \ldots , \overline{\pi}^t_{\mathbf{c_1},\mathbf{c_2}}\right) .$$

Note that the dimension of $\overline{\pi}$ equals $\frac{1}{2}(c_1 + 1)(c_2^2 + 3c_2 + c_1 + 2)$. The components of the above steady-state distribution can be described as follows: $\overline{\pi}_{\boldsymbol{i}}$ is the probability vector that is defined when there are no customers present in the secondary queue, whereas $\overline{\pi}_{\boldsymbol{ij}}$ is the probability vector that is defined when there are customers present in the secondary queue (so the primary queue is full). Any probability that is a component of the first type of vector has general form $\pi_{i,j}$ and any probability that is a component of the second type of vector has general form $\pi_{i,i',j'}$. For every tuple listed above, there is an additional label s representing the class of customer *in service* in case the MPDQ is non-preemptive. Thus, the dimension of the steady-state distribution vector is increased to $(c_1 + 1)(c_2^2 + 3c_2 + c_1 + 2) + 1$.

The infinitesimal generator matrix $\boldsymbol{A}$. Since the Markov process describing the MPDQ is an ergodic CTMC, the steady-state distribution $\overline{\pi}^t$ exists and is obtained by solving the system of balance equations

$$\overline{\pi}^t \boldsymbol{A} = \boldsymbol{0}\,, \tag{52.27}$$

where $\boldsymbol{0}$ is the zero vector and $\boldsymbol{A}$ is the infinitesimal generator matrix of the process. From the description of the dual-queueing system, $\boldsymbol{A}$ can be partitioned into submatrices whose detailed structure will be described in detail below. The general structure of $\boldsymbol{A}$ is given by

$$\boldsymbol{A} = \begin{pmatrix} \boldsymbol{\Lambda}_0 & \boldsymbol{\Pi}_0 & 0 & \dots & \dots & 0 \\ \boldsymbol{\Omega}_1 & \boldsymbol{\Lambda}_1 & \boldsymbol{\Pi}_1 & \ddots & & \vdots \\ 0 & \ddots & \ddots & \ddots & \ddots & \vdots \\ 0 & \ddots & \ddots & \ddots & \ddots & 0 \\ \vdots & & \ddots & \boldsymbol{\Omega}_{c_1-1} & \boldsymbol{\Lambda}_{c_1-1} & \boldsymbol{\Pi}_{c_1-1} \\ 0 & \dots & & 0 & \boldsymbol{\Omega}_{c_1} & \boldsymbol{\Lambda}_{c_1} \end{pmatrix},$$

where

$$\boldsymbol{\Lambda}_0 = \begin{pmatrix} \boldsymbol{D}_0 & \boldsymbol{M}_{0,\lambda_2} & \boldsymbol{M}_{0,\lambda_1} & 0 & & 0 \\ \boldsymbol{O}_{0,\mu_2} & \boldsymbol{D}_{0,0} & \boldsymbol{Q}_{0,\lambda_1} & 0 & & \\ 0 & 0 & \boldsymbol{D}_{0,1} & \boldsymbol{R}_{0,1,\lambda_1} & & \\ \vdots & & \ddots & \ddots & \ddots & 0 \\ & & & \ddots & \ddots & \boldsymbol{R}_{0,c_2-1,\lambda_1} \\ 0 & & \dots & & 0 & \boldsymbol{D}_{0,c_2} \end{pmatrix},$$

$$\boldsymbol{\Pi}_0 = \begin{pmatrix} \boldsymbol{N}_{0,\lambda_1} & 0 & & \dots & & 0 \\ 0 & 0 & & & & \\ \boldsymbol{S}_{0,\mu_2} & \boldsymbol{U}_{0,1} & \ddots & & & \vdots \\ 0 & 0 & \ddots & \ddots & & \\ \vdots & & \ddots & \ddots & \ddots & \\ 0 & \dots & & 0 & \boldsymbol{U}_{0,c_2} & 0 \end{pmatrix},$$

and for $i = 1, 2, \dots, c_1$

$$\boldsymbol{\Lambda}_i = \begin{pmatrix} \boldsymbol{D}_i & \boldsymbol{M}_{i,\lambda_2} & \boldsymbol{M}_{i,\lambda_1} & 0 & & \dots & 0 \\ 0 & \boldsymbol{D}_{i,0} & \boldsymbol{Q}_{i,\lambda_1} & 0 & & & \\ \boldsymbol{S}_{i,\mu_1} & \boldsymbol{U}_{i,1} & \boldsymbol{D}_{i,1} & \boldsymbol{R}_{i,1,\lambda_1} & \ddots & & \vdots \\ 0 & 0 & \boldsymbol{U}_{i,2} & \boldsymbol{D}_{i,1} & \ddots & \ddots & \\ \vdots & & \ddots & \boldsymbol{U}_{i,2} & \ddots & \ddots & 0 \\ & & & \ddots & \ddots & \ddots & \boldsymbol{R}_{i,c_2-1,\lambda_1} \\ 0 & & \dots & & 0 & \boldsymbol{U}_{i,c_2} & \boldsymbol{D}_{i,c_2} \end{pmatrix},$$

$$\boldsymbol{\Omega}_i = \begin{pmatrix} \boldsymbol{P}_{i,\mu_1} & 0 & \dots & 0 \\ \boldsymbol{Y}_{i,\mu_1} & \boldsymbol{T}_{i,\mu_1} & & \\ 0 & 0 & & \vdots \\ \vdots & & \ddots & \vdots \\ & & & \\ 0 & & \dots & 0 \end{pmatrix},$$

and

$$\boldsymbol{\Pi}_i = \begin{pmatrix} \boldsymbol{N}_{i,\lambda_1} & 0 & \dots & 0 \\ 0 & 0 & & \vdots \\ \vdots & & \ddots & \vdots \\ 0 & & \dots & 0 \end{pmatrix}.$$

Each submatrix represents all state transitions generated by the arrival/departure patterns of the MPDQ and incorporates the rate parameters λ_i and μ_i, $i = 1, 2$. We remark that not every submatrix is a square matrix and hence invertible. For example,

$$D_{i,j} = \begin{pmatrix} -(\mu_1+\lambda) & \lambda_2 & 0 & \dots & 0 \\ 0 & -(\mu_1+\lambda) & \ddots & & \\ & 0 & \ddots & \ddots & \vdots \\ \vdots & & \ddots & \lambda_2 & 0 \\ & & \ddots & -(\mu_1+\lambda) & \lambda_2 \\ 0 & & \dots & 0 & -\mu_1 \end{pmatrix}$$

is a square matrix of dimension $(c_2 - j + 1)$ representing transitions between states in $\boldsymbol{ij}$, $i = 1, 2, \dots, c_1$, $j = 1, 2, \dots, c_2$ while

$$N_{i,\lambda_1} = \begin{pmatrix} \lambda_1 & 0 & \ddots & 0 \\ 0 & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & 0 \\ \vdots & & 0 & \lambda_1 \\ 0 & \dots & \dots & 0 \end{pmatrix}$$

is a matrix of dimension $(c_1 - i + 1) \times (c_1 - i)$ representing the transition from (i, j) to $(i+1, j)$ where $i = 0, 1, \dots, c_1 - 1$, $j = 0, 1, \dots, c_1 - i - 1$. Detailed of the other submatrices can be obtained from [52.12].

Technically speaking, any linear numerical procedure could be used to solve (52.27). However, this would ignore the structure of the system and the fine detail of the submatrices outlined above, especially the fact that

not all the submatrices are square matrices and that A is not in a workable block-tridiagonal form. This could render standard numerical procedures difficult or even impossible to apply; so, in [52.12], an algorithm which takes into account the structure of the system is proposed and shown to be very fast and easy to implement.

52.2.3 The Waiting-Time Distribution

The derivation of the waiting-time distribution, especially for class 2 customers, is based on the matrix analytic method pioneered by *Neuts* [52.28]. Our method generalizes the method proposed in [52.29] for the non-preemptive SQ. Matrix analytic methods exploit the special structures of the transition matrices or infinitesimal generators of some Markov processes occurring in queueing models and an important feature of these methods, which add to their utility, is that they are computational in character. In the subsequent analysis, we distinguish between two cases: when the primary queue is not full and when it is.

The Primary Queue is not Full

Class 1 customers: in this case, a tagged class 1 customer C_1 who joins the queue is concerned only with the number of class 1 customers ahead of him. If C_1 sees no class 1 customers ahead of him, then he goes to the head of the line and ejects the class 2 customer, if any, who is being served. If C_1 sees n, $0 < n < c_1$ class 1 customers ahead of him, then he has to wait until these customers have completed their services. Therefore, his waiting time is the sum of n exponential (μ_1) random variables. Let

$$\Pi_{Q_1} = \sum_{0 \le i+j < c_1} \pi_{i,j}$$

i. e. the probability that queue 1 is not full, then the conditional density of the waiting time of C_1 given that queue 1 is not full is

$$W_1^{(1)}(t) = \frac{1}{\Pi_{Q_1}} \left[\left(\sum_{j=0}^{c_1-1} \pi_{0,j} \right) \delta(t) + \sum_{j=0}^{c_1-2} \sum_{i=1}^{c_1-1-j} \pi_{i,j} f_{i,\mu_1}(t) \right] ,$$

where $\delta(t)$ is the Dirac delta function and

$$f_{n,\mu_1}(t) = \frac{\mu_1^n}{(n-1)!} t^{n-1} \mathrm{e}^{-\mu_1 t} ,$$

i. e. the Erlang distribution with n phases and parameter μ_1.

Class 2 customers: the derivation of the waiting time of an arbitrary class 2 customer C_2 entering the secondary queue is quite complex as it is affected by subsequent arrivals of both class 1 and class 2 customers. Suppose C_2 joins the queue and finds at least one customer in front of him, he will be pushed back in the queue by subsequent class 1 arrivals. Also, any subsequent class 2 arrivals will reduce the available spaces in the buffer, thus improving his chances of moving to the front of the line. The waiting time of C_2 will depend on the absorption time into a particular set $\mathcal{A}_1$ [defined by (52.28)] experienced by the stochastic process $Z(t)$, $t \ge 0$, where

$$Z(t) = [l_{11}(t), L_{21}(t), F_1(t)]$$

where $l_{11}(t)$ is the number of class 1 customers in the primary queue, $L_{21}(t)$ is the number of class 2 customers in front and including C_2 in the primary queue, and $F_1(t)$ is the amount of free space in the primary queue. Due to the assumptions underlying the MPDQ, $Z(t)$ is a continuous-time Markov chain taking values in the set

$$\mathcal{R}_1 = \{(l_{11}, L_{21}, F_1) \in \mathcal{N}_0^3 : 0 \le l_{11} \le c_1 , \; 0 \le L_{21} \le c_1 , \; 0 \le F_2 \le c_1 \} .$$

Define the set of states $\mathcal{A}_1 \subset \mathcal{R}_1$ by

$$\mathcal{A}_1 = \{(0, 1, F_1) : 0 \le F_1 \le c_1 - 1\} . \qquad (52.28)$$

Let $T_1(l_{11}, L_{21}, F_1)$ denote the first-passage time for the process $Z(t)$ into $\mathcal{A}_1$ starting initially in state (l_{11}, L_{21}, F_1) where $L_{21} \ge 1$, i. e.

$$T_1(l_{11}, L_{21}, F_1) = \min\{t \ge 0 : Z(t) \in \mathcal{A}_1 | Z(0) = (l_{11}, L_{21}, F_1)\} .$$

Note that this is precisely the time it will take for C_2 to be served. Denote the Laplace transform of $T_1(l_{11}, L_{21}, F_1)$ by $\hat{W}_{l_{11},L_{21},F_1}(s)$, i. e.

$$\hat{W}_{l_{11},L_{21},F_1}(s) = E(\mathrm{e}^{-sT_1(l_{11},L_{21},F_1)}) , \qquad (52.29)$$

where $\mathrm{Re}(s) > 0$. Using the Poisson arrivals see time averages (PASTA) property [52.30], which posits that a Poisson arrival would observe the steady-state distribution at any random time point, the Laplace transform of the time to absorption of $Z(t)$ given that C_2 can join the primary queue is therefore

$$\hat{W}_1^{(2)}(s) = \frac{1}{\Pi_{Q_1}} \left[\sum_{0 \le i+j < c_1} \pi_{i,j} \hat{W}_{i,j+1,c_1-i-j-1}(s) \right] . \qquad (52.30)$$

Inversion of (52.30) will in principle gives us the distribution of the waiting time of a class 2 customer. However, for most practical purposes, it suffice to compute its k-th moment, $k = 1, 2, \ldots$. A recursive and computationally efficient algorithm using matrix analytic methods is introduced in [52.26], which achieved this purpose.

The Primary Queue is Full

Class 1 customers: here, C_1 joining the secondary queue either sees no class 1 customers or at least one class 1 customer in the primary queue. In the first case, he has to wait for the services of all class 1 customers ahead of him in the secondary queue and that of the class 2 customer at the head of the queue to finish. In the second case, he has to wait until all class 1 customers in front of him in the combined queue have been served. Thus the conditional density of his waiting time given that the primary queue is full is

$$W_2^{(1)}(t) = \frac{1}{\Pi_{Q_2}} \left[\sum_{0 \le i'+j' < c_2} \pi_{0,i',j'} f_{1,\mu_2} \star f_{i',\mu_1}(t) + \sum_{i=1}^{c_1} \sum_{0 \le i'+j' < c_2} \pi_{i,i',j'} f_{i+i',\mu_1}(t) \right] \tag{52.31}$$

where $\star$ refers to the convolution operator and

$$\Pi_{Q_2} = \sum_{i=0}^{c_1} \sum_{0 \le i'+j' < c_2} \pi_{i,i',j'}$$

is the probability that the primary queue is full.

Class 2 customers: similar to the first case, the waiting time of an arbitrary class 2 customer C_2 is equal to the absorption time of a stochastic process into a targeted set. Define

$$Y(t) = [l_{11}(t), l_{12}(t), L_{22}(t), F_2(t)] ,$$

where $l_{11}(t)$ is the number of class 1 customers in the primary queue, $l_{12}(t)$ is the number of class 1 customers in the secondary queue, $L_{22}(t)$ is the number of class 2 customers in front and *including* C_2 in the dual queue, and $F_2(t)$ is the amount of free space in the secondary queue. The time for $Y(t)$ to first enter the targeted set $\mathcal{A}_2$ [defined by (52.32)] is equal to the waiting time of C_2. Note that $Y(t)$ is a continuous-time Markov chain which takes values in the set

$$\begin{aligned} \mathcal{R}_2 = \{(l_{11}, l_{12}, L_{22}, F_2) \in \mathcal{N}_0^4 : & 0 \le l_{11} \le c_1 , \\ & 0 \le l_{12} \le c_2 , \\ & 0 \le L_{22} \le c_1 + c_2 , \\ & 0 \le F_2(t) \le c_2 \} . \end{aligned}$$

The waiting time of C_2 is the first-passage time $T_2(l_{11}, l_{12}, L_{22}, F_2)$ for the process Y to enter into $\mathcal{A}_2 \subset \mathcal{R}_2$ defined by

$$\mathcal{A}_2 = \{(0, l_{12}, 1, F_2) : 0 \le l_{12} < c_2, 0 \le F_2 \le c_2\} \tag{52.32}$$

starting initially in state $(l_{11}, l_{12}, L_{22}, F_2)$, where $L_{22} \ge 1$. Denote the Laplace transform of $T_2(l_{11}, l_{12}, L_{22}, F_2)$ by $\hat{W}_{l_{11},l_{12},L_{22},F_2}(s)$. By the PASTA property, the Laplace transform of the time to absorption of Y into $\mathcal{A}_2$ given that a class 2 customer enters the secondary queue is

$$\hat{W}_2^{(2)}(s) = \frac{1}{\Pi_{Q_2}} \left[\sum_{i=0}^{c_1} \sum_{0 \le i'+j' < c_2} \pi_{i,i',j'} \times \hat{W}_{i,i',j'+c_1-i+1,c_2-i'-j'-1}(s) \right] . \tag{52.33}$$

Again, inverting (52.33) will technically gives us the distribution of the waiting time of a class 2 customer. However, as in previous case, a more viable alternative is to provide a recursive algorithm (which we have done in [52.26]) which will allow us to compute all the k-th, $k = 1, 2, \ldots$ moments of the waiting time for class 2 customers in the secondary queue.

52.3 Distributed Systems and Load Balancing

Many recent studies have shown that distributed computing environments exhibit a wide range of task sizes, often spanning many orders of magnitude. These so-called *heavy-tailed* workloads have been found to exist in a number of computing environments. *Crovella* et al. [52.31, 32] found that a number of file-size distributions measured on the World Wide Web (WWW) exhibit heavy tails, including file requests by users, files transmitted via the network and files stored on servers. Further examples of observed heavy-tailed workload include the size of files stored in Unix file systems [52.33] and the Unix process central processing unit (CPU) requirements measured at UC Berkley [52.34]. More recently, traffic measurements of the 1998 World

Cup [52.35] and the 1998 Winter Olympics [52.36] have exhibited some heavy-tailed characteristics. There are significant questions raised by these findings with regards to task assignment policies, as much of the existing work in the area was formulated under an assumption of an exponentially distributed workload.

Heavy-tailed distributions have very high variance, where 1% of tasks can take 50% of the computing resources. These distributions are characterized by the property

$$\Pr(X > x) \sim x^{-\alpha} ,$$

where $0 \leq \alpha \leq 2$. Any set of tasks that is said to follow a heavy-tailed distribution is described as having the following properties [52.37, 38]:

1. Decreasing failure rate. That is, the longer a task has run, the longer it is expected to continue running.
2. Infinite variance, and if $\alpha \leq 1$, infinite mean.
3. A very small fraction (less than 1%) of the very largest jobs make up a large fraction (half) of the workload. This is commonly referred to as the *heavy-tailed property*. It is this property that makes the load very difficult to balance effectively.

For the purpose of analysis, we assume that the task sizes show some maximum (but large) value. This is a reasonable assumption in many cases, such as a web server, which would have some largest file. A *bounded Pareto* distribution is therefore used, which has a lower and upper limit on the task size distribution. The probability density function for the bounded Pareto $B(k, p, \alpha)$ is:

$$f(x) = \frac{\alpha k^{\alpha}}{1-(k/p)^{\alpha}} x^{-\alpha-1}, k \leq x \leq p , \qquad (52.34)$$

where α represents the task size variation, k is the smallest possible task, and p is the largest possible task. By varying the value of α we can observe distributions that exhibit moderate variability ($\alpha \approx 2$) to high variability ($\alpha \approx 1$). Typical measured values of the α parameter are 0.9–1.3 [52.31, 32, 37], with an empirically measured mean of $\alpha \approx 1.1$. The next table provides some α values associated with the heavy-tailed distributions of some files.

52.3.1 Classical Load-Distribution Policies

The problem of optimal task assignment in a distributed system has been a well-researched area for many years. Most of the so-called *classical* approaches were created under the assumption that service times are exponentially distributed. Many of these policies are still widely used, due to their simplistic nature and ease of implementation.

Random and Round-Robin

Classical task assignment policies such as *random* and *round-robin* [52.39] have traditionally been used in distributed systems, and are still widely used for many applications. Under the random policy, tasks are assigned to each back-end server with equal probability. Using a round-robin policy, tasks are assigned to servers in a cyclical fashion. Both policies equalize the expected number of tasks allocated to each server, and are frequently used as a baseline to compare with other task distribution policies. Tasks are assigned with no consideration of each host's load or the distribution of task sizes. Despite this, random and round-robin are still commonly used in many scheduling environments (most likely due to ease of implementation). It has been shown previously [52.34] that random and round-robin both have similar performance characteristics.

Dynamic Policies

Dynamic policies intelligently assign tasks based on knowledge of the current load at each host. The LLF (least loaded first) approach assigns tasks to the server with the least amount of work remaining, attempting to achieve instantaneous load balance. The work remaining can be approximated by the queue length (shortest queue), or assuming the task's service requirement is known a priori. By keeping the load balanced, the waiting time in the queue can be reduced. It is known that balancing the load minimizes the mean response time [52.40] in the type of distributed system that we consider in this paper. Despite this, a number of caveats exist. Firstly, the best performance is not always obtained by balancing the load, particularly if you are interested in different measures of performance, such as the mean slowdown. Secondly, balancing the load is not always practical, as you are often depending on approximate measures of the load, such as the queue length. Under highly variable workload it is highly probable that the length of a queue can be misleading as an indicator of congestion.

Central Queue

The central-queue policy holds tasks in a queue at the dispatcher until a host is idle. Such a policy has proved to be equivalent to a least-work-remaining policy, showing that equivalent performance can be obtained without any prior knowledge of a task's size [52.37, 38]. Recently, two variations of the central-queue policy have

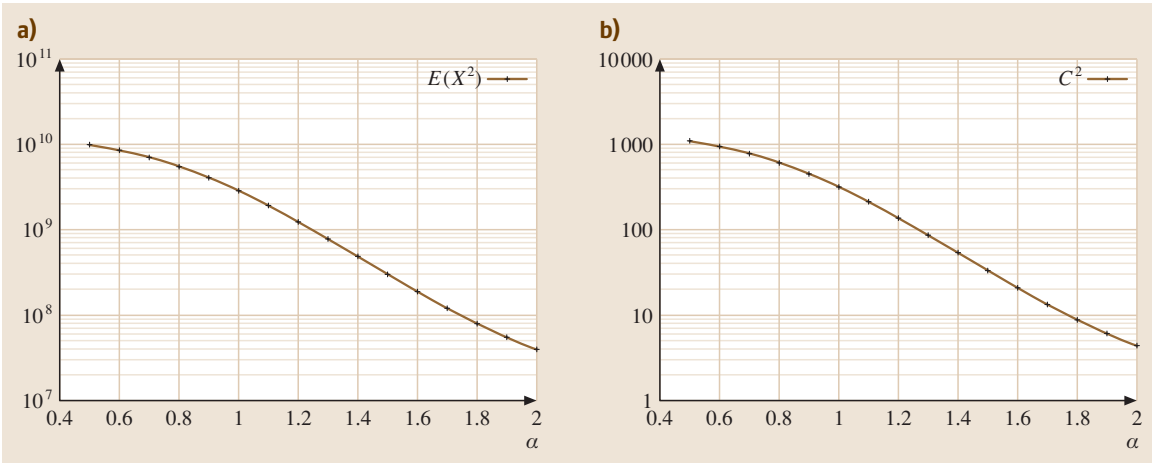

Fig. 52.10a,b The second moment of a bounded Pareto distribution ($E\{X\} = 3000$, $p = 10^7$) is shown in **(a)**, where α is varied from 0.5 to 2.0. The squared coefficient of variation ($C^2 = E\{X^2\}/E\{X\}^2$) is shown in **(b)**

been proposed – cycle stealing with immediate dispatch (CS-ID) and cycle stealing with central queue (CS-CQ) [52.41]. CS-ID immediately dispatches tasks to a back-end server, while CS-CQ holds tasks in a central queue at the dispatcher until a host is idle. Both policies are evaluated against a dedicated policy. In a dedicated policy, one host is *dedicated* to servicing all short jobs, while the other host services long jobs. Both CS-ID and CS-CQ follow a similar arrangement, but can steal cycles from an idle host if available and it is prudent to do so. Both CS-ID and CS-CQ show improvement over a dedicated policy in many areas (notably for short tasks). The application of these policies are limited to domains where a priori knowledge of a tasks size is known, and in the case of CS-CQ, there needs to be constant feedback between the dispatcher and the back-end hosts to notify the dispatcher of an idle host.

Some Known Results

The round-robin policy results in a slightly less variable arrival stream to the back-end hosts than the random policy. Despite this, the performance of the random and round-robin policies have been shown to be roughly equivalent [52.38].

Assuming an $M/M/c$ queueing system, a shortest-queue policy has been shown to be optimal with respect to maximizing the number of jobs completed by a certain time [52.42]. Under more general assumptions, *Nelson* and *Phillips* [52.43] claim that the central-queue (and therefore least-work-remaining) policy is optimal.

A least-work-remaining policy is not analytically tractable under $M/GI/c$ queuing systems. Nonetheless, this policy has been shown to be equivalent to a central-queue policy [52.38], for which there exists known approximations to its queue size using the following result given in [52.44]:

$$E(L_{M/GI/c}) = E(L_{M/M/c})\frac{E(X^2)}{E(X^2)}\,, \tag{52.35}$$

where X is the service requirement, and L_{model} represents the queue length under the model specified. We remark that, for the queueing model (M/GI/1), the expected waiting time in the queue is given by the famous *Pollaczek–Khinchin mean value formula* [52.19]

$$E(W_{\text{q}}) = \frac{\lambda E(X^2)}{2(1-\rho)}\,. \tag{52.36}$$

Limitation of Classical Load Distribution Policies

The task assignment policies listed above are not suitable for heavy-tailed distributions such as the Pareto distribution. Consider the metrics (52.35) and (52.36); what is immediately apparent is that all these metrics depend on the second moment of the service requirement distribution, $E\{X^2\}$ and for policies, such as the least-work-remaining policy, they will depend on the squared coefficient of variation $C^2 = E\{X^2\}/E\{X\}^2$. Figure 52.10 shows an example of one such highly variable distribution (where the y-axis is on a log scale). We can see that, as α decreases, the variation (as represented by the second moment of the distribution, and the squared coefficient of variation) increases substantially. Clearly,

as the variability of the service time distribution increases, the performance of the distributed system will decrease rapidly using these classical load balancing policies.

52.3.2 Size-Based Load Distribution Policies

In the previous section we have highlighted substantial recent research indicating the frequent occurrence of heavy-tailed workloads in many distributed computing environments. The characteristics of these heavy-tailed workloads make them very challenging to manage using traditional load distribution policies. Indeed, many of these policies were created under the $M/M/c$ queueing model, where the distribution of service requirements follows an exponential distribution. To deal with heavy-tailed $M/G/c$ workloads, where G is a heavy-tailed distribution, new load distribution techniques need to be employed. In particular, they must address the characteristics of these workloads, such as their highly variable nature, which cause such poor performance under traditional load distribution policies. In recent years, there have been several load distribution techniques specifically created to exploit the special characteristics of heavy-tailed workloads. They can be broadly classified as *size-based* policies where the workload is partitioned into distinct size ranges, with each size range dedicated to a specific server. For example, you may have a two server system where one server processes only small tasks, while another server processes only large tasks.

These size-based policies can be further classified by what knowledge they assume is known at the dispatcher. Some policies assumes that a task's size is known a priori at the dispatcher, and as such can assign the task directly to the server that is responsible for servicing tasks in that range. This obviously restricts the application of these policies to domains where exact (or reasonably accurate) a priori knowledge of a task's size is available.

Other size-based policies have less restrictive assumptions regarding what information is available at the dispatcher. Policies such as task assignment based on guessing size (TAGS) and task assignment based on prioritizing traffic flows (TAPTF), which are discussed later, assume no knowledge of a task's size at the dispatcher. They do, however, require knowledge of the distribution of task sizes.

SITA-E/V/U – Known Task Size

Size interval task assignment with equal load (SITA-E) [52.38] is a sized-based approach proposed by *Harchol-Balter* et al. that associates a unique size range with each host in the distributed system. These size ranges are chosen specifically to equalize the expected load received at each host. Whilst proving effective under conditions of high task-size variability, SITA-E is not the best policy in circumstances of lower task-size variability, where a dynamic policy is more suitable.

Size interval task assignment with variable load (SITA-V) [52.40] intentionally operates the hosts in a distributed system at different loads, and directs smaller tasks to lighter-loaded servers. The authors note that, depending on which performance metrics are of interest, the conventional notion that balancing the load on the respective hosts may not result in optimal performance, especially when the size distribution is heavy-tailed. SITA-V, like SITA-E, assigns tasks to a given host based on their size. However, SITA-V exploits the heavy-tailed property of the task size distribution by running the vast majority of tasks (i. e. the small tasks) on lightly-loaded hosts, while running the minority of tasks (the larger sized tasks) on the heavily-loaded hosts, thus preventing small tasks getting held up behind large tasks and allowing them to be processed quickly. Thus, mean slowdown is reduced, and the throughput is not adversely affected, but it can result in an increase in mean waiting time – which is expected, since minimal mean waiting time is known to occur when load is balanced.

A size-based approach that is specifically suited for batch computing environments under supercomputing workloads is size interval task assignment with unbalanced load (SITA-U) [52.45]. SITA-U purposely unbalances the load among the hosts while also being *fair*, i. e. achieving the same expected slowdown for all jobs. Two variations of SITA-U are considered: SITA-U-opt, where service requirement cutoffs are chosen to minimize mean slowdown, and SITA-U-fair, where service requirement cutoffs are chosen to maximize fairness. The simulation results showed that both variations of SITA-U performed better under a range of load conditions – with system loads in the range 0.1–0.8. SITA-U-fair achieved significant performance gains over the load range 0.5–0.8, demonstrating an improvement of 4–10 times with regards to mean slow down, and from 10–100 times with regards to variability in slowdown.

Most size-based policies perform well under very high task-size variation, but their advantage over existing approaches is reduced as variation decreases. Most importantly, the application of the task assignment poli-

cies listed above is limited by the assumption that the service requirement of each task is known a priori, which is frequently not the case.

TAGS/TAPTF – Unknown Task Size

The size-based approaches considered thus far all assume that the exact service requirements are known at the dispatcher in advance. Often this is not the case – in many environments a task's service requirement is not known until execution time on a given host. Task assignment based on guessing size (TAGS) [52.37] assumes no prior knowledge of a task's service requirement. Like SITA-V, TAGS is slightly counterintuitive in that it unbalance the load, and also considers the notion of *fairness*, i.e. that all tasks should experience the same expected slowdown. The TAGS approach works by associating a processing time limit with each host. Tasks are executed on a host, starting with host 1 (refer to Fig. 52.2), up until the designated time limit associated with that host; if the task has not completed by this point, it is aborted and restarted from scratch at the next host. These cutoffs are a function of the distribution of task sizes and the external arrival rate, and can be computed to optimize certain metrics, such as waiting time or slowdown.

The design of the TAGS policy purposely exploits properties of the heavy-tailed distribution, such as decreasing failure rate – where the longer a task has run, the longer it is expected to run – and the fact that a tiny fraction (less that 1%) of the very longest tasks can make up over half the load.

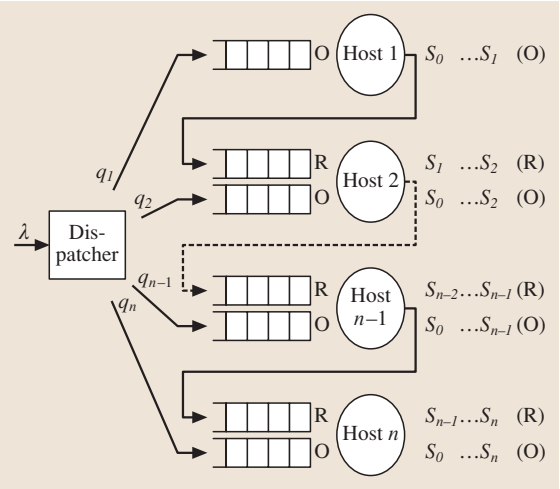

Fig. 52.11 TAPTF queueing system

Like other size-based approaches, under higher loads and less variable conditions, TAGS does not perform so well. TAGS gains much of its performance by exploiting the heavy-tailed property, by moving the majority of the load onto host 2, allowing the vast majority of small tasks to be processed quickly on host 1. TAGS also suffers under high loads due to *excess* – the extra work created by restarting many jobs from scratch. As noted in [52.37], " . . . overall excess increases with load because excess is proportional to λ, which is in turn proportional to load."

Recently a new approach to task assignment in a distributed system, task assignment based on prioritizing traffic flows (TAPTF) [52.46], was introduced (Fig. 52.11). TAPTF is a flexible policy that addresses some of the shortcomings of existing approaches to task assignment. TAPTF showed improved performance under heavy-tailed workloads for certain classes of traffic by controlling the influx of tasks to each host. Tasks can potentially be dispatched to any host, rather than just the first host, as in the TAGS approach. This approach is beneficial under two important scenarios. First, when task size variation decreases it becomes harder to exploit the so-called heavy-tailed properties. When the workload becomes more uniformly distributed, improved performance is gained from spreading the incoming tasks over multiple hosts. Second, when the system load is high the first host (which in a TAGS system receives *all* incoming tasks) can become overloaded, causing a bottleneck and resulting in a decrease in the overall performance metrics.

TAPTF introduces multiple queues with processing time limits (cutoffs). Each host has an ordinary queue which receives tasks directly from the dispatcher. Each host (excluding the first) also has a restart queue that receives restarted tasks from the host directly above it. The use of dual queues (combined with cutoffs at each host) enables service differentiation at each host, allowing smaller tasks to be executed quickly without being delayed by larger tasks. To achieve this, tasks that exceed the cutoff on a given host are migrated to the next host's restart queue (to be restarted from scratch). As the ordinary queue has priority over the restart queue, a potentially small task is not delayed by larger tasks that may exist in the restart queue.

Improved performances were observed both in mean waiting time and mean slowdown, the key areas where TAGS and random policies suffer. Most significantly, TAPTF exhibited improved performance under low to high task size variation and high system load by reducing

the excess associated with a large number of restarts and by intelligently controlling the influx of tasks to each back-end host.

Performance Under Heavy-Tailed Workloads

In this section, we illustrate how such size-based approaches are effective at counteracting the high variability in workloads that can affect the performance of traditional approaches to load balancing. Consider a size-based policy that partitions the workload between the back-end hosts. A size-based policy assigns unique size ranges to each of the n back-end hosts by partitioning the range of task sizes $[k, p]$, i. e. $k = s_0 < s_1 < s_2 < \ldots < s_n = p$. For example, in a two-host system, host 1 would service tasks with sizes between s_0 and s_1, while host 2 would handle the remaining tasks, with sizes between s_1 and $s_2 = p$.

