Introduction

Aims and Scope

The New Economic History (a term proposed by Jonathan Hughes) or Cliometrics (coined by Stan Reiter), meaning literally the measurement of history, is of very recent origin. Its first practitioners are considered to be Alfred Conrad and John Meyer, who published "Economic Theory, Statistical Inference, and Economic History" in the *Journal of Economic History* in 1957 after its presentation earlier that year at the joint meetings of the Economic History Association and the NBER Conference on Research in Income and Wealth. They followed that up in 1958 with a paper demonstrating the cliometric methodology as it applied to slavery in antebellum America. Robert Fogel's seminal research work on the impact of the railroad on American economic growth is in extension a true revolution in the history of economics, even a complete break with the tradition. It reestablished a role for history in economics by expressing it in the language of the discipline. Today, one can even say that it is an expanding domain in economics, contributing to new debates and challenging conventional wisdom. The use of econometric techniques and economic theory has contributed to the rejuvenation of economic history debates, made quantitative arguments unavoidable, and contributed to the emergence of a new historical awareness among economists.

Cliometrics does not concern economic history in the limited, technical meaning of the term. It modifies historical research in general. It represents the quantitative projection of social sciences in the past. The question of knowing whether slavery benefited the United States before the Civil War or if railways had substantial effects on the development of the US economy is as important for general history as for economic history and will necessarily weigh on any interpretation or appraisal (anthropological, legal, political, sociological, psychological, etc.) of the course of American history.

Furthermore, cliometrics challenges one of the basic hypotheses of the idealistic school: that history can never provide scientific proof because it is impossible to subject unique historical events to experimental analysis. On the contrary, cliometricians have shown that such experimentation is possible by construction of a

counterfactual that can be used to measure the deviation between what actually happened and what could have happened under different circumstances.

Robert Fogel famously used a counterfactual to measure the impact of the railroad on American economic growth. This methodological principle is perhaps, along with historical time series econometrics, the most important contribution of cliometrics for researchers in social science in general, and historians in particular.

The Methodological Features

Fogel defined the methodological features of cliometrics. He considered it fundamental that cliometrics should stress measurement while recognizing the existence of close links between measurement and theory. Indeed, unless it is accompanied by statistical and/or econometric processing and systematic quantitative analysis, measurement is just another form of narrative history. It is true that it replaces words with figures, but it does not bring in any new factors. In contrast, cliometrics is innovative when it is used to attempt to model all the explanations of past economic development. In other words, the main characteristic of cliometrics is the use of hypotheticodeductive models that call on the closest econometric techniques with the aim of establishing the interaction between variables in a given situation in mathematical form.

This generally consists of constructing a model – of general or partial equilibrium – that represents the various components of the economic evolution in question and showing the way in which they interact. Correlations and/or causalities can thus be established to measure the relative importance of each over a given period of time.

The final ingredient of the cliometric approach concerns the concepts of a market and price. Even in areas where there is no explicit market, the cliometric approach will often study the subject by analogy with the market concepts of supply, demand, and price.

So far, hypotheticodeductive models have mainly been used to determine the effects of innovations, institutions, and industrial processes on growth and economic development. As there are no records saying what would have happened if the innovations in question had not occurred or if the factors involved had not been present, this can only be found out by drawing up a hypothetical model used for deducing a hypothesized alternative situation – i.e., the counterfactual. It is true that the use of propositions contrasting with the facts is not new in itself. Such propositions are implicitly involved in a whole series of judgments, some economic and others not.

The use of such counterfactual analysis has not escaped criticism. Many researchers still believe that the use of hypotheses that cannot be verified generates quasihistory rather than history proper. Furthermore, the results obtained by the most elaborate cliometric applications have been less decisive than many cliometricians had hoped for. Critics are doubtless right to conclude that economic analysis in itself, with the use of econometric tools, is unable to provide causal explanations for the process and structure of change and development. There appear to be nonsystematic

breaks in normal economic life (wars, bad harvests, collective hysteria during market crashes, etc.) that require overall analysis but that are too frequently considered as extrinsic and abandoned to the benefit of an a priori formulation of theoretical suppositions.

Nevertheless, in spite of the disappointments resulting from some of its more extreme demonstrations, cliometrics also has its successes, together with continuous theoretical progress. The risk would obviously be that of allowing economic theory to neglect a whole body of empirical documentation that can enrich our knowledge about the reality of economic life. Conversely, theory can help to bring out certain constants, and only mastery of theory makes it possible to distinguish between the regular and the irregular and the foreseeable and the unforeseeable.