Let p_i equal the fraction of tasks whose destination, i. e. where it will run to completion, is host i. That is, tasks whose size is between s_{i-1} and s_i. Using a bounded Pareto distribution (52.34), this is given by:

$$\begin{aligned} p_i &= P(s_{i-1} \le X \le s_i) \\ &= \frac{\alpha k^\alpha}{1-(k/p)^\alpha} \int_{s_{i-1}}^{s_i} x^{-\alpha-1}\,\mathrm{d}x \\ &= \frac{k^\alpha}{1-(k/p)^\alpha}\left(s_{i-1}^{-\alpha} - s_i^{-\alpha}\right) . \end{aligned} \tag{52.37}$$

Let us now consider only those tasks which are dispatched to and run-to-completion at host i. Let $E\left(X_i^j\right)$ be the j-th moment of the distribution of tasks that are dispatched to host i's queue. We have:

$$E\left(X_{iO}^j\right) = \int_{s_{i-1}}^{s_i} x^j f(x)\,\mathrm{d}x \tag{52.38}$$

$$= \begin{cases} \dfrac{\alpha s_{i-1}^\alpha}{(j-\alpha)\left[1-\left(\frac{s_{i-1}}{s_i}\right)^\alpha\right]} & \text{if } j \neq \alpha \\ \dfrac{s_{i-1}s_i}{s_i - s_{i-1}}(\ln s_i - \ln s_{i-1}) & \text{otherwise .} \end{cases} \tag{52.39}$$

Consider first the following example: a four-host system, utilizing the SITA-E task assignment policy. The arrival is Poisson and the service time distribution follows a bounded Pareto distribution. As described previously, SITA-E chooses its size ranges in order to equalize the expected load assigned to each back-end host. Figure 52.12a shows the C^2 values experienced by each back-end host as α varies. We can see a significant reduction in variation that has been achieved by partitioning the workload and assigning it to different hosts – effectively grouping like-sized tasks together. Indeed, the first two hosts have C^2 values that are less than one from $\alpha = 1.1$ to $\alpha = 2.0$. Nevertheless, we can see that the variation at the latter hosts is still quite high, approaching the value of C^2 of the task size distribution itself (i. e. before it is partitioned). This is not a problem in itself, as we can see in Fig. 52.12b. There, using the formula for p_i given in (52.37), we see that the vast majority of tasks are processed by the lower hosts, and predominantly the first host. These hosts have a significantly lower variance, and, given they process nearly

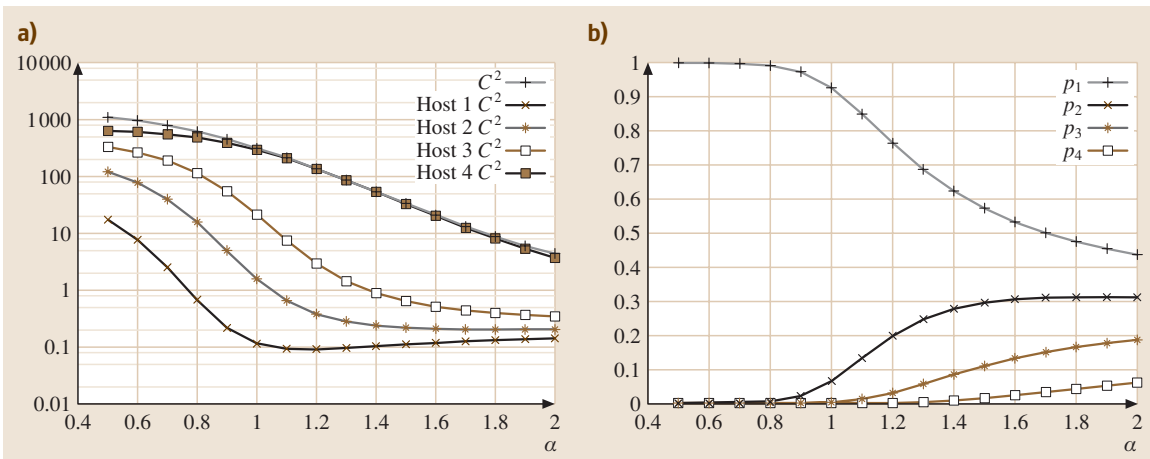

Fig. 52.12a,b The squared coefficient of variation experienced at each host ($C^2 = E\{X^2\}/E\{X\}^2$) in a four-host SITA-E system is shown in **(a)**. The fraction of tasks assigned to each host is shown in **(b)**

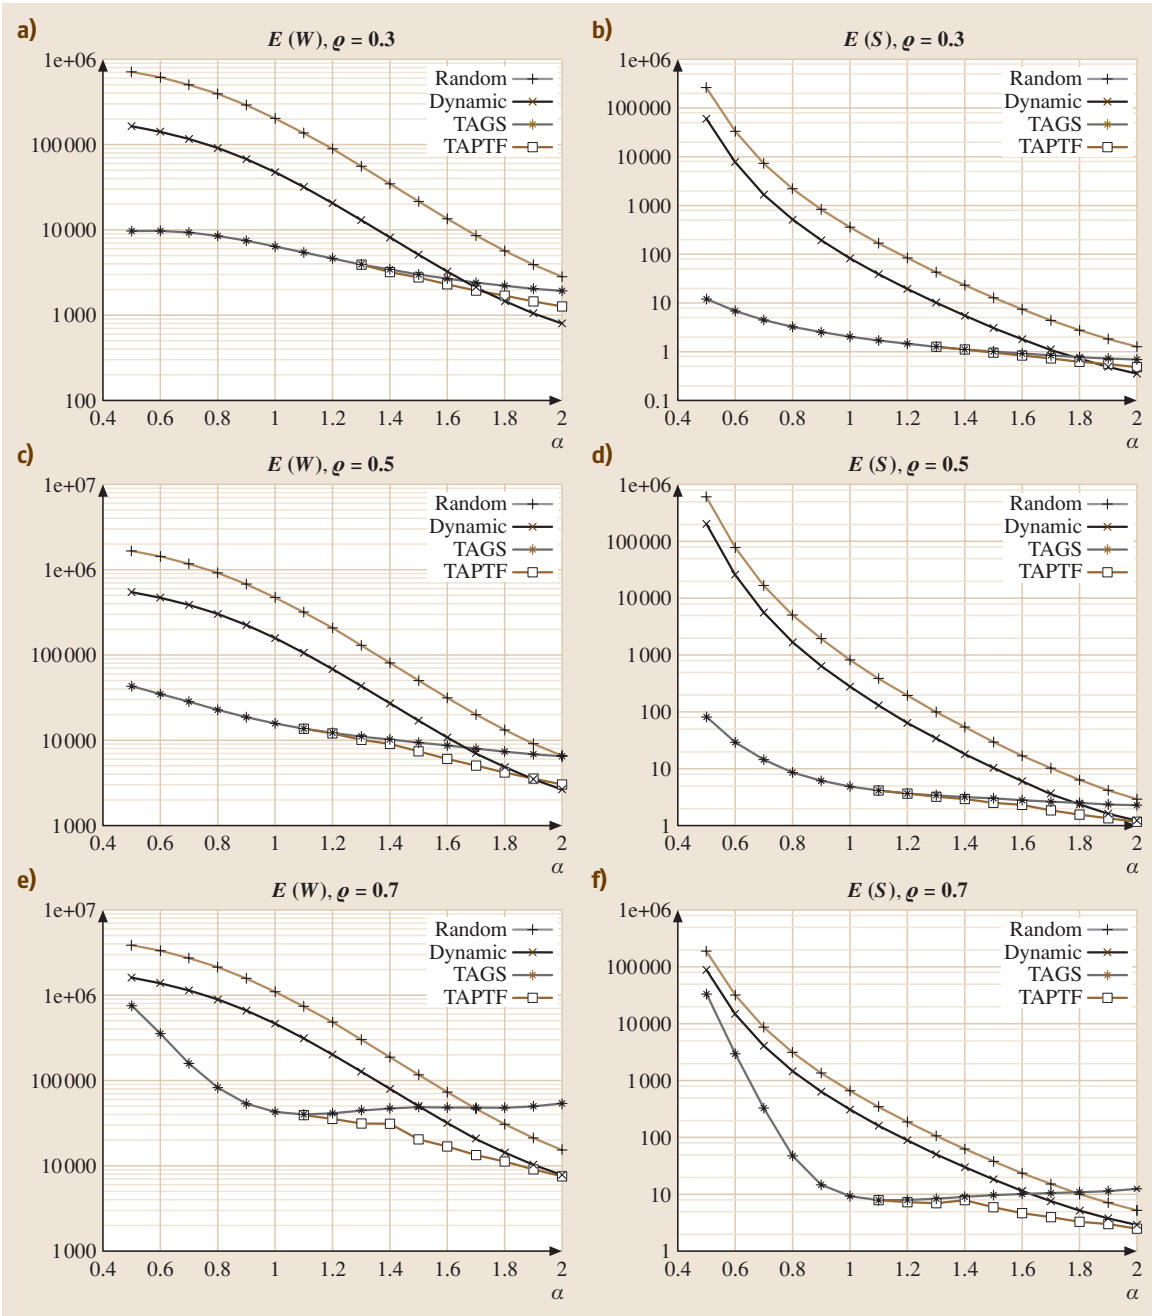

Fig. 52.13 Performance of a two-host distributed system with system load of 0.3, 0.5 and 0.7. The expected waiting time and slowdown are depicted under each load scenario

all tasks, they therefore contribute most to the overall system metrics, such as expected waiting time and slowdown. Recall that our system metrics depend on the second moment of the task size distribution; therefore, by reducing the variance experienced by the majority of tasks, size-based task assignment policies can signif-

icantly improve a system's performance over traditional techniques under heavy-tailed workloads. Next, we consider the performance of a distributed server cluster, where again our arrival is Poisson and our service time follows a bounded Pareto distribution. We set p (our largest task) to 10^7, and vary k (our smallest task) to keep the distributional mean, $E\{X\}$, fixed at 3000.

Figure 52.13 shows a comparison between the random, dynamic, TAGS and TAPTF policies in a two-host distributed system. The system load is varied, showing performance where $\rho = 0.3$ (low load), $\rho = 0.5$ (moderate load) and $\rho = 0.7$ (high load). The metrics used are the expected waiting time and mean slowdown.

As observed in Sect. 52.3.1, the performance metrics of both the random and dynamic policies are dependant on the variation of the task size distribution. As the variation increases (when α decreases) the expected waiting time and slowdown increase rapidly. Also, we note that the scale of improvement shown by the dynamic policy over the random policy decreases slightly as the system load increases. As the system load increases, there is a lower probability of a host being idle, even under the random policy. As such the dynamic policy has less scope for improvement.

Significantly, we can see an enormous improvement for the size-based task assignment policies, especially under conditions of high and extreme task size variations. These policies by their very nature reduce the variance of task sizes at each host, by partitioning the workload amongst each host. This has the effect of grouping similarly sized tasks together at the queues of each host, consequently reducing the variance at each host.

52.4 Active Queue Management for TCP Traffic

A description of how the TCP congestion control mechanism works, using a sliding congestion window to control the flow of packets through the system, is given in Sect. 52.0.3. The way in which the window size changes depends on the version of TCP used, the most common being the standard algorithms, slow start and congestion avoidance.

52.4.1 TCP Algorithms

Slow Start

Most versions of TCP that use the slow start algorithm are greedy and will attempt to take as large a share of the network resources as possible. The larger the window size a connection has, the larger the amount of resources it has. The purpose of slow start is to attempt to find the largest congestion window size a connection can have without causing too much congestion on the network. The following describes how slow start changes the window size from the commencement of a connection. In the algorithm described next, $W(a)$ refers to the window size after a acknowledgements.

1. The window size is set to one and a single packet is transmitted: $W(0) = 1$.
2. When an acknowledgement (ACK) for a packet arrives, the window size is increased by one and slides, allowing two new packets to be transmitted and acknowledging that the previous packet has been received correctly:
$$W(a+1) = W(a) + 1 \,.$$
3. When the window size reaches a slow-start threshold W_t (ssthresh), the slow-start phase ends and the congestion-avoidance phase begins.

Notice that the number of packets transmitted grows exponentially due to an increase in the number of ACKs received as the window size increases. For example, send one packet, receive one ACK, now send two packets and receive two ACKs, each of which can send a further two packets and so on.

Congestion Avoidance

Congestion avoidance usually commences after a slow-start packet has been lost; its purpose is to increase the window size slowly in an attempt to provide optimum utilization while preventing packet loss. The following are the steps of the congestion-avoidance algorithm:

1. After an ACK for one packet arrives, the window moves across one slot and one new packet can be transmitted.
2. After an ACK for every packet in an entire window arrives, the window size is increased by one, which allows two new packets to be transmitted. Therefore the window size changes according to (52.40):
$$W(a+1) = W(a) + \frac{1}{\lfloor W(a) \rfloor} \,, \qquad (52.40)$$

where $\lfloor x \rfloor$ refers to the *floor function*. For example, if $W(a) = 5$, then an arrival of an ACK would change the window to $W(a+1) = 5.2$ and five ACKs must arrive in total for the window to increase to 6.

3. Congestion avoidance ends when a maximum window size (MWS) is reached or when a packet loss occurs.

The above algorithm linearly increases the window size. The window size will only increase by one when all the ACKs from the window are received. Notice that to find the value of the window size at any a we must always take the floor of $W(a)$.

Retransmission Algorithms

In TCP packet loss is an indicator of congestion in the network and can occur in both slow start and congestion avoidance. Two common methods for detecting packet loss are fast retransmit and timeout.

Fast Retransmit. When the receiving end (client) acknowledges a packet it also indicates what the next required packet is. This will always be the packet that has the lowest sequence number. For example if the client received packets 1, 3 and 4 the next packet required is 2. Every time a new packet arrives packet 2 will be requested (in an ACK) until packet 2 arrives. These acknowledgements are called duplicate ACKs. Fast retransmit is based on the number of duplicate ACKs that are received which is usually three. If three duplicate ACKs arrive at the sender then fast retransmit will occur. This is only possible if at least three packets have been transmitted after the lost packet. Figure 52.14a shows the sequence of events in a fast retransmit where only one packet is lost. Notice packet 2 is transmitted after the third duplicate ACK for packet 2 arrives.

Timeout. Every time a packet is transmitted a timer is started, this timer will timeout, i. e. expire, after an estimated ACK arrival time. This estimated ACK arrival time is based on the mean and standard deviation of previous ACK arrival times. A timeout loss is detected when an ACK fails to arrive within the estimated arrival time and if three duplicate ACKs are *not* received. This means a timeout can only occur when a fast retransmit does not occur. Figure 52.14b shows the sequence of

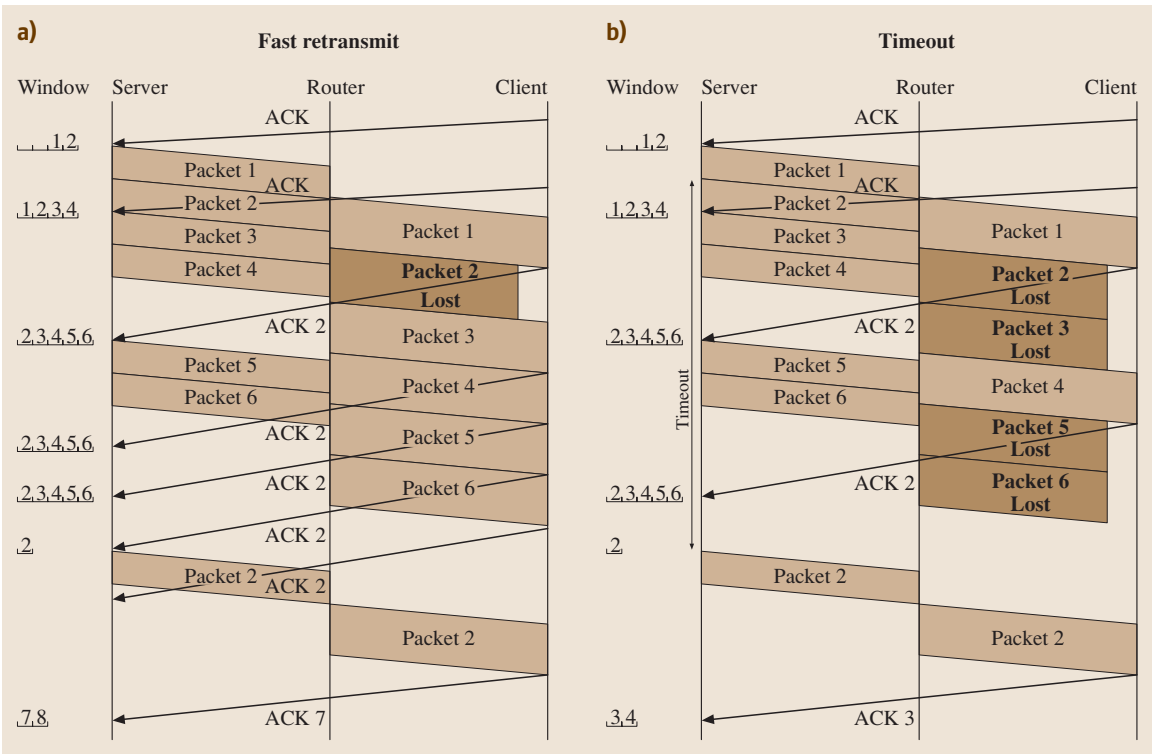

Fig. 52.14 Examples of fast retransmit and timeout

events for a timeout loss. Notice that only one packet is successfully transmitted after the first packet loss and only one duplicate ACK is received. Also notice that packets 5 and 6 are transmitted even though a packet loss has occurred.

52.4.2 Modeling Changes in TCP Window Sizes

Many models of TCP behavior have been proposed; most concentrate on finding the throughput of a TCP connections given some distribution of packet loss. Some models concentrate on short flows [52.47, 48] while other only consider long- or infinite-duration flows [52.49, 50]. A small number of models such as that of *Casetti* and *Meo's* [52.51] consider a mixture of long and short flows, which is the more realistic scenario. When short flows are modeled it is important to consider slow start because most short flows spend a majority of their time in slow start. For long flows, congestion avoidance is important because long flows spend most of their time in congestion avoidance. In [52.51], a model of the TCP congestion window size which represents both long and short finite-duration flows is presented.

In [52.52], the window size distribution is modeled as a Markov chain $\{U_k\}$, where k is the epoch of the change in window size. The state space of the process comprises four sets: active (N), idle (I), timeout (T) and fast retransmit (F), as shown in Fig. 52.15. N represents the set of states where data is available for TCP to transmit and members of this set are represented by the vector (W, W_t, N), where W is the window size, W_t the window threshold and W_M is the maximum received window size. The active states model the dynamic way the window size changes for both slow start and congestion avoidance. When a loss event occurs, the process makes a transition to one of two loss states, T and F, i.e to state (W, T) representing timeout has occurred, or (W, F) representing that fast retransmit has occurred. A transition to an idle set I models the situation when a connection has no data to send.

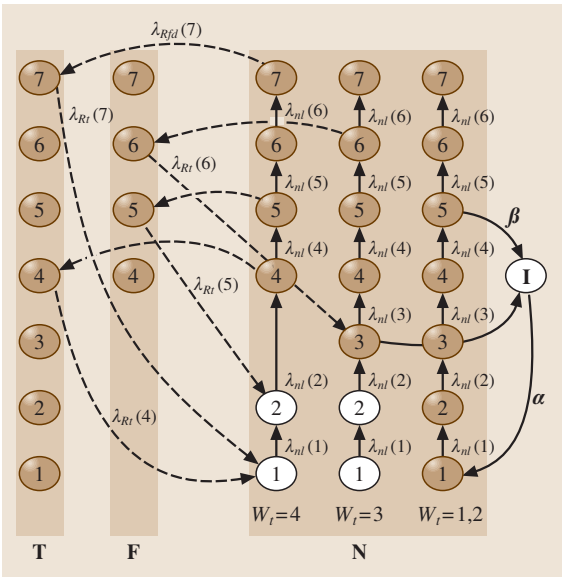

Fig. 52.15 Transitions between states in Markov model

From each of the active states N there are three different types of transition: timeout, fast retransmit and normal (i. e. no packets drop); each transition has a probability of occurrence of P_{Rt}, P_{Rf} and P_{nl}, respectively, which are used implicitly in calculating the transition rates between states. $U_k = (W, W_t, N)$ is an active transmitting state. All transitions from state U_k to U_{k+1} are summarized in (52.41) with their corresponding transition rates (the λs in the equations). For example if $W_M = 8$ and the current state is $(4, 2, N)$ then a transition to state $(5, 2, N)$ occurs if no packets are dropped. If a loss occurs then there is a transition to either state $(4, T)$, if it is a timeout, or $(4, F)$, if it is a fast retransmit. If there is no more data to send then there is a transition to state I.

$$U_{k+1} = \begin{cases} (2W, W_t, N)\lambda_{nl} & W < W_t \\ & 2W < W_t \\ (W_t, W_t, N)\lambda_{nl} & W < W_t \\ & 2W \geq W_t \\ (W+1, W_t, N)\lambda_{nl} & W_t \leq W < W_M \\ (W, T) & \lambda_{Rtd} \\ (W, F) & \lambda_{Rfd} \\ \mathrm{I} & \lambda_I \end{cases} \tag{52.41}$$

A timeout reduces the window size to one and the window threshold to $W/2$, which is half the window size, when a loss occurred. So from the timeout state $U_k = (W, T)$ a transition can occur to an active state $(1, \lceil W/2 \rceil, N)$ or the idle state if there is no more data to send, i. e.

$$U_{k+1} = \begin{cases} (1, \lceil W/2 \rceil, N) & \lambda_{Rt} \\ \mathrm{I} & \lambda_I\,. \end{cases} \tag{52.42}$$

Transitions from the fast-retransmit state $U_k = (W, F)$ are the same as the timeout state except the window size is reduced to half the loss window size instead of one, i. e.

$$U_{k+1} = \begin{cases} (\lceil W/2 \rceil, \lceil W/2 \rceil, N) & \lambda_{\mathrm{Rf}} \quad W > 3 \\ \mathrm{I} & \lambda_{\mathrm{I}} \,. \end{cases} \tag{52.43}$$

A transition from the idle state $U_k = \mathrm{I}$ to the initial active state $(1, \lceil W_M/2 \rceil, N)$ occurs with an arrival, i. e.

$$U_{k+1} = (1, \lceil W_{\mathrm{M}}/2 \rceil, N) \quad \alpha \tag{52.44}$$

where α is the arrival rate.

The stationary distribution π_{U} of $\{U_k\}$ can be obtained by solving the balance equations described by the transitions displayed in (52.41), (52.42), (52.43) and (52.44) in a similar way to that obtained for the MPDQ in Sect. 52.2.2. Note that the rates λ_{nl}, λ_{Rt} and λ_{Rf} are all functions of the window size W and must be defined from the packet-loss probability, loss distribution and delays of the network. A separate network model is required to define these parameters. Details of these derivations can be obtained from [52.52].

52.4.3 Modeling Queues of TCP Connections

The network that supports TCP connections is usually made up of a number of interconnected routers. Each router contains one or more buffers and a number of links. Bottlenecks can occur when a number of connections all attempt to utilize one link. Even though queueing can occur in any router, the bottleneck is usually most important because this is where the majority of queueing delay will occur. The most common type of queueing discipline assumed in routers are FCFS, the so called *droptail queues*. Recently active queue management (AQM) queues have been introduced specifically for TCP traffic. One of the most popular is the random early-detection queue (RED) [52.53]. In the following sections the FCFS droptail and RED queues will be described in more detail.

FCFS Droptail Queues

The most basic router queue on the internet is the droptail FCFS queue. A droptail queue has a finite buffer and drops packets if it is full. Packets arrive at the queue at the rate λ and are served at the rate μ. The arrival rate depends on the number of TCP connections connected to the queue and their maximum transmission rates. For example, if there are ten TCP connections with a maximum send rate of ten packets per second, then the maximum arrival rate would be one hundred packets per second. The departure rate μ is the number of packets that can be served on the outgoing link and depends on the bandwidth of the link. For example the outgoing link bandwidth may be 80 packets per second. The service time of each packet is deterministic because most packets of a TCP connection are the same size. The load of the network ρ is defined in Sect. 52.1.2. If the load is greater than one the network is considered congested and packets must be dropped from the queue. TCP aims to reduce the arrival rate of packets to the queue to a value close to one in an effort to minimize dropped packets and prevent packet retransmission, which adds further load.

An $M/D/1/K$ queue is a good model for approximating a queue of TCP connections because the arrival process of packets can be approximated as Poisson when there is a large number of sources, service time is deterministic and the queue has a finite capacity K. However, most of the operational parameters of an $M/D/1/K$ queue, such as average waiting time and drop probability P_K, i. e. the queue is full, cannot be obtained explicitly and the $M/M/1/K$ queue has been found to provide a good approximation [52.51]. As exhibited in Sect. 52.1.4, this simpler model has explicit equations for drop probability P_{K}, average waiting time $E(W_{\mathrm{q}})$ and average number of packets in the queue $E(L_{\mathrm{q}})$.

The average waiting time and packet drop probability together with the TCP send rate can be used to find the equilibrium point of a network using fixed-point analysis. The TCP send-rate equation finds the send rate (arrival rate to the queue) as a function of packet drop probability and average waiting time while the queue model finds the average waiting time and packet drop probability as a function of arrival rate.

Random Early Detection (RED)

As explained in previous sections, packet drops can control the send rate of a TCP connections. When the network contains droptail queues, the control of the TCP send rates is passive because only the queue length affects the packet drop probability. In active queue management the packet loss probability is controlled by the system administrator through various algorithms. These algorithms attempt to drop packets in strategic ways to control the send rate of TCP sources. One of the most common algorithms is RED [52.53].

RED attempts to control the rate of TCP traffic sources by dropping packets based on the average queue

Table 52.1 Some heavy-tail distributions

Description of files	α
Unix process CPU requirements [52.34]	1.0
Sizes of files transmitted over the internet [52.31,32]	1.1 – 1.3
1998 World Cup web site file size distribution [52.36]	1.37

size, estimated using exponential weighted moving average (EWMA). It attempts to keep the average queue size low and reduce delay. A number of thresholds are used by the RED algorithm, which are defined as follows:

- $\min_{\text{th}}$ – the average queue size at which packets will start to be dropped. When the average queue size is less than $\min_{\text{th}}$ no packets are dropped.
- $\max_{\text{th}}$ – the average queue size at which all packets will be dropped if it is exceeded.
- $p_{\max}$ – the maximum probability of dropping a packet.

Using these threshold, RED calculates and sets the probabilities p_b and p_a, which it uses in selecting packets to drop. These probabilities are given by (52.45) and (52.46), which are functions of average queue sizes avg:

$$P_b(\text{avg}) = \begin{cases} 0 & \text{avg} < \min_{\text{th}} \\ 1 & \text{avg} > \max_{\text{th}} \\ p_{\max}\frac{\text{avg}-\min_{\text{th}}}{\max_{\text{th}}-\min_{\text{th}}} & \min_{\text{th}} \le \text{avg} \le \max_{\text{th}} \end{cases} \tag{52.45}$$

$$P_a = \frac{P_b}{1 - i P_b}\,, \tag{52.46}$$

where i is the number of packets since the last dropped or marked packet. As the average queue size increases so does the probability that packets are dropped randomly from the queue. The relationship between the average queue size and drop probability p_b is linear within the $\min_{\text{th}}$ to $\max_{\text{th}}$ range (with values from 0 to $p_{\max}$, respectively). When the average queue size is below $\min_{\text{th}}$ no packets are dropped and when it is above $\max_{\text{th}}$ all packets are dropped. Using average queue sizes allows the queue to grow up to its maximum size in order to accommodate erratic (bursty) traffic flows. We refer the reader to [52.53] for details regarding the choice between using p_b and p_a in marking and dropping packets.

The RED algorithm is also useful in providing differentiated services because it can control the rate in which different classes of packets enter the network. In the next section we will investigate how RED is applied to provide differentiated services.

Table 52.2 Scheduling variables

Variable	Description
x	Priority state (high $x = 1$, low $x = 2$)
L	The queue that obtains service
Q_x	The instantaneous queue length of priority x queue
W_x	The weight assigned to the priority x queue
R_1	Average goodput, i. e. the amount of packets that gets transmitted through a system (packets/second)
T_1	Goodput threshold of high priority traffic

52.4.4 Differentiated Services

Differentiated services allow differing traffic to be categorized into a number of different service groups that provide different levels of service. For example, some packets may require low delay, while for others high throughput may be important. In a network, service is provided to a packet at the router buffers. The router can then schedule the order in which packets are allowed access to the link. The two common scheduling algorithms are weighted round-robin (WRR) and priority scheduling, which we have discussed earlier in Sect. 52.2. Another popular method of differentiating service at a buffer is by exploiting TCPs congestion control mechanism to control the rate at which packets enter the network. Packets can be actively dropped to signal to the TCP sources to slow down and prevent the packets from entering the network in the first place. Algorithms that achieved this are weighted RED (WRED) and RED in/out (RIO). These and other mechanisms of differentiated services will be explained in the following sections. For simplicity only two groups of service (high and low priority) will be assumed when describing differentiated services. Table 52.2 gives a list of variables that will be used in the ensuing discussions.

Weighted Round-Robin (WRR)

Weighted round-robin is used in class-based queues (CBQ) as an extension to round-robin scheduling (cf. Sect. 52.3.1) where each priority has a separate first-in first-out (FCFS) queue with a weight (refer to Fig. 52.16). Each queue is assigned a number of slots depending on its weight and for each slot, a queue can transmit a packet of data. For example, say there is a total of three slots and the high-priority queue is assigned two of the three slots, the low-priority queue has the remain-

ing slot. The slots are served in a round-robin fashion by a single server who moves from queue to queue so that the high-priority queue gets twice as much service as the low-priority queue. Note that packets are also serviced in order of priority with two-high priority packets serviced then followed by one low-priority packet, and so on. This can be formally described as follows:

$$S = W_1 + W_2 \,,$$

$$L = \begin{cases} 1 & Q_2 = 0,\, Q_1 > 0 \\ 1 & Q_1 > 0,\, (a \bmod S) \le W_1 \\ 2 & Q_1 = 0,\, Q_2 > 0 \\ 2 & Q_2 > 0,\, W_1 \le (a \bmod S) < S \end{cases} ,$$

where S is the total weight and the variable a is discrete and increments by one after each service or when a queue is empty.

The benefit of WRR is that no class denies any other class services, the low-priority class will always get its allocated amount of bandwidth. This provides a degree of fairness to all classes much akin to that provided by the dual queue in a MPDQ.

Priority Queues

A priority queue has been discussed in previous sections but in the context of customers rather than packets. Here, a priority queue can be a single queue which rearranges packets based on their priority (as is assumed in Sect. 52.2) or it can be multiple queues which have a priority of services. A single-priority queue involves complex rearrangement of packets within the queue, which can be processor-intensive and hence difficult to implement in practice. For this reason, we will mainly concentrate on a priority CBQ where each queue serves packets of a single priority and the service of the queues is prioritized, i. e. a queue with high-priority packets are always served before that with low-priority packets. The only time a low-priority packet can be served is when the high-priority queue is empty. The scheduling algorithm is then simply:

$$L = \begin{cases} 1 & Q_1 > 0 \\ 2 & Q_1 = 0,\, Q_2 > 0 \,. \end{cases}$$

As we have seen, in priority queues if the amount of high-priority traffic is large the low-priority traffic can be starved of service completely. The major advantage of priority queues in packet networks is that high-priority packets have much lower delay because they are always served first [52.54].

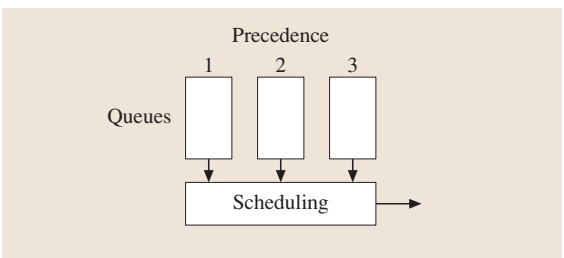

Fig. 52.16 A class-based queue

Flow-Based Quality of Service (QoS) with RED

A single flow is made up of many different types of packets, each of which can be given different levels of services. For example, a flow of size 60 packets could have 40 high-priority packets that must get to the other end and 20 low-priority packets that may get to the other end if there is available bandwidth. Weighted RED and RED in/out are a couple of ways that have been suggested to provide this differentiation within a flow.

Weighted RED (WRED). WRED [52.55] extends RED to allow different classes of packets to be treated differently. For example a high-priority class may have a lower probability of packet drop than a lower-priority class. WRED uses a single queue and maintains a single average queue size in exactly the same way as RED. It differs from RED by providing different $\min_{\text{th}}$, $\max_{\text{th}}$ and $p_{\max}$ for each class of packet. For example, WRED could be configured to have a larger $\min_{\text{th}}$ and $\max_{\text{th}}$ for high-priority traffic. This would make the high-priority packet-drop probability lower than that for low priority packets for all average queue sizes. A higher drop probability would mean that low-priority TCP sources would decrease their sending rate more than high-priority sources, thereby allowing more high-priority traffic through the link.

RED in/out (RIO). RIO [52.56] is similar to WRED except that it keeps a separate average queue length for the high-priority (*in*) packets and for the low-priority (*out*) packets. The reason different average queue sizes are used is to isolate the effect of *out* packets from *in* packets. For example if a single queue is used then a large load of *out* packets will increase the queue size and cause *in* packets as well as *out* packets to be dropped. By having a separate average queue size for *in* packets the number of *in* packets dropped is independent of the load of the *out* packets. RIO suffers the same prob-

lem as WRED in that when there is a large amount of *in* traffic it can starve low-priority *out* traffic of service.

Class-Based QoS with RED

A CBQ system can be combined with RED packet dropping to provide service differentiation between flows. Note this is a different level of service for an entire flow of packets rather than for individual packet. RED plus scheduling is an advantage over scheduling with FIFO because RED can control the source rate rather than just allocate desired bandwidth between different priority classes. For example if the high-priority traffic is allocated 1 Mbps out of 3 Mbps bandwidth, the high-priority load could be 2 Mbps. Rather than drop 1 Mbps of packets RED would attempt to adjust the load to 1 Mbps to fit the available bandwidth. The CBQ could use WRR or priority scheduling to serve each class of queue.

WRR RED. WRR RED simply combines WRR scheduling with RED. The WRR parameters are the same: each RED queue is allocated a number of service slots out of the total slots. Each RED queue can then use the same $\min_{\text{th}}$, $\max_{\text{th}}$ and $p_{\max}$, since the aim is to try to optimize the average queue length for the bandwidth allocated to the queue by WRR. WRR RED shares the advantages and disadvantages of WRR where high-priority packets are delayed by low-priority packets.

Table 52.3 DPRQ parameters

Parameter	Description
K	Maximum Buffer Size of both Queues
x	Priority (high $x = 1$, low $x = 2$)
D	Propagation delay
S_x	Number of priority x TCP sources
λ_x	Arrival rate of priority x packets
μ	Service rate of packets
P_{FS}	Probability of exceeding threshold given the current state is F and next state is S (above threshold S or $F = 1$, below threshold S or $F = 0$)
T_x	Goodput threshold of priority x queue
r_x	Average RED packet drop probability of priority x queue
g_x	Average RED packet no drop probability of priority x queue
d_x	Average total packet drop probability of priority x queue. RED plus queue full
q_x	Average queuing delay of priority x packets

Priority RED. Priority scheduling can also be combined with RED, just like WRR. Each RED queue is assigned a priority of services. For example if the highest-priority RED queue has packets in it, then it will always get service first. Priority RED faces the same advantages and disadvantages as the normal priority queueing discussed earlier. When there is a large amount of high-priority traffic it can starve low-priority traffic, with the advantage being that there would be a much lower delay for high-priority traffic.

Dynamic-Priority RED Queue (DPRQ)

Recently, we introduced the DPRQ [52.57], which extends the priority RED queue by adding a threshold to the amount of high priority traffic that is allowed service. The DPRQ scheduling algorithm allows a goodput i. e. successfully transmitted packets, threshold T_1 to be placed on high-priority traffic. The aim of the threshold is to prevent high-priority traffic from starving low-priority traffic, a drawback associated with the RED queues we have discussed earlier. The scheduling algorithm is as follows (Table 52.2):

$$L = \begin{cases} 1 & R_1 \le T_1,\ Q_1 > 0 \\ 2 & R_1 > T_1,\ Q_2 > 0 \\ 2 & Q_1 = 0,\ Q_2 > 0 \\ 1 & Q_1 > 0,\ Q_2 = 0 \end{cases} . \qquad (52.47)$$

When the average goodput of high-priority traffic R_1 is less than the threshold T_1 the high-priority queue will have priority in service. If R_1 increases beyond the threshold T_1 then it has exceeded its allowed goodput and the low-priority queue will be served with priority until R_1 is reduced. In this case R_1 naturally reduces because the high-priority queue is not being serviced. When there are no high-priority packets the low-priority queue will be serviced, if it is not empty. If the low-priority queue is empty then the high-priority queue is serviced. The average goodput R_1 is calculated over a specified time period using an exponential weighted average, just like that used to find the average queue length in the RED algorithm.

The DRPQ model and algorithm [52.57] will now be described in detail using the parameters which we have collected in Table 52.3.

As stated before in RED, the packet-drop probability depends on the average queue length. If the RED router is well configured the average queue length will not change a great deal over a large period of time. Over this period the average packet drop probability will be

Table 52.4 States of the DPRQ

Range	Description
$m = 0, n = 0$	Both queues empty
$m = 0, 0 < n < K$	High priority queue is empty
$m = 0, n = K$	High priority queue empty and the low priority queue full
$0 < m < K, n = 0$	Low priority queue empty
$m = K, n = 0$	Low priority queue empty and the high priority queue full
$0 < m < K, 0 < n < K$	General queue
$m = K, 0 < n < K$	High priority queue full
$0 < m < K, n = K$	Low priority queue full
$m = K, n = K$	Both queues full

P_b from (52.45). The probability of a packet not being dropped is therefore $g_x = 1 - P_b$, where x represents the priority of the queue.