The Main Achievements

To date, the main achievements of cliometrics have been to slowly but surely establish, in the Fogel tradition, a solid set of economic analyses of historical evolution by means of measurement and theory and, following the path blazed by Douglass North, to recognize the limits of neoclassical theory and bring into economic models the important role of institutions. Indeed, this latter focus ultimately spawned a new branch of economics altogether, the new institutional economics. Nothing can now replace rigorous statistical and econometric analysis based on systematically ordered data. Impressionistic judgments supported by doubtful figures and fallacious methods and whose inadequacies are padded by subjective impressions have now lost all credibility. Economic history in particular should cease to be a "simple" story, illustrating with facts the material life during different periods, and become a systematic attempt to provide answers to specific questions. The ambition should be to move from the *Verstehen*, or understanding, to the *Erklären*, or explanation epistemology.

By extension, the more the quest for facts is dominated by the conception of the problems, the more research will address what forms the true function of economic history in the social sciences. This change of intellectual orientation, of cliometric reformulation, can thus reach other human and social science disciplines (law, sociology, political science, geography, etc.) and engender similar changes.

Indeed, the most vigorous new trend in the social sciences is without a doubt the preoccupation with quantitative and theoretical aspects. It is the feature that best distinguishes the concepts of the current generation of scholars from its forbears. Even the most literary of our colleagues is ready to agree to this. There is nothing surprising about this interest. One of the characteristic features of today's younger generation of scholars is most certainly that their intellectual training is much more deeply marked by science and the scientific spirit than that of the generations that preceded them. It is, therefore, not surprising that young scientists should have lost patience with regard to the tentative approach of traditional historiography and have sought to build their work on foundations that are less "artisanal."

Human and social sciences are thus becoming much more elaborate in the technical respect, and it is difficult to believe that a reversal of the trend is likely to occur. However, it is also clear that a significant proportion of human and social scientists have not yet accepted the new trends aimed at using more elaborate methodology and clear concepts conforming to new norms in order to develop, in a Fogelian tradition, a truly scientific human and social science.

A Branch of History?

For many authors – and many of its protagonists – cliometrics appears to be first of all a branch of history. Using economic tools, techniques, and theories, it provides answers to historical, rather than economic, debates per se.

The meaning of the word "empirical" for (American) economic historians has varied considerably with the passing of time. One can observe a shift from a concept of empirical fact as understood by the "classical historian" (for whom anything, as opposed to only quantitative data, retrieved from archives can be used in his demonstration) to one as understood by (applied) economists (the empirical aspect consists of analyzing numerical time series) and a convergence of theoretical viewpoints of historians and economists thanks to a common interest in the building of theories of development.

Here, Simon Kuznets seems to have played a key role by emphasizing the importance of performing at the onset a serious macroeconomic analysis of the major quantitative macrochanges in the past economic history before possibly identifying certain sectors that are deemed central for economic development. One should note that even in his concern to combine history with economic analysis, he thought of a theory of development that remained inductively based upon the observation of the major past evolution enlightened by the analysis of long-run time series patiently accumulated by the economic historian.

This (inductive) view is therefore intimately linked with the historical current in economics, the German Historical School, despite the use of more sophisticated techniques. It could be said that the two disciplines became closer but probably within the frame of "inductive" economics. On top of that, despite those early interests in building a kind of historically (i.e., inductively) grounded development economics, cliometrics mainly tried to provide answers to historiographical questions – and therefore spoke more to the historian than to the standard economist. Econometric techniques may be used with the reconstitution of time series and identification of missing figures by interpolation or extrapolation – something, by the way, that annoys professional historians. But these cliometric procedures have nonetheless a historical vocation – that of shedding light on historical questions – considering economic theory or econometrics as auxiliary disciplines of history. And when the cliometric approach was mobilized to build a development theory based upon clearly measured facts, it developed an economics more akin to the objectives of the German Historical School than one participating in the movement toward

highly abstract and deductive theory that characterized the development of the neoclassical school of the time.