Two possible states are defined for the threshold: either the threshold has been exceeded which is represented by a 1 or the threshold has not been exceeded, represented by a 0. The probability of the threshold changing from state F to state S is P_{FS}. For example, P_{01} is the probability, given that the threshold is currently not exceeded, that it will be exceeded in the next transition. Clearly, P_{FS} satisfy the following equations:

$$P_{00} + P_{01} = 1 ,$$
$$P_{10} + P_{11} = 1 .$$

We assume that the number of packets served in any time interval has a Poisson distribution, which is a valid assumption if the number of packets traversing the queue is large, as it is in this case. Therefore, the goodput R_1 is also Poisson with mean $\mu_1 = S_1 g_1 \lambda_1$ and standard deviation $\sigma_1 = \sqrt{S_1 g_1 \lambda_1}$. If the mean is large, which it is here since λ and S_x are usually large, the cumulative normal distribution can be used to approximate the cumulative Poisson distribution, i. e. we approximate R_1 by a normal random variable X. Therefore, for $y \geq 0$

$$P(R_1 \leq y) \approx P(X \leq y) = \frac{1}{2}\left[1 + \operatorname{erf}\left(\frac{y - \mu_1}{\sigma_1 \sqrt{2}}\right)\right] , \quad (52.48)$$

where $\operatorname{erf}(z) = \dfrac{2}{\sqrt{\pi}} \displaystyle\int_0^z \mathrm{e}^{-t^2}\,\mathrm{d}t$

is the error function. To approximate the probability that the threshold T_1 is not exceeded, simply set $y = T_1$ in (52.48) giving the following equation:

$$P_{00} = P_{10} = \frac{1}{2}\left[1 + \operatorname{erf}\left(\frac{T_1 - \mu_1}{\sigma_1 \sqrt{2}}\right)\right] .$$

The queue length process is modeled using the Markov chain $\{V_k\}$ defined at the epoch of the k-th packet arrival to the queue. The states of $\{V_k\}$ are represented by the vectors (m, n, G), where m is the number of packets in the high-priority queue, n is the number of packets in the low-priority queue and G represents whether the threshold is exceeded in the high-priority queue: $G = 1$ signifies that the threshold is exceeded while $G = 0$ signifies that it is not. Table 52.4 indicates the possible range of states of V_k.

Different rate diagrams are needed for the different ranges shown in Table 52.4 but, due to lack of space, we will only show diagrams for the general range $0 < n < K$ and $0 < m < K$. We note that there are two sets of diagrams describing these transitions, one when $G = 0$ and another when $G = 1$. When the threshold has not been exceeded, the transitions from state $V_k = (m, n, 0)$ to V_{k+1} when $0 < m < K$ and $0 < n < K$ are described by (52.49) with corresponding transition rates:

$$V_{k+1} = \begin{cases} (m, n+1, 0) & g_2 \lambda_2 \\ (m+1, n, 0) & g_1 \lambda_1 \\ (m-1, n, 0) & P_{00}\mu \\ (m-1, n, 1) & P_{01}\mu . \end{cases} \quad (52.49)$$

When the threshold has been exceeded, the transition from $V_k = (m, n, 1)$ to V_{k+1} when $0 < m < K$ and $0 < n < K$ are described by (52.50).

$$V_{k+1} = \begin{cases} (m, n+1, 1) & g_2 \lambda_2 \\ (m+1, n, 1) & g_1 \lambda_1 \\ (m, n-1, 0) & P_{10}\mu \\ (m, n-1, 1) & P_{11}\mu. \end{cases} \quad (52.50)$$

Figure 52.17 shows the general transition-rate diagram. When the threshold is not exceeded the interactive

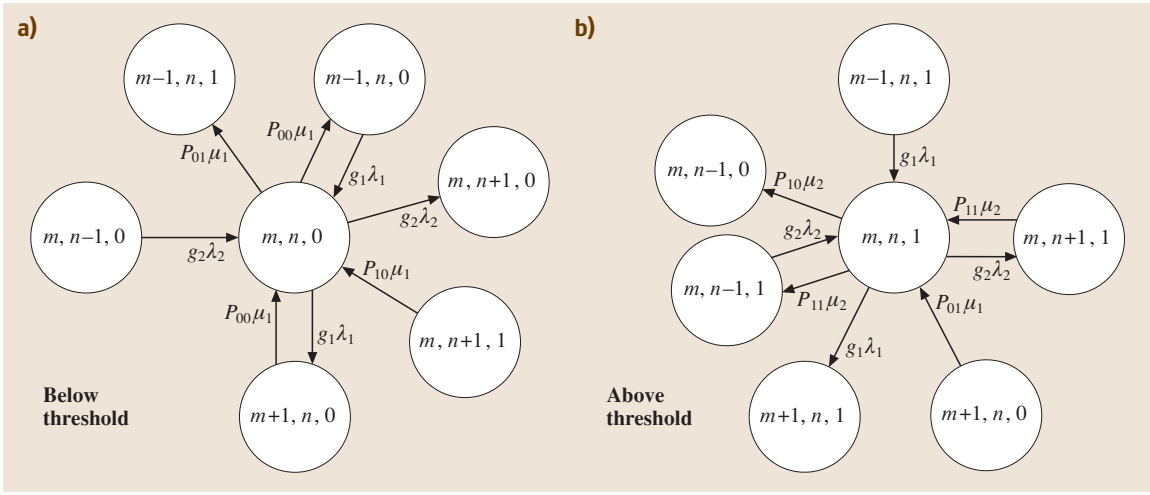

Fig. 52.17 DPRQ Markov process model ($0 < n < K$) and ($0 < m < K$)

queue has priority, therefore interactive packets are only served from states where the threshold has not been exceeded ($G = 0$ states). Similarly the low-priority queue is only serviced when the threshold has been exceeded therefore transitions can only occur from the low-priority queue when $G = 1$. Arrival of packets to either queue will cause the queue to increase in size.

Finally, extensive simulations based on the DPRQ and reported in [52.57] show general performance improvements, such as the reduction of packet loss, when compared to RED CBQ.

52.5 Conclusion

Modern communication systems, as exemplified by web server systems, continue to grow in complexity and level of sophistication. Queueing models have been extensively used to model and test new communication systems with the aim of improving QoS to users. In this chapter, we have discussed several approaches that have been advocated to reduce congestion and improve load balancing in these systems. We have considered both theoretical and practical aspects of analyzing and evaluating new systems, especially when the traffic flows are differentiated into different priority classes. The MPDQ discussed in Sect. 52.2 have been analyzed thoroughly, both in the theoretical and practical sense. However, a complete theoretical analysis of the network of multiple dual queues used in load balancing in Sect. 52.3 remains a challenge, as is the dynamic-priority RED queue (DPRQ) discussed in Sect. 52.4. All this is tied up with the feasibility of a comprehensive theoretical analysis of networks of queues with a specific type of node. Success in this venture would provide a unique opportunity to extend the range of problems that arise when designing new and reliable communication systems.

53. Support Vector Machines for Data Modeling with Software Engineering Applications

This chapter presents the basic principles of support vector machines (SVM) and their construction algorithms from an applications perspective. The chapter is organized into three parts. The first part consists of Sects. 53.2 and 53.3. In Sect. 53.2 we describe the data modeling issues in classification and prediction problems. In Sect. 53.3 we give an overview of a support vector machine (SVM) with an emphasis on its conceptual underpinnings. In the second part, consisting of Sects. 53.4–53.9, we present a detailed discussion of the support vector machine for constructing classification and prediction models. Sections 53.4 and 53.5 describe the basic ideas behind a SVM and are the key sections. Section 53.4 discusses the construction of optimal hyperplane for the simple case of linearly separable patterns and its relationship to the Vapnik–Chervonenkis dimension. A detailed example is used for illustration. The relatively more difficult case of nonseparable patterns is discussed in Sect. 53.5. The use of inner product kernels for nonlinear classifiers is described in Sect. 53.6 and is illustrated via an example. Nonlinear regression is described in Sect. 53.7. The issue of specifying SVM hyperparameters is addressed in Sect. 53.8, and a generic SVM construction flowchart is presented in Sect. 53.9. The third part details two case studies. In Sect. 53.10 we present the results of a detailed analysis of module-level NASA data for developing classification models. In Sect. 53.11, effort data from 75 projects is used to obtain nonlinear prediction models and analyze their performance. Section 53.12 presents some concluding remarks, current activities in support vector machines, and some guidelines for further reading.

53.1 Overview

The problem of predictive data modeling is of both academic and practical interest in many engineering and scientific disciplines, including software engineering. It is the process of building a model of the input–output relationship from historical or experimental data. This model is used to predict the output of a future occurrence for which only the input will be known. Such models have their roots in traditional statistics. However, recent advances in machine learning and related disciplines have been shifting focus away from statistical methods toward these approaches. In particular, a new type of learning machine, called a support vector machine (SVM), has gained prominence within the last decade. These machines are based on statistical learn-

ing theory, possess some very nice properties, and have exhibited impressive performance in a wide range of applications.

In this chapter we present the basic principles of support vector machines and their construction algorithms, with emphasis on applications. In Sect. 53.2 we formally describe data modeling for classification and prediction in software engineering and some important considerations in model development. Support vector machines are introduced in Sect. 53.3. Section 53.4 deals with the case of developing maximal margin classifiers for linearly separable classes and their relationship to the important concept of the Vapnik–Chervonenkis (VC) dimension. An illustrative example is used to explain the computations involved. Next, the more difficult problem of nonseparable patterns is presented in Sect. 53.5. Nonlinear classifiers using inner-product kernels are discussed in Sect. 53.6, and their computational steps are illustrated via an example. The development of nonlinear prediction models using the SVM algorithm is discussed in Sect. 53.7 and some comments about selecting SVM hyperparameters are summarized in Sect. 53.8. In Sect. 53.9, a generic SVM flow chart is presented to depict the development of classification and prediction models using SVM. In Sect. 53.10 a case study for module classification is detailed using public-domain software metrics data. Software effort-prediction using SVM nonlinear regression modeling is presented in Sect. 53.11 for some commercial software projects. A summary, a mention of current activities in SVM, and suggestions for further reading are included in Sect. 53.12.

For readers who want to get a general understanding of support vector machines, Sects. 53.2, 53.3, 53.4.1, 53.4.3, and 53.10 should be adequate. Section 53.6 is useful in understanding how SVM develops classifiers for practical classification problems. The remaining sections provide a description of related issues and SVM nonlinear regression.

53.2 Classification and Prediction in Software Engineering

53.2.1 Classification

A classification model is constructed from a set of data for which the attributes and the true classes are known and is employed to assign a class to a new object on the basis of its observed attributes or features. In software engineering, metric-based classification models are employed to classify a module as fault-prone or not fault-prone. Other terms that are used for module classes are high or low risk, high or low criticality, etc. An ability to identify fault-prone modules early in their lifecycle is of practical significance in software engineering because it enables allocation of appropriate resources such as additional reviews and testing to these modules and will thus enhance the quality of the delivered system.

Formally, the problem can be stated as follows. We have available metrics data ($\boldsymbol{x}_i$) about n modules and their corresponding class labels, y_i, denoted as

$$S = \left\{(\boldsymbol{x}_i, y_i), \boldsymbol{x}_i \in \mathbb{R}^d, y_i \in (-1, +1)\right\}, i = 1, 2, \ldots, n, \quad (53.1)$$

where d is the dimensionality of the input metrics data. Here the value of y_i as -1 or $+1$ is based on some threshold value of the numbers of faults found in the module. The modeling task is to construct a support vector classifier (SVC) that captures the unknown pattern between the inputs and the outputs, based on the evidence provided by the data. The developed model is then used to predict the criticality class of a future module whose software metrics values ($\boldsymbol{x}$) would be known, but not the class (y).

The objective is to develop a model with good accuracy on both the training data and on future predictions. A common measure used for assessing accuracy is the classification error (CE), which is the ratio of the number of modules classified correctly to the total number of modules. To seek an objective measure of the future performance of the classification model, one approach is to partition the sample data randomly into three sets: training, validation, and test, as shown in Fig. 53.1. The first set is used for model development, i. e., for training.

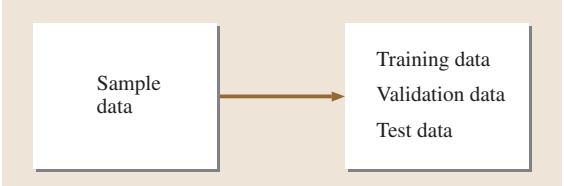

Fig. 53.1 Sample-data partitioning

The candidate models are evaluated on the validation data and usually the model with the smallest CE is selected. Then, the selected model is used to classify the data in the test set, and this error is considered to be an objective measure of future performance, or generalization error, of the selected model. The relative sizes of these sets are application-dependent. However, 50% of the data is often used for training, 25% for validation, and 25% for testing. This is called the *hold out* approach. Sometimes, only two subsets are created, training and the test, and the test set is used for model selection.

If the data set is small, the generalization error is estimated using cross validation. For k-fold cross validation (KCV), the data set is randomly divided into almost equal k sets and the model is developed from $(k-1)$ sets and tested on the omitted k-th set. The process is repeated k times, leaving a different set out each time. The average CE on the k omitted sets is called the *KCV error* of the model. Commonly used values for k are five and ten. Sometimes, we use $k = 1$. Then, the estimated error is called the *leave one out* (*Loo*) error.

53.2.2 Prediction

The development of such models can also be seen as finding input–output mapping, but now between the project features and the effort. This problem can be stated as follows. Given some input and output data about previous projects, find a suitable functional relationship between them. Suppose we are given a training data set,

$$S = \left\{ (\boldsymbol{x}_i, y_i), \boldsymbol{x}_i \in \mathbb{R}^d, y_i \in \mathbb{R} \right\}, i = 1, 2, \ldots, n \,, \tag{53.2}$$

where $\boldsymbol{x}$ are the software project features, d is the number of features, y is the effort, and n is the number of projects in the data set. Then, the goal is to find a function or mapping that maps $\boldsymbol{x}_i$ to y_i, $i = 1, \ldots, n$, such that the training and generalization errors are small. Two error evaluation measures commonly employed in software effort research are the mean magnitude of relative error (MMRE) and PRED(25), defined as follows:

$$\text{MMRE} = \frac{1}{n} \sum_{i=1}^{n} \frac{\left| \text{Actual effort}, y_i - \text{Predicted effort}, \hat{y}_i \right|}{\text{Actual effort}, y_i} \,; \tag{53.3}$$

$$\text{PRED}\,(25) = \frac{\text{Number of estimates within 25\% of actual } y}{n} \,. \tag{53.4}$$

These are measured for the model using the training data set and evaluated on the test data, usually by the Loo cross validation, since the number of projects used for effort estimation is generally small. Note that MMRE is a measure of error, while PRED(25) is a measure of accuracy. Therefore, we seek low MMRE and high PRED(25) values. The model performance on test data is used as a measure of its generalization ability, that is, a measure of the predictive accuracy on future projects for which the effort would be estimated.

53.3 Support Vector Machines

In this section we provide a very brief introduction to support vector machines. Consider the classification and regression tasks we just discussed. The statistical techniques for dealing with these require a knowledge of the underlying distribution. In many practical situations this distribution is not known and has to be assumed. Due to this restriction we seek alternative, distribution-free procedures. A support vector machine provides such a procedure that is relatively new and has some very nice properties. In particular, SVM is a learning procedure that can be used to derive learning machines such as polynomial approximators, neural networks, and radial basis functions. The origins of SVMs are in statistical learning theory (SLT) and they represent an approximate implementation of the principle of structural risk minimization (SRM). These are discussed in-depth in [53.1, 2] and are beyond the scope of this chapter. Briefly, the SRM principle is based on the fact that the test error of a learning machine, that is, the generalization error, is bounded by the sum of two quantities. The first is the training error, that is, the error on the training set. The second quantity is a function of the Vapnik–Chervonenkis (VC) dimension [53.1] and is called the VC bound. The underlying theory shows that a learning machine with a low VC bound will have a low generalization error. Thus, a low-VC classifier will have a low CE on new data. Similarly, a prediction model with a low VC bound will have a low MMRE or a high PRED(25)

when used for future predictions. Consider the classification problem for a set of separable patterns. For this case, SVM derives a learning machine with a training error of zero. It also minimizes the second term.

However, in practice, the VC dimension of nonlinear classifiers or predictors, such as radial basis functions, cannot be accurately estimated and hence the results of this theory cannot be precisely implemented. That is why the statement above about SVM used the words approximate implementation. What is discussed in subsequent sections is a practical realization of this theory. We first show how the SVM develops classifiers for the separable case. SVM algorithms are then derived to deal with the more difficult cases of nonseparable patterns. These ideas are then extended to nonlinear prediction models.

53.4 Linearly Separable Patterns

This is the simplest classification task and was the first to be introduced for support vector machines (SVM) [53.1]. It is applicable for data that are linearly separable in the input space. Although not very useful for many real-world applications, it helps focus on the key aspects for developing SVM classifiers for more complex applications. We are given training data as in (53.1). We seek to determine a decision function D such that $D(\boldsymbol{x}) = y$, where y is the class label of data point $\boldsymbol{x}$. The goal is to find a D that minimizes generalization error. The decision boundary is given by the hyperplane

$$D(\boldsymbol{x}) : \boldsymbol{w}^T \boldsymbol{x} + b = 0 \,, \tag{53.5}$$

where $\boldsymbol{w}$ is a d-dimensional weight vector, and b is the bias term. If the data is separable, it will be correctly classified, i. e., for $i = 1, 2, \ldots, n$,

$$\begin{aligned} &\boldsymbol{w}^T \boldsymbol{x}_i + b \geq 0 \text{ for } y_i = +1 \\ \text{and} \quad &\boldsymbol{w}^T \boldsymbol{x}_i + b < 0 \text{ for } y_i = -1 \,. \end{aligned} \tag{53.6}$$

Separation between the decision function and the closest data point is called the *margin of separation* and equals $1/||\boldsymbol{w}||$. There can be many possible hyperplanes that separate the two classes. However, intuitively, the larger the margin, the lower the generalization error. This is so because points closest to the decision surface are harder to classify, and by providing a maximal separation between the two classes it should be easier to classify a new data point. For illustration, sample data points from two classes are shown in Fig. 53.2 with two margins, small and large. The boundaries with a larger margin can be seen to be preferable.

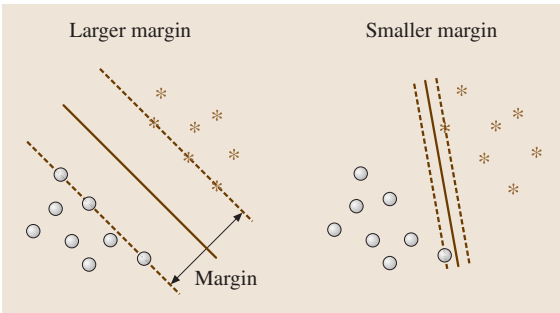

Fig. 53.2 Two linearly separable classes

53.4.1 Optimal Hyperplane

Given the linearly separable training data, the hyperplane that maximizes the margin is sought in the support vector machine formulation. Equivalently, we seek $(\boldsymbol{w}, b)$, which solves the following problem:

$$L\,(\mathrm{w}) = \min_{w\,b} \left(\frac{1}{2} \boldsymbol{w}^{\mathrm{T}} \boldsymbol{w} \right) \,. \tag{53.7}$$

$$\text{subject to} \quad y_i \left(\boldsymbol{w}^{\mathrm{T}} \boldsymbol{x}_i + b \right) \geq 1, \quad i = 1,\ 2, \ldots,\ n \,. \tag{53.8}$$

The aforementioned optimization problem may be solved by the method of Lagrange multipliers. Usually, the dual of this primal problem is solved. For details, see [53.3, 4]. The dual problem can then be stated as finding the Lagrange multipliers for the data in (53.1) that maximize the following objective function:

$$L_{\mathrm{D}} \equiv \sum_{i=1}^{n} \alpha_i - \frac{1}{2} \sum_{i,\,j} \alpha_i \alpha_j y_i y_j \boldsymbol{x}_i^{\mathrm{T}} \cdot \boldsymbol{x}_j \,, \tag{53.9}$$

The constraints are

$$\sum_{i=1}^{n} \alpha_i y_i = 0 \,, \tag{53.10}$$

$$\alpha_i \geq 0, \quad i = 1,\ 2, \ldots,\ n \,. \tag{53.11}$$

Note that in the dual only the input data appears in (53.9) in the form of dot products of $\boldsymbol{x}_i$ and $\boldsymbol{x}_j$, $i, j = 1, 2, \ldots, n$.

The solution yields the Lagrange multipliers α_i^*, $i = 1, 2, \ldots, n$. The optimal weight vector and the bias term are then given by

$$\boldsymbol{w}^* = \sum_{i=1}^{n} \alpha_i^* y_i \boldsymbol{x}_i \tag{53.12}$$

$$\text{and } \boldsymbol{w}^{*\mathrm{T}} \boldsymbol{x} + b \geq 1 \,. \tag{53.13}$$

The optimal decision hyperplane can now be obtained by substituting for $\boldsymbol{w}^*$ and b^* in (53.5) as

$$D(x) : \boldsymbol{w}^{*\mathrm{T}} \cdot \boldsymbol{x} + b^* = 0 \,. \tag{53.14}$$

To classify a new data point, only its $\boldsymbol{x}$ will be known, and its y is determined based on (53.12) and (53.14) as

$$\text{class of new data} = \operatorname{sgn}\left[\sum_{i=1}^{n} \alpha_i^* y_i \, (\boldsymbol{x}_i \cdot \boldsymbol{x}) + b^*\right] . \tag{53.15}$$

Note from (53.15) that only nonzero α_i^* participate in determining the class. The indices of these determine the data points that determine the class. These points are support vectors.

53.4.2 Relationship to the SRM Principle

To see how minimization in (53.7), or equivalently maximizing the margin, is related to implementing the SRM principle, suppose that the following bound holds,

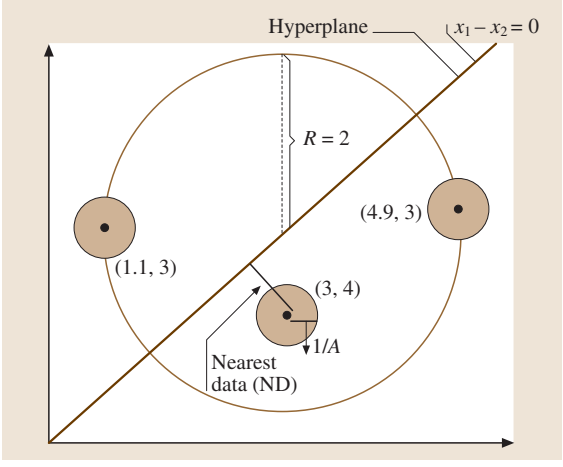

Fig. 53.3 Relationship between maximal margin and VC dimension

$||\boldsymbol{w}|| < A$, which means that the distance $d(\boldsymbol{w}, b; \boldsymbol{x})$ of a point from the hyperplane $(\boldsymbol{w}, b)$ is greater than or equal to $1/A$. The VC dimension, h, of the set of canonical hyper planes in n-dimensional space is bounded by

$$h \leq \min\left[R^2 A^2, n\right] + 1 \,,$$

where R is the radius of a hypersphere enclosing all the data points. Minimizing the above is equivalent to minimizing an upper bound on the VC dimension. Let us illustrate this by a simple numerical example.

Consider three ($n = 3$) data: (1.1, 3), (3, 4), and (4.9, 3), as shown in Fig. 53.3. The radius of a hypersphere enclosing all the data points, R, is 2. The distance between the nearest point (3, 4) and hyperplane $(x_1 - x_2) = 0$ is

$$\begin{aligned} d(\boldsymbol{w}, b; \boldsymbol{x}) &= \frac{\left|\boldsymbol{w} x_p \pm b\right|}{\|\boldsymbol{w}\|} \\ &= \frac{\left|w_1 x_{1p} + w_2 x_{2p} + \hbar\, w_n x_{np} \pm b\right|}{\sqrt{w_1^2 + w_2^2 + \hbar + w_n^2}} \\ &= \frac{|(1)\,(3) + (-1)\,(4)|}{\sqrt{1^2 + (-1)^2}} = 0.7071 \,. \end{aligned}$$

Therefore, $1/A \leq 0.7071 \approx 1.4142 \leq A$. In this example, we define $A = 1.5$ and $\min[R^2 A^2, n] + 1 = \min\left[\left(2^2\right)\left(1.5^2\right), 2\right] + 1 = \min[9, 2] + 1 = 3$. Therefore, the VC dimension, $h \leq 3$. Also, we can show that the norm of the weight vector should be equal to the inverse of the distance of the nearest point in the data set to the hyperplane. Here, the inverse of the distance between the nearest point (3, 4) and the hyperplane is $1/0.7071 = 1.4142$, which is equal to the norm of the weight vector $[1 - 1]$, $\sqrt{1^2 + (-1)^2} = 2 = 1.4142$.

53.4.3 Illustrative Example

We take a simple data set to illustrate in detail the computational steps involved in deriving the optimal separating hyperplane. Consider five normalized input data points in a two-dimensional plane along with their class labels, as shown in Table 53.1. Recall that our goal is to solve (53.9) subject to the constraints (53.10) and (53.11). We first compute the dot-product kernel of the input points and then compute $H(i, j) = y_i \cdot y_j \cdot \boldsymbol{x}_i^{\mathrm{T}} \cdot \boldsymbol{x}_j$

as shown below.

$$x_i^{\mathrm{T}} \cdot x_j = \begin{pmatrix} x_1^{\mathrm{T}}x_1 & x_1^{\mathrm{T}}x_2 & x_1^{\mathrm{T}}x_3 & x_1^{\mathrm{T}}x_4 & x_1^{\mathrm{T}}x_5 \\ \hbar & & \hbar & & \hbar \\ x_5^{\mathrm{T}}x_1 & x_5^{\mathrm{T}}x_2 & x_5^{\mathrm{T}}x_3 & x_5^{\mathrm{T}}x_4 & x_5^{\mathrm{T}}x_5 \end{pmatrix}$$

$$= \begin{pmatrix} \left(0\ 0\ \begin{pmatrix}0\\0\end{pmatrix}\right) & \left(0\ 0\ \begin{pmatrix}0\\1\end{pmatrix}\right) & \left(0\ 0\ \begin{pmatrix}0.3333\\0.75\end{pmatrix}\right) & \left(0\ 0\ \begin{pmatrix}0.6667\\0.75\end{pmatrix}\right) & \left(0\ 0\ \begin{pmatrix}1\\1\end{pmatrix}\right) \\ \hbar & & \hbar & & \hbar \\ \left(1\ 1\ \begin{pmatrix}0\\0\end{pmatrix}\right) & \left(1\ 1\ \begin{pmatrix}0\\1\end{pmatrix}\right) & \left(1\ 1\ \begin{pmatrix}0.3333\\0.75\end{pmatrix}\right) & \left(1\ 1\ \begin{pmatrix}0.6667\\0.75\end{pmatrix}\right) & \left(1\ 1\ \begin{pmatrix}1\\1\end{pmatrix}\right) \end{pmatrix}$$

$$= \begin{pmatrix} 0 & 0 & 0 & 0 & 0 \\ \hbar & & \hbar & & \hbar \\ 0 & 1.0000 & 1.0833 & 1.4167 & 2.0000 \end{pmatrix},$$

$$H = \begin{pmatrix} y_1 & y_1 & \hbar & y_1 \\ \hbar & \hbar & \hbar & \\ y_5 & y_5 & \hbar & y_5 \end{pmatrix} .* \begin{pmatrix} y_1 & y_2 & & y_5 \\ \hbar & & \hbar & \hbar \\ y_1 & y_2 & & y_5 \end{pmatrix} .* \boldsymbol{x}_i^{\mathrm{T}} \cdot \boldsymbol{x}_j$$

$$= \begin{pmatrix} -1 & -1 & \hbar & -1 \\ \hbar & \hbar & \hbar & \\ -1 & -1 & \hbar & -1 \end{pmatrix} .* \begin{pmatrix} -1 & +1 & \hbar & -1 \\ \hbar & & \hbar & \hbar \\ -1 & +1 & \hbar & -1 \end{pmatrix} .* \begin{pmatrix} 0 & 0 & \hbar & 0 \\ \hbar & & \hbar & \hbar \\ 0 & 1.0000 & \hbar & 2.0000 \end{pmatrix},$$

$$\text{or } H = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 \\ 0 & 1.0000 & 0.7500 & -0.7500 & -1.0000 \\ 0 & 0.7500 & 0.6736 & -0.7847 & -1.0833 \\ 0 & -0.7500 & -0.7847 & 1.0069 & 1.4167 \\ 0 & -1.0000 & -1.0833 & 1.4167 & 2.0000 \end{pmatrix}.$$

With the expression H as above, we now use the quadratic programming (QP) program, MATLAB Support Vector Machine Toolbox [53.5] to solve the dual problem given in (53.9), subject to the constraints in (53.10) and (53.11). The solution yields the optimal Lagrange multipliers given as

$$\left(\alpha^*\right)^{\mathrm{T}} = (7.11,\ 0.00,\ 32.22,\ 25.11,\ 0.00)\,.$$

Next, the optimal weight vector is obtained from (53.12) and its norm $||\boldsymbol{w}^*|| = \sqrt{64.44}$. Thus the maximal margin separating the hyperplanes is $2/||\boldsymbol{w}^*|| = 0.25$. Finally, the optimal bias from (53.13) is obtained as $b^* = -1.0$.

As mentioned before, only the nonzero values of the Lagrange multipliers participate in the solution, and they are $\alpha_1^* = 7.11, \alpha_3^* = 32.22, \alpha_4^* = 25.11$.

The input data points (1, 3, and 4) corresponding to the indices of these become the support vectors; the other two data points (2 and 5) can be ignored for classification decision. Thus the decision function of (53.15) can be written as

$$D(\boldsymbol{x}) = \operatorname{sgn}\left(\sum_{i=1}^{5} y_i \alpha_i^* \boldsymbol{x}_i^{\mathrm{T}} \boldsymbol{x} + b^*\right). \qquad (53.16)$$

Next, we illustrate how a new data point for which only the $\boldsymbol{x}$ values are known is labeled by the above classifier. We first normalize the new data point according to the same scheme as used for the training data. Let the new point be (0.67, 1.00). The class computations proceed as follows. First, compute the dot product and H for the

Table 53.1 Data points for the illustrative example

X		Y
0.00	1.00	−1
0.00	1.00	+1
0.33	0.75	+1
0.67	0.75	−1
1.00	1.00	−1

new point and then substitute in (53.16), which yields the class as +1.

A graphical representation of the five data points used to develop the classifier, the optimal separating hyperplane, and the decision boundaries for classes −1 and +1 are shown in Fig. 53.4 in the normalized input space. We note that data points 1 and 4 are on the boundary for class −1, and data 3 is on the boundary of class +1. These are the three support vectors that participate in classification decisions. The other two points, 2 and 5, play no role in classification decisions.

53.5 Linear Classifier for Nonseparable Classes

In real-world applications, it is not realistic to construct a linear decision function without encountering errors. If the data are noisy, in general there will be no linear separation in the input space. Two situations may arise. In the first, data points fall in the region of separation, but on the right side so that the classification is correct. In the second case, data points fall on the wrong side and misclassification of points occurs. To accommodate such situations, the problem of the separable case is modified as follows. First, the classification constraints for the separable case are revised by adding slack variables (ξ_i). Next, the cost of constraint violation is set to C. With these modifications the function to be minimized becomes

$$L(\boldsymbol{w}, \xi_i) = \frac{1}{2}\boldsymbol{w}^{\mathrm{T}}\boldsymbol{w} + C\sum_{i=1}^{n}\xi_i \,, \tag{53.17}$$

$$\text{subject to } y_i(\boldsymbol{w}^{\mathrm{T}}\boldsymbol{x}_i + b) \geq 1 - \xi_I \tag{53.18}$$

$$\text{and } \xi_i \geq 0, i = 1, 2, \ldots, n \,. \tag{53.19}$$

Minimizing $\boldsymbol{w}^{\mathrm{T}}\boldsymbol{w}$ is related to minimizing the Vapnik–Chervonenkis (VC) dimension of the SVM, and the second term in (53.17) is an upper bound on the number of test errors. Thus, C controls the tradeoff between maximum margin and classification error, and ξ_i measures the deviation of a data point from the ideal condition of separability. If $0 \leq \xi_i \leq 1$, the data point is inside the decision region, but on the right side. If $\xi_i > 1$, the data point is on the wrong side. The data points that satisfy the above constraints are the support vectors. Proceeding as for the separable case with Lagrange multipliers α_i, the new dual problem is to

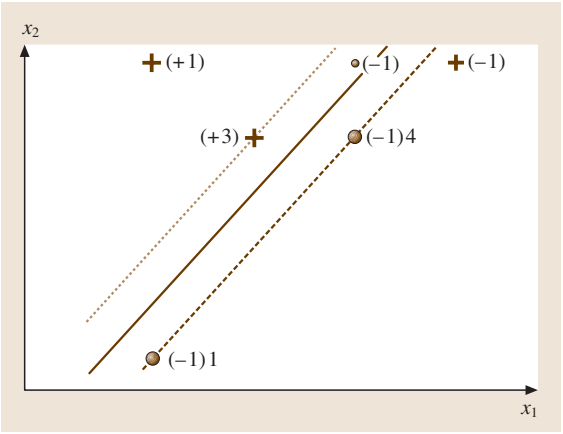

Fig. 53.4 Graphical representation of illustrative example

maximize

$$L(\alpha) = \sum \alpha_i - \frac{1}{2}\sum_{i=1}^{n}\sum_{j=1}^{n}\alpha_i\alpha_j y_i y_j \boldsymbol{x}_i^{\mathrm{T}}\boldsymbol{x}_j \tag{53.20}$$

$$\text{subject to } \sum_{i=1}^{n}\alpha_i y_i = 0 \tag{53.21}$$

$$\text{and } 0 \leq \alpha_i \leq C, i = 1, 2, \ldots, n \,. \tag{53.22}$$

Then the optimal weights are

$$\boldsymbol{w}^* = \sum_{i=1}^{n}\alpha_i^* y_i \boldsymbol{x}_i \,. \tag{53.23}$$

Again, only those points with nonzero α_i^* contribute to $\boldsymbol{w}^*$, i. e., only those points which are the support vectors.

53.6 Nonlinear Classifiers

This situation arises when the data are linearly nonseparable in the input space and the separation lines are nonlinear hypersurfaces. This is a common case in practical applications. Here, we seek nonlinear decision boundaries in the input space. For this, the approach described above is extended to derive nonlinear decision

boundaries. This is achieved by first mapping the input data into a higher-dimensional feature space using an inner-product kernel $K(\boldsymbol{x}, \boldsymbol{x}_i)$. Then, an optimum separating hyperplane is constructed in the feature space. This hyperplane is defined as a linear combination of the feature space vectors and solves a linear classification problem in the feature space. Together, these two steps produce the solution for the case of nonlinear classifiers.

53.6.1 Optimal Hyperplane

We provide below a brief justification for the above two-step procedure. According to Cover's theorem [53.3, 6], a nonseparable space may be nonlinearly transformed into a new feature space where the patterns are very likely separable. Three inner-product kernels employed for SVMs are listed in Table 53.2. Among these, the Gaussian kernel is most commonly used in practical applications.

Finally, the dual of the constrained optimization problem for this case can be obtained as

$$Q(\alpha) = \sum_{i=1}^{n} \alpha_i - \frac{1}{2} \sum_{i=1}^{n} \sum_{j=1}^{n} \alpha_i \alpha_j y_i y_j K\left(\boldsymbol{x}_i, \boldsymbol{x}_j\right), \tag{53.24}$$

where $Q(\alpha)$ has to be maximized with respect to the α_i subject to

$$\sum_{i=1}^{n} \alpha_i y_i = 0 \tag{53.25}$$

$$\text{and } 0 \le \alpha_i \le C, i = 1, 2, \ldots, n . \tag{53.26}$$

Here the parameter C is to be specified by the user. In the above, $K(\boldsymbol{x}_i, \boldsymbol{x}_j)$ is the ij-th element of the symmetric $n \times n$ matrix $\mathbf{K}$. A solution of the above problem yields the optimum Lagrange multipliers α_i^*, which yield the optimal weights as

$$w^* = \sum_{i=1}^{n} \alpha_i^* y_i \boldsymbol{\phi}(\boldsymbol{x}_i) , \tag{53.27}$$

where $\boldsymbol{\phi}(\boldsymbol{x}_i)$ represents the mapping of the input vector $\boldsymbol{x}_i$ into the feature space.