The conflict between Kuznets and Walt Rostow regarding the stages in economic development was actually based upon the empirical foundations of Rostow's theory and not at all on a debate concerning the shortcomings of a very inductive and aggregate perspective lacking formal rigor (no use of growth theories) or micro-foundations, which would doubtless be the main subject of criticism today. In short, either cliometrics is still a (modernized) branch of (economic) history – in the same way as the modernization of methods in archaeology (from carbon-14 measurement to the use of statistical techniques such as discriminant analysis) does not turn the discipline into a branch of natural science – or the cliometric approach is mobilized to obtain theoretical results grounded more on induction from collected time series than from a deductive explicit modeling exercise, i.e., economic theory that must be primarily founded on facts and a generalization of empirical evidence. In this way, it contributes to an economic science that is more related to the German Historical School than to the neoclassical perspective.

An Auxiliary Discipline of Economics?

But this is not the end of the story. Some recent work in cliometrics performed by economists (stricto sensu) reveals the possibility of a cliometrics that could also be an auxiliary discipline of economics per se. As such, it should be part of the toolkit and competencies of all economists. However, as the term auxiliary discipline indicates, it could only fulfill its proper role for economics if it remains slightly (not too much) outside the realm of standard neoclassical economics. It must be a compound of the application of the newest econometric techniques and economic theory with the old institutional and factual culture characterizing the old economic history.

History is indeed always a discipline of synthesis. It should also be the case for cliometrics. If not, if cliometrics were to be deprived of all its "historical dimensions," it would simply cease to exist (it would only be economics applied to the past or mere retrospective econometric exercises). To be helpful for the economics profession at large, its main job should be to mobilize all the relevant information that can be gathered from history to enrich or even challenge economic theory (or theories). And this relevant information should also include cultural or institutional development, provided that they can be properly presented as useful for the profession.

A conventional belief among economists (in fact that of Lord Kelvin) is that "qualitative is poor quantitative." But could it not be possible that "quantitative is poor qualitative" might also sometimes be true? A big difference between economists and historians is the sense of so-called historical criticism and the desire to avoid any anachronism. In addition to close examination of the historical sources, this involves the close examination of the institutional, social, and cultural context that forms the framework constraining the players' behavior. It is true that the (new)

economic history will not build a general theory – it shares too strongly the belief in the necessity of examining economic phenomena in their context – but it could suggest a few useful ideas and insights, based upon solid investigations and correctly estimated stylized facts, to economists who are attempting to develop laws of economic behavior (unlike history, economics is still a nomological science). Economists and cliometricians can also cooperate and jointly author research. This is a view shared by Daron Acemoglu, Simon Johnson, James Robinson, and Oded Galor, among others, trying to use the material derived from traditional history to build new ideas useful for economic theorists.

In summary, it could be contended that a good cliometric practice is not an easy exercise. Becoming too narrowly "economic," it would not be possible for cliometrics to answer certain questions that would require, for example, more information about the microstructure of financial markets or the actual functioning of stock exchanges during the period under scrutiny – it would only measure phenomena that it cannot explain. It would require the specific approach (and extraneous information) of the historian to describe the reasons for the lack of relevance (or understand the shortcoming) of such an economic theory in a given context (precise place and period). It is perhaps only in this regard that cliometrics can provide something for economists by suggesting lines of research. However, if it became too "historical," cliometrics would cease to appeal to the economics profession. Economists need new economic historians aware of their debates and their interests.

A Full-Fledged Field of Economic Theory?

Last, but not least, cliometrics could one day be more than just an ancillary discipline of economics and instead become a full-fledged field of economic theory. There is indeed another possibility: viewing cliometrics as the science of the emergence of institutional and organizational structures, and that of path dependence. Economic history would use the old techniques of the discipline coupled with the state-of-the-art arsenal of econometrics in order to reveal stylized facts about the efficiency of various institutional arrangements as well as the causes and consequences of institutional change. It would help the theorist in developing a true theory of institutional change, i.e., one that at the same time would be general (serving the needs of policymakers today, for example) and theoretically solid (grounded on economic principles) while solidly grounded on empirical regularities as put forward by a joint economic and historical analysis. This analysis of institutional morphogenesis would be the true theoretical part of a cliometric science that would emancipate itself from its apparently purely empirical fate – being the playing ground of long-run econometricians. It is clear that economists' desire for generality and their fascination for the mathematical science do not encourage them to pay too much attention to contextualization. However, neoinstitutionalist economists like North warn us to seriously consider institutional (including cultural) contexts.

Our ambition for the *Handbook of Cliometrics* was thus also aimed at encouraging economists to examine more systematically these theories grounded upon history and nevertheless aiming at the determining general laws on the creation of institutions or of institutional changes. Beyond the study of long-run quantitative data sets, a branch of cliometrics is more and more focused on the role and evolution of institutions by aiming at combining the economist's desire for generality with the concern for the precise context in which economic players act that characterizes historians and other social scientists. This middle road between pure empiricism and disincarnate theory might perhaps open the door to a better economic theory. This will enable economists to interpret current economic issues in the light of the past and, in so doing, understand more deeply the historical working of economies and societies. This is the path to offering better policy advice for today.

The Contents

When putting together the first edition of this handbook, the most difficult question we faced was what to include. The possibilities were endless, but the space was limited. For this second edition we were allocated much more space, and the results are obvious: we have tripled the size of the original handbook, adding 43 new chapters to the original 22, of which several were revised and updated by their original authors. Even with this expanded coverage, there are still techniques and topics of importance that are not included. Their absence should not by any means be considered as an indictment of their importance or historical significance. In some cases, we had chapters committed, but for a variety of reasons the author was unable to meet our publication deadline. In this situation the chapters will be added to the online version of the handbook, which can be found at: https://link.springer.com/referencework/10.1007/978-3-642-40458-0

The expanded selection of chapters in this edition still represents only a sampling of the topics that cliometrics has helped to transform over the past half century. It includes topics that established cliometrics as the "new" economic history in the 1960s, including Richard Sutch's chapter on slavery and Jeremy Atack's contribution on railroads. It features chapters that have long been at the center of cliometric analysis, such as Greg Clark's chapter on the industrial revolution, Larry Neal's chapter on financial markets, and the contribution by Chris Hanes on the Great Depression. And we offer chapters on narrower topics that have been developed largely as a result of the cliometric approach, such as the age heaping work discussed by Franziska Tollnek and Joerg Baten, Douglas Puffert's chapter on path dependence, Thomas Rahlf's contribution on statistical inference, and Florian Ploeckl's chapter on spatial modeling. In between, we have included articles by Stanley Engerman, Deirdre McCloskey, Roger Ransom, and Peter Temin, who began plying their trade when cliometrics really was the "new" way of studying economic history, and young scholars who represent the next generation of cliometricians, including Matthew Jaremski and Chris Vickers. The common link running throughout the Handbook is the focus on the contributions of cliometrics.

The *Handbook of Cliometrics* is a milestone in the field of historical economics and econometric history through its emphasis on the concrete contribution of cliometrics to our knowledge in the fields of economics and history. It is a work of tertiary literature. As such, it contains digested knowledge in an easily accessible format. The articles are not original research or review articles, but rather an overview of the contributions of cliometrics to the topic of discussion. The articles stress the usefulness of cliometrics for economists, historians, and social scientists in general. The Handbook offers a wide range of topical coverage, with each article providing an overview of the contributions of cliometrics to a particular topic.

The book is organized into eight parts, grouping the 65 contributions by general topic, starting with six chapters on the history of economic history and cliometrics, and the contributions of its two most prominent practitioners, Robert Fogel and Douglass North. The second part focuses on human capital, with nine chapters ranging from broad topical coverage of labor markets, education and gender, to two specific surveys of the role of clio in age heaping and church book registry.

Part III takes the big picture into consideration with nine papers on economic growth. We feature chapters on industrial growth, the industrial revolution, antebellum growth, trade, market integration, and economic-demographic interactions, to name but a handful. Part IV covers institutions, both broadly defined (institutions, political economy, property rights, merchant empires) and more narrowly focused (slavery, colonial America, water rights).

The largest section is Part V, which features a dozen articles on money, banking and finance in a variety of formats. Early capital markets, origins of the U.S. financial system, and antebellum banking lead off the coverage, followed by big picture coverage of financial markets and systems, panics, and interest rates. Also included are chapters on the Great Depression, central banking, sovereign debt, and corporate governance.

In Part VI we offer eight chapters on the topics of government, health, and welfare. Clio offspring are featured here, including anthropometrics and agricliometrics. Chapters on income inequality, nutrition, health care, war, and the role of the government in the Great Depression can also be found. Part VII covers innovation both mechanical and creative, railroads, transportation, and tourism.