53.6.2 Illustrative Example

We illustrate the development of nonlinear classifiers using a Gaussian kernel for a small data set. The step-by-step solution procedure can be stated as follows:

- Preprocess input data
- Specify C, the kernel and its parameter
- Compute the inner-product matrix H
- Perform optimization using quadratic programming and compute the optimum α^*
- Compute the optimum weight vector $\boldsymbol{w}^*$
- Obtain support vectors and the decision boundary

Consider a data set of five points that consists of a 5×2 input matrix and a 5×1 vector y. Here, $\boldsymbol{x}_1$ is the normalized fan-in, $\boldsymbol{x}_2$ is the normalized module size in lines of code, and y is the module class.

$$\begin{array}{cc} X & y \\ \left(\begin{array}{cc:c} 0.29 & 0.00 & +1 \\ 1.00 & 0.02 & -1 \\ 0.00 & 0.19 & -1 \\ 0.06 & 1.00 & +1 \\ 0.02 & 0.17 & -1 \end{array}\right) & \end{array}$$

We use the radial basis function (rbf) kernel with $\sigma = 1.3$, and C is taken to be 100. Note that selection of C and σ is an important problem, as will be discussed later. These values are selected for illustrative purpose and are based on some preliminary analysis.

Next, the matrix H is obtained as

$$H(i, j) = \sum_{i=1}^{n} \sum_{j=1}^{n} y_i * y_j * \text{kernel}\left(rbf, \boldsymbol{x}_i, \boldsymbol{x}_j\right)$$
$$\equiv (5 \times 5)^* . (5 \times 5)^* . (5 \times 5) .$$

Table 53.2 Three common inner-product kernels

Type	$K(\boldsymbol{x}, \boldsymbol{x}_i), i = 1, 2, \ldots, n$	Comments
Linear	$\boldsymbol{x}^{\mathrm{T}} \boldsymbol{x}_i$	
Polynomial	$(\boldsymbol{x}^{\mathrm{T}} \boldsymbol{x}_i + 1)^b$	b is user-specified
Gaussian	$\exp\left[-(1/2\sigma^2)(\|\|\boldsymbol{x} - \boldsymbol{x}_i\|\|^2)\right]$	σ^2 is user-specified

By substituting the appropriate values, the computations for H proceed as shown below. Here the symbol $\hbar$ represents entries not shown but obtained similar to the shown entries.

$$
\begin{aligned}
H &= \begin{pmatrix} y_1 & \hbar & y_1 \\ y_2 & \hbar & y_2 \\ y_3 & \hbar & y_3 \\ y_4 & \hbar & y_4 \\ y_5 & \hbar & y_5 \end{pmatrix} .* \begin{pmatrix} y_1 & y_2 & y_3 & y_4 & y_5 \\ \hbar & \hbar & \hbar & \hbar & \hbar \\ y_1 & y_2 & y_3 & y_4 & y_5 \end{pmatrix} \\
&\quad .* \begin{pmatrix} rbf(\sigma), x_1, x_1 & rbf(\sigma), x_1, x_2 & rbf(\sigma), x_1, x_3 & rbf(\sigma), x_1, x_4 & rbf(\sigma), x_1, x_5 \\ rbf(\sigma), x_2, x_1 & rbf(\sigma), x_1, x_2 & rbf(\sigma), x_1, x_3 & rbf(\sigma), x_1, x_4 & rbf(\sigma), x_1, x_5 \\ rbf(\sigma), x_3, x_1 & rbf(\sigma), x_1, x_2 & rbf(\sigma), x_1, x_3 & rbf(\sigma), x_1, x_4 & rbf(\sigma), x_1, x_5 \\ rbf(\sigma), x_4, x_1 & rbf(\sigma), x_1, x_2 & rbf(\sigma), x_1, x_3 & rbf(\sigma), x_1, x_4 & rbf(\sigma), x_1, x_5 \\ rbf(\sigma), x_4, x_1 & rbf(\sigma), x_1, x_2 & rbf(\sigma), x_1, x_3 & rbf(\sigma), x_1, x_4 & rbf(\sigma), x_1, x_5 \end{pmatrix} .* \\
&= \begin{pmatrix} 1 & \hbar & 1 \\ -1 & \hbar & -1 \\ -1 & \hbar & -1 \\ 1 & \hbar & 1 \\ -1 & \hbar & -1 \end{pmatrix} .* \begin{pmatrix} 1 & -1 & -1 & 1 & -1 \\ \hbar & \hbar & \hbar & \hbar & \hbar \\ 1 & -1 & -1 & 1 & -1 \end{pmatrix} \\
&\quad .* \begin{pmatrix} \exp\left(-\frac{\left\|\begin{pmatrix}0.29\\0.00\end{pmatrix}-\begin{pmatrix}0.29\\0.00\end{pmatrix}\right\|^2}{2(1.3)^2}\right) & \hbar & \exp\left(-\frac{\left\|\begin{pmatrix}0.29\\0.00\end{pmatrix}-\begin{pmatrix}0.02\\0.17\end{pmatrix}\right\|^2}{2(1.3)^2}\right) \\ \hbar & \hbar & \hbar \\ \exp\left(-\frac{\left\|\begin{pmatrix}0.02\\0.17\end{pmatrix}-\begin{pmatrix}0.29\\0.00\end{pmatrix}\right\|^2}{2(1.3)^2}\right) & \hbar & \exp\left(-\frac{\left\|\begin{pmatrix}0.02\\0.17\end{pmatrix}-\begin{pmatrix}0.02\\0.17\end{pmatrix}\right\|^2}{2(1.3)^2}\right) \end{pmatrix} \\
&= \begin{pmatrix} 1 & -0.86 & -0.97 & 0.73 & -0.97 \\ -0.86 & 1 & 0.74 & -0.58 & 0.75 \\ -0.97 & 0.74 & 1 & -0.82 & 1.00 \\ 0.73 & -0.58 & -0.82 & 1 & -0.82 \\ -0.97 & 0.75 & 1.00 & -0.82 & 1 \end{pmatrix} .
\end{aligned}
$$

After performing optimization by quadratic programming, the optimal α values are obtained. Then the optimal vector $\boldsymbol{w}$ is computed from α^* and H. Its squared length is computed from these as below, where $\alpha^{*\prime}$ is the transpose of α^*

$$
\begin{aligned}
w^2 &= \alpha^{*\prime} * H * \alpha^* \\
&= \begin{pmatrix} 100 & 29.40 & 0 & 20.60 & 92.90 \end{pmatrix} \\
&\quad * \begin{pmatrix} 1 & -0.86 & -0.97 & 0.73 & -0.97 \\ -0.86 & 1 & 0.74 & -0.58 & 0.75 \\ -0.97 & 0.74 & 1 & -0.82 & 1.00 \\ 0.73 & -0.58 & -0.82 & 1 & -0.82 \\ -0.97 & 0.75 & 1.00 & -0.82 & 1 \end{pmatrix} * \begin{pmatrix} 100 \\ 29.40 \\ 0 \\ 20.60 \\ 92.90 \end{pmatrix} \\
&= 102.
\end{aligned}
$$

The indices of the support vectors are those α^* that satisfy $0 < \alpha^* \leq C$. Here, $\alpha_3^* = 0$ so that points 1, 2, 4, and 5 become the support vectors for this classification problem; point 3 plays no role and can be ignored.

A graphical illustration of the decision boundaries in the input space is shown in Fig. 53.5. Also, note that the decision boundaries are nonlinear, while the decision hyperplane in the feature space computed from the feature vector is expected to be linear. Finally, for this problem, data point 1 is misclassified as being in class -1 rather than in class $+1$, i. e., the classification error of the model derived here is 20%. To classify a new point, suppose its normalized values using the same normalization as for the training data are

(0.03, –0.03). The classification computations proceed as follows:

$$
\begin{aligned}
H(i,j) &= \sum_{i=1}^{m}\sum_{j=1}^{n} y_j * \text{kernel}\left(rbf, xt_i, x_j\right) \\
&= \begin{pmatrix} y_1 & y_2 & y_3 & y_4 & y_5 \end{pmatrix} \\
&\quad * \begin{pmatrix} (rbf(\sigma), xt_1, x_1) \\ (rbf(\sigma), xt_1, x_2) \\ (rbf(\sigma), xt_1, x_3) \\ (rbf(\sigma), xt_1, x_4) \\ (rbf(\sigma), xt_1, x_5) \end{pmatrix}^{\top} \\
&= \begin{pmatrix} 1 & -1 & -1 & 1 & -1 \end{pmatrix} \\
&\quad .* \begin{pmatrix} \exp\left(-\frac{\left\| \begin{pmatrix} 0.03 \\ -0.03 \end{pmatrix} - \begin{pmatrix} 0.29 \\ 0.00 \end{pmatrix} \right\|^2}{2.(1.3)^2}\right) \\ \hbar \\ \exp\left(-\frac{\left\| \begin{pmatrix} 0.03 \\ -0.03 \end{pmatrix} - \begin{pmatrix} 0.02 \\ 0.17 \end{pmatrix} \right\|^2}{2.(1.3)^2}\right) \end{pmatrix}^{\top} \\
&= \begin{pmatrix} 0.98 & -0.76 & -0.98 & 0.73 & -0.99 \end{pmatrix} ; \\
y &= \text{sgn}\left(H * \alpha + \text{bias}\right)
\end{aligned}
$$

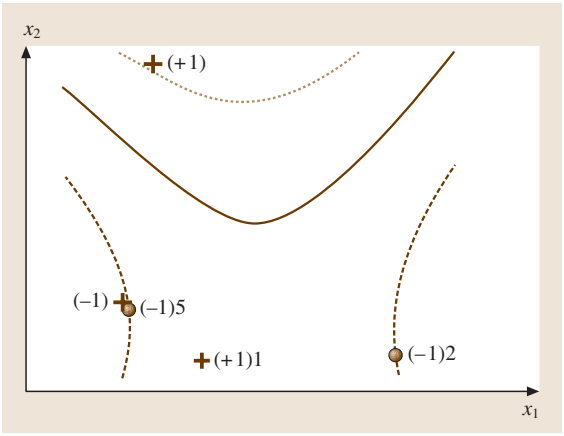

Fig. 53.5 Graphical illustration of nonlinear decision boundaries

$$
\begin{aligned}
&= \text{sgn}\left(\begin{pmatrix} 0.98 \\ -0.76 \\ -0.98 \\ 0.73 \\ -0.99 \end{pmatrix}^{\top} * \begin{pmatrix} 100.00 \\ 29.40 \\ 0.00 \\ 20.60 \\ 92.90 \end{pmatrix} + 0 \right) \\
&= \text{sgn}\left(-0.92\right) = -1 .
\end{aligned}
$$

The new module belongs to class –1.

53.7 SVM Nonlinear Regression

As mentioned earlier, the support vector technique was initially developed for classification problems. This approach has been extended to nonlinear regression where the output y are real-valued. A general nonlinear regression model for y based on $\boldsymbol{x}$ can be written as

$$y = f(\boldsymbol{x}, \boldsymbol{w}) + \delta \,, \tag{53.28}$$

where f represents a function, $\boldsymbol{w}$ is a set of parameters, and δ represents noise. In terms of some nonlinear basis functions, as discussed earlier, we can write $\hat{y}$, an estimate of y, as

$$\hat{y} = \boldsymbol{w}^{\mathrm{T}} \phi(\boldsymbol{x}) \,. \tag{53.29}$$

Next, we employ the commonly used Vapnik's ε-loss function and estimate $\hat{y}$ via support vector regression as summarized below. The ε-loss is defined as

$$\text{Loss}_{\varepsilon}\left(y, \hat{y}\right) = \begin{cases} |y - \hat{y}| - \varepsilon, & \text{if } |y - \hat{y}| \geq \varepsilon \,. \\ 0 \quad\quad\quad , & \text{otherwise} \end{cases}$$

The dual problem for regression can be formulated using an approach similar to that for classification. The optimization problem now is to maximize Q:

$$
\begin{aligned}
Q\left(\alpha_i, \alpha_i'\right) &= \sum_{i=1}^{n} y_i \left(\alpha_i - \alpha_i'\right) - \varepsilon \sum_{i=1}^{n} \left(\alpha_i + \alpha_i'\right) \\
&\quad - \frac{1}{2} \sum_{i=1}^{n}\sum_{j=1}^{n} \left(\alpha_i - \alpha_i'\right) \\
&\quad \times \left(\alpha_j - \alpha_j'\right) K\left(\boldsymbol{x}_i, \boldsymbol{x}_j\right)
\end{aligned} \tag{53.30}
$$

$$\text{subject to} \quad \sum_{i=1}^{n} \left(\alpha_i - \alpha_i'\right) = 0 \,, \tag{53.31}$$

$$0 \le \alpha_i, \alpha_i' \le C, i = 1, 2, \ldots, n \,. \tag{53.32}$$

In (53.30–53.32), ε and C are user-specified values. The optimal values of α_i and α_i' are used to find the optimal value of the weight vector. The estimated $\hat{y}$ is given by

$$\hat{y}\,(\boldsymbol{x}, \boldsymbol{w}) = \boldsymbol{w}^{\mathrm{T}}\boldsymbol{x} = \sum_{i=1}^{n} \left(\alpha_i - \alpha_i'\right) K\,(\boldsymbol{x}, \boldsymbol{x}_i) \,.$$

53.8 SVM Hyperparameters

The classification and regression modeling problems using SVM are formulated as quadratic programming (QP) optimization problems. Many algorithms are available for solving QP problems and are commonly used for support vector modeling applications. However, there are some parameters that are to be specified by the user. These are called *the SVM hyperparameters* and are briefly described below.

For the linearly nonseparable case, we need to specify the penalty parameter C. It controls the tradeoff between the small function norm and empirical risk minimization. Further, for nonlinear classifiers, we also need to specify the kernel and its parameters. For example, for the radial basis function kernel, its width, σ, needs to be specified by the user. In practical applications, there are no easy answers for choosing C and σ. In general, to find the best values, different combinations are tried and their performances are compared, usually via an independent data set, known as the validation set. However, some empirical rules for their determination have been proposed in the literature [53.7, 8].

For nonlinear regression, a loss function is specified. In support vector machine applications, a commonly used loss function is the so-called *ε-loss function* as indicated above. Thus, for regression problems this additional hyperparameter is to be specified by the user. Generally, a trial-and-error approach is used to evaluate the performance of different hyperparameter combinations on some validation data set.

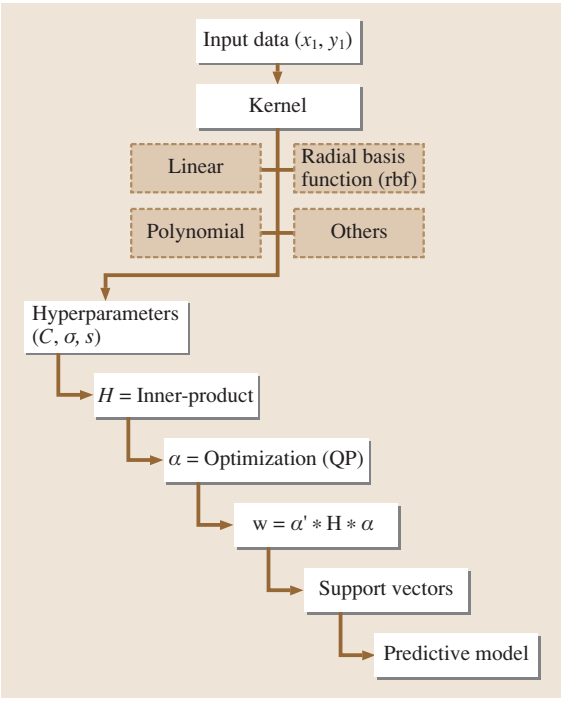

Fig. 53.6 Support vector modeling flow chart

53.9 SVM Flow Chart

A generic flow chart depicting the development of support vector classification and regression models is shown in Fig. 53.6. For given data ($\boldsymbol{x}$, y), the kernel is selected by the user, followed by the appropriate hyperparameters. Computation of several intermediate quantities and optimization by quadratic programming yields the weights and support vectors. Finally, these values are used to define the classification or regression model.

53.10 Module Classification

There are several reasons for developing software classification models. One is the limited availability of resources. Not all modules can be treated in the same way. The potentially critical modules require a more time-consuming and costly development process that involves activities such as more rigorous design and code reviews, automated test-case generation and unit testing, etc. Another reason is that faults found later in the development life-cycle are more expensive to correct than those found earlier.

The problem of software module classification has been addressed in the software engineering literature for more than thirty years. Different techniques have been applied by many authors with varying degrees of predictive accuracy [53.9, 10]. Most of the early work on this topic used statistical techniques such as discriminant analysis, principle-component analysis, and factor analysis, as well as decision or classification trees [53.11]. In recent years, machine learning techniques and fuzzy logic have also been used for software module classification. Typical of these are classification and regression trees (CART), case-based reasoning (CBR), expert judgment, and neural networks [53.10]. The main problem with most of the current models is their low predictive accuracy. Since the published results vary over a wide range, it is not easy to give a specific average accuracy value achieved by current models.

In this section, we develop support vector classification models for software data obtained from the public-domain National Aeronautics and Space Administration (NASA) software metrics database [53.12]. It contains several product and process metrics for many software systems and their subsystems. The fifteen module-level metrics used here and a brief description of each are given in Table 53.3. The metric x_7 is the number of faults, while x_9 to x_{22} are module-level product metrics which include the design-based metrics (x_9, x_{10}, x_{18}) and primarily coding metrics (x_{13}, x_{14}, x_{15}). Metrics x_{19} to x_{22} are Halstead's software science measures; x_{19} and x_{20} are the vocabulary, while x_{21} and x_{22} are measures of program size. Other metrics are self-explanatory. These represent typical metrics used in module classification studies. This system consists of 67 modules with a size of about 40k lines of code.

Table 53.3 List of metrics from NASA database

X_7	Faults
X_9	Fan out
X_{10}	Fan in
X_{11}	Input–output statements
X_{12}	Total statements
X_{13}	Size of component in program lines
X_{14}	Number of comment lines
X_{15}	Number of decisions
X_{16}	Number of assignment statements
X_{17}	Number of formal statements
X_{18}	Number of input–output parameters
X_{19}	Number of unique operators
X_{20}	Number of unique operands
X_{21}	Total number of operators
X_{22}	Total number of operands

Here, faults are the outputs and the others are the inputs. Referring to (53.1), we have $n = 67$ and $d = 14$. We first preprocess the input data. After transformation, this data set resides in a fourteen-dimensional unit cube. To determine module class, we use a threshold value of 5 so that, if $x_7 \leq 5$, the class is -1, and $+1$ otherwise.

We now develop nonlinear classifiers for this data set using the SVM algorithm of Sect. 53.6 [53.13]. The

Table 53.4 Classification results

Set	σ	C	SV	Classification error (average)	
				Training	5CV
I	0.8	1	30.6	0.18	0.21
II	1.2	100	26.8	0.10	0.20
III	1.6	1000	27.2	0.12	0.20

optimization problem to be solved is given by (53.24–53.26). First, we choose a kernel. Since Gaussian is a popular choice, we also choose it. Next we need to specify the hyperparameters, that is, the width of the Gaussian and the penalty parameter C. To determine the best combination of these two, we follow the common practice of performing a grid search. In this case the grid search is on the two parameters C and σ. We took $C = 10^{-2}(10)10^4$ and $\sigma = 0.8(0.4)4.0$ for a total of 56 grid points. For each combination, we use the SVM algorithm for nonlinear classifiers of Sect. 53.6. Further, we used five-fold cross validation (5CV) as a criterion for selecting the best hyperparameter combination. Thus, we are essentially doing a search for the best set of hyperparameters among the 56 potential candidates by constructing $56 \times 5 = 280$ classifiers, using the approach described in Sect. 53.6.

As an example, a list of nine sets and their corresponding classification errors is given in Table 53.4. The average number of input points that became support vectors for the given model is also included. Data such as that in Table 53.4 is used to select the best set.

From this we select set VII with $C = 1000$ and kernel width 3.2. To further study the behavior of the five-fold cross validation test error versus (C, σ), its surface and the contours are shown in Fig. 53.6. We note that the surface for this data is relatively flat for high (σ, C) values and sharp for low σ and high C. This behavior is quite typical for many applications. Also shown in the contour plot is the chosen set with $\sigma = 3.2$ and $C = 1000$. Finally, these values are used as the SVM hyperparameters to solve the optimization problem of (53.24–53.26) using quadratic programming. This gives the desired, possibly best, classification model for this data set. The developed model is likely to have an error of about 17% on future classification tasks.

53.11 Effort Prediction

Development of software effort-prediction models has been an active area of software engineering research for over 30 years. The basic premise underlying these models is that historical data about similar projects can be employed as a basis for predicting efforts for future projects. For both engineering and management reasons, an accurate prediction of effort is of significant importance in software engineering, and improving estimation accuracy is an important goal of most software development organizations. There is a continuing search for better models and tools to improve predictive performance.

The so-called general-purpose models are generally algorithmic models developed from a relatively large collection of projects that capture a functional relationship between effort and project characteristics [53.14, 15]. The statistical models are derived from historical data using statistical methods, mostly regression analysis. The statistical models were some of the earliest to be developed. Exam-

Table 53.5 Performance of effort prediction models

Data set	LooMMRE		LooPred(25)	
	expected training	expected test	average training	average test
D	0.54	0.52	0.33	0.46
$D-1$	0.28	0.35	0.72	0.54
$D-2$	0.24	0.24	0.72	0.64
$D-3$	0.12	0.25	0.44	0.80

ples of such models are the meta-model [53.16] and the MERMAID [53.17]. Recently, machine learning techniques have been used for software effort prediction modeling. These include neural networks [53.18], rule induction, and case-based reasoning.

The effort-modeling problem can be restated as follows from Sect. 53.2 above. We are given data about n projects $\{\boldsymbol{x}_i, y_i\} \in \mathbb{R}^n \times \mathbb{R}$, $i = 1, \ldots, n$, each consisting of d software features the y are the effort values. A general nonlinear regression model for y based on $\boldsymbol{x}$ was given in (53.28).

In this section we summarize the prediction model development by support vector nonlinear regression from [53.13]. The effort data and the project features are taken from [53.19]. The data were collected from a Canadian software house. It consists of 75 projects developed in three different environments. The data is grouped by each environment ($D-1$, $D-2$, $D-3$) and as combined projects (D). There were six features collected for each project. Thus, for data set D, $n = 75$ and $d = 6$ in (53.2).

The methodology for developing SVM nonlinear regression models is very similar to that used for module classification in Sect. 53.10. The optimization problem to be solved now is given in (53.30–53.32). Further, assuming a Gaussian kernel, three hyperparameters have to be specified. Therefore, a three-dimensional grid search has to be performed for selecting σ, C, and ε. The criterion for this selection can be MMRE or Pred(25). Note that we seek a low MMRE error and a high Pred(25) accuracy.

The final results of SVM modeling for the above data sets are summarized in Table 53.5 for both selection criteria. For projects in D, the best model obtained has test values of LooMMRE $= 0.52$ and LooPred(25) $= 0.46$. However, for $D-1$, $D-2$ and $D-3$, model performance is much better due to the fact that the projects in these data sets were developed in more homogeneous environments than those in D.

53.12 Concluding Remarks

We have presented an introduction to support vector machines, their conceptual underpinnings and the main computational techniques. We illustrated the algorithmic steps via examples and presented a generic SVM flowchart. Results from two software engineering case studies using SVM were summarized.

SVM is a very active area of research and applications. An impressive body of literature on this topic has evolved during the last decade. Many open problems, theoretical and applied, are currently being pursued. These include hyperparameter selection, Bayesian relevance vector machines, reduced SVM, multiclass SVM, etc. Applications include intrusion detection, data mining, text analysis, medical diagnosis and bioinformatics. Papers on these aspects regularly appear in the machine learning and related literature.

For further reading, chapters in *Kecman* [53.4], *Cherkassky* et al. [53.20] and *Haykin* [53.3] provide good insights. Books on SVM include *Cristianini* et al. [53.21], *Scholkopf* et al. [53.22], and *Vapnik* [53.1]. Tutorials, such as *Burges* [53.23], and other useful information is available at websites dealing with support vector machines and kernel machines. Software packages are also available from several websites.

54. Optimal System Design

The first section of this chapter describes various applications of optimal system design and associated mathematical formulations. Special attention is given to the consideration the randomness associated with system characteristics. The problems are described from the reliability engineering point of view. It includes a detailed state-of-the-art presentation of various spares optimization models and their applications.

The second section describes the importance of optimal cost-effective designs. The detailed formulations of cost-effective designs for repairable and nonrepairable systems are discussed. Various cost factors such as failure cost, downtime cost, spares cost, and maintenance cost are considered. In order to apply these methods for real-life situations, various constraints including acceptable reliability and availability, weight and space limitations, and budget limitations are addressed.

The third section describes the solution techniques and algorithms used for optimal system-design problems. The algorithms are broadly classified as exact algorithms, heuristics, meta-heuristics, approximations, and hybrid methods. The merits and demerits of these algorithms are described. The importance of bounds on the optimal solutions are described.

The fourth section describes the usefulness of hybrid methods in solving large problems in a realistic time frame. A detailed description of the latest research findings relating to hybrid methods and their computational advantages are provided. One of the major advantages of these algorithms is finding the near-optimal solutions as quickly as possible and improving the solution quality iteratively. Further, each iteration improves the search efficiency by reducing the search space as a result of the improved bounds. The efficiency of the proposed method is demonstrated through numerical examples.

54.1 Optimal System Design

In everyday life, we come across various kinds of decision-making problems, ranging from personal decisions related to investment, travel, and career development to business decisions related to procuring equipment, hiring staff, product design, and modifications to existing design and manufacturing procedures. Decision analysis involves the use of a rational process for selecting the best of several alternatives. The solution to decision-making problem requires the identification of three main components.

1. What are the decision alternatives?
   Examples: Should I select vendor X or vendor Y? Should I keep an additional spare component or not?
2. Under what restrictions (constraints) is the decision to be made?

Examples: Do not spend more than $ 10 000 for procuring new equipment. On average, downtime of the system should not exceed two days in a year.

3. What is an appropriate objective criterion for evaluating the alternatives?
   Examples: Overall profit is maximum. Overall availability is maximum. Overall cost is minimum.

Generally, the alternatives of the decision problem may take the form of unknown variables. The variables are then used to construct the restrictions and the objective criterion in appropriate mathematical functions. The end results is a mathematical model relating the variables, constraints, and objective function. The solution of the model then yields the values of the decision variables that optimize (maximize or minimize) the value of the objective function while satisfying all the constraints [54.1]. The resulting solution is referred to as the optimum feasible solution (or simply optimal solution). A typical mathematical model for optimal decision-making is organized as follows:

Maximize or minimize (objective function)
subject to (constraints) .

In the mathematical models for optimization, the decision variables may be integer or continuous, and the objective and constraint functions may be linear and nonlinear. It should be noted that the discrete variables, such as component reliability choices that are restricted to the set {0.6, 0.75, 0.9}, as well as categorical variables such as names can be converted into equivalent integer variables (by using mapping). The optimization problems posed by these models give rise to variety of problem formulations. Each category of problem formulation (or the model) can be solved using a class of solution methods, each designed to account for the special mathematical properties of the model.

1. Linear programming problem: where all objective and constraint functions are linear, and all the variables are continuous.
2. Linear integer programming: is a linear programming problem with the additional restriction that all the variables are integers.
3. Nonlinear programming: where the objective or at least one constraint function is nonlinear, and all the variables are continuous.
4. Nonlinear integer programming: is a nonlinear programming problem with the additional restriction that all the variables are integers.
5. Nonlinear mixed integer programming: is a nonlinear programming problem where some variables are integers and other variables are continuous.

Problems with integer variables and nonlinear functions are difficult to solve. The difficulty further increases if there exist both integer and continuous variables.

54.1.1 System Design

System design is one of the important applications of optimal decision-making problems. One of the important goals of system design is to build the system such that it performs its functions successfully. When a system is unable to perform its functions, this is called a system failure. Several factors related to system design as well as external events influence the system functionality. In most cases, the effects of these factors are random, which means that they cannot be determined precisely but can only be explained through probability distributions. Therefore, failure events or the time to system failure are random variables. The engineering discipline that deals with the successful and unsuccessful (failure) operations of systems is known as reliability engineering. Reliability is one of the important system characteristics and is defined as the probability that the system performs its intended (or specified) functions successfully over a specified period of time under the specified environment. One of the goals of reliability engineering is to illustrate how high reliability, through careful design and analysis, can be built into systems within the limits of economical and physical constraints. Some important principles for enhancing system reliability are [54.2–4]:

1. Keep the system as simple as compatible with performance requirements. This can be achieved by minimizing the number of components in series and their interactions.
2. Increase the reliability of the components in the system. This can be achieved by reducing the variations in the components' strength and applied load (better quality control and controlled operational environment), increasing the strength of the components (better materials), and reducing the applied loads (derating). Alternatively, to some extent, this can be achieved by using large safety factors or management programs for product improvement.
3. Use burn-in procedures for components that have high infant mortality to eliminate early failures in the field.

4. Use redundancy (spares) for less-reliable components; this can be achieved by adding spares in the parallel or standby redundancy.
5. Use fault-tolerant design such that system can continue its functions even in the presence of some failures. This can be achieved using sparing redundancy, fault-masking, and failover capabilities.

In addition to this, if system or its components are repairable, the availability of the system should be considered as a system performance index. The availability of the system is the probability that the system is operational at a specified time. In the long run, the system availability estimate reaches an asymptotic value called the steady-state availability [54.5]. Therefore, in most cases, we focus our attention on improving the steady-state availability of the system. The system availability can be increasing by reducing the downtime. Some important principles for enhancing system reliability are:

1. Use methods that increase the reliability of the system.
2. Decrease the downtime by reducing delays in performing the repair. This can achieved by keeping additional spares on site, providing better training to the repair personnel, using better diagnosis procedures, and increasing the size of the repair crew.
3. Perform preventive maintenance such that components are replaced by new ones whenever they fail, or at some regular time intervals or age, whichever comes first.
4. Perform condition-based maintenance such that downtime related to either preventive or corrective maintenance is minimal.
5. Use better arrangement for exchangeable components.

Implementation of the above steps often consume some resources. The resources to improve system performance (reliability or availability) may be limited. This resources limitation may include available budget, space to keep components, and weight limitations. In such cases, the objective should be to obtain the maximum performance within the utilization of available resources. However, in some cases, achieving high performance may not lead to high profit (or low cost). In such cases, optimal designs should be performed to achieve the most cost-effective solution that strikes a balance between system failure cost and the cost of efforts for reducing the system failures.

54.1.2 System Design Objectives

Depending on the situation, the objective of optimal system design can be one of the following.

1. Maximize system performance.
   There are a number of measures that indicate the performance of a system. For nonrepairable systems, reliability is an important performance measure. For repairable systems, the availability or total uptime is important. When the system has several levels of performance (multi-state systems), the average capacity or throughput is important.
2. Minimize the losses associated with unwanted system behaviors.
   We can also design the system such that the losses associated with downtime can be minimized. Therefore, we can focus on reducing the unreliability, unavailability, downtime, or number of failures.
3. Maximize the overall profit (or minimize the overall cost) associated with the system.

In general, the optimal design corresponding to the maximum system performance (or minimum unwanted behavior) may not exactly coincide with the optimal design that maximizes system profit (or minimum overall cost). In such cases, the objective should be minimizing the overall cost associated with the system that meets the acceptable system performance as well as resource consumption.

In order to solve these optimization problems, we should specify the objectives in a mathematical form. Therefore, we should express the objective functions in a mathematical form.

54.1.3 Notation

m	number of subsystems in the system,
n_i	number of components in subsystem i; $i \in [1, \cdots, m]$,
k_i	minimum number of good components required for successful operation of the subsystem i; $1 \le k_i \le n_i$,
s_i	number of spares in subsystem i; $s_i = n_i - k_i$,
$\boldsymbol{n}$	vector of components; $\boldsymbol{n} = [n_1, \cdots, n_m]$,
$\boldsymbol{n^K}$	vector of components with $n_i = k_i$; $\boldsymbol{n^K} = [k_1, \cdots, k_m]$,
n^*	optimal value of n,
$n^{\mathrm{L}}, n^{\mathrm{U}}$	[lower, upper] bound on the optimal value of n; $n^{\mathrm{L}} \le n^* \le n^{\mathrm{U}}$; n_i^{L} and n_i^{U} are the

	lower and upper bounds on n_i^*; $\boldsymbol{n}^{\mathrm{L}}$ and $\boldsymbol{n}^{\mathrm{U}}$ are the lower and upper bounds on $\boldsymbol{n}^*$,
$\phi_i, \psi_i, \varphi_i$	[mean time to failure = MTTF, mean time to repair = MTTR, mean logistic delay time = MLDT] of a component in subsystem i,
γ_i	fixed miscellaneous cost per each repair of a component in subsystem i,
δ_i	variable cost per unit repair time for a component in subsystem i,
ν_i	frequency of failures for a component in subsystem i,
c_i	maintenance cost per unit time for each component in subsystem i,
c_{f}	cost of system downtime per unit time,
r_i or R_i	reliability of subsystem i,
Q_i	unreliability of subsystem i; $Q_i = 1 - R_i$,
R_{s}	reliability of the system,
Q_{s}	unreliability of the system; $Q_{\mathrm{s}} = 1 - R_{\mathrm{s}}$,
$f(.)$	is a function; $f(r_1, \cdots, r_m)$ is a function in r_i, which is used to represent system reliability in terms of component reliabilities,
$g_i(.)$	is a function; $g_i(r_1, \cdots, r_m)$ is a function in r_i, which is used to represent the constraints in terms of component reliabilities,
r_j^{l}	explicit lower limit on r_j,
r_j^{u}	explicit upper limit on r_j,
$T_{\mathrm{d}}(\boldsymbol{n})$	average downtime cost per unit time with component vector $\boldsymbol{n}$,
$T_{\mathrm{m}}(\boldsymbol{n})$	average maintenance cost per unit time with component vector $\boldsymbol{n}$,
$T(\boldsymbol{n})$	average system cost per unit time with component vector $\boldsymbol{n}$,
C_K	total maintenance cost with $\boldsymbol{n}^{\boldsymbol{K}}$; $C_K = T_{\mathrm{m}}(\boldsymbol{n}^{\boldsymbol{K}}) = \sum_{i=1}^{m} k_i c_i$
C_{U}	total maintenance cost at the upper bound $\boldsymbol{n}^{\mathrm{U}}$; $C_{\mathrm{U}} = T_{\mathrm{m}}(\boldsymbol{n}^{\mathrm{U}}) = \sum_{i=1}^{m} n_i^{\mathrm{U}} c_i$,
C_{L}	total maintenance cost at the lower bound $\boldsymbol{n}^{\mathrm{L}}$; $C_{\mathrm{L}} = T_{\mathrm{m}}(\boldsymbol{n}^{\mathrm{L}}) = \sum_{i=1}^{m} n_i^{\mathrm{L}} c_i$,
p_i, q_i	[availability, unavailability] or [reliability, unreliability] of a component in subsystem i,
A_i, U_i	[availability, unavailability] of subsystem i when there are n_i components in that subsystem; $A_i \equiv A_i(n_i)$; $U_i \equiv U_i(n_i)$,
$A(\boldsymbol{n}), U(\boldsymbol{n})$	[availability, unavailability] of the system with component vector $\boldsymbol{n}$,
h_i^1, h_i^0	Pr{system is operating | subsystem i is [operating, failed]},
binf$(k; p, n)$	cumulative distribution function of binomial distribution; binf$(k; p, n) \equiv \sum_{i=0}^{k} \binom{n}{i} p^i (1-p)^{n-i}$; binfc$(k; p, n) \equiv 1 - \mathrm{binf}(k; p, n)$,
gilb$(\cdot)$	greatest integer lower bound; floor$(\cdot)$

54.1.4 System Reliability

If the objective is maximization of system reliability, then we should express the system reliability in a mathematical form. The form of the reliability expression varies with system configuration.