The Handbook concludes with a section on technique and measurement, two hallmarks of cliometrics. Here you will find chapters on analytic narratives, path dependence, spatial modeling, and statistical inference alongside offerings on African economic history, output measurement, and the census of manufactures.

We enjoyed the process of putting this second edition together. What began nearly a decade ago as an innocent query (Why isn't there a handbook of cliometrics?) has now grown to two editions with more than five dozen entries. The process was a labor of love and the result is an assemblage of top scholars analyzing the role that cliometrics has played in the advancement of knowledge across a wide array of topics. We present it to you, and dedicate it to all cliometricians, past, present, and future.

Preface to Second Edition

Welcome to the second edition of the *Handbook of Cliometrics*, a part of the Springer Reference Library. This second edition builds on the first, published in 2016, by including the original 22 chapters and adding 43 new chapters. In order to foster world-class research, this edition, like its predecessor, includes economists and economic historians of the highest caliber from around the world. The handbook impacts historical economics and econometric history through its emphasis on the concrete contribution of cliometrics to our knowledge of economics and history.

Cliometrics dates formally to the joint meeting of the Economic History Association and the Conference on Research in Income and Wealth (under the purview of the NBER) in 1957. The concept of cliometrics, the application of economic theory and quantitative techniques to the study of history, is somewhat older. Regardless of its precise origin, this focus on the use of theory and formal modeling that distinguishes cliometrics from "old" economic history has redefined the discipline and made an indelible mark on economics. The works in this handbook recognize these contributions and highlight them in a variety of subdisciplines.

The handbook is a work of tertiary literature. As such, it contains digested knowledge in an easily accessible format. The chapters provide an overview of the contributions of cliometrics to various subdisciplines in the field of economic history. Each one stresses the usefulness of cliometrics for economists, historians, and social scientists in general.

A project of this size and scope does not come to a successful conclusion without the contributions of many people. We want to thank all those who helped to bring this idea to fruition and see it through to its conclusion. First and foremost, we thank our authors, who have produced articles of the highest quality under demanding deadlines and through numerous drafts. Their time and expertise are what elevates this handbook to the highest level. We also need to thank the editorial and production team, who turned this work from concept to final printed and online product: Martina Bihn, who nourished our idea from the beginning, and Shruti Datt and Rebecca Urban, our editors, who kept us on task and provided copious and valuable advice at every turn. Many thanks also to Michael Hermann for his unconditional support. We would also like to thank the Board of Trustees of the Cliometric Society, who inspired us to carry on with our initial proposal to create a handbook and cheered us on when we added a second edition.

Finally, we would be remiss if we did not thank our spouses, Valérie and Mary Ellen, who put up with late nights over computers, long days at the office, and our general demeanor as we stared down deadlines, all while working at their careers while tolerating our obsession.

May 2019

About the Editors

Claude Diebolt is CNRS research professor of economics at the University of Strasbourg. He is the founder and the editor in chief of the journal *Cliometrica*. He is also the coeditor of the *Handbook of Cliometrics* and was the organizer of the 8th World Congress of Cliometrics. Claude Diebolt is the current president of the *Comité National de la Recherche Scientifique* (CNRS Section 37, Economics and Management Science) and the president of the *Association Française de Science Economique*. He is the founding president of the *Association Française de Cliométrie* and a former chair of the board of trustees of the *Cliometric Society* in the United States. On March 6, 2019, Claude Diebolt received the 2018–2019 Sarton Medal for his research in Cliometrics.

Michael Haupert is professor of economics at the University of Wisconsin-La Crosse and executive director of the Economic History Association. Previously, he served in the same position for 8 years for the Cliometric Society. His research interests are the economic history of the sports and entertainment industries and the history of the economic history discipline. He has authored two books on the history of the entertainment industry in America and coauthored a book on the economics of baseball in the 1920s. His research has also appeared in *Cliometrica*, *The Journal of Economic History*, and *The Journal of Money, Credit and Banking*, among others.

Contents

Abstract

Economic historians have contributed to the development of economics by combining theory with quantitative methods, constructing and revising databases, discovering and creating new ones entirely, and adding the variable of time to traditional economic theories. This has made it possible to question and reassess earlier findings, thus increasing our knowledge, refining earlier conclusions, and correcting mistakes. It has contributed greatly to our understanding of economic growth and development. The use of history as a crucible to examine economic theory has deepened our knowledge of how, why, and when economic change occurs. The focus of this essay is to detail the history of the discipline of cliometrics, the quantitative study of economic history, and outline its evolution within the discipline of economic history.

Introduction

Economic historians have contributed to the development of economics by combining theory with quantitative methods, constructing and revising databases, discovering and creating new ones entirely, and adding the variable of time to traditional economic theories. This has made it possible to question and reassess earlier findings, thus increasing our knowledge, refining earlier conclusions, and correcting mistakes. It has contributed greatly to our understanding of economic growth and development.[1] The use of history as a crucible to examine economic theory has deepened our knowledge of how, why, and when economic change occurs.

In December of 1960, the "Purdue Conference on the Application of Economic Theory and Quantitative Techniques to Problems of History" was held on the campus of Purdue University.[2] It is recognized as the first meeting of what is now known as the Cliometric Society.[3] While it was the first formal meeting of a group of like-minded applicants of economic theory and quantitative methods to the study of economic history, it was not the first time such a concept had been broached, practiced, or even mentioned in the literature.[4] Cliometrics was a long time in coming, but when it arrived, it eventually overran the approach to the discipline of economic history, leading to a bifurcation of the economists and historians who practice the art and the blurring of the distinction between cliometricians (i.e., economic historians) and theorists who use historical data.

Before there was a Cliometric Society, there was the *Economic History Association* (*EHA*). And before the *EHA*, there were a number of societies that American economic historians could join, but none that they could really call their own. The closest thing they had was the *Economic History Society*, founded in 1926 and headquartered in the UK. In the USA, economic historians spread themselves out among a variety of associations according to their primary historical interests, such as the *Agricultural History Society* (founded in 1916), the *American Historical Association* (1884), the *Business Historical Society* (1926), and the *American Economic Association* (1885). None of these precisely fit the bill, however. As a

[1] See Drukker (2006), for example.

[2] A selection of the papers presented in these early meetings was published by Purdue University in 1967.

[3] The Cliometric Society was formally organized in 1983 by Sam Williamson and Deirdre (nee Donald) McCloskey.

[4] The first use of the term in print: "the logical structure necessary to make historical reconstructions from the surviving debris of past economic life essentially involves ideas of history, economics and statistics . . . has been labeled "Cliometrics" (Davis et al. 1960, p. 540).

result, a movement began in early 1937 to establish an American organization that was dedicated to the study and teaching of economic history. Actually, two different organizations were formed to meet these goals: the *Industrial History Society*, organized in 1939, followed by the *EHA* 1 year later.

What makes economic historians unique is not their use of historical data or their focus on the past but that they study the growth and evolution of economies over the long term. In this way, economic history's closest kin is development economics. In addition, the attention that economic historians give to noneconomic factors, such as legal and political systems, distinguishes them from economic theorists. Given the longer time span economic historians consider, doing so gives fuller attention to changes in institutions.[5]

Clio's roots are historical in nature, and its focus on theory has actually come full circle over the last century and a half. A mathematical movement in the economics discipline, advanced computing technology, and a shift in the focus of the role of history within economics all contributed to the proliferation of the "new" economic history that rewrote the landscape of the discipline. The emphasis on theory and formal modeling that distinguishes cliometrics from the "old" economic history now blurs the distinction between economic history and economic theory, to the extent that the need for economic historians is questioned and indeed no longer considered necessary in many economics departments.[6] The focus of this essay is to detail the history of the discipline of cliometrics, the quantitative study of economic history, and outline its evolution within the discipline of economic history.

Cliometrics

Cliometrics has been defined and summarized in numerous scholarly articles.[7] They all pretty much start with the obvious, that cliometrics is the application of economic theory and quantitative techniques to study history, and then move on to the origin of the name, the joining of *Clio* (the muse of history), with *metrics* ("to measure," or "the art of measurement"), allegedly coined by economist Stanley Reiter while collaborating with economic historians Lance Davis and Jonathan Hughes.[8] From there they recount the evolution of the discipline, highlight its major contributions, and mention its detractors. While some of that ground will be retread here, the focus of this essay is less about adding another history of cliometrics[9] and more about

highlighting the literature in the history of the discipline that is cliometrics and from whence clio came.

de Rouvray (2004a, b, 2014), in her research on US economic history, describes the discipline as one aimed at understanding the origin, dynamics, and consequences of past economic events. She categorizes cliometrics as a movement that transformed that study from a narrative to a mathematical format. Her definition is not unique, but her attention to the historical detail which begat the cliometric revolution is without equal.