Series Configuration

Series configuration is the simplest and perhaps one of the most common configurations. Let m be the number of subsystems (or components) in the system. In this configuration, all m subsystems (components) must be operating to ensure system operation. In other words, the system fails when any one of the m subsystems fails. Therefore, the reliability of the series system, when all subsystems are independent, is the product of reliabilities of its systems

$$R_{\mathrm{s}} = \prod_{i=1}^{m} R_i \,. \tag{54.1}$$

Parallel Configuration

In the parallel configuration, several paths (subsystems) perform the same operation simultaneously. Therefore, the system fails if all of the m subsystems fail. This is also called an active redundant configuration. The parallel system may occur as a result of the basic system structure or may be produced as a results of additional spares included to improve the system reliability. The parallel system configuration is successful if any one of the m subsystems is successful. In other words, the system fails when all m subsystems fail. Thus the unreliability of the parallel system, when all subsystems are independent, is the product of the unreliabilities of its components

$$Q_{\mathrm{s}} = \prod_{i=1}^{m} Q_i \,,$$

$$R_{\mathrm{s}} = 1 - Q_{\mathrm{s}} = 1 - \prod_{i=1}^{m} Q_i = 1 - \prod_{i=1}^{m} (1 - R_i) \,. \tag{54.2}$$

Standby Configuration

Standby components are used to increase the reliability of the system. There are three types of redundancy [54.6, 7]: (1) cold standby, (2) warm standby, and (3) hot

standby. In the cold-standby redundancy configuration, a component (or subsystem) does not fail before it is put into operation. In warm-standby redundancy configuration, the component can fail in standby mode. However, the chances of failure (failure rate in standby) are less than the chances of failure in operation (failure rate in operation). If the failure pattern of a standby component does not depend on whether the component is idle or in operation, then it is called hot standby. In this chapter, the analysis is provided for cold- and hot-standby components only.

If the redundant components operate simultaneously from time zero, even though the system needs only one of them at any time, such an arrangement is called parallel (or active) redundancy. This arrangement is essential when switching or starting a good component following a component failure is ruled out. The mathematical models for hot-standby and parallel redundancy arrangements are equivalent. In the cold-standby redundancy configuration, the redundant components are sequentially used in the system at component failure times. The system fails when all components fails. Cold-standby redundancy provides longer system life than hot-standby redundancy.

For a cold-standby system with a total of m components where initially the first component is in operation and the rest of the $m-1$ components are in standby, the system reliability at time t is

$$\begin{aligned} &R_\mathrm{s}(t) \\ &= \Pr(\text{system operates successfully until time } t) \\ &= \Pr(X_1 + X_2 + \cdots + X_\mathrm{m} \geq t)\,, \end{aligned} \tag{54.3}$$

where X_i is the random variable that represents the failure time of component i. The final expression for the system reliability is a function of the parameters of the component failure-time distribution. If all components are identical and follow exponential failure-time distributions with hazard rate λ, then the reliability of the cold-standby system with m components is [54.7, 8]

$$\begin{aligned} R_\mathrm{s}(t) &= \exp(-\lambda t)\left(\sum_{i=0}^{m-1}\frac{(\lambda t)^i}{i!}\right) \\ &= p\left(\sum_{i=0}^{m-1}\frac{[-\ln(p)]^i}{i!}\right)\,, \end{aligned} \tag{54.4}$$

where $p = \exp(-\lambda t)$ is the reliability of each component.

k-out-of-n Active Standby Configuration

In this configuration, the system consists of n active components in parallel. The system functions successfully when at least k of its n components function. This is also referred to as a k-out-of-n:G parallel (or hot or active standby) system or simply a k-out-of-n system. A parallel system is a special case of a k-out-of-n system with $k = 1$, i. e., a parallel system is a 1-out-of-n system. Similarly, a series system is a special case of a k-out-of-n system with $n = 1$, i. e., a series system is an n-out-of-n system.

When all components (or subsystems) are independent and identical, the reliability of a k-out-of-n system with component reliability equal to p is [54.3, 8, 9]:

$$\begin{aligned} R_\mathrm{s} &= \sum_{i=k}^{n}\binom{n}{i}p^i(1-p)^{n-i} \\ &= 1 - \sum_{i=0}^{k-1}\binom{n}{i}p^i(1-p)^{n-i} \\ &= \mathrm{binfc}(k-1;\, p, n)\,. \end{aligned} \tag{54.5}$$

k-out-of-n Cold-Standby Configuration

In this configuration, the system consists of a total of n components. Initially, only k components are in operation and the remaining (n-k) redundant components are kept in cold standby. The redundant components are sequentially used to replace the failed components. When all components (or subsystems) are identical and the failure distribution is exponential, the reliability of a k-out-of-n cold-standby system is [54.8]:

$$\begin{aligned} R_\mathrm{s}(t) &= \exp(-k\lambda t)\left(\sum_{i=0}^{k-1}\frac{(k\lambda t)^i}{i!}\right) \\ &= p^k\left(\sum_{i=0}^{k-1}\frac{[-k\ln(p)]^i}{i!}\right)\,. \end{aligned} \tag{54.6}$$

General System Configuration

It is well known that the reliability of a system is a function of the component reliabilities or its parameters. Hence, we have [54.8]

$$R_\mathrm{s} = h(R_1, \cdots, R_\mathrm{m})\,. \tag{54.7}$$

Here, h is the function that represents the system reliability in terms of the component reliabilities. The actual formula for $h(R_1, \cdots, R_\mathrm{m})$ depends on the system configuration. Several algorithms are available [54.7] to compute (54.7). Recent literature [54.10] has shown

that, in many cases, algorithms based on binary decision diagrams are more efficient in computing (54.7).

54.1.5 System Availability

If the objective is to maximize the system availability, then we should express the system availability in a mathematical form. The form of the availability expression varies with system configuration. In this section, we provide the availability expressions for some specific configurations. These expressions are valid under the following assumptions.

1. The failure- and repair-time distributions of all components are independent.
2. There are sufficient repair resources such that repair of a failed component starts immediately.

Series Configuration

The availability of the series system is [54.7]

$$A_s = \prod_{i=1}^{m} A_i \,, \tag{54.8}$$

where A_i is the availability of component (subsystem) i and m is the number of components.

Parallel Configuration

The availability of the parallel system is [54.7]:

$$A_s = 1 - \prod_{i=1}^{m} A_i = 1 - \prod_{i=1}^{m} (1 - A_i) \,, \tag{54.9}$$

where A_i is the availability of component (subsystem) i and m is the number of components.

k-out-of-n Active-Standby Configuration

The availability of a k-out-of-n system with identical components is [54.7, 9]

$$\begin{aligned} A_s &= \sum_{i=k}^{n} \binom{n}{i} p^i (1-p)^{n-i} \\ &= \text{binfc}(k-1;\, p, n) \,, \end{aligned} \tag{54.10}$$

where p represents the component availability.

General System Configuration

When failure and repair processes of all components or subsystems are independent, then we can represent the system availability as a function of component availabilities. Hence, we have

$$R_s = h(A_1, \cdots, A_m). \tag{54.11}$$

Here, h is the function that represents the system availability in terms of component availabilities. The actual formula for $h(A_1, \cdots, A_m)$ depends on the system configuration. In this cases, the same algorithms used for system reliability can be used for computing system availability.

54.1.6 Other Objective Functions

Similarly, we can also find the other objective functions analytically [54.11–17]. When closed-form expression are not available the objective function can be calculated using either numerical methods or simulation [54.7]. In such cases, the methods for finding the optimal solutions should not depend on the form of the objective function. The generic nature of these solution methods may lose the advantages associated with the specific form of the objective function. In this section, we provide the expressions for some of the objective functions.

Unreliability

In some systems, the objective would be minimization of unreliability. The unreliability of a system can be obtained from its reliability [54.7]

$$\begin{aligned} &\text{Unreliability} = 1 - \text{Reliability}, \\ &Q_s = 1 - R_s \,. \end{aligned} \tag{54.12}$$

Unavailability

In some systems, the objective would be minimization of unavailability. We have [54.7]

$$\begin{aligned} &\text{Unavailability} = 1 - \text{Availability}, \\ &U_s = 1 - A_s \,. \end{aligned} \tag{54.13}$$

Total Uptime

In some systems, the objective would be the maximization of total uptime (or operational time) over a period of time. We have [54.7]

$$TUT_s(t) = \int_0^t A_s(x)\,\mathrm{d}x \,. \tag{54.14}$$

Total Downtime

In some systems, the objective would be minimization of total downtime during a specified period of time. We have [54.7]

$$TDT_s(t) = \int_0^t U_s(x)\,\mathrm{d}x = t - TUT_s(t) \,. \tag{54.15}$$

Mean Availability

In some systems, the objective would be maximization of system mean availability over a period of time. We have [54.7]

$$A_{\mathrm{M}}(t) = \frac{TUT_{\mathrm{s}}(t)}{t} \,. \tag{54.16}$$

Mean Unavailability

In some systems, the objective would be minimization of mean unavailability over a period of time. We have [54.7]

$$U_{\mathrm{M}}(t) = \frac{TDT_{\mathrm{s}}(t)}{t} = 1 - A_{\mathrm{M}}(t) \,. \tag{54.17}$$

Average cost

In the majority of applications, the objective of system design is to minimize the overall cost associated with the system. The total cost is the sum of several cost factors. These include:

1. System failure cost,
2. Cost of components and spares,
3. Cost of maintenance (repair, replacement, and inspection costs),
4. Warranty costs,
5. Cost associated with downtime (or loss of production).

The actual formulas and cost factors vary with the applications. For details, see [54.11–15, 17].

Decision Variables

These are the values that we are interested to find such that the specified objective is minimized or maximized [54.1]. The decision variables include:

1. Type of system configuration,
2. Types of components or spares,
3. Number of spares in a specific application (or subsystem),
4. Number of repair personnel.

The type of a component is applicable if there are several alternative components for the same application with various costs, weights, volumes, and failure rates (or reliabilities).

Constraints

The optimal solutions should be obtained within the allowed resource restrictions. These are also called constraints of the optimization problem. The constraints include:

1. Desired reliability,
2. Desired availability,
3. Desired mean time to failure (MTTF) or mean time between failures (MTBF),
4. Allowed downtime,
5. Allowed unavailability,
6. Allowed budget (for spares or repair resources),
7. Allowed weight,
8. Available space (or volume).

54.1.7 Existing Optimization Models

As described in the previous sections, there are several possibilities for objective functions, constraints, and decision variables. Furthermore, the diversity of the system configurations and their special properties lead to several optimization models. In this section, we present some well-studied optimization models and associated mathematical formulations. A detailed treatment of these problems is presented in [54.6].

In all these models, it is assumed that the system consists of several stages (subsystems or modules). In most cases, the objective is to maximize the system reliability by optimally assigning the component reliabilities and/or redundancy levels at various stages, subject to resources constraints.

Allocation of Continuous Component Reliabilities

In this formulation, the system reliability can be improved through the selection of component reliabilities at stages subject to resource constraints. Therefore, the decision variables are the reliabilities of the stages $(r_1, \cdots, r_m)$. The problem of maximizing system reliability through the selection of component reliabilities subject to resource constraints can be expressed as:

$$\begin{aligned} &\text{Maximize } R_{\mathrm{s}} = f(r_1, \cdots, r_m) \\ &\quad \text{subject to:} \\ &g_i(r_1, \cdots, r_m) \le b_i \qquad \text{for } i = 1, \cdots, k \,, \\ &r_j^{\mathrm{l}} \le r_j \le r_j^{\mathrm{u}} \qquad \text{for } j = 1, \cdots, m \,. \end{aligned} \tag{54.18}$$

This is a nonlinear programming problem.

Allocation of Discrete and Continuous Component Reliabilities

In this formulation, we have u_j discrete choices for component reliability at stage j for $j = 1, \cdots, s$ and the choice for the component reliability at stages $s+1, \cdots, m$ is on a continuous scale. Therefore, the decision variables are the reliabilities of stages $(r_1, \cdots, r_m)$. Because we have discrete choices for the reliability

at stage j for $j = 1, \cdots, s$, selecting the reliability at each stage is equivalent to selecting the related choice, which can be expressed as an integer. Hence, the decision variables are: $(x_1, \cdots, x_s, R_{s+1}, \cdots, R_m)$. Alternatively, they are equivalent to specifying $[R_1(x_1), \cdots, R_s(x_s), R_{s+1}, \cdots, R_m]$. The problem of maximizing system reliability through the selection of component reliabilities subject to resource constraints can be expressed as:

$$\begin{aligned}
&\text{Maximize} \\
&R_s = f(R_1(x_1), \cdots, R_s(x_s), R_{s+1}, \cdots, R_m) \\
&\text{subject to:} \\
&g_i[R_1(x_1), \cdots, R_s(x_s), R_{s+1}, \cdots, R_m] \le b_i \\
&\qquad\qquad \text{for } i = 1, \cdots, k\,, \\
&x_j \in \{1, 2, \cdots, u_j\} \qquad \text{for } j = 1, \cdots, s\,, \\
&r_j^{\mathrm{l}} \le r_j \le r_j^{\mathrm{u}} \qquad \text{for } j = 1, \cdots, m\,.
\end{aligned} \tag{54.19}$$

This problem is called the reliability allocation problem. This problem can be simplified when the separability assumption is applicable. With the separability assumption, we have

$$g_i(R_1, \cdots, R_m) = \sum_{j=1}^{m} g_{ij}(r_i)\,. \tag{54.20}$$

This problem is a nonlinear mixed integer programming problem.

Redundancy Allocation

System reliability can be improved through the selection of redundancy levels at stages, subject to resource constraints. Therefore, the decision variables are the redundancy levels of stages $(x_1, \cdots, x_m)$. Alternatively, they are equivalent to specifying $[R_1(x_1), \cdots, R_m(x_m)]$. The problem of maximizing the system reliability through the selection of optimal redundancy levels, $x_1, \cdots, x_n$, subject to resource constraints can be expressed as:

$$\begin{aligned}
&\text{Maximize } R_s = f(x_1, \cdots, x_n) \\
&\text{subject to:} \\
&g_i(x_1, \cdots, x_n) \le b_i \qquad \text{for } i = 1, \cdots, k\,, \\
&l_j \le x_j \le u_j \qquad \text{for } j = 1, \cdots, m\,, \\
&x_j \qquad \text{is an integer}\,.
\end{aligned} \tag{54.21}$$

This problem is called the redundancy allocation problem. It is a nonlinear integer programming problem. As in other cases, this problem can be simplified with the separability assumption, which is often applicable in real life. With the separability assumption, we have

$$g_i(x_1, \cdots, x_m) = \sum_{j=1}^{m} g_{ij}(x_i)\,. \tag{54.22}$$

This problem is thoroughly discussed in the literature [54.3, 4, 6, 18–21].

Reliability–Redundancy Allocation

In this formulation, the system reliability can be improved through the selection of component reliabilities as well as redundancy levels at stages, subject to resource constraints. Therefore, the decision variables are the pair of values containing the reliability and level of redundancy for each stage $s(r_s, x_s)$. Hence, the decision variables are both $(x_1, \cdots, x_n)$ and $(r_1, \cdots, r_n)$. The problem of finding simultaneously the optimal redundancy levels $(x_1, \cdots, x_n)$ and the optimal component reliabilities $(r_1, \cdots, r_n)$ that maximize system reliability subject to the resource constraints can be expressed as:

$$\begin{aligned}
&\text{Maximize} \\
&R_s = f(x_1, \cdots, x_n; r_1, \cdots, r_n) \\
&\text{subject to:} \\
&g_i(x_1, \cdots, x_n; r_1, \cdots, r_n) \le b_i \quad \text{for } i = 1, \cdots, k\,, \\
&l_j \le x_j \le u_j \qquad \text{for } j = 1, \cdots, m\,, \\
&r_j^{\mathrm{l}} \le r_j \le r_j^{\mathrm{u}} \qquad \text{for } j = 1, \cdots, m\,, \\
&x_j \qquad \text{is an integer}\,.
\end{aligned} \tag{54.23}$$

This problem is called the reliability-redundancy allocation problem. It is a nonlinear mixed integer programming problem. This problem can also be simplified when the separability assumption is applicable. With the separability assumption, we have:

$$g_i(x_1, \cdots, x_m; r_1, \cdots, r_n) = \sum_{j=1}^{m} g_{ij}(x_i, r_i)\,. \tag{54.24}$$

Redundancy Allocation for Cost Minimization

In this formulation, the objective is cost minimization. In traditional models, the overall cost of the system is expressed as the sum of the cost of all components (stages). The cost of each stage is a function of the redundancy level of the stage. Therefore, the decision variables are the redundancy levels at states $(x_1, \cdots, x_n)$. The problem of finding simultaneously optimal the redundancy levels $(x_1, \cdots, x_n)$ that minimize the system cost subject

to resource constraints can be expressed as:

$$\begin{aligned} &\text{Minimize } C_s = \sum_{j=1}^{m} C_j(x_j) \\ &\text{subject to:} \\ &g_i(x_1, \cdots, x_n) \le b_i \qquad \text{for } i = 1, \cdots, k\,, \\ &l_j \le x_j \le u_j \qquad \text{for } j = 1, \cdots, m\,, \\ &x_j \qquad \text{is an integer}\,. \end{aligned} \tag{54.25}$$

Here, $c_j(x_j)$ is the cost of x_j components at stage j.

Cost-minimization problems are less studied in the literature. Furthermore, there is a lot of scope to improve this formulation by incorporating various cost factors associated with system.

Other Formulations

Other formulations include:

1. Allocation of discrete component reliabilities and redundancies. In this formulation, depending on the type of stage, we can select either a discrete component reliability or the redundancy level (which is also discrete). Therefore, it is a nonlinear integer programming problem. A generalization to this formulation could be by allowing a combination of discrete and continuous choices for component reliability along with choosing the redundancies levels at each stage. Hence, this generalization problem becomes a mixed integer nonlinear programming problem.
2. Component assignment problem. This is applicable when components at various stages can be interchangeable
3. Multi-objective optimization problem. This is applicable when there are multiple simultaneous objectives such as maximization of reliability and minimization of cost, volume, weight, etc.

For more details on these formulations, see [54.6].

54.2 Cost-Effective Designs

In most of the problems studied in the literature, the objective is to maximize the system reliability. However, as we discussed earlier, the optimal solution that maximizes reliability may not necessarily minimizes the overall cost associated with the system. Even though some formulations allow the specification of cost factors in the constraints, they do not minimize the cost. Instead they provide optimal solutions within the specified cost constraints, such as an allowed budget. Further, the well-known cost-minimization problem minimizes the total cost of components subject to other constraints such as desired reliability and allowed volume, weight, etc. However, the cost of the system not only includes the cost of components but also includes various other factors, which are discussed in Sect. 54.1.6. The optimal solution should strike a balance between various competing cost factors such that the overall cost of the system is minimized and at the same time all constraints are satisfied. The cost factors varies with the system type, failure mode, and other details related to a specific system.

54.2.1 Nonrepairable Systems

General Cost Structure

For nonrepairable systems, the major cost factors are the cost of spares and the cost of failure. The system failure cost can be minimized by using reliable system designs. System reliability can be improved by using the redundancy of spares, which can be kept in hot- or cold-standby mode (or in some cases in warm-standby mode). Although the reliability of a system increases with the addition of spares, the cost of the system also increases due to the number of redundant components added to the system. Thus, it is desirable to derive a cost-effective solution that strikes a balance between the system failure cost and the cost of spares in the system. Therefore, the objective is to minimize the average cost associated with the system

$$\begin{aligned} &\text{Average cost} \\ &= \text{Cost of minimum required components} \\ &\quad + \text{Cost of spares} + \text{Cost of failure}\,. \end{aligned} \tag{54.26}$$

Because the cost of the minimum required components is a fixed initial cost, this cost can be eliminated. Alternatively, minimizing the cost using (54.26) and (54.27) are mathematically the same and produce the same optimal solution for the spares. Therefore, depending on convenience, we can use one of these formulations

$$\text{Average cost} = \text{Cost of spares} + \text{Cost of failure}\,. \tag{54.27}$$

The cost of failure can be modeled in several ways. There can be a cost (fixed or randomly distributed with a finite mean) for not completing the mission successfully.

Therefore,

$$\begin{aligned}&\text{Average cost of failure}\\&= \text{Cost of failure of a mission} \times \text{Unreliability}\,.\end{aligned} \tag{54.28}$$

For example, this kind of cost is applicable for missions such as landing on a planet or a moon. Finally, the average system cost is

$$\begin{aligned}\text{Average cost} &= \text{Cost of spares}\\&\quad + \text{Cost of failure of a mission}\\&\quad \times \text{Unreliability}\,.\end{aligned} \tag{54.29}$$

In some scenarios the cost of system failure may depend on the time at which the failure occurs. If the system fails at the beginning of the mission, the losses are high compared to if the system fails almost at the end of the mission. If the cost is linearly proportional to the remaining mission time, then we can express the average system cost in terms of the average remaining mission time. Therefore,

$$\begin{aligned}&\text{Average cost of failure}\\&= \text{Cost of failure of a mission per unit time}\\&\quad \times \text{Remaining mission}\\&= \text{Cost of failure of a mission per unit time}\\&\quad \times \text{Mission duration}\\&\quad \times \text{Average unreliability or unavailability}\\&= \text{Cost of failure of a mission per unit time}\\&\quad \times \text{Mean downtime}\,.\end{aligned} \tag{54.30}$$

In most cases, the problem of minimizing the average cost of the system can be converted into the problem of maximizing the average profit of the system. When there is a fixed profit for each successful operation of the mission, we can easily show that these two problems are identical.

$$\begin{aligned}&\text{Average system profit}\\&= \text{Profit during success} \times \text{Reliability}\\&\quad - \text{Losses during failure} \times \text{Unreliability}\\&\quad - \text{Cost of components}\\&= \text{Profit during success}\\&\quad - (\text{Profit during success} - \text{Losses during failure})\\&\quad \times \text{Unreliability}\\&\quad - \text{Cost of components}\,.\end{aligned} \tag{54.31}$$

Because the *profit during success* is fixed, it is a constant. Therefore, the problem of maximizing the system profit is reduced to maximization of Function1 shown in (54.32):

$$\begin{aligned}&\text{Function1}\\&= -(\text{Profit during success} - \text{Losses during failure})\\&\quad \times \text{Unreliability}\\&\quad - \text{Cost of components}\,.\end{aligned} \tag{54.32}$$

Because maximizing $[f(x)]$ is equivalent to minimizing $[-f(x)]$, the problem is equivalent to minimizing the Function2 in (54.33). For details, see [54.1].

$$\begin{aligned}&\text{Function2}\\&= (\text{Profit when success} - \text{Losses during failure})\\&\quad \times \text{Unreliability}\\&\quad + \text{Cost of components}\,.\end{aligned} \tag{54.33}$$

The objective functions shown in (54.29) and (54.33) have the same form. Therefore, the same methods that are used for cost-minimization problems can also be used for profit-maximization problems.

A specific Model for Nonrepairable Systems

In this section, we provide a detailed model for a specific class of nonrepairable systems. The system consists of several subsystems, which are arranged in a network configuration. Each subsystem requires a minimum number of identical components to perform its functions. The additional spare components in each subsystem can be kept online or in cold- or hot-standby mode. Therefore, each subsystem behaves like a k-out-of-n:G cold/hot-standby system. The objective of the problem considered in this chapter is to find the optimal cost-effective design of the overall system. This means that the optimal number of components in each subsystem must be found to minimize the overall cost associated with the system.

Assumptions.

1. The system consists of m subsystems. The subsystems can be arranged in a complex network configuration [54.22].
2. System structure function is coherent with respect to the subsystems.
3. All subsystems are statistically independent.
4. Each subsystem consists of $n_i \equiv k_i + s_i$ identical components.
5. Subsystem i requires k_i components for its successful operation.
6. Subsystem i can have s_i spares. Spares of a subsystem can be kept in hot- or cold-standby mode.

7. The failure rate of an operational component is constant. The failure rate of a hot-standby component is equivalent to the failure rate of an operational component. The failure rate of a cold-standby component is zero.

Problem Formulation. Because the subsystems are independent, we can compute the reliability of each subsystem separately and use those results to compute the overall system reliability. The reliability calculation of a subsystem depends on the type of spares used.

1. Hot standby

$$R_i = \text{binfc}(k_i - 1;\, p_i, n_i)\,. \tag{54.34}$$

2. Cold standby

$$\begin{aligned} R_i &= \exp(-k_i\lambda_i t)\left(\sum_{j=0}^{s_i}\frac{(k_i\lambda_i t)^j}{j!}\right) \\ &= p_i^{k_i}\left(\sum_{j=0}^{s_i}\frac{[-k_i\ln(p_i)]^j}{j!}\right)\,. \end{aligned} \tag{54.35}$$

System reliability is a function of the subsystem reliabilities

$$\begin{aligned} R(\boldsymbol{n}) &= h(R_1, \cdots, R_m) \\ &= R_i h_i^1 + (1 - R_i)h_i^0 \\ &= \left(h_i^1 - h_i^0\right)R_i + h_i^0\,. \end{aligned} \tag{54.36}$$

The average cost of the system, $T_s(n)$, is the cost incurred when the system has failed, plus the cost of all components in the system

$$T(\boldsymbol{n}) = \sum_{i=1}^{m} c_i n_i + c_f\left[1 - R(\boldsymbol{n})\right]\,. \tag{54.37}$$

The objective is to find the optimal $\boldsymbol{n}$ that minimizes $T(\boldsymbol{n})$. The problem can be further refined by considering minimum acceptable reliability (R_a), acceptable upper limit on total weight & volume, and allowable budget for spares acquisition. Therefore, the constraints are

$$\begin{aligned} &\text{Budget constraint:} && \sum_{i=1}^{m} s_i.c_i \le B \\ &\text{Volume constraint:} && \sum_{i=1}^{m} v_i \le V \\ &\text{Weight constraint:} && \sum_{i=1}^{m} w_i \le W \\ &\text{Reliability constraint:} && R(\boldsymbol{n}) \ge R_a\,, \end{aligned} \tag{54.38}$$

where B is the allowed budget, V is the maximum allowed volume, W is the maximum allowed weight, and R_a is the minimum acceptable reliability.

In addition, we can also add explicit constraints on the number of components in each subsystem. However, in general, the problem is difficult to solve when no explicit constraints on the decision variables are specified. The solution can be simplified by finding the explicit bounds for each decision variable, i. e., the number of components. It is a nonlinear integer programming problem.

54.2.2 Repairable Systems

General Cost Structure

For repairable systems, the major cost factors are:

- initial cost of spares,
- cost of failures,
- cost of repair and replacement,
- cost of storage.

However, in the long run, the cost of the initial cost of spares is negligible compared to the other costs. The cost of failure can be minimized by minimizing the system unreliability, which in turn can be achieved by increasing the number of spares in the system. However, the increase in the number of spares can also increase the maintenance and operational costs of spares, which include repair, replacement and storage costs. Thus, it is desirable to derive a cost-effective solution that strikes a balance between the system failure cost and the cost of maintenance and operation

$$\begin{aligned} &\text{Average system cost} \\ &= \text{Cost of maintenance} \\ &\quad + \text{Cost of failure} \times \text{Unavailability}\,. \end{aligned} \tag{54.39}$$

However, for short-duration systems, we have

$$\begin{aligned} &\text{Average system cost} \\ &= \text{Initial cost of components and spares} \\ &\quad + \text{Cost of set up} \\ &\quad + \text{Cost of maintenance} \\ &\quad + \text{Cost of failure} \times \text{Unavailability} \\ &\quad + \text{Cost of disposal}\,. \end{aligned} \tag{54.40}$$

The cost of disposal can be positive or negative (for resale value it is negative). When we can calculate the cost of each component including the cost of procurement,

set up, and resale values. The problem can be reduced to

$$\begin{aligned}&\text{Average system cost}\\&= \text{Effective cost of components and spares}\\&\quad + \text{Cost of maintenance}\\&\quad + \text{Cost of failure} \times \text{Unavailability}\,.\end{aligned} \tag{54.41}$$

A Specific Model for Repairable Systems

The majority of engineering and manufacturing systems consist of several subsystems [54.22], which are usually nonidentical. In general, all subsystems need not be in series, but can be arranged in any configuration. The success logic of these types of systems can be represented using networks or reliability block diagrams, which are collectively known as combinatorial reliability models [54.23]. Each subsystem can have one or more functionally similar components [54.24]. For successful operation of a subsystem, there must be at least a specified number of components in operation. Such subsystems, known as k-out-of-n subsystems [54.9], have a wide range of applications [54.9, 12, 13, 25]. A special case of a k-out-of-n subsystem with $k = 1$ is called a parallel subsystem [54.26].

In general, systems and components are repairable. Therefore, systems and components undergo several failure–repair cycles that include logistic delays while performing repairs [54.27]. In the long run, the downtime costs are directly related to the asymptotic unavailability of the system. System unavailability can be reduced by increasing the availability of its subsystems, which in turn can be increased by additional spares for each subsystem. Although the availability of a system increases with the addition of spares, the cost of the system also increases due to the added operational and maintenance costs. Thus, it is desirable to derive a cost-effective solution that strikes a balance between the system downtime cost and the operational and maintenance costs of spares in the system. The objective of the cost-effective solution is to find the optimal number of spares in each subsystem that minimizes the overall system cost.

Assumptions.

1. The system consists of m subsystems. All subsystems are statistically independent.
2. Subsystem i consists of $n_i \equiv k_i + s_i$ components, where subsystem i requires at least k_i components for its successful operation.
3. Failure, repair, and logistic delay times of all components are independent and can follow any distribution.
4. System failure cost is proportional to the downtime.
5. There is a fixed miscellaneous cost for each repair of a component. In addition to the fixed cost, the cost of repair has a variable cost, which is proportional to the amount of repair time. The downtime of a component is the sum of the repair time and logistic delay time.

Problem Formulation.

The average system cost is the sum of the average cost of downtime plus the average cost of maintenance

$$T(\boldsymbol{n}) = T_{\mathrm{d}}(\boldsymbol{n}) + T_{\mathrm{m}}(\boldsymbol{n})\,. \tag{54.42}$$

The cost of downtime can be calculated from the percentage of downtime within a unit time duration and the loss (cost) per unit downtime. As time progresses, the system reaches a steady-state condition. Under steady-state conditions, the percentage of downtime is equivalent to the steady-state unavailability. Hence,

$$T_{\mathrm{d}}(\boldsymbol{n}) = c_{\mathrm{f}} U(\boldsymbol{n}) = c_{\mathrm{f}}\left[1 - A(\boldsymbol{n})\right]\,. \tag{54.43}$$

System availability is a function of the subsystem availabilities

$$A(\boldsymbol{n}) = h(A_1, \cdots, A_{\mathrm{m}})\,. \tag{54.44}$$

The actual formula for $h(A_1, \cdots, A_m)$ depends on the system configuration. For example, if the system configuration is series, then

$$A(\boldsymbol{n}) = \prod_{i=1}^{m} A_i(n_i)\,. \tag{54.45}$$

Several algorithms are available [54.7] to compute (54.44). Recent literature [54.10] has shown that, in many cases, algorithms based on binary decision diagram are more efficient in computing (54.44).

If the system is under steady-state conditions, and the failure and repair processes of all components are independent, the availability of each component can be calculated using its mean time to failure (MTTF), mean time to repair (MTTR), and mean logistic delay time (MLDT). Because each subsystem consists of identical components and the configuration of each subsystem is k_i-out-of-n_i, we have:

$$\begin{aligned}A_i = A_i(n_i) &= \mathrm{binf}(n_i - k_i;\, q_i, n_i)\\&= \mathrm{binfc}(k_i - 1;\, p_i, n_i)\end{aligned} \tag{54.46}$$

where p_i and q_i are, respectively, the operational availability and unavailability of a component in subsystem i. Furthermore, given that $q_i = 1 - p_i = (\psi_i + \varphi_i)/(\phi_i$

$+\psi_i+\varphi_i)$, where ϕ_i is the MTTF, ψ_i is the MTTR, and φ_i is the MLDT of a component in subsystem i.

The cost of maintenance is proportional to the cost associated with the repairs of individual components. The cost of repair of a failed component includes the miscellaneous fixed cost as well as the variable cost based on the repair time. Therefore, if the repair of a failed component in the subsystem i takes on average ψ_i units of time, then the average cost of repair for each instance of repair is

$$R_i = \gamma_i + \psi_i \delta_i \; . \tag{54.47}$$

Let ν_i be the failure frequency, i. e., expected number of failures per unit time, of a component in subsystem i. Because all components in a subsystem are identical, on average, we have $N_i \equiv n_i f_i$ failures per unit time. Under steady-state conditions, we have

$$\begin{aligned} \nu_i &= \frac{1}{\phi_i+\psi_i+\varphi_i} \\ N_i &= \frac{n_i}{\phi_i+\psi_i+\varphi_i} \; . \end{aligned} \tag{54.48}$$

Hence, the cost of maintenance of a subsystem per unit time is $\theta_i(n_i)$

$$\theta_i(n_i) = N_i R_i = n_i \nu_i R_i \; . \tag{54.49}$$

The cost of maintenance of the entire system is

$$T_{\mathrm{m}}(\boldsymbol{n}) = \sum_{i=1}^{m} \theta_i(n_i) = \sum_{i=1}^{m} n_i \nu_i R_i \; . \tag{54.50}$$

It should be noted that, in the long run, the initial cost of the spares per unit time is negligible and need not be considered.

Therefore, the average cost of the system is

$$\begin{aligned} T(\boldsymbol{n}) &= \sum_{i=1}^{m} c_i n_i + c_{\mathrm{f}} U(\boldsymbol{n}) \; , \\ c_i &= \frac{\gamma_i + \psi_i \delta_i}{\phi_i+\psi_i+\varphi_i} \; , \\ U(\boldsymbol{n}) &= 1 - A(\boldsymbol{n}) \; , \\ A(\boldsymbol{n}) &= h(A_1, \cdots, A_m) \; , \\ A_i &\equiv A_i(n_i) = \mathrm{binf}(n_i - k_i; q_i, n_i) \; , \\ q_i &= \frac{\psi_i+\varphi_i}{\phi_i+\psi_i+\varphi_i} = 1 - \frac{\phi_i}{\phi_i+\psi_i+\varphi_i} \; . \end{aligned} \tag{54.51}$$

The objective is to find the optimal $\boldsymbol{n}$ that minimizes $T(\boldsymbol{n})$. The problem can be further refined by considering the maximum acceptable unavailability (U_{a}) and the acceptable upper limit on total weight and volume. Therefore, the constraints are

$$\begin{aligned} \text{Volume constraint:} \quad & \sum_{i=1}^{m} v_i \le V \; ; \\ \text{Weight constraint:} \quad & \sum_{i=1}^{m} w_i \le W \; ; \\ \text{Unavailability constraint:} \quad & U(\boldsymbol{n}) \le U_{\mathrm{a}} \; . \end{aligned} \tag{54.52}$$

Similarly, we can also add explicit constraints on the number of components in each subsystem. This is a nonlinear integer programming problem. More specific forms of average cost functions are studied in [54.11–15, 17].

54.3 Optimal Design Algorithms

54.3.1 An Overview

In this section, we discuss various methods for solving optimal system problems. We demonstrate these methods for solving the problems associated with cost-effective designs. The same algorithms can also be applied for the other problem formulations. The algorithms can be broadly classified as follows:

1. *Exact methods*. These methods produce exact optimal solutions. It is generally difficult to develop efficient exact methods for spares optimization problems. This is because the objective function, which is the function to be minimized, is nonlinear and involves several integer variables, which are the components to be optimized. In addition, the objective function may have several peaks and may not possess monotonic increasing or decreasing characteristics. Therefore, exact methods involve more computational effort and usually require large amounts of computer memory.
   One exact method is exhaustive searching, where the objective function is computed for all possible combinations of the decision variables, which would be the quantities of spares. However, exhaustive searching is infeasible even for a moderately size problem for optimizing the number of spares. Other algorithms in this category involve dynamic

programming, branch-and-bound methods, and nonlinear mixed integer programming techniques. Some researchers have developed exact methods that have closed-form or computationally efficient solutions for some well-structured systems such as *k*-out-of-*n* systems, parallel–series, and series–parallel systems.