The origin of cliometrics can be found in the origin of economic history, which evolved as a separate discipline in Germany and England in the late nineteenth century. It migrated to the USA in 1892 in the person of W. J. Ashley and ultimately flourished. It was neither a rapid nor accepted emergence, however.

Cliometrics today is closely related to, but not necessarily the same thing as its progenitor, economic history. While there is considerable overlap between the membership of the Cliometric Society and its American brethren, the *Economic History Association*, the latter has many more members who reside in history departments than does the Cliometric Society. Indeed, one of the great criticisms of the cliometric movement is the wedge that it has driven between the practitioners of economic history in history and economics departments (Boldizzoni 2011)[10] due to its focus on quantitative measures and neoclassical theory.[11]

Despite the current strains, cliometrics does owe its very existence to economic history, having grown out of that discipline in the last half of the twentieth century. The skills of a cliometrician include those of any other economic historian. In his inaugural presidential address to the *EHA*, Edwin Gay (1941) noted that economic historians required two sets of skills, which they needed to wed in order to accomplish their task. He believed the molding of the skills of the economist and historian was essential, but not easy to accomplish.[12] That has not changed over the past three quarters of a century. What has changed is the degree to which those economic skills have become more formalized and technically demanding.

The clash between cliometricians and historians today is not all that different from the clash between economists and historians that began in the nineteenth century. Carl Menger (1884) compared historians to foreign conquerors, complaining that they were forcing their terminology and methods on economists. Half a century later, Ashton (1946) accused those who objected to the idea that economic theory should be applied to history of not truly understanding the nature of economics.

[10]For earlier laments about the encroachment of theory and mathematics on the study of history, see Braudel (1949) and Polanyi (1944).

[11]Perhaps more than anyone, D.N. McCloskey has been responsible for holding all economists, not just economic historians, accountable for moving the frontiers of knowledge forward and not simply using the latest techniques to measure something because it can be measured. For example, see McCloskey (1978, 1985, 1987, 2006).

[12]See also Ashley (1927), Ashton (1946), Gallman (1965), McCloskey (1986), and Nef (1941) for viewpoints of the melding of the skills of historians and economists.

While economic history had been dominated by qualitative studies, cliometrics was not the first application of quantitative methods to the discipline. As early as the seventeenth century, scholars attempted to infer an explanation of some aspects of economic history by examining data (D'Avenant 1699; Graunt 1662). In 1707, Bishop William Fleetwood wrote *Chronicon Preciosum*, a precursor of what a good cliometric article would become. He used archival records of prices and wages to measure the decline in the value of money over time. Uncharacteristic of a typical cliometric argument, however, his research was conducted in an effort to protect his Cambridge fellowship.

In fact, the discipline originated largely as a revolt against classical theory, and in its early years, it shunned the use of statistical techniques. By the 1920s, the attitude toward theory and statistics began to soften. Cliometrics is the continuation of this theoretical-quantitative tradition now nearly a century old and fortified by advances in economic theory, the melding of economics with approaches from other disciplines, and the growth of computing power. The latter has had profound impacts on the ability to analyze and disseminate data.

The Economic History Discipline

Economic history as a formal discipline dates only to the late nineteenth century, though books on topics considered to be economic history existed well before this. Harte (1971) noted the existence of historical treatments of economic problems as early as the seventeenth century, regarding macroeconomic issues created by the fashion for "political arithmetic." Among the earliest works recognized today as economic history were by Sir William Temple (1672) and John Evelyn (1674). Both were written to address concerns over contemporary international political and economic rivalries.

In the UK, there were antecedents to the English historical economists. As early as the 1850s, Richard Jones, who taught political economy at Haileybury, was calling for greater attention to historical context in which economic activity took place. And in the following generation, John Kells Ingram and T. E. Cliffe Leslie, both in Ireland, were distinguished advocates of a more historical approach to economics.

Before economic history, there were political economics departments and history departments, and neither was a natural home for economic history. Political economics departments tended not to focus on history. And as Cole (1968) discusses in his overview of economic history in America, the general approach by scholars trained in history departments in the nineteenth century was to consider economic factors as only one cause of change and not always necessarily the most important one.