2. *Approximation methods*. Some of the difficulties of spares optimization problem are due to the presence of an integer variable (the number of spares), the variable forms of cost functions (the number of terms in the cost function is based on the number of spares), and non-polynomial cost functions. In addition, the cost function may have several peaks and valleys. By using approximation methods, these complex problems can be modeled in a simpler form by considering continuous variables for spares quantities and approximate forms for the cost function. This approach produces near-optimal solutions, or solutions that are very close to the exact solution result. However, approximation methods cannot guarantee the global optimal solutions, which are exact solutions that actually minimize the objective functions.
3. *Heuristic methods*. Finding exact optimal solutions for large complex systems is not always feasible because such problems involve resource-intensive computation efforts and usually require large amounts of computer memory. For these reasons, researchers in reliability optimization have placed more emphasis on heuristic approaches, which are methods based on rules of thumb or guidelines that generally find the solutions but do not guarantee an exact solution. In most of these approaches, the solution is improved in each iteration. One of the simple heuristic approaches is the greedy method, where the quantity of spares is incremented for the subsystem where the maximum reduction in cost is achieved. This iterative process is stopped when a point is reached where adding spares to any component increases the cost. Heuristic methods typically produce local optimal solutions within a short time. However, they may not guarantee the global optimal solutions and may produce local optimal solutions, which is an optimal solution in a local neighborhood. For spares optimization, there may exist several local optimal solutions, where changing any variable slightly (increasing or decreasing any spare) increases the total cost. The global optimal solution corresponds to the minimal solution out of all such local optimal solutions.
4. *Meta-heuristic methods*. These methods are based more on artificial reasoning than classical mathematics-based optimization. They include genetic algorithms (GA) and simulated annealing (SA). GAs seek to imitate the biological phenomenon of evolutionary production through parent–child relationships. SA is based on a physical process in metallurgy. Most of these methods use stochastic searching mechanisms. Meta-heuristic methods can overcome the local optimal solutions and, in most cases, they produce efficient results. However, they also cannot guarantee the global optimal solutions.
5. *Hybrid methods*. These methods use combinations of different optimization techniques. An example of a hybrid method would be to find the initial solution with different heuristic approaches or approximations and then apply meta-heuristic methods to search for better solutions.

54.3.2 Exact Methods

In order to find an exact solution to the optimization problem, we should either compute the objective function for all possible combinations of decision variables or systematically identify all potential combinations of decision variables. Therefore, exact methods are appli-

Table 54.1 Exhaustive search results

n_1	n_2	R_s	C_s	Remarks
1	1	0.600 000	–	C5 violated
1	2	0.720 000	–	C5 violated
1	3	0.744 000	–	C5 violated
1	4	0.748 800	–	C5 violated
2	1	0.750 000	–	C5 violated
2	2	0.900 000	106.000 000	
2	3	0.930 000	78.000 000	
2	4	0.936 000	74.000 000	
3	1	0.787 500	–	C5 violated
3	2	0.945 000	62.000 000	
3	3	0.976 500	32.500 000	
3	4	0.982 800	28.200 000	
4	1	0.796 875	–	C5 violated
4	2	0.956 250	51.750 000

5	2	0.959 062	49.937 500	
5	3	0.991 031	19.968 750	
5	4	0.997 425	–	C3, C4 violated

cable only when the problem size is very small or it posses a special properties that can be used to identify the potential optimal solutions. Many exact methods were developed before 1980 and documented in *Tillman* et al. [54.4].

Exhaustive Searching

In this method, compute the objective function for all possible combination of decision variable. In order to achieve this goal, we should know the lower and upper limits on the decision variables. This method is demonstrated for a nonrepairable system consisting of two subsystems in series. The objective is to find the optimal number of online spares in each subsystem that minimizes the average cost associated with the system

$$\begin{aligned}
&\text{Minimize } C_s = n_1c_1 + n_2c_2 + c_f[1 - R_s(n_1, n_2)] \\
&\quad \text{where,} \qquad (54.53)\\
&R_s(n_1, n_2) = R_1(n_1)R_2(n_2)\,, \\
&R_1(n_1) = 1 - (q_1)^{n_1}\,, \\
&R_2(n_2) = 1 - (q_2)^{n_2}\,, \\
&c_f = 1000,\ c_1 = 1,\ c_2 = 2\,, \\
&p_1 = 0.75,\ p_2 = 0.8
\end{aligned}$$

subject to:

$$\begin{aligned}
C1: &\quad 1 \le n_1 \le 5 \\
C2: &\quad 1 \le n_2 \le 6 \\
C3: &\quad n_1 + n_2 \le 8 \quad \text{total number constraint} \\
C4: &\quad 2.n_1 + 3.n_2 \le 20 \quad \text{weight constraints} \\
C5: &\quad R_s(n1, n2) \ge 0.9\,.
\end{aligned}$$

Because we know the explicit limits on n_1 and n_2, we can find all possible combinations of the possible solutions. For each possible solution combination, we check the other constraints. If any constraint is violated, we discard that combination and go for the next combination. For all valid combinations, we compute the objective function. The combination that correspond to the minimum value for the objective function is the optimal solution. This is described in the Table 54.1.

The optimal solution is ($n_1 = 4$, $n_2 = 4$) and the corresponding cost is 17.5. If there are no constraints for this problem, the optimal solution is ($n_1 = 5, n_2 = 4$) and the corresponding cost is 15.575.

Although it is easy to understand and program exhaustive searching methods, they are infeasible for large systems. This is because the search space increases exponentially with the problem size. Therefore, researchers proposed methods that can only search within a reduced space. *Misra* [54.20] has proposed an exact algorithm for optimal redundancy allocation problem with a reliability maximization objective based on a search near the boundary of the feasible region. This method was later implemented by *Misra* and *Sharma* [54.28], and *Misra* and *Misra* [54.29] to solve various redundancy allocation problems. This does not always gives an exact optimal solution. *Prasad* and *Kuo* [54.30] recently developed a partial enumeration method based on lexicographic search with an upper bound on system reliability. This method was demonstrated for both small and large problems. An overview of other exact methods can be found in [54.6]. With some minor modifications, the same concepts can also be used for cost-effective design.

Dynamic Programming

Dynamic programming (DP) is a solution methodology based on Richard Bellman's principle of optimality. DP is an approach for solving a wide spectrum of decision-making problems and is highly effective at solving certain types of deterministic and stochastic optimization problems. In this approach, a decision-making problem involving n variables is reduced to a set of n single-variable problems, which are derived sequentially in such a way that the solution of each problem is obtained using the preceding answer. The DP approach transforms an n-variable optimization problem into a multi-stage decision-making process. Such a transformation is not always straightforward and it quite often requires a lot of ingenuity. For this reason, it is not easy to describe the general DP approach as an algorithm. An outline of DP is given for various optimization problems in [54.6].

The basic DP approach is generally used to solve optimization problems with, at most, one constraints and with or without bounds on the decision variables. In this section, we demonstrate the DP approach solving a three-unit series system without constraints and

bounds.

Minimize

$$C_s = n_1c_1 + n_2c_2 + n_3c_3 + c_f[1 - R_s(n_1, n_2, n_3)]$$

where, (54.54)

$$\begin{aligned} R_s(n_1, n_2, n_3) &= R_1(n_1)R_2(n_2)R_3(n_3)\,, \\ R_1(n_1) &= 1 - (q_1)^{n_1}\,, \\ R_2(n_2) &= 1 - (q_2)^{n_2}\,, \\ R_3(n_3) &= 1 - (q_3)^{n_3}\,, \\ c_f &= 10,\ c_1 = 1,\ c_2 = 1,\ c_3 = 0.2\,, \\ p_1 &= 0.75,\ p_2 = 0.5,\ p_3 = 0.33\,. \end{aligned}$$

For example assume that the optimal configurations for stages 2 and 3 are fixed, i. e., n_2 and n_3 are fixed. Therefore, $n_2c_2 + n_3c_3$ and $R_2(n_2)R_3(n_3)$ are also fixed. Let us define v_i as the probability that the stages $i, \cdots, 3$ are working. Hence, the problem is reduced to:

$$\text{Minimize } C_s = n_1c_1 + c_f[1 - v_2R_1(n_1)]\,. \quad (54.55)$$

The solution to this problem depends on the value of v_2. For variable values of v_2, we find optimal value of n_1, n_1^*, using simple search techniques. We can also find the optimal solution analytically. Let the corresponding value for C_s be $f_1(v_2)$. The results are provided in Table 54.2. Now the remaining problem is to find the value of v_2 corresponding to the optimal values of n_2 and n_3. Let us assume that we know the value of n_3. Therefore, we also know $v_3 \equiv R_3(n_3)$. Hence, the problem is reduced to:

Minimize

$$\begin{aligned} C_s &= n_1c_1 + n_2c_2 + c_f[1 - v_3R_1(n_1)R_2(n_2)] \\ &= n_2c_2 + f_1[v_3R_2(n_2)]\,. \end{aligned} \quad (54.56)$$

For any fixed v_3, we can find the value of C_s for varying values of n_2. In this process, we need to compute $f_1(v)$ for given value of x_2. This can be done through interpolation. For example, the value of $f_1(v)$ for $v = 0.88$ is determined by interpolation of $f_1(0.9)$ and $f_1(0.8)$ obtained in the previous stage (see Table 54.2). Once we compute the C_s for various values of n_2, we can find the n_2^* that minimize C_s. Let the corresponding value for C_s for a fixed v_3 be $f_2(v_3)$.

Now the problem is reduced to find the value of v_3 corresponding to the optimal value of n_3. The cost function can be rewritten as

Minimize

$$\begin{aligned} C_s &= n_1c_1 + n_2c_2 + n_3c_3 + c_f[1 - R_s(n_1, n_2, n_3)] \\ &= n_3c_3 + f_2(R_3(n_3)) \end{aligned} \quad (54.57)$$

Table 54.2 Dynamic programming solution

v_2	$n_1^*(v_2)$	$f_1(v_2)$	$n_2^*(v_3)$	$f_2(v_3)$
1.0	2	2.625	1.0	6.997
0.9	2	3.563	0.9	7.617
0.8	2	4.500	0.8	8.375
0.7	2	5.438	0.7	9.031
0.6	2	6.375	0.6	9.625
0.5	1	7.250	0.5	10.125
0.4	1	8.000	0.4	10.500
0.3	1	9.750	0.3	10.875
0.2	1	9.500	0.2	11.250
0.1	1	10.250	0.1	11.125

We can find the value of $R_3(n_3)$ for varying values of n_3. Hence, we can compute $f_2(v)$ and C_s for varying values of n_3. Hence, we can find the value n_3^* that minimizes C_s. The optimal value of n_3 is $n_3^* = 7$, and the corresponding minimum cost is 8.6787. This is the minimum cost for the overall system. From this we can calculate the corresponding $v_3 = R_3(n_3^*) = 0.94$. Using the backtracking method, we can compute $n_2^*(v_3) = n_2^*(0.94) = 3$. Similarly, we can compute $v_2 = 0.82$. The optimal choice for n_1 is $n_1^*(v_2) = n_1^*(0.82) = 2$ and the corresponding v_1 is 0.77.

Therefore, the optimal solution is $(n_1^*, n_2^*, n_3^*) = (2,3,7)$ and the corresponding minimum average cost is 8.6787.

It should be noted that the whole process can be expressed using the following recursive relationship. Let $f_i(v_{i+1})$ denote the minimum expected average profit due to redundancy at stages $1, \cdots, i$, where v_{i+1} is the probability that the stages $i+1, \cdots, 3$ work. Let $v_4 = 1$. Then, for $i = 1, \cdots, 3$, we have the following recursive relationship

$$f_i(v_i + 1) = \min \arg_{n_i}\{f_{i-1}[v_{i+1}R_i(x_i)] + c_ix_i\} \quad (54.58)$$

for $i = 2, 3$. For $i = 3$, it is enough to consider only the value 1.0 for v_{i+1}. Let $n_i{}^*(v_{i+1})$ denote the value of n_i that maximizes $f_{i-1}[v_{i+1}R_i(n_i)] + c_in_i$, then

$$\begin{aligned} f_1(v_2) &= \min \arg_{n_1}\{c_fv_2[1 - (1 - r_1)^{n_1}] + c_1n_1\}, \\ f_2(v_3) &= \min \arg_{n_2}\{f_1(v_3[1 - (1 - r_2)^{n_2}]) + c_2n_2\}, \\ f_3(1.0) &= \min \arg_{n_3}\{f_2[1 - (1 - r_3)^{n_3}] + c_3n_3\}\,. \end{aligned} \quad (54.59)$$

Although recursive relations are available, it is not computationally feasible to evaluate $f_i(v)$ for all v in the

continuous interval [0, 1]. Thus, $f_i(v)$ is evaluated on a grid of v for $i = 1$ and 2. Linear interpolation is done when $f_i(v)$ is needed, but not available, for a required value of v.

54.4 Hybrid Optimization Algorithms

54.4.1 Motivation

The problem of finding the optimal number of spares is known as a redundancy allocation problem. It is a nonlinear programming problem involving integer variables [54.31]. *Chern* [54.18] has shown that the problem is NP-hard even for series–parallel systems. A summary of approaches to determine optimal or near optimal solutions in this area is presented in [54.2, 3]. In most of the published articles, the objective is the maximization of a system performance measure such as reliability or availability that satisfies a set of given constraints. In a cost-effective solution, the objective should be the minimization of the total costs associated with the system, which is the sum of the cost of initial spares, cost of maintenance, and cost of downtime. The publications on cost-effective designs are limited [54.9, 12, 32, 33]. Furthermore, even though the majority of systems are repairable, few publications exist on the optimal design issues of repairable systems [54.12, 21, 33, 34].

In general, it is difficult to obtain the optimal solution for complex systems. There exist several heuristics algorithms [54.35–37] in the literature to find near-optimal solutions. However, the efficiency and computational effort of those methods depend on the lower and upper bounds of the decision variables [54.2]. In this chapter we present a new method to find tighter bounds for obtaining the optimal number of spares. The main contributions of this research is a development of a new method to find tighter bounds for the optimal number of spares for each subsystem. The efficiency of the proposed bounds is demonstrated through several examples.

54.4.2 Rationale for the Hybrid Method

Under some mild assumptions the cost-effective solutions of both repairable and nonrepairable systems can be represented using the same mathematical formulation. For example, the cost-effective formulations used in Sects. 54.1 and 54.2 are in the same form. Therefore, the same optimization methods can used for solving these two problems. Although, the underlying problem is NP-hard, when there is only one subsystem in the system, we can find the exact solution in an efficient way even when spares are in cold- or hot-standby mode. Furthermore, we can find the exact solution even if the subsystem adopt the k-out-of-n configuration. Using our latest research findings, we can show that, when the cost of failure is the same, optimal value obtained for the subsystem in a stand-alone analysis is in fact the upper bound in the entire analysis. The upper bound can be used find the lower bounds. Further, using these lower and upper bounds, we can find better bounds in an iterative way until we reach stable bounds. This new way of finding bounds reduces the search space considerably and hence improves the solution quality.

We first describe this method for repairable systems. Then we apply the same method for the nonrepairable case.

54.4.3 Repairable Systems

Cost Minimization with One Subsystem

Before solving the actual problem, first consider a simpler problem that contains only one subsystem, i. e., $m = 1$. Say it is the subsystem i. Therefore, the cost of the system is

$$T(n_i) = c_i n_i + c_f [1 - A_i(n_i)] \ ,$$
$$A_i(n_i) \equiv \text{binf}(n_i - k_i; q_i, n_i) \ . \qquad (54.60)$$

It should be noted that the exact solution for this problem cannot be found with simple searching methods, where adding spares is stopped once a spares quantity that increases the overall system cost is reached. This is because there can exist multiple discontinuous regions where the average system cost increases with additional spares. For details, refer to [54.32]. Therefore, we need efficient algorithms to solve these optimization problems. Optimal design policies for k-out-of-n systems, i. e., systems with single subsystems, are studied in [54.9, 33].

Definition

$$f(n_i) \equiv A_i(n_i + 1) - A_i(n_i)$$
$$= \binom{n_i}{k_i - 1} p_i^{k_i} q_i^{n_i - k_i + 1} \ ,$$

$$m_0 \equiv \max\left[k_i, \text{gilb}\left(\frac{k_i-1}{p_i}\right)\right] ,$$
$$m_1 \equiv \frac{T(k_i)}{c_i} ,$$
$$m_2 \equiv \inf\{n_i \in [m_0, m_1] : f(n_i) < c_i/c_f\} . \quad (54.61)$$

It should be noted that m_2 can be evaluated efficiently using binary searching methods. When sequential searching is performed, we can use the following relationship to reduce the computational efforts

$$f(n_i) = f(n_i-1)\frac{n_i q_i}{n_i - k_i + 1} ,$$
$$f(k_i - 1) = 1 . \quad (54.62)$$

Theorem 54.1

For fixed k_i, p_i, c_i, and c_f, the optimal value of n_i that minimizes $T(n_i)$ is n_i^*:

if $f(m_0) < c_i/c_f$, then $n_i^* = k_i$
else if $f(k_i) \geq c_i/c_f$, then $n_i^* = m_2$
else if $T(k_i) > T(m_2)$, then $n_i^* = m_2$
else $n_i^* = k_i$.

Proof: The form of the cost function for this problem is equivalent to the form of the cost function used in references [54.9, 33] for minimizing the total cost of a nonrepairable k-out-of-n system. Therefore, the underlying mathematical problem is the same. For details, refer to [54.9, 33]. ■

Corollary 54.1

If the configuration of the subsystem is parallel, i. e., $k_i = 1$, then for fixed p_i, c_i, and c_f, the optimal value of n_i that minimizes $T(n_i)$ is $n_i^* = e_1$

$$e_0 \equiv \frac{\ln\left(\frac{c_i}{c_f \cdot p_i}\right)}{\ln(q_i)} ,$$
$$e_1 \equiv \max[1, \text{gilb}(e_0) + 1] . \quad (54.63)$$

Proof: For parallel systems, $f(n) = q^n p$ [54.33]. Therefore, the rest of the proof is straightforward from Theorem 54.1. It should be noted that Corollary 54.1 is a special case of Theorem 54.1. ■

Corollary 54.2

For fixed k_i, p_i, and c_i, the optimal value of n_i that minimizes $T(n_i)$ is nondecreasing with an increase in c_f.

Proof: Because c_i/c_f is decreasing, $k_i \leq m_2$, and $f(n_i)$ is decreasing in $[m_0, m_1]$, the proof is straightforward. ■

Cost Minimization with Multiple Subsystems

The system consists of several subsystems. Except for one subsystem (say subsystem i), the configurations of these subsystems are fixed. The system availability can be expressed using conditional probabilities based on Shannon's decomposition formula [54.10]. The theorem related to this formula is known as the total probability theorem [54.7]. Let us consider that subsystem i is the pivotal element (also called the key element) in the decomposition; then

$$\begin{aligned} A(\boldsymbol{n}) &= h(A_1, \cdots, A_m) \\ &= A_i h_i^1 + (1 - A_i) h_i^0 \\ &= \left(h_i^1 - h_i^0\right) A_i + h_i^0 . \end{aligned} \quad (54.64)$$

Here h_i^1 and h_i^0 are the conditional availabilities of the system given that subsystem i is operating and nonoperating, respectively. Therefore, the total system cost with n_i components in subsystem i is

$$\begin{aligned} T(n_i) &= \sum_{j=1}^{m} c_j n_j + c_f\left[1 - \left(h_i^1 - h_i^0\right) A_i(n_i) - h_i^0\right] \\ &= c_0 + c_f\left(1 - h_i^1\right) + c_i n_i \\ &\quad + c_f\left(h_i^1 - h_i^0\right)\left[1 - A_i(n_i)\right] , \\ c_0 &= \sum_{j=1;\, j\neq i}^{m} c_j n_j . \end{aligned} \quad (54.65)$$

Because $\left[c_0 + c_f\left(1 - h_i^1\right)\right]$ is independent of n_i, minimizing $T(n_i)$ in (54.65) is equivalent to minimizing $T_1(n_i)$ in (54.66)

$$T_1(n_i) = c_i n_i + c_f\left(h_i^1 - h_i^0\right)\left[1 - A_i(n_i)\right] . \quad (54.66)$$

The cost equations (54.60) and (54.66) are similar. Therefore, we can find the optimal n_i using Theorem 54.1. However, instead of using c_f, we need to use the modified system cost $c_f\left(h_i^1 - h_i^0\right)$ in Theorem 54.1. The results are presented in Corollary 54.3.

Definition

$$m_2' \equiv \inf\left\{n_i \in [m_0, m_1] : f(n_i) < \frac{c_i}{c_f\left(h_i^1 - h_i^0\right)}\right\} . \quad (54.67)$$

Corollary 54.3

For fixed configurations of all subsystems (except subsystem i) and for fixed k_i, p_i, c_i, and c_f, the optimal value of n_i that minimizes $T(n_i)$ is n_i^*:

$$\begin{aligned}&\text{if } f(m_0) < \frac{c_i}{c_f(h_i^1 - h_i^0)}, \text{ then } n_i^* = k_i\\ &\text{else if } f(k_i) \geq \frac{c_i}{c_f(h_i^1 - h_i^0)}, \text{ then } n^* = m_2'\\ &\qquad \text{else if } T(k_i) > T(m_2), \text{ then } n_i^* = m_2'\\ &\qquad\qquad \text{else } n_i^* = k_i .\end{aligned}$$

Proof: The proof is straightforward from Theorem 54.1. ■

Corollary 54.4

If all subsystems are in series and the configuration of each subsystem is parallel, then for fixed configurations of all subsystems (except subsystem i) and for fixed h_i^1, p_i, c_i, and c_f, the optimal value of n_i that minimizes $T(n_i)$ is $n_i^* = e_3$:

$$e_2 \equiv \frac{\ln\left(\frac{c_i}{c_f h_i^1 p}\right)}{\ln(q)} ,$$

$$e_3 \equiv \max[1, \text{gilb}(e_2) + 1] . \tag{54.68}$$

Proof: For series systems: $h_i^0 = 0$ and $A_i(n_i) = 1 - q_i^{n_i}$. Hence, the rest of the proof follows from Corollaries 1 and 3. ■

It should be noted that Corollary 54.4 is also applicable even if all subsystems are not in series. The only requirement is that subsystem i is in series with the rest of the system.

Corollary 54.5

The optimal n that minimizes the average system cost is always less than or equal to the n that minimizes average cost of the subsystem with the same failure cost.

Proof: Because $c_f(h_i^1 - h_i^0) \leq c_f$, from Corollary 54.2, the proof is straightforward. ■

Simultaneous Optimization

It is well known that simultaneous optimization of the components in all subsystems is a nonlinear integer programming problem consisting of a vector of decision variables. It is important to know the bounds on the decision variables for applying general-purpose optimization algorithms such as GA or SA. The efficiency of optimization algorithms, in terms of computational time as well as solution quality, can be improved by reducing the search space [54.6].

It is reasonable to assume that all subsystems must contain at least the minimum number of components that are required for its successful operation. This assumption is valid as long as we are not allowed to change the system configuration by removing some subsystems. In this chapter, we assume that we are not allowed to change the system configuration and subsystem i must have at least k_i components. Therefore, $n_i^L = k_i$; i. e., the default lower bound is $\boldsymbol{n}^L = \boldsymbol{n}^K$.

Furthermore, it is well known that the maintenance cost of all components should be less than or equal to the cost of downtime. Therefore,

$$\sum_{i=1}^{m} n_i c_i \leq c_f . \tag{54.69}$$

In the worst case, the above equation can lead to the following upper bound on n_i^* [54.33]

$$n_i^U = \text{gilb}\left(\frac{c_f}{c_i}\right) . \tag{54.70}$$

However, a better upper bound [54.33] could be:

$$n_i^U = k_i + \text{gilb}\left(\frac{c_f[1 - A(\boldsymbol{n}^K)]}{c_i}\right) . \tag{54.71}$$

Within a given set of lower and upper bounds, the total number of solution vectors in the search space is equivalent to M

$$M = \prod_{i=1}^{m} \left(n_i^U - n_i^L + 1\right) . \tag{54.72}$$

In general, these lower and upper bounds are very wide (refer to the examples). At the same time, there seems to be no method that finds the better bounds in a systematic way. In this chapter, we show that the results presented in the previous sections can be used to find tighter bounds that reduce the search space and hence increase the efficiency of the solution procedure.

Upper Bound. According to Corollary 54.5, the upper bound on n_i^* (i. e., n_i^U) that minimizes the average system cost is always less than or equal to the n_i^* that minimizes the average cost of the subsystem with the same failure cost. Therefore, the optimal value obtained using Theorem 54.1 is an upper bound for n_i^*. An improved upper bound can be found using Theorem 54.2.

Theorem 54.2

If $\boldsymbol{n}^L$ is a lower bound for $\boldsymbol{n}^*$ and $\boldsymbol{n}^U$ is an upper bound for $\boldsymbol{n}^*$, then the improved upper bound on n_i^* is equal

to $n_i^{U'}$.

$$
\begin{aligned}
n_i^{U'} &\equiv \text{optimal value obtained using Corollary 54.3 with the following parameters,}\\
h_i^1 &\equiv h_i^1(\boldsymbol{n}^{\mathrm{U}}) = \text{conditional availability with } \boldsymbol{n}^{\mathrm{U}} \text{ given that subsystem } i \text{ is operating}\\
&\equiv h\left(A_1^{\mathrm{U}}, \cdots, A_i^{\mathrm{U}} = 1, \cdots, A_m^{\mathrm{U}}\right) ,\\
A_j^{\mathrm{U}} &\equiv \mathrm{binf}(n_j - k_j; q_j, n_j^{\mathrm{U}}) ,\\
h_i^0 &\equiv h_i^0(\boldsymbol{n}^{\mathrm{L}}) = \text{conditional availability with } \boldsymbol{n}^{\mathrm{L}} \text{ given that subsystem } i \text{ is nonoperating}\\
&\equiv h\left(A_1^{\mathrm{L}}, \cdots, A_i^{\mathrm{L}} = 0, \cdots, A_m^{\mathrm{L}}\right) ,\\
A_j^{\mathrm{L}} &\equiv \mathrm{binf}\left(n_j - k_j; q_j, n_j^{\mathrm{L}}\right) .
\end{aligned}
\tag{54.73}
$$

Proof: Because the system is coherent, $h_i^1(\boldsymbol{n}^{\mathrm{U}})$ is greater than or equal to $h_i^1(\boldsymbol{n}^*)$, and $h_i^0(\boldsymbol{n}^{\mathrm{L}})$ is less than or equal to $h_i^0(\boldsymbol{n}^*)$. Therefore, $(h_i^1 - h_i^0)$ at the optimal point is always less than or equal to $[h_i^1(\boldsymbol{n}^{\mathrm{U}}) - h_i^0(\boldsymbol{n}^{\mathrm{L}})]$. From Corollary 54.2, the optimal value is decreasing with a decrease in c_{f} (the effective c_{f}). Therefore, n_i^{U}, obtained from Theorem 54.2 using Corollary 54.3, is the better upper bound. ■

Lower Bound. The default lower bound is $\boldsymbol{n}^{\mathrm{L}} = \boldsymbol{n}^{\boldsymbol{K}}$. The upper bound $\boldsymbol{n}^{\mathrm{U}}$ can be computed using the procedure presented in Sect. 54.4.3. In this section, we provide an improved lower bound for a given set of previous lower and upper bounds: $\boldsymbol{n}^{\mathrm{L}}$ and $\boldsymbol{n}^{\mathrm{U}}$.

Theorem 54.3

If $\boldsymbol{n}^{\mathrm{L}}$ is a lower bound for $\boldsymbol{n}^*$ and $\boldsymbol{n}^{\mathrm{U}}$ is an upper bound for $\boldsymbol{n}^*$, then the improved lower bound on n_i^* is equal to $n_i^{L'}$

$$
\begin{aligned}
n_i^{L'} &\equiv \inf\{n_i \geq n_i^{\mathrm{L}} : A_i(n_i) \geq B_i\}\\
B_i &\equiv \frac{A(\boldsymbol{n}^{\mathrm{U}}) - h_i^0(\boldsymbol{n}^{\mathrm{U}}) - \frac{(C_{\mathrm{U}} - C_{\mathrm{L}})}{c_{\mathrm{f}}}}{h_i^1(\boldsymbol{n}^{\mathrm{U}}) - h_i^0(\boldsymbol{n}^{\mathrm{L}})} .
\end{aligned}
\tag{54.74}
$$

Proof: It should be noted that the average cost of the system at the optimal point should always be less than or equal to the cost of the system at any other $\boldsymbol{n}$. Hence,

$$
T(\boldsymbol{n}^*) \leq T(\boldsymbol{n}^{\mathrm{U}}) = C_{\mathrm{U}} + c_{\mathrm{f}} U(\boldsymbol{n}^{\mathrm{U}}) . \tag{54.75}
$$

Maintenance cost is a strictly increasing function in $\boldsymbol{n}^*$. Therefore, $C_{\mathrm{L}} \leq T_{\mathrm{m}}(\boldsymbol{n}^*)$. Hence,

$$
\begin{aligned}
&C_{\mathrm{L}} + c_{\mathrm{f}} U(\boldsymbol{n}^*) \leq C_{\mathrm{U}} + c_{\mathrm{f}} U(\boldsymbol{n}^{\mathrm{U}}) ,\\
&\left[h_i^1(\boldsymbol{n}^*) - h_i^0(\boldsymbol{n}^*)\right] A_i(n_i^*) + h_i^0(\boldsymbol{n}^*)\\
&\qquad \geq A(\boldsymbol{n}^{\mathrm{U}}) - \frac{(C_{\mathrm{U}} - C_{\mathrm{L}})}{c_{\mathrm{f}}} .
\end{aligned}
\tag{54.76}
$$

Because the system is coherent, we have

$$
\begin{aligned}
&h_i^0(\boldsymbol{n}^{\mathrm{U}}) \geq h_i^0(\boldsymbol{n}^*) ,\\
&h_i^1(\boldsymbol{n}^{\mathrm{U}}) - h_i^0(\boldsymbol{n}^{\mathrm{L}}) \geq h_i^1(\boldsymbol{n}^*) - h_i^0(\boldsymbol{n}^*) .
\end{aligned}
\tag{54.77}
$$

Hence,

$$
A_i(n_i^*) \geq \frac{A(\boldsymbol{n}^{\mathrm{U}}) - h_i^0(\boldsymbol{n}^{\mathrm{U}}) - \frac{(C_{\mathrm{U}} - C_{\mathrm{L}})}{c_{\mathrm{f}}}}{h_i^1(\boldsymbol{n}^{\mathrm{U}}) - h_i^0(\boldsymbol{n}^{\mathrm{L}})} \equiv B_i . \tag{54.78}
$$

Because $A_i(n_i^*)$ is an increasing function n_i^*, the new lower bound is

$$
n_i^{L'} \equiv \inf[n_i : A_i(n_i) \geq B_i] . \tag{54.79}
$$

■

Corollary 54.6

If $\boldsymbol{n}^{\mathrm{L}}$ is a lower bound for $\boldsymbol{n}^*$, $\boldsymbol{n}^{\mathrm{U}}$ is an upper bound for $\boldsymbol{n}^*$, and the configuration of subsystem i is parallel, then the improved lower bound on n_i^* is equal to $n_i^{L'}$.

$$
\begin{aligned}
n_i^{L'} &\equiv \max[1, \mathrm{gilb}(L_i) + 1] ,\\
L_i &\equiv \frac{\ln(1 - B_i)}{\ln(q_i)} .
\end{aligned}
\tag{54.80}
$$

B_i is defined in (54.74).

Proof: For parallel subsystems, $A_i(n_i^*) = 1 - q_i^{n_i^*}$. Hence, the rest of the proof is straightforward from Theorem 54.3.

If the subsystem i is in series with the rest of the system, then the equation for B_i can be simplified as shown in (54.81).

$$
B_i \equiv A_i\left(n_i^{\mathrm{U}}\right)\left(1 - \frac{(C_{\mathrm{U}} - C_{\mathrm{L}})}{c_{\mathrm{f}} A(\boldsymbol{n}^{\mathrm{U}})}\right) . \tag{54.81}
$$

■

Algorithm

1. Find the default lower bound. It is $\boldsymbol{n}^{\mathrm{L}} = \boldsymbol{n}^{\boldsymbol{K}} = [k_1, \cdots, k_m]$.
2. Find the optimal value for each subsystem using Theorem 54.1, considering that there is only one subsystem in the system and the cost of failure is c_{f}. Let the optimal value for subsystem i be n_i^{U}. From Corollary 54.5, it is the upper bound for n_i^*.
3. Find $A_i(n_i^{\mathrm{L}})$ and $A_i(n_i^{\mathrm{U}})$ for each subsystem.
4. Find $A(\boldsymbol{n}^{\mathrm{L}})$ and $A(\boldsymbol{n}^{\mathrm{U}})$.
5. Find $h_i^0(n_i^{\mathrm{L}})$, $h_i^0(n_i^{\mathrm{U}})$, $h_i^1(n_i^{\mathrm{L}})$, and $h_i^1(n_i^{\mathrm{U}})$ for each subsystem. For series configurations, we

have: $h_i^0(n_i^{\mathrm{L}}) = 0$, $h_i^0(n_i^{\mathrm{U}}) = 0$, $h_i^1(n_i^{\mathrm{L}}) = \frac{A(\boldsymbol{n}^{\mathrm{L}})}{A_i(n_i^{\mathrm{L}})}$, and $h_i^1(n_i^{\mathrm{U}}) = \frac{A(\boldsymbol{n}^{\mathrm{U}})}{A_i(n_i^{\mathrm{U}})}$.

6. Using Theorem 54.2, find the updated $\boldsymbol{n}^{\mathrm{U}}$.
7. Using Theorem 54.3, find the updated $\boldsymbol{n}^{\mathrm{L}}$.
8. If stable lower and upper bounds are reached, i. e., if there are no change in the lower and upper bounds, then continue to Step 9. Otherwise (if there is a change), repeat from Step 3.
9. Using n_i^{L} and n_i^{U} as the bounds for optimal n_i, find the optimal vector that minimizes $T(\boldsymbol{n})$.
   - We can use any search algorithm for optimization including GA [54.38, 39], SA [54.40], or any other general-purpose optimization algorithms [54.35–37, 41].
   - In this chapter, we use an exhaustive searching algorithm to illustrate the example problems.

Numerical Examples

Series System with Parallel Subsystems. Consider a system consisting of five parallel subsystems arranged in a series configuration. The reliability block diagram of the system is shown in Fig. 54.1.

The failure-time distribution of a component in subsystem i is Weibull with characteristic life η_i and shape parameter β_i. There exist several forms of probability density function (PDF) for the Weibull distribution. The form of the Weibull distribution considered in this chapter is

$$f_i(t) = \frac{\beta_i}{\eta_i}\left(\frac{t}{\eta_i}\right)^{\beta_i - 1} \exp\left[-\left(\frac{t}{\eta_i}\right)^{\beta_i}\right] . \qquad (54.82)$$

Hence, the MTTF of each component (ϕ_i) is

$$\phi_i = \eta_i \Gamma(1/\beta_i + 1) . \qquad (54.83)$$

The repair-time distribution of a component in subsystem i is lognormal with parameters μ_i and σ_i. Hence,

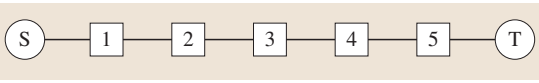

Fig. 54.1 Reliability block diagram for a series system

4	0.96746	0.03254	0.00129	83.27819	0.10706
5	0.79644	0.20356	0.00159	393.22117	0.62662

the MTTR of each component (ψ_i) is

$$\psi_i = \exp\left(\mu_i + \frac{\sigma_i^2}{2}\right) . \qquad (54.84)$$

In this example, the MLDT associated with repairs is considered to be zero for all components. Using the system parameters in Table 54.3, we can find the other parameters of the components in each subsystem. These parameters include availabilities (p_i), unavailabilities (q_i), failure frequencies (ν_i), cost of each repair (R_i), and repair cost per unit time (c_i). Values for these parameters are provided in Table 54.4.

1. Because the configuration of the system is series, the system availability expression can be obtained using (54.1).
2. Without the results of this chapter, $\boldsymbol{n}^{\mathrm{L}} = \{1, 1, 1, 1, 1\}$ and $\boldsymbol{n}^{\mathrm{U}} = \{4060, 2113, 6291, 3802, 650\}$. Therefore, the search space contains more than 1.3×10^{17} solution vectors. It is unrealistic to search for an exact solution within such a large solution space.
3. Using common-sense reasoning, we may guess that the actual optimal solution will be somewhere between the following bounds: $\boldsymbol{n}^{\mathrm{L}} = \{1, 1, 1, 1, 1\}$ and

Table 54.3 Parameters for a series system

Subsystem ID	Failure distribution Weibull			Repair distribution Lognormal			Repair cost Parameters	
i	η_i	β_i	ϕ_i	μ_i	σ_i	ψ_i	γ_i	δ_i
1	1125	2	997.01	4.00	1.10	99.98	10.00	1.00
2	540	1.3	498.73	3.20	1.50	75.57	20.00	1.20
3	2200	1.5	1986.04	3.75	0.60	50.91	30.00	2.00
4	800	1.2	752.52	3.20	0.25	25.31	20.00	2.50
5	475	0.9	499.79	4.35	1.00	127.74	10.00	3.00

Cost per unit downtime (c_{f}) = 1000 cost units

$\boldsymbol{n}^{\mathrm{U}} = \{100, 100, 100, 100, 100\}$. Even this search space contains 10^{10} solution vectors. To reduce the search space, we may guess that the upper bound might be $\boldsymbol{n}^{\mathrm{U}} = \{10, 10, 10, 10, 10\}$. This contains 10^5 solution vectors. To reduce the search space even further, we might guess that $\boldsymbol{n}^{\mathrm{U}} = \{4, 4, 4, 4, 4\}$. This search space contains 1024 solution vectors. Now, if we can compute the objective function (cost function) for each vector, we can find the exact solution. However, if the optimal vector is not within the assumed lower and upper bounds, then we will not obtain correct results. Therefore, a systematic procedure to find the bounds is essential.

4. Using Theorem 54.1 (Corollary 54.1) and Corollary 54.5, $\boldsymbol{n}^{\mathrm{U}} = \{4, 5, 3, 3, 5\}$. Even without applying the proposed lower bound, i.e, even with $\boldsymbol{n}^{\mathrm{L}} = \{1, 1, 1, 1, 1\}$, we have 900 solution vectors. The number of solution vectors using this upper bound is less than the number of solution vectors of the above wild guess (which leads to incorrect results).
5. Further, using Theorem 54.2 (Corollary 54.6), we have $\boldsymbol{n}^{\mathrm{L}} = \{3, 3, 2, 2, 4\}$. Therefore, now there are only 48 solution vectors within the bounds.
6. With exhaustive searching, the optimal vector of components that minimizes $T(\boldsymbol{n})$ is $\boldsymbol{n}^* = \{4, 5, 3, 3, 5\}$. For this example, $\boldsymbol{n}^* = \boldsymbol{n}^{\mathrm{U}}$. The corresponding system availability is 0.99949, and the corresponding minimum cost per unit time is 5.521.

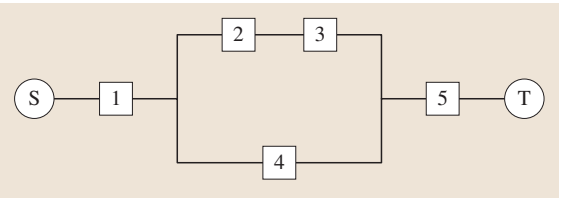

Fig. 54.2 A hypothetical reliability block diagram

Hypothetical Reliability Block Diagram. Consider a hypothetical example where subsystems are connected using the reliability block diagram shown in Fig. 54.2. The failure and repair times of each component follow exponential distributions. The logistic delay follows a deterministic time distribution. The parameters of the system are shown in Table 54.5. The parameters required for optimization are provided in Table 54.6.

1. The expression for the availability as a function of the subsystems availabilities can be obtained as follows.

$$\begin{aligned} A(\boldsymbol{n}) &= h(A_1, A_2, A_3, A_4, A_5) \\ &= A_1 A_5 \left[1 - (1 - A_2 A_3)(1 - A_4)\right] , \end{aligned} \tag{54.85}$$

   where A_i can be calculated using (54.51).
2. The default lower bound for n_i^* is $n_i^{\mathrm{L}} = k_i$. Therefore, $\boldsymbol{n}^{\mathrm{L}} = \{2, 3, 2, 3, 2\}$.
3. Without using the results of this chapter, $\boldsymbol{n}^{\mathrm{U}} = \{2860, 1472, 1889, 7765, 1386\}$. This pro-

Table 54.5 Parameters for a hypothetical reliability block diagram

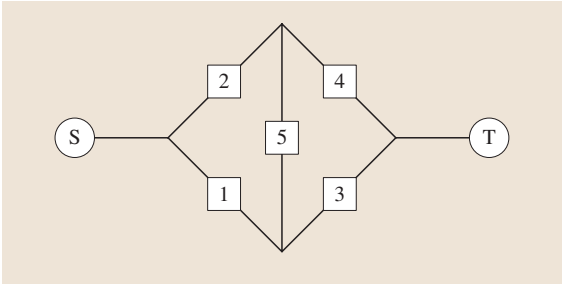

Fig. 54.3 A repairable bridge network

duces more than 8.5×10^{16} solution vectors (points of the search space).
4. Using Theorem 54.1 and Corollary 54.5, $\boldsymbol{n}^{\mathrm{U}} = \{6, 8, 5, 5, 5\}$. At present, the search space contains 1440 solution vectors.
5. Within two iterations, we obtain the stable $\boldsymbol{n}^{\mathrm{L}} = \{5, 3, 2, 3, 4\}$ and $\boldsymbol{n}^{\mathrm{U}} = \{6, 6, 4, 5, 5\}$. Now the search space contains 144 solution vectors.
6. With exhaustive searching, the optimal vector of components that minimizes $T(\boldsymbol{n})$ is $\boldsymbol{n}^* = \{6, 3, 2, 5, 5\}$. The corresponding system availability is 0.9998, and the corresponding minimum cost is 3.1065.

We observe that, in most cases, if a subsystem is in series with the rest of the system, then its optimal value is equivalent or very close to its upper bound. Therefore, using this information, we can further reduce the search space. Hence, the effective search space contains only 36 solution vectors.

Bridge Network. Consider a hypothetical example where subsystems are connected as a bridge network as shown in Fig. 54.3. The parameters used in Table 54.5 and Table 54.6 are considered for this example.

1. The expression for the availability as a function of the subsystem availabilities can be obtained using (54.86).

$$\begin{aligned} A(\boldsymbol{n}) &= h(A_1, A_2, A_3, A_4, A_5) \\ &= A_1A_3 + A_2A_4(1 - A_1A_3) \\ &\quad + A_1A_4A_5U_2U_3 + A_2A_3A_5U_1U_4 \,, \end{aligned} \tag{54.86}$$

where A_i can be calculated using (54.51).
2. The default lower bound for n_i^* is $n_i^{\mathrm{L}} = k_i$. Therefore, $\boldsymbol{n}^{\mathrm{L}} = \{2, 3, 2, 3, 2\}$.
3. Using Theorem 54.1 and Corollary 54.5, $\boldsymbol{n}^{\mathrm{U}} = \{6, 8, 5, 5, 5\}$. At present, the search space contains 1440 solution vectors.
4. Within one iteration, we obtain the stable $\boldsymbol{n}^{\mathrm{L}} = \{2, 3, 2, 3, 2\}$ and $\boldsymbol{n}^{\mathrm{U}} = \{5, 7, 4, 5, 4\}$. Now the search space contains 540 solution vectors.
5. With exhaustive searching, the optimal vector of components that minimizes $T(\boldsymbol{n})$ is $\boldsymbol{n}^* = \{5, 3, 4, 3, 2\}$. The corresponding system availability is 0.9998, and the corresponding minimum cost is 2.5631.

54.4.4 Nonrepairable Systems

The same algorithms that are used for repairable systems can also be used for nonrepairable systems. However, the individual subsystems should be solved using different methods.

The general form for the cost of the single subsystem is

$$\begin{aligned} &T(n_i) = c_i n_i + c_{\mathrm{f}}\left[1 - R(n_i)\right] \,, \\ &R(n_i) \equiv R_i(n_i) \,. \end{aligned} \tag{54.87}$$

Optimal design policies for k-out-of-n systems, i. e., systems with single subsystems, are studied in [54.9,25,33]. Theorem 54.1 presents optimal design policies for k-out-of-n cold/hot-standby systems. Let

Case 1: For hot-standby systems:

$$\begin{aligned} f(n_i) &\equiv \binom{n_i}{k_i - 1} p_i^{k_i} q_i^{n_i - k_i + 1} \\ m_0 &\equiv \max\left[k_i, \mathrm{gilb}\left(\frac{k_i - 1}{p_i}\right)\right] \,; \end{aligned} \tag{54.88}$$

Case 2: For cold-standby systems:

$$\begin{aligned} f(n_i) &\equiv \exp(-k_i\lambda_i t) k_i \lambda_i \frac{(k_i\lambda_i t)^{n_i - k_i}}{(n_i - k_i)!} \,, \\ m_0 &\equiv \max\left[k_i, \mathrm{gilb}\left(k_i\lambda_i t + k_i - 1\right)\right] \,; \end{aligned} \tag{54.89}$$

Definition

$$\begin{aligned} m_1 &\equiv \frac{T(k_i)}{c_i} \,, \\ m_2 &\equiv \inf\{n_i \in [m_0, m_1] : f(n_i) < c_i/c_{\mathrm{f}}\} \,. \end{aligned} \tag{54.90}$$

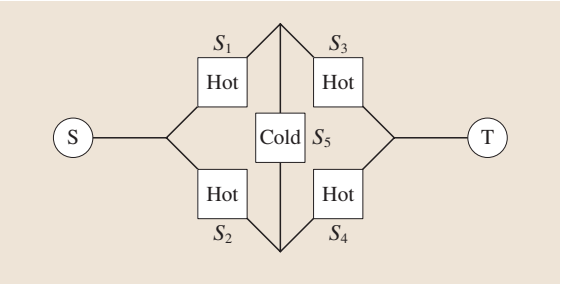

Fig. 54.4 A non-repairablebridge network

Theorem 54.4
For fixed k_i, p_i, c_i, and c_f, the optimal value of n_i that minimizes $T(n_i)$ is n_i^*:
if $f(m_0) < c_i/c_f$, then $n_i^* = k_i$
else if $f(k_i) \geq c_i/c_f$, then $n_i^* = m_2$
else if $T(k_i) > T(m_2)$, then $n_i^* = m_2$
else $n_i^* = k_i$.

Proof: Refer to [54.9, 33]. ■

Numerical Examples

Bridge Network. Consider a hypothetical example where subsystems are connected as a bridge network (Fig. 54.4). The parameters of the system are shown in Table 54.7.

1. The lower bound for n_i^* is $n_i^L = k_i$. Therefore, $\boldsymbol{n}^L = \{2, 3, 3, 2, 3\}$.
2. Without using the results of this chapter, i. e., from reference [54.32], $\boldsymbol{n}^U$ is $\{665, 334, 268, 223, 192\}$. This produces more than 2.4×10^{12} solution vectors. Therefore, exhaustive searching is almost impossible.
3. Using Theorem 54.1 and Corollary 54.3, $\boldsymbol{n}^U$ is $\{6, 6, 7, 5, 8\}$. At present, the search space contains 2, 400 solution vectors. The search space can be reduced further by using the proposed iterative procedure.
4. Within two iterations, we obtain the stable $\boldsymbol{n}^U = \{5, 6, 6, 4, 6\}$. Now the search space contains 768 solution vectors.
5. With exhaustive searching, the optimal vector of components that minimizes $T(\boldsymbol{n})$ is $\boldsymbol{n}^* = \{5, 3, 6, 2, 3\}$. The corresponding system reliability is 0.9998, and the corresponding minimum cost is 44.7640.

Table 54.7 Parameters for a bridge network

Subsystem	k_i	Standby	λ_i	p_i	c_i

Mission time (t) = 1000 time units
Cost per unit downtime (c_f) = 10 000 cost units

The algorithm presented in this chapter reduced the search space and allowed us to use exhaustive searching to find the optimal component vector.

Series System. Consider a hypothetical space vehicle consisting of the following subsystems arranged in a series configuration:

- guided control subsystem consisting of computers,
- monitoring subsystem consisting of sensors,
- power-generating subsystem.

1. The lower bound for n_i^* is $n_i^L = k_i$. Therefore, $\boldsymbol{n}^L$ is $\{2, 3, 2\}$.
2. Because it is a series system, $h_i^0 = 0$ for all i.
3. Using Theorem 54.1 and Corollary 54.3, $\boldsymbol{n}^U$ is $\{6, 13, 10\}$.
4. In this example, with exhaustive searching, the optimal vector of components that minimizes $T(\boldsymbol{n})$ is $\boldsymbol{n}^* = \{6, 13, 10\}$, which is equivalent to $\boldsymbol{n}^U$. The corresponding system reliability is 0.9834, and the corresponding minimum cost is 139.63.

54.4.5 Conclusions

The proposed lower and upper bounds are easy to find. The computational complexity to find these bounds is linearly proportional to the number of subsystems (m). The lower and upper bounds reduce the search space drastically. Therefore, within a practical time frame, high-quality optimal solutions can be found.

The numerical results demonstrate that, if a subsystem is in series with the rest of the system, then the optimal value for that subsystem is generally equivalent to its upper bound. Therefore, the configuration of such a subsystem can be considered as fixed while performing the simultaneous optimization. This reduces the search space further. For example, in a series system, all subsystems are in series with the rest of the system. Therefore, the optimal solution vector matches with the vector of the upper bounds.

Computational Advantages

One of the main contributions of this chapter is providing the lower and upper bounds on the optimal number of spares in each subsystem. The upper bound for parallel subsystems can be found in constant time using Corollary 54.1. Therefore, the computational complexity of finding the upper bound for this case is O(1). For the general case, the upper bound can be found from Theorem 54.1 using binary searching methods. Therefore, the computational complexity for the general case in finding the upper bound is O[log(m_1)], which is equivalent to O[log(k_i)].

1. For series systems with parallel subsystems, it is known that the near-optimal solution, which is the optimal solution in most cases, is equivalent to its upper bound. Because there are m subsystems, the computation complexity is O(m).
2. For series systems with k-out-of-n subsystems, it is known that the near-optimal solution, which is the optimal solution in most cases, is equivalent to its upper bound. Because there are m subsystems, the computation complexity is O[m log(k)].
3. For the general case, where k-out-of-n type subsystems are arranged in a complex network configuration, the tighter bounds on the decision variable reduces the search space exponentially. Let $r < 1$ be the reduction factor in the width of the bounds obtained by using the proposed tighter bounds with respect to some existing wider bounds on the decision variables [54.33]. Then, the search space is reduces by r^m times. If stochastic algorithms are used to find the optimal solution, then the chances of finding the exact solution will be high with the reduced search space. Let S_o be the search space with some existing bounds, and S_r be the search space with the proposed bounds. Here $S_r = r^m S_o$. Now, randomly select M vectors from the search space. With the original search space, we can find the exact solution with probability $\frac{M}{S_o}$. With the reduced search space, we can find the exact solution with probability $\frac{M}{S_r} \equiv \frac{M}{r^m S_o}$. Therefore, the chances of finding the exact solution increases exponentially. However, evolutionary algorithms, such as GA and SA, find the exact solutions with high probability compared to pure random algorithms. Therefore, the advantage may not be exponential in this case. However, the reduced search space always increase the chances of finding better-quality solutions. If the iterations are not fixed, the same quality of solutions can be obtained quickly with the reduced search space. Our further research will be in the experimental comparison of various algorithms with and without using the proposed bounds.

About the Authors

Susan L. Albin

Rutgers University
Department of Industrial and Systems Engineering
Piscataway, NJ, USA
salbin@rci.rutgers.edu

Chapter B.12

Susan L. Albin is professor and director of the Graduate Program of Industrial and Systems Engineering at Rutgers University. Dr. Albin's area of research is quality engineering, multivariate statistics, process control, and data mining. Her work has been applied in semiconductor manufacturing, plastics recycling, food processing, and medical devices and has been supported by NSF, FAA, DOD, and industrial organizations. Dr. Albin is secretary of INFORMS and Focus Issue editor for IIE Transactions on Quality and Reliability Engineering.

Suprasad V. Amari

Senior Reliability Engineer Relex Software Corporation
Greensburg, PA, USA
suprasad.amari@relex.com

Chapter F.54

Dr. Amari is a senior reliability engineer at Relex Software Corporation. He received both his M.S. and Ph.D. in reliability engineering from the Indian Institute of Technology, Kharagpur, India. He is an editorial board member of the International Journal of Reliability, Quality and Safety Engineering and International Journal on Performability Engineering, and management committee member of RAMS. He is an ASQ-certified reliability engineer and is a senior member of IEEE, IIE and ASQ.

Y. Alp Aslandogan

The University of Texas at Arlington
Computer Science and Engineering
Arlington, TX, USA
alp@cse.uta.edu
http://ranger.uta.edu/~alp

Chapter D.36

Dr. Aslandogan's main areas of research are biomedical informatics, data mining, multimedia information retrieval and visualization. He received his Ph.D. in computer science from the University of Illinois at Chicago in 2001. He has served and continues to serve on the technical program committees of IEEE International Conference on Information Technology and IEEE International Conference on Information Reuse and Integration. His recent research projects include a 3D change detection system for surface structures, a biomedical data mining web service and a concept-based multimedia search agent.

Jun Bai

JP Morgan Chase
Card Services
Wilmington, DE, USA
jun.bai@comcast.net
http://www.stat.rutgers.edu/~jbai

Chapter A.7

Dr. Jun Bai is a senior analyst at JP Morgan Chase Card Services. He obtained his Ph.D. in industrial and systems engineering from Rutgers – the State University of New Jersey in 2004. His research interests include warranty analysis, maintenance, reliability and applied statistics. Currently his research activities focus on risk management and statistical modelling in the financial industry.

Jaiwook Baik

Korea National Open University
Department of Information Statistics
Seoul, South Korea
baik@knou.ac.kr

Chapter A.5

Jaiwook Baik received the Ph.D. degree from the Department of Statistics, Virginia Polytechnic Institute and State University in 1991. Since 1992 he has been with the Department of Information Statistics, Korea National Open University, where he is currently a professor of the same department. His current research interests include warranty data analysis and applications of quality control techniques to solve industrial problems. He is a member of the Korean Reliability Society and the Korean Society for Quality Management.

Amit K. Bardhan

University of Delhi – South Campus
Department of Operational Research
New Delhi, India
amit@or.du.ac.in
http://people.du.ac.in/amit

Chapter C.25

Amit Kumar Bardhan is a senior lecturer in the Department of Operational Research, University of Delhi – South Campus. He obtained his Ph.D. in operational research from University of Delhi in 2003. His Ph.D. thesis was judged the best thesis in O.R. of the year by the Operational Research Society of India. His research interests are mathematical modelling, quality and reliability analysis and marketing models.

Anthony Bedford

Royal Melbourne Institute of Technology University
School of Mathematical and Geospatial Sciences
Bundoora, Victoria, Australia
anthony.bedford@rmit.edu.au
http://www.rmit.edu.au/math-geo

Chapter F.52

Dr. Bedford is a senior lecturer and researcher in statistics at Royal Melbourne Institute of Technology (RMIT) University. He completed his Ph.D. in 2003 on multi-priority finite buffer queueing models. His main areas of research are queueing theory in telecommunications systems, advances in medical statistics and sports statistics. He is also involved in postgraduate statistics research in occupation health and safety and the medical sciences.

James Broberg

Royal Melbourne Institute of Technology University
School of Computer Science & Information Technology
Melbourne, Victoria, Australia

Chapter F.52

James Broberg is currently a Ph.D. student working at Royal Melbourne Institute of Technology (RMIT) University, Melbourne (Australia). He is a member of the "Distributed Systems and Networking" discipline at RMIT, and has worked and published in the area of task assignment (e.g. scheduling policies) to enable effective load balancing and load sharing in distributed systems.

Michael Bulmer

University of Queensland
Department of Mathematics
Brisbane, Qld, Australia
m.bulmer@uq.edu.au
http://www.maths.uq.edu.au/~mrb

Chapter A.5

Dr. Bulmer is a senior lecturer in mathematics and statistics at the University of Queensland. He obtained his Ph.D. from the University of Tasmania in 1996 on the topic of automated algebraic reasoning. His current research interests include computational methods in statistics and operations research, stochastic modelling in astrophysics, and mathematics and statistics education.

Zhibin Cao

Arizona State University
Computer Science & Engineering Department
Tempe, AZ, USA
zbcao@asu.edu
http://www.public.asu.edu/~zcao2/

Chapter C.24

Mr. Zhibin Cao received his M.S. degree from Computer Science & Engineering Department at Arizona State University. Currently he is a Ph.D. candidate in the department. He worked at Peiking University Research and Development Institute, China and at Bell-Labs China before joining Arizona State University. His research areas include software engineering, service-oriented computing, service-oriented modelling and model-based development.

Philippe Castagliola

Université de Nantes and IRCCyN UMR CNRS 6597 Institut Universitaire de Technologie de Nantes
Qualité Logistique Industrielle et Organisation
Carquefou, France
philippe.castagliola@univ-nantes.fr
http://philippe.castagliola.free.fr/

Chapter B.17

Philippe Castagliola graduated (Ph.D. 1991) from the Université de Technologie de Compiègne, France (UTC). He is currently a professor at the IUT (Institut Universitaire de Technologie) de Nantes, France, and he is also a member of the IRCCyN (Institut de Recherche en Communications et Cybernétique de Nantes), UMR CNRS 6597. He is associate editor for the Journal of Quality Technology and Quantitative Management and for the International Journal of Reliability, Quality and Safety Engineering. His research activity includes developments of new SPC techniques (non-normal control charts, optimized EWMA type control charts, multivariate capability indices, and monitoring of batch processes).

Giovanni Celano

University of Catania
Dipartimento di Ingegneria Industriale e Meccanica
Catania, Italy
gcelano@diim.unict.it
http://www.diim.unict.it/users/gcelano/

Chapter B.17

Giovanni Celano received his Ph.D. in 2003 from the University of Palermo for work on the sequencing of mixed model assembly lines. He is currently assistant professor of technology and manufacturing systems at the University of Catania, Italy. His research is focused on statistical quality control and production scheduling. He is a member of the AITEM and of the ENBIS.

Ling-Yau Chan

The University of Hong Kong
Department of Industrial and Manufacturing Systems Engineering
Hong Kong
plychan@hku.hk
http://www.hku.hk/imse

Chapter B.13

Dr. Chan's research areas include design of industrial experiments, optimal design, uniform design, statistical quality control, reliability, maintenance, quality management, and supply chain management. He has published over 80 papers in these areas, and is collaborating with scholars worldwide on various research topics. He is the head of the Department of Industrial and Manufacturing Systems Engineering, University of Hong Kong.

Ted Chang

University of Virginia
Department of Statistics
Charlottesville, VA, USA
tcc8v@virginia.edu
http://www.stat.virginia.edu/chang.html

Chapter D.31

Ted Chang received his Ph.D. in mathematics from the University of California (Berkeley) in 1972. After about a decade of working in algebraic topology, he switched his research concentration to statistical problems in which geometry and symmetries play an important role. The primary applications of his work are in the estimation of the statistical errors in tectonic plate reconstructions, image reconstruction, and human motion data.

Victoria Chen

University of Texas at Arlington
Industrial and Manufacturing Systems Engineering
Arlington, TX, USA
vchen@uta.edu
http://ie.uta.edu/index.cfm?fuseaction=professordescription&userid=1945

Chapter D.36

Dr. Victoria Chen joined the University of Texas at Arlington in 2001. From 1993–2001 she was on the Industrial and Systems Engineering faculty at the Georgia Institute of Technology. She earned her Ph.D. in operations research and industrial engineering from Cornell University. Dr. Chen is co-founder of the Informs Section on Data Mining and is currently serving as chair.

Yinong Chen

Arizona State University
Computer Science and Engineering Department
Tempe, AZ, USA
yinong.chen@asu.edu
http://www.public.asu.edu/~ychen10/

Chapter C.24

Dr. Yinong Chen received his Ph.D. from the University of Karlsruhe, Germany. He worked at LAAS-CNRS, France, and at Wits University, South Africa, before joining Arizona State University. His research areas include dependable computing, software engineering, and service-oriented computing. He has coauthored five books and over 80 research papers in these areas.

Peter Dimopoulos

Royal Melbourne Institute of Technology University
Computer Science and IT
Melbourne, Australia
dimpet@cs.rmit.edu.au
http://www.cs.rmit.edu.au/~dimpet

Chapter F.52

Peter is currently completing his Ph.D. in computer science at RMIT University (Royal Melbourne Institute of Technology) in the area of Internet congestion control. Prior to his Ph.D. he worked at Agilent Technologies and completed a double degree in computer science and computer systems engineering at RMIT University.

Fenghai Duan

Department of Preventive and Societal Medicine
Omaha, NE, USA
fduan@unmc.edu

Chapter D.33

Fenghai Duan was born in Heilongjiang, China. After completing his bachelor's degree in biochemistry at Fudan University in 1995, he received his master's degree in molecular biology from Institute of Biophysics, Academia Sinica in 1998. In the year 2000, Duan joined the Ph.D. program in biostatistics at Yale University and worked on his thesis in the lab of Professor Heping Zhang. Duan's doctoral dissertation was about the analysis of microarray experiments and was awarded the Ph.D. degree in May 2005. Currently, he is an assistant professor of the Department of Preventive and Societal Medicine at University of Nebraska Medical Center. His research interests are in the development of statistical methods for the analysis of high-dimensional biological data.

Veronica Esaulova

Otto-von-Guericke-University
Magdeburg
Department of Mathematics
Magdeburg, Germany
veronica.esaulova@gmail.com

Chapter C.20

Miss Esaulova has submitted her Ph.D. dissertation devoted to hazard rate modeling in heterogeneous populations and about to defend it in June 2006. She has publications in the fields of survival analysis and nonparametric statistics and is interested in the development of statistical methodology and its applications.

Luis A. Escobar

Louisiana State University
Department of Experimental Statistics
Baton Rouge, LA, USA
luis@lsu.edu
http://www.stat.lsu.edu/faculty/Escobar

Chapter C.22

Luis A. Escobar is a professor at Louisiana State University. His research interests include analysis of reliability data and accelerated testing. Luis is an associate editor for LIDA and past associate editor for Technometrics. He is a Fellow of the ASA and elected member of the ISI. Luis was awarded the 1999 Jack Youden Prize.

Chun Fan

Arizona State University
Computer Science & Engineering Department
Tempe, AZ, USA
fanchun@asu.edu
http://whoknows.eas.asu.edu/~whoknows/

Chapter C.24

Mr. Chun Fan is a Ph.D. student in the Department of Computer Science and Engineering at Arizona State University. He received his B.E. degree from the University of Science and Technology of China, China. His research areas include software engineering, software architecture, and computer-based simulation.

Kai-Tai Fang

Hong Kong Baptist University
Department of Mathematics
Kowloon Tong, Hong Kong
ktfang@hkbu.edu.hk
http://www.math.hkbu.edu.hk/~ktfang

Chapter B.13

Professor Fang is an elected fellow of the Institute of Mathematical Statistics and of the American Statistical Association. He was chair professor at the Hong Kong Baptist University from 1993 to 2006. His research interest: involve multivariate analysis, experimental design, data mining and statistical inference. He has been associate editor for Statistics & Probability Letters, Statistica Sinica and Journal of Multivariate Analysis. He has published more than 220 research papers and 18 books.

Qianmei Feng

University of Houston
Department of Industrial Engineering
Houston, TX, USA
qfeng@central.uh.edu

Chapter B.11

Dr. Qianmei Feng is an assistant professor in the Department of Industrial Engineering at the University of Houston, TX. Her research interests are quality and reliability engineering, especially inspection strategies, tolerance design and optimization, experimental design, and Six Sigma. She is a member of IIE, INFORMS and Alpha Pi Mu.

Emilio Ferrari

University of Bologna
Department of Industrial and Mechanical Engineering (D.I.E.M.)
Bologna, Italy
emilio.ferrari@unibo.it

Chapter F.48

Emilio Ferrari is full professor of industrial logistics at the Department of Mechanical Constructions (DIEM) at the University of Bologna, director of the master degree in "integrated logistics" at the Faculty of Engineering in Bologna and of the Summer School "Francesco Turco" on industrial plants. He is author of more than 70 publications, most of them about industrial logistics and industrial plant design and management.

Sergio Fichera

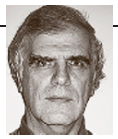
University of Catania
Department Industrial and Mechanical Engineering
Catania, Italy
sfichera@diim.unict.it

Chapter B.17

Sergio Fichera is an associate professor of Technology and Manufacturing System at the Dipartimento di Ingegneria Industriale eMeccanica of the University of Catania, Italy. He holds an M.B.A. degree from the Schools of Management at the University of Turin. His research interests are in production scheduling and statistical quality control. He is a member of the AITEM (Italian association for manufacturing).

Maxim Finkelstein

University of the Free State
Department of Mathematical Statistics
Bloemfontein, South Africa
finkelm.sci@mail.uovs.ac.za
www.uovs.ac.za/departments/mathstats/finkelsteinms



Chapter C.20

Professor Maxim Finkelstein is a specialist in reliability theory and other applications of stochastic modeling. He has published about 140 papers and 4 books on various aspects of reliability and survival analysis. His current major interest is in stochastic modeling of heterogeneity for engineering and biological applications. He is a member of editorial boards of a number of reliability oriented journals.

Mitsuo Gen

Waseda University
Graduate School of Information, Production & Systems
Kitakyushu, Japan
gen@waseda.jp

Chapter E.42

Mitsuo Gen received his Ph.D. degree from Kogakuin University, Japan, in 1974. He is a professor at the Graduate School of Information, Production and Systems, Waseda University. He was a visiting professor at the University of California, Berkeley in 1999–2000. His research interests include genetic algorithms, neural networks, fuzzy logic, and the applications to network design, scheduling, system reliability design, and the like.

Amrit L. Goel

Syracuse University
Department of Electrical Engineering and Computer Science
Syracuse, NY, USA
goel@ecs.syr.edu

Chapters D.35, F.53

Amrit L. Goel is a professor of EECS at Syracuse University. His Ph.D. was in mechanical engineering from the University of Wisconsin, Madison. His academic activities have included quality control and reliability, software engineering, databases, and data mining using radial basis functions (RBF) and support vector machines. He has advised fifteen Ph.D. dissertations on these and related topics. He is a co-author of a book on object-oriented software testing with Dr. Bashir, of the Goel–Okumoto software reliability model and, most recently, of the Shin–Goel algorithm for RBF design. He was elected a fellow of IEEE for contributions to software reliability.

Thong N. Goh

National University of Singapore
Industrial and Systems Engineering Dept.
Singapore, Republic of Singapore
isegohtn@nus.edu.sg
http://www.ise.nus.edu.sg/staff/gohtn

Chapter B.16

Professor Thong N. Goh (Ph.D. University of Wisconsin – Madison, USA) is academician of the International Academy for Quality, fellow of the American Society for Quality, and IEEE Engineering Management Society Educator of the Year 2004. Specializing in statistical methodologies for engineering applications, he now serves on the editorial boards of several leading international research journals on quality management and quality engineering.

Raj K. Govindaraju

Massey University
Institute of Information Sciences
and Technology
Palmerston North, New Zealand
k.govindaraju@massey.ac.nz

Chapter B.15

Dr. Govindaraju holds a Ph.D. degree from Madras University and has been engaged in statistics teaching and consulting for the last 20 years. His research interest is in the statistical aspects of quality and data analysis. He is an associate editor of the International Journal for Economic Quality.

Xuming He

University of Illinois at
Urbana-Champaign
Department of Statistics
Champaign, IL, USA
x-he@uiuc.edu
http://www.stat.uiuc.edu/~x-he

Chapter D.30

Professor He's research focuses on statistical inference for regression models. He is an elected fellow of the Institute of Mathematical Statistics, and currently serves on the editorial boards of The Annals of Statistics and Journal of the American Statistical Association. His research has been supported by the NSF, NSA and NIH.

Chengcheng Hu

Harvard School of Public Health
Department of Biostatistics
Boston, MA, USA
cchu@hsph.harvard.edu
http://www.hsph.harvard.edu/faculty/ChengchengHu.html

Chapter C.21

Dr. Chengcheng Hu is an assistant professor of biostatistics at the Harvard School of Public Health and a senior statistician at the Statistical and Data Analysis Center of the Pediatric AIDS Clinical Trials Group. He earned his Ph.D. in biostatistics from the University of Washington in 2001. His research interests are in the areas of failure time data analysis, measurement error, missing data, longitudinal data analysis, and design of clinical trials.

Feifang Hu

University of Virginia
Department of Statistics
Charlottesville, VA, USA
fh6e@virginia.edu
http://www.stat.virginia.edu/hu.html

Chapter E.37

Dr. Hu is an associate professor of Statistics at the University of Virginia. He has a Ph. D. from the University of British Columbia and has worked at the National University of Singapore and Cornell University. His main research areas are: bootstrap methods; biostatistics; likelihood inference and data mining.

Hai Huang

Intel Corp CH3-20
Component Automation Systems
Chandler, AZ, USA
hai.huang2@intel.com

Chapter C.24

Dr. Hai Huang received his Ph.D. from the Arizona State University, USA. Currently he works in the Component Automation Systems (CAS) Group at Intel Corp. His research areas include software verification and validation, test automation, Web services, service-oriented architecture, and compiler technology.

Jian Huang

University of Iowa
Department of Statistics and Actuarial
Science
Iowa City, IA, USA
jian-huang@uiowa.edu
http://www.stat.uiowa.edu/~jian/

Chapter E.40

Dr. Jian Huang obtained his Ph.D. in statistics from The University of Washington in Seattle. His current research interests include statistical analysis of high-dimensional data with applications to biomedical research, statistical genetics, survival analysis, and semiparametric models.

Tao Huang

Yale University, School of Medicine
Department of Epidemiology and Public Health
New Haven, CT, USA
t.huang@yale.edu

Chapter D.34

Dr. Tao Huang is a postdoctoral associate in Department of Epidemiology and Public Health at Yale University School of Medicine. He obtained his Ph.D. degree in statistics from the University of North Carolina at Chapel Hill. His current research interests include nonparametric and semiparametric modeling, functional and longitudinal data analysis, model selection and computational biology and statistical genetics.

Wei Jiang

Stevens Institute of Technology
Department of Systems Engineering and Engineering Management
Hoboken, NJ, USA
wjiang@stevens.edu
http://www.stevens.edu/engineering/seem/People/jiang.html

Chapters B.10, D.36

Dr. Wei Jiang is an assistant professor of systems engineering and engineering management at Stevens Institute of Technology. He obtained his Ph.D. degree in industrial engineering and engineering management from Hong Kong University of Science and Technology in 2000. Prior to joining Stevens, he worked as a statistical consultantat AT&T Labs, Morristown. His current research activities include statistical methods for quality control, data mining and enterprise intelligence.

Richard Johnson

University of Wisconsin – Madison
Department of Statistics
Madison, WI, USA
rich@stat.wisc.edu

Chapter B.18

Richard A. Johnson is a professor of statistics at the University of Wisconsin. His research and consulting interests include reliability and life length analysis, applied multivariate analysis, and applications to engineering. He is a fellow of the American Statistical Association, fellow of the Institute of Mathematical Statistics, and elected member of the International Statistical Institute. He has been editor of Statistics and Probability Letters since it began 25 years ago, and is co-author of six books and several book chapters, and over 100 papers in the statistical and engineering literature.

Kailash C. Kapur

University of Washington
Industrial Engineering
Seattle, WA, USA
kkapur@u.washington.edu
http://faculty.washington.edu/kkapur/

Chapter B.11

Dr. Kailash C. Kapur is a professor of industrial engineering at the University of Washington. He received Ph.D. degree (1969) in industrial engineering from the University of California at Berkeley. He received the Allan Chop Technical Advancement Award and the Craig Award from ASQ. He is a Fellow of ASQ and IIE, and a registered professional engineer. In his present position at the University of Washington, Dr. Kapur is responsible for teaching and research in the areas of quality engineering, design reliability, industrial experimental design, system optimization and control, and productivity improvement.

P. K. Kapur

University of Delhi
Department of Operational Research
Delhi, India
pkkapur@or.du.ac.in

Chapter C.25

P.K. Kapur is professor and head in the Department of Operational Research, University of Delhi. He obtained his Ph.D. degree from the University of Delhi in 1977. He has published extensively in Indian journals and abroad in the areas of hardware reliability, optimization, queueing theory, and maintenance and software reliability. He is currently the president of the Operational Research Society of India.

Kyungmee O. Kim

Konkuk University
Department of Industrial Engineering
Seoul, S. Korea
kyungmee@konkuk.ac.kr
http://mail.konkuk.ac.kr/~kyungmee

Chapter A.9

Dr. Kim is an assistant professor of industrial engineering at Konkuk University in Seoul, Korea. She obtained her Ph.D. degree in the Department of Industrial Engineering from Texas A&M in 1999. Her research interests include statistical quality control, burn-in, yield and reliability optimization, fault diagnosis and condition-based maintenance.

Taeho Kim

Korea Telecom
Strategic Planning Office
Sungnam, Kyonggi-do, S. Korea
taehokim@kt.co.kr

Chapter A.9

Taeho Kim received his Ph.D. from Texas A&M University in 1998. He is assistant vice-president of Korea Telecom. Since he joined KT in 1986 he has been doing many projects related with service quality, facility reliability, and network performance. His current fields of interest include six sigma for continuous growth and quality innovation in the telecom industry.

Way Kuo

University of Tennessee
Department of Electrical and Computer Engineering
Knoxville, TN, USA
way@utk.edu
http://www.ece.utk.edu/bios/Faculty/Kuo.html

Chapter A.9

Dr. Way Kuo is university distinguished professor and dean of engineering at the University of Tennessee. He is an elected member of the US National Academy of Engineering, Academia Sinica, Taiwan, R.O.C., and the International Academy for Quality. He has co-authored five textbooks and currently serves as the editor of IEEE Transactions on Reliability. He is recognized as one of the principal scholars responsible for developing cost-effective methodologies for reducing infant mortality in the fast-evolving microelectronics industry. His contributions to industry include advancing the development of the fundamentals of reliability design as well as introducing new industrial applications of parametric and nonparametric analysis.

Paul Kvam

Georgia Institute of Technology
School of Industrial and Systems Engineering
Atlanta, GA, USA
pkvam@isye.gatech.edu
http://www.isye.gatech.edu/~pkvam/

Chapter A.2

Paul Kvam is an associate professor in the School of Industrial and Systems Engineering (ISyE). He joined ISyE in 1995 after working for four years as scientific staff at the Los Alamos National Laboratory. Dr. Kvam received his B.S. in mathematics from Iowa State University in 1984, an M.S. in statistics from the University of Florida in 1986, and his Ph.D. in statistics from the University of California, Davis in 1991. His research interests focus on statistical reliability with applications to engineering, nonparametric estimation, and analysis of complex and dependent systems. He is a member of the American Statistical Association, Institute of Mathematical Statistics, Institute for Operations Research and Management Science, and IEEE.

Chin-Diew Lai

Massey University
Institute of Information Sciences and Technology
Palmerston North, New Zealand
c.lai@massey.ac.nz
http://www-ist.massey.ac.nz/ResearchGroups/DisplayStaff.asp?StaffID=24

Chapter A.3

Chin-Diew Lai received his Ph.D. in statistics from Victoria University of Wellington, New Zealand in 1975. His main research interests are in quality and reliability engineering. He is a co-author of three books and has published over 90 journal articles and book chapters.

Jae K. Lee

University of Virginia
Public Health Sciences
Charlottesville, VA, USA
jaeklee@virginia.edu
http://www.healthsystem.virginia.edu/internet/hes/personnel/leejk.cfm

Chapter D.32

Professor Lee received his Ph.D. in statistical genetics from the University of Wisconsin – Madison in 1995. He has worked on statistical research in molecular genetics and bioinformatics, including genetic population inference, DNA structure analysis, linkage association study, and high-throughput gene chip data analysis on various biomedical studies. In particular, he has pioneered the statistical development of small-sample microarray data analysis techniques such as LPE (local pooled error) and HEM (heterogeneous error model) for practical, genomic biomedical investigations.

Kit-Nam F. Leung

City University of Hong Kong
Department of Management Sciences
Kowloon Tong, Hong Kong
msknleun@cityu.edu.hk

Chapter F.49

Dr. Kit-Nam Francis Leung received a B.Sc. degree in mathematics in 1984 and M.Sc. degree in operational research in 1985, both from London University, and his Ph.D. in 2003 from Curtin University, Australia. Since 1988 he has been a lecturer in the Management Sciences Department at the City University of Hong Kong and has been responsible for teaching management science and Statistics. His research interests are maintenance, reliability and warranty.

Ruojia Li

Global Statistical Sciences
Lilly Corporate Center
Indianapolis, IN, USA
liru@lilly.com

Chapter B.18

Dr. Ruojia Li is a research scientist at Eli Lilly and Company. She received her Ph.D. degree in statistics from the University of Wisconsin – Madison in 2004. Her research interests include multivariate quality monitoring schemes and statistical applications in pharmaceutical research.

Wenjian Li

Javelin Direct, Inc.
Marketing Science
Irving, TX, USA
wenjian.li@javelindirect.com

Chapter E.45

Dr. Wenjian Li is a marketing research scientist with Javelin Direct, Inc., whose current work focuses on econometrics, forecasting, and survival analysis. Dr. Li earned his Ph.D. from Rutgers University where his primary research interests included reliability, maintenance theory, applied statistics and manufacturing automation.

Xiaoye Li

Yale University
Department of Applied Mathematics
New Heaven, CT, USA
xiaoye.li@yale.edu

Chapter D.34

Xiaoye Li is currently a Ph.D. candidate in the Applied Mathematics Department of Yale University. He is interested in machine learning and statistical learning theory and the application of machine learning techniques to various data mining problems, especially those arising from genomics and proteomics studies. His dissertation takes an initiative step to analyze the popular classification algorithm Random Forest and to improve the random subspace method.

Yi Li

Harvard University
Department of Biostatistics
Boston, MA, USA
yili@jimmy.harvard.edu
http://www.hsph.harvard.edu/faculty/YiLi.html

Chapter E.38

Dr. Li is an associate professor of biostatistics at the University of Cincinnati. He obtained his Ph.D. degree in biostatistics from the University of Michigan in 1999. He has been working on survival analysis, longitudinal/spatial data analysis and observational studies, He is the recipient of several prestigious awards, including the David P. Byar Young Investigator Award, John van Ryzin Award and Roger L. Nichols Excellence in Teaching Award. He is a member of the review panel of Mathematical Reviews and is an associate editor of Biometrics.

Hojung Lim

Korea Electronics Technology Institute (KETI)
Ubiquitous Computing Research Center
Seongnam-Si, Gyeonggi-Do, Korea
hlim@keti.re.kr

Chapter F.53

Hojung Lim received her Ph.D. in computer and information science from Syracuse University, New York. Her research interests are in support vector machines and software modelling. Currently she is involved in ubiquitous sensor networks and radio frequency identification (RFID).

Haiqun Lin

Yale University School of Medicine
Department of Epidemiology and Public Health
New Haven, CT, USA
haiqun.lin@yale.edu
http://publichealth.yale.edu/faculty/lin.htm

Chapter E.41

Haiqun Lin received her Ph.D. in biometry from Cornell University. She also holds a medical degree from Beijing Medical University, China. Haiqun Lin's current research focuses on latent variable modelling and missing data issues in longitudinal data. In the last a few years, Haiqun Lin has been collaborating with scientific researchers in the fields of cancer research, psychiatry, and geriatric medicine.

Nan Lin

Washington University in Saint Louis
Department of Mathematics
St. Louis, MO, USA
nlin@math.wustl.edu
http://www.math.wustl.edu/~nlin

Chapter D.30

Dr. Lin received his Ph.D. degree in statistics from the University of Illinois at Urbana-Champaign in 2003. He is an assistant professor in the Department of Mathematics, Washington University in Saint Louis. His research interest includes robust statistics, Bayesian modeling, and applications of statistical methodologies in bioinformatics studies such as protein–protein interaction prediction and topological structure inference in yeast.

Wei-Yin Loh

University of Wisconsin – Madison
Department of Statistics
Madison, WI, USA
loh@stat.wisc.edu
http://www.stat.wisc.edu/~loh

Chapter D.29

Wei-Yin Loh has a Ph.D. from Berkeley. He is a fellow of the American Statistical Association and the Institute of Mathematical Statistics. He invented the GUIDE regression tree algorithm and co-authored the CRUISE, LOTUS, and QUEST algorithms. He currently serves on the editorial boards of the ACM Transactions on Knowledge Discovery from Data and the Journal of Machine Learning Research.

Jye-Chyi Lu

The School of Industrial and Systems Engineering
Georgia Institute of Technology
Atlanta, GA, USA
jclu@isye.gatech.edu
http://www.isye.gatech.edu/~JCLU;
http://www.isye.gatech.edu/faculty-staff/profile.php?entry=jl234

Chapter A.2

Jye-Chyi (JC) Lu is a professor in the School of Industrial and Systems Engineering (ISyE). He received a Ph.D. in statistics from University of Wisconsin at Madison in 1988, and joined the faculty of North Carolina State University (NCSU) where he remained until 1999 when he joined ISyE. Dr. Jye-Chyi Lu's research areas cover industrial statistics, signal processing, semiconductor and electronic manufacturing, data mining, bioinformatics, supply-chain management, logistics planning and nanotechnology. He has about 58 disciplinary and interdisciplinary publications, which have appeared in both engineering and statistics journals. Currently, he is an associate editor for Technometrics, IEEE Transactions on Reliability and Journal of Quality Technology.

William Q. Meeker, Jr.

Iowa State University
Department of Statistics
Ames, IA, USA
wqmeeker@iastate.edu
http://www.public.iastate.edu/~wqmeeker

Chapter C.22

Dr. Meeker is distinguished professor of statistics at Iowa State University. He is a fellow of the American Statistical Association and a past editor of Technometrics. He is co-author of the books *Statistical Methods for Reliability Data*, and *Statistical Intervals*, and of numerous publications in the engineering and statistical literature. He has consulted extensively on problems in reliability and accelerated testing.

Mirjam Moerbeek

Utrecht University
Department of Methodology and Statistics
Utrecht, Netherlands
m.moerbeek@fss.uu.nl
http://www.fss.uu.nl/ms/moerbeek

Chapter E.39

Dr. Mirjam Moerbeek studied biometrics at Wageningen Agricultural University, the Netherlands. She obtained her Ph.D. from Maastricht University, the Netherlands. She is currently employed at Utrecht University, the Netherlands. In 2003 she received a prestigious research grant from the Dutch government for young researchers. Her research topic is on the design and analysis of experiments with nested data.

Terrence E. Murphy

Yale University School of Medicine
Department of Internal Medicine
New Haven, CT, USA
terrence.murphy@yale.edu

Chapter B.10

Terrence E. Murphy earned his Ph.D. in industrial and systems engineering from the Georgia Institute of Technology in 2004. Prior to his graduate work in engineering statistics, he worked for the Eastman Kodak and Johnson & Johnson companies in the manufacture and development of clinical instrumentation. His interests include multivariate statistics, experimental design and medical decision making.

D.N. Pra Murthy

The University of Queensland
Division of Mechanical Engineering
Brisbane, QLD, Australia
p.murthy@uq.edu.au

Chapters A.3, A.5

Pra Murthy obtained his Ph.D. degree from Harvard University. He has authored or co-authored 5 books, 20 book chapters and 150 journal papers and co-edited 2 books. His current areas of research deal with various topics in product reliability and product warranty. He has held visiting appointments at several universities in the USA, Europe and Asia and is on the editorial boards of nine international journals.

H. N. Nagaraja

Ohio State University
Department of Statistics
Columbus, OH, USA
hnn@stat.ohio-state.edu
http://www.stat.ohio-state.edu/~hnn

Chapter A.4

H.N. Nagaraja, Ph.D., is a professor in the Departments of Statistics and Internal Medicine and serves as a General Clinical Research Centre Biostatistician at Ohio State University. He is interested in order and record statistics, general distribution theory, stochastic modelling, and biostatistical applications. He is a fellow of the American Statistical Association, and an elected member of the International Statistical Institute.

Toshio Nakagawa

Aichi Institute of Technology
Department of Marketing and
Information Systems
Toyota, Japan
toshi-nakagawa@aitech.ac.jp
http://www.aitech.ac.jp/

Chapter E.46

Toshio Nakagawa received his Ph.D. from Kyoto University in 1977. He is now a professor of marketing and information systems at Aichi Institute of Technology in Toyota. His research interests are optimization problems, and computer and information systems in reliability and maintenance theory.

Joseph Naus

Rutgers University
Department of Statistics
Piscataway, NJ, USA
naus@stat.rutgers.edu
http://www.stat.rutgers.edu/people/faculty/naus.html

Chapter E.43

Joseph Naus is a professor of statistics at Rutgers University. He received his Ph.D in statistics from Harvard University. He was elected a Fellow of The American Statistical Association based on his research into scan statistics, a continuing research area for more than 40 years.

Harriet B. Nembhard

Pennsylvania State University
Harold and Inge Marcus Department of
Industrial and Manufacturing Engineering
University Park, PA, USA
hbn2@psu.edu
http://www.ie.psu.edu/People/IEFaculty/facultypage.cfm?FacID=18

Chapter B.14

Dr. Nembhard's research mission is to investigate the design and implementation of concepts and methods of quality, economics, productivity, and improvement for manufacturing systems. She is also an ASQ certified Six Sigma Black Belt and has served as an expert consultant for several major companies. She is on the editorial boards of Quality Engineering and Quality and Reliability Engineering International.

Douglas Noe

University of Illinois
at Urbana-Champaign
Department of Statistics
Champaign, IL, USA
dnoe@uiuc.edu

Chapter D.30

Douglas Noe is a Ph.D. candidate in the Department of Statistics at the University of Illinois at Urbana-Champaign. He earned an M.S. from this department in 2003 and received his M.A. in economics from the University of Michigan in 2000. His research explores statistical aspects of data mining.

Arrigo Pareschi

University of Bologna
Department of Industrial and Mechanical Engineering (D.I.E.M.)
Bologna, Italy
arrigo.pareschi@unibo.it

Chapter F.48

Arrigo Pareschi is is full professor of industrial logistics at the Department of Mechanical Constructions (DIEM) of the University of Bologna. He has been dean of Faculty of Engineering of Bologna from 1955 to 2001 and president of the Commission for Scientific Research and of the "Spin-Off" Committee of the University of Bologna. He is author of over 90 scientific papers (both experimental and theoretical) on industrial mechanical plants.

Francis Pascual

Washington State University
Department of Mathematics
Pullman, WA, USA
jpascual@math.wsu.edu

Chapter C.22

Dr. Francis Pascual received his Ph.D. in statistics from Iowa State University. He has a joint appointment in the Department of Statistics and the Department of Mathematics at Washington State University. His research interests include statistical analysis of reliability data, accelerated life test planning, statistical process control, and analysis of spatial correlations.

Raymond A. Paul

C2 Policy
U.S. Department of Defense (DoD)
Washington, DC, USA
raymond.paul@osd.mil

Chapter C.24

Ray Paul has been a professional electronics engineer, software architect, developer, tester and evaluator for the past 24 years, holding numerous positions in the field of software engineering. Currently, he serves as the deputy for C2 Metrics and Performance Measures for Software for the Department of Defense (DoD) Chief Information Officer (CIO). In this position, he supervises development of objective, quantitative data on the status of software resources in DoD information technology (IT) to support major investment decisions. These metric data are required to meet various congressional mandates, most notably the Clinger-Cohen Act. He holds a doctorate in software engineering and is an active member of the IEEE Computer Society. He has published more than 50 articles on software engineering in various technical journals and symposia proceedings, primarily under IEEE sponsorship.

Alessandro Persona

University of Padua
Department of Industrial and Technology Management
Vicenza, Italy
alessandro.persona@unipd.it

Chapter F.48

Alessandro Persona is a full professor of industrial plants and logistics in the Department of Management and Technology at Padua University. The scientific activity has been carried out in many areas of research in industrial plants, logistic and maintenance topics. He is author of more than 90 publications. In 2005 he received the award for the best paper printed in the Int. Journal of Manufacturing Technology Management. He is member of the editorial board of the International Journal on Operational Research. Currently he manages the Ph.D. on Mechatronics and Industrial Systems and he is the president of mechanical engineering degree at Padua University.

Daniel Peña

Universidad Carlos III de Madrid
Departamento de Estadistica
Getafe (Madrid), Spain
daniel.pena@uc3m.es
http://halweb.uc3m.es/daniel_pena

Chapter D.28

Daniel Peña is professor of statistics at the Universidad Carlos III of Madrid. He was full professor of statistics at Universidad Politécnica de Madrid and visiting full professor at the Universities of Wisconsin – Madison and Chicago. He has published 13 books and more than 150 research papers on time series, linear models, robust and diagnostic methods, bayesian statistics, econometrics, multivariate analysis and quality methods. He is a member of ISI and IMS fellow.

Hoang Pham

Rutgers University
Department of Industrial and Systems Engineering
Piscataway, NJ, USA
hopham@rci.rutgers.edu

Chapters A.1, A.7, C.27, E.45

Dr. Hoang Pham is professor in the Department of Industrial and Systems Engineering at Rutgers University. Before joining Rutgers, he was a senior engineering specialist at the Boeing Company, Seattle, and the Idaho National Engineering Laboratory, Idaho Falls. His research interests include software reliability, system reliability modeling, maintenance, fault-tolerant computing, and biological systemability-risk assessment. He is the author/editor of more than 15 books and is currently the editor of the Springer Series in Reliability Engineering. He has published more than 90 journal articles and 30 book chapters. Dr. Hoang Pham is a fellow of the IEEE.

John Quigley

University of Strathclyde
Department of Management Science
Glasgow, Scotland
j.quigley@strath.ac.uk
http://www.managementscience.org/staff/john.asp

Chapter A.6

Dr. John Quigley earned a BMath in actuarial science from the University of Waterloo, Canada and a Ph.D. from the Department of Management Science, University of Strathclyde, Scotland. His research interests include applied probability modelling, statistical inference and reliability growth modelling. He is a member of the Safety and Reliability Society, a chartered statistician and an associate of the Society of Actuaries.

Alberto Regattieri

Bologna University
Department of Industrial and Mechanical Engineering
Bologna, Italy
alberto.regattieri@mail.ing.unibo.it

Chapter F.48

Alberto Regattieri is a professor in the Department of Industrial and Mechanical Engineering at the University of Bologna. He received his Ph.D. degree from Parma University in 1999. His current research interests include the optimal design of manufacturing systems, production planning and control, and the maintenance of industrial plants. In 2005 he received the Williamson Award [Emerald Literati Club (UK)] for his studies. He has authored or co-authored several books and over 50 technical publications.

Miyoung Shin

Kyungpook National University
School of Electrical Engineering and Computer Science
Daegu, Republic of Korea
shinmy@knu.ac.kr

Chapter D.35

Dr. Miyoung Shin is an assistant professor in the School of Electrical Engineering and Computer Science at Kyungpook National University. She earned her Ph. D. degree in computer and information science from Syracuse University in 1998 and was awarded the All-University Doctoral Prize for her outstanding Ph.D. thesis. Prior to joining to Kyungpook National University in 2005, she had worked as a senior member of research staff in the Electronics and Communications Research Institute. Her current research interests include data mining algorithms, bioinformatics and context-awareness computing.

Karl Sigman

Columbia University in the City of New York,
School of Engineering and Applied Science
Center for Applied Probability (CAP)
New York, NY, USA
karl.sigman@columbia.edu
http://www.columbia.edu/~ks20

Chapter A.8

Professor Sigman's areas of research include stochastic modeling, stochastic networks and queueing theory, point processtheory, and insurance risk. He was a recipient of the Presidential Young Investigator Award from the National Science Foundation, and continues to be co-director of Columbia's Center for Applied Probability.

Loon C. Tang

National University of Singapore
Department of Industrial and Systems Engineering
Singapore, Singapore
isetlc@nus.edu.sg
http://www.ise.nus.edu.sg/staff/tanglc/index.html

Chapter C.23

Dr. Loon Ching Tang, a faculty member of National University of Singapore, obtained a Ph.D. degree in 1992 from Cornell University in the field of operations research. He has published more than 50 papers in international journals in the field of quality, reliability and operations research. In particular, his research interest lies in the application of probability, statistics and optimization techniques in solving real world problems. He is currently the area editor of the International Journal of Performability Engineering.

Charles S. Tapiero

Polytechnic University
Technology Management and Financial Engineering
Brooklyn, NY, USA
ctapiero@poly.edu

Chapter F.47

Charles S. Tapiero is the Topfer Chair Professor of Financial Engineering and Technology Management at the Polytechnic University of New York. He has a worldwide reputation as an active researcher and consultant in risk and computational finance and risk management. He is currently the area editor for finance in the Journal of Applied Stochastic Models for Business and Industry as well as a member of the editorial board of several other journals. Professor Tapiero has published 12 books and over 250 papers on a broad range of issues spanning risk management, stochastic modeling and applied stochastic control in operations, insurance and finance.

Zahir Tari

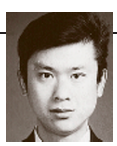
Royal Melbourne Institute of Technology University
School of Computer Science and Information Technology
Melbourne, Victoria, Australia
zahirt@cs.rmit.edu.au
http://www.cs.rmit.edu.au/~zahirt

Chapter F.52

Dr. Zahir Tari is a full professor at RMIT University and the director of Distributed Systems and Networking at the School of Computer Science and Information Technology. He has extensively published in the area of middlewares and Web services, especially in the area of performance (caching and load balancing), security (i.e. access control and information flow control) and service discovery.

Xiaolin Teng

Time Warner Inc.
Research Department
New York, NY, USA
xiaolin_teng@timeinc.com



Chapter C.27

Xiaolin Teng received his Ph.D. in industrial engineering from Rutgers University in 2001. He also holds master degrees in statistics, computer science, and automation. He is a member of ASA, INFORMS, IEEE and IIE. Currently Dr. Teng works at Time Warner Inc. as a research manager. His research interests include reliability, quality control, inventory optimization and data mining.

Wei-Tek Tsai

Arizona State University
Computer Science & Engineering
Department
Tempe, AZ, USA
wtsai@asu.edu
http://cse.asu.edu/directory/faculty/tsai.php

Chapter C.24

Professor Tsai received his Ph.D. from University of California at Berkeley 1985 and is professor of Computer Science and Science at Arizona State University. His research areas include service-oriented computing, software engineering, dependable computing, software engineering, software testing, and embedded systems. He has coauthored more than 300 research papers in these areas.

Kwok-Leung Tsui

Georgia Institute of Technology
School of Industrial and Systems Engineering
Atlanta, GA, USA
ktsui@isye.gatech.edu
http://www.isye.gatech.edu/~ktsui

Chapters B.10, D.36

Kwok-Leung Tsui is professor at Georgia Institute of Technology. He has a Ph.D. in statistics from the University of Wisconsin. Dr. Tsui is a (elected) fellow of American Statistical Association and was a recipient of the NSF Young Investigator Award. He is currently the departmental editor of the IIE Transactions.

Fugee Tsung

Hong Kong University of Science and Technology
Department of Industrial Engineering and Logistics Management
Kowloon, Hong Kong
season@ust.hk

Chapter F.50

Dr. Fugee Tsung is an associate professor in the Department of Industrial Engineering and Logistics Management at the Hong Kong University of Science and Technology. He received both his M.S. and Ph.D. in industrial and operations engineering from the University of Michigan, Ann Arbor. He is an associate editor of Technometrics, a department editor of the IIE Transactions, and on the editorial boards for the International Journal of Reliability, Quality and Safety Engineering (IJRQSE) and the International Journal of Six Sigma and Competitive Advantage (IJSSCA). He is an ASQ Certified Six Sigma Black Belt, ASQ authorized Six Sigma Master Black Belt Trainer, and former chair of the Quality, Statistics, and Reliability (QSR) Section at INFORMS. He is also the winner of the Best Paper Award for the IIE Transactions focus issue on Quality and Reliability in 2003. His research interests include quality engineering and management, statistical process control, monitoring and diagnosis.

Lesley Walls

University of Strathclyde
Department of Management Science
Glasgow, Scotland
lesley.walls@strath.ac.uk
http://www.managementscience.org/staff/lesley.asp

Chapter A.6

Lesley Walls has a Ph.D. (applied statistics). She is an IEC/TC56/WG2 expert and editorial board member of several reliability journals. Her research includes reliability modelling, business processes and risk assessment. She is a fellow of the UK Safety and Reliability Society, chartered statistician and was awarded the 2002 Simms prize by the Royal Aeronautical Society for REMM modelling research.

Wei Wang

Dana-Farber Cancer Institute
Department of Biostatistics and Computational Biology
Boston, MA, USA
wwang@jimmy.harvard.edu

Chapter C.21

Dr. Wang is assistant professor of biostatistics at Harvard School of Public Health and Dana-Farber Cancer Institute. She obtained her Ph.D. degree in statistics from the University of California at Davis. Dr. Wang's current research interests are mainly in developing semi-parametric and non-parametric methods in areas of survival analysis, longitudinal data analysis and functional data analysis. Dr. Wang also works at the statistical center of the Eastern Cooperative Oncology Group (ECOG) on collaborative research in cancer clinical trials.

Kenneth Williams

Yale University
Molecular Biophysics and Biochemistry
New Haven, CT, USA
kenneth.williams@yale.edu
http://info.med.yale.edu/wmkeck/

Chapter D.34

Dr. Williams received the Ph.D. degree in biochemistry from the University of Vermont in 1976. In 1980 he founded the Keck Laboratory (http://info.med.yale.edu/wmkeck/) and in 1986 he was one of the six founding members of the Association of Biomolecular ResourceFacilities (http://www.abrf.org/). He has 155 publications and directs the Yale/NHLBI Proteomics Center, NIDA Neuroproteomics Center, and the Proteomics Core of the Northeast Biodefense Center.

Richard J. Wilson

The University of Queensland
Department of Mathematics
Brisbane, Australia
rjw@maths.uq.edu.au
http://www.maths.uq.edu.au/~rjw

Chapter A.5

Dr. Wilson is a senior lecturer in statistics at The University of Queensland. His main research interests are in random processes, extremes and reliability, from both theoretical and applied statistics perspectives. Accordingly, he has worked on such diverse topics as modelling mineral phases in ores at the micro level, investigating warranty policies in manufacturing, exploring the relationship between the location of nerves to wisdom teeth and various factors, modelling wind downbursts, fitting models to significant wave height data and investigating aspects of the combustion of metal rods.

Baolin Wu

University of Minnesota, School of Public Health
Division of Biostatistics
Minneapolis, MN, USA
baolin@biostat.umn.edu
http://www.biostat.umn.edu/~baolin

Chapter D.34

Baolin Wu received the B.Sc. degree in probability and statistics from Beijng University in 1999 and the Ph.D. degree in biostatistics from Yale University in 2004. In 2004 he joined the Division of Biostatistics at the University of Minnesota as an assistant professor. His current research areas focus on computational biology and statistical learning.

Min Xie

National University of Singapore
Dept. of Industrial & Systems Engineering
Singapore, Singapore
mxie@nus.edu.sg
http://www.ise.nus.edu.sg/staff/xiemin/

Chapters A.3, B.16

Dr. Min Xie is a professor at National University of Singapore. He received his Ph.D. from Linköping University, Sweden in 1987 and has published over 100 articles in refereed journals and six books. He is an editor of International Journal of Reliability, Quality and Safety Engineering, a regional editor of Economic Quality Control, a department editor of IIE Transactions and associate editor IEEE Trans on Reliability. He is a fellow of IEEE.

Chengjie Xiong

Washington University in St. Louis
Division of Biostatistics
St. Louis, MO, USA
chengjie@wubios.wustl.edu
http://www.biostat.wustl.edu/faculty_staff/xiongc.shtml

Chapter C.19

Dr. Chengjie Xiong is a research assistant professor of biostatistics at Washington University School of Medicine. He received a B.S. in Mathematics from Xiangtan University (P.R. China), an M.S. in Applied Mathematics from Peking University (P. R. China), and a Ph.D. in statistics from Kansas State University in 1997. Dr. Xiong's research interests include statistical design of experiments, linear and nonlinear mixed models, longitudinal data analysis, survival analysis and reliability, categorical data analysis, order restricted statistical inferences, and their applications in medicine, biology, education, and engineering. Dr. Xiong has provided statistical consulting for researchers across the US in the areas of biology, medicine, agriculture, marketing and education and is the principal investigator of a NIH-funded project to study the statistical application in medical research. He is a member of the American Statistical Society.

Di Xu

Amercian Express
Dept. of Risk Management and Decision Science
New York, NY, USA
di.w.xu@aexp.com

Chapter B.12

Di Xu is a director in risk management and decision science in the consumer card services group at American Express. His research interests are multivariate statistical modelling, data mining, mathematical optimization, and their application in process control, product design, risk management and direct marketing acquisition. He graduated from Rutgers Univerity with a Ph.D. in Industrial Engineering in 2001.

Shigeru Yamada

Tottori University
Department of Social Systems Engineering
Tottori-shi, Japan
yamada@sse.tottori-u.ac.jp
http://www.sse.tottori-u.ac.jp/jouhou_source/hpsubmit/index.html

Chapter C.26

Dr. Yamada has been working as a professor in the Department of Social Systems Engineering at Tottori University, Japan, since 1993. He received his Ph.D. degree from Hiroshima University, Japan, in 1985. He has published numerous technical papers and books in the area of software reliability engineering, reliability engineering, and statistical quality. Dr. Yamada received the Best Author Award (1992) from the Information Processing Society of Japan, the TELECOM System Technology Award (1993) from the Telecommunications Advancement Foundation, the Best Paper Award (1999) from the Reliability Engineering Association of Japan, and the International Leadership Award in Reliability Engineering Research (2003) from the ICQRIT/SREQOM.

Jun Yan

University of Iowa
Department of Statistics and Actuarial Science
Iowa City, IA, USA
jyan@stat.uiowa.edu
http://www.stat.uiowa.edu/~jyan/

Chapter F.51

Dr. Jun Yan earned a Ph.D. in statistics from the Universityof Wisconsin – Madison in 2003. His research interests are functionaldata analysis, survival analysis, spatial statistics, statisticalcomputing, and cross-disciplinary statistical applications.

Shang-Kuo Yang

Department of Mechanical Engineering
National ChinYi Institute of Technology
Taiping City, Taiwan, R.O.C.
skyang@ncit.edu.tw
http://irw.ncit.edu.tw/mechanical/skyang/skyang.htm

Chapter E.44

Professor Yang received his B.S. in 1982 and the M.S. in 1985 in automatic control engineering from Feng Chia University, Taiwan. From 1985 to 1991 he was an assistant researcher and instrumentation system engineer of Flight Test Group, Aeronautic Research Laboratory, Chung Shan Institute of Science and Technology, Taiwan. Since 1991, he has been with the Department of Mechanical Engineering at National Chin Yi Institute of Technology, Taiwan, where he is a full professor and the chairperson. He received a Ph.D. in 1999 in mechanical engineering from National Chiao Tung University, Taiwan. His research interests are in reliability, data acquisition, and automatic control.

Kai Yu

Washington University in St. Louis, School of Medicine
Division of Biostatistics
St. Louis, MO, USA
yuka@mail.nih.gov

Chapter C.19

Dr. Yu is a research assistant professor at the Division of Biostatistics at Washington University, St. Louis. He obtained his Ph.D. in biostatistics from University of Pittsburgh in 2000. He completed a one-year postdoctoral training in statistical genetics in 2001 at Stanford University. His current research interests include biostatistics and genetic epidemiology.

Weichuan Yu

Yale Center for Statistical Genomics
and Proteomics, Yale University
Department of Molecular Biophysics
and Biochemistry
New Haven, CT, USA
weichuan.yu@yale.edu
http://noodle.med.yale.edu/~weichuan

Chapter D.34

Weichuan Yu received his Ph.D. degree in computer vision and image analysis from the University of Kiel, Germany in 2001. He was a postdoctoral associate at Yale University from 2001 to 2004. Currently he is a research faculty member in the Center for Statistical Genomics and Proteomics at Yale University. He is interested in computational analysis problems with biological and medical applications.

Panlop Zeephongsekul

Royal Melbourne Institute of Technology
University
School of Mathematical and Geospatial
Sciences
Melbourne, Victoria, Australia
panlopz@rmit.edu.au

Chapter F.52

Dr. Zeephongsekul received his B.Sc. degree with honors from Melbourne University and a Ph.D. degree in statistics from the University of Western Australia. He is currently an associate professor in the School of Mathematical and Geospatial Sciences at RMIT University, Melbourne, Australia. His research interests are broad, being in stochastic point processes, fuzzy sets, game theory, queuing theory and software reliability analysis. He has published in all those areas and his papers have appeared in many well-known international journals. He is also involved in many consulting projects with diverse clients, especially in applied statistics and the design and analysis of experiments.

Cun-Hui Zhang

Rutgers University
Department of Statistics
Piscataway, NJ, USA
czhang@stat.rutgers.edu
http://www.stat.rutgers.edu/people/faculty/zhang.html

Chapter E.40

Cun-Hui Zhang received his Ph.D. in statistics from Columbia University in 1984. He is currently a professor in the Department of Statistics at Rutgers University. His research interests include empirical Bayes, nonparametric and semiparametric methods, functional MRI, biased and incomplete data, networks, multivariate data, biometrics, and probability theory.

Heping Zhang

Yale University School of Medicine
Department of Epidemiology
and Public Health
New Haven, CT, USA
heping.zhang@yale.edu
http://peace.med.yale.edu

Chapter D.33

Heping Zhang is professor of biostatistics, child study, and statistics. He is interested in development of statistical methods and software and their applications in biomedical studies, particularly in behavioural science, epidemiology, genetics, psychiatry, and pregnancy outcomes. He publishes extensively on tree- and spline-based methods as well as latent variable models for genetic studies of ordinal traits. He is a fellow of the American Statistical Association.

Hongyu Zhao

Yale University School of Medicine
Department of Epidemiology
and Public Health
New Haven, CT, USA
hongyu.zhao@yale.edu
http://publichealth.yale.edu/faculty/zhao.html

Chapter D.34

Hongyu Zhao received a Ph.D. degree from the University of California at Berkeley in 1995. He is the Ira V. Hiscock Associate Professor at Yale University. He is interested in addressing statistical and computational problems in molecular biology and genetics. He has published more than 120 articles and is an associate editor for multiple journals including Biometrics and Statistica Sinica.

Kejun Zhu

China University of Geosciences
School of Management
Wuhan, Peoples Republic of China
zhubingl@pubilc.wh.hb.cn

Chapter C.19

Dr. Zhu's main area of research is soft computing where he has been working in the fields of system engineering and information systems. He is an associate editor of the Forecasting Journal. His current research activities include fuzzy systems, neural networks and genetic algorithms. He has presided over two programs of the National Natural Science Foundation of China.