The first formal organization of economic history as an academic discipline appeared in Germany in the mid-nineteenth century. In part, this was the result of German interest in establishing the most appropriate economic policies to be followed by the developing states of that time. In turn, it became an academic

discipline in the UK at the end of that century largely as a result of social concern over the poverty of the urban industrial working class.[13]

In Germany, the approach to economics was altered by the publication of Wilhelm Roscher's *Grundriss* (1843). Roscher was a historical economist. Along with Friedrich List, Bruno Hildebrand, and Karl Knies, and later followed by Gustav Schmoller, they focused on economic activities and institutions in the past as well as in the present. Before the end of the century, they published much of their economic history research relating to England, though little of it was ever translated into English.[14]

The earliest form of economic history was narration fortified with the occasional bit of quantitative data. When formal economic history began to evolve in Germany and England in the late nineteenth century, however, leading scholars such as Schmoller in Germany and Sir John Clapham in England sought to develop it independent of standard economic theory. Clapham (1929) argued that the central problems of economic theory, though stated in terms of a particular historical phase, were in essence independent of history. With few exceptions, this general view permeated the writing of economic history for more than half a century. Data were only occasionally collected, and when they were, they were seldom manipulated or used to test mathematical propositions, and economic models were practically unknown.

By the 1870s, political economy had devolved into a methodological debate (Methodenstreit) about whether economics should be inductive (develop theories providing evidence of the truth) or deductive (gather facts leading to a certain conclusion). Three developments coming out of this debate helped pave the way for historical economics: political economy begot economics, which was less simplistic; the thorough investigation of social problems and their origins fostered an interest in the origins of economic-based issues as well; and the ideas of evolution generated by the explosion of "historical" natural sciences (think Darwinism).

Economic history emerged as a distinct discipline during the course of the revolt against the deductive theories of classical economics. Led by Roscher, Knies, Hildebrand, List, and Schmoller in Germany and by Leslie, Ingram, William Ashley, and Clapham in England, the original aim of the historical school was to replace what they believed to be the unrealistic theories of deductive economics with theories developed inductively through the study of history. They held that history was the key source of knowledge about humans and human organizations, and because it was culture and time specific, it could not be generalized over time or space; hence, general theories were useless. Their view was that economics was best approached from the vantage point of empirical and historical analysis, not abstract theory and deduction.

[13]Ashley (1893, 1927), Cameron (1976), Clapham (1931), Harte (1971), Kadish (1989), Maloney (1976), and Mitch (2010, 2011), all wrote about the evolution of the economic history discipline.

[14]See Reinert and Carpenter (2014) for an overview of German language economics texts written before 1850.

The historical school was a reaction against abstract theory, and it was highly critical of the method, fundamental assumptions, and results thereof. List (1877) was the mouthpiece for the rising nationalistic rivalry of Germany with England, where modern political economy, founded on the practices of abstract theory, ruled. He accused theorists of failing to recognize historical relativity in the stages of national economic development and the use of the productive forces of a nation.

Knies (1853) weighed in against the "absolutism of theory" and the economists, such as Ricardo and Smith, who he claimed based their entire deductive system upon the operation of self-interest for the greater good. Like the other historical economists, he demanded that the whole complex of motives and interests, varying among themselves in intensity at different occasions and times should always be taken into account when considering any type of human behavior. All members of the historical school, but chiefly Roscher, stressed the importance of the comparative method as essential to the understanding of any people or institutions.

Before Schmoller, the historical economists had focused their work more on the field of history than economics. The distinguishing characteristic of Schmoller's work was that it aimed to account for the origin, growth, persistence, and variation of institutions in so far as they affected the economic aspect of life. While he was trained in the historical school, he differed in his emphasis on economics, making him perhaps the first true economic historian.

Schmoller, who studied with Roscher, did not believe the social sciences were suited for any but the simplest mathematical treatment due to the plethora of social interactions that need be considered. He considered statistics, for those variables that could be measured, an invaluable auxiliary to historical research, but always questioned the source and interpretation of the data in relation to other cognate facts and theories. However, the fact that he was willing to go this far is what distinguished him from his mentor and the elder historical scholars.

In the 1880s, the historical school of economics began to diverge. The more conservative branch, the historical economists who followed in the line of the original historical school (the elder branch), abandoned the use of theory altogether. This line was headed by Adolph Wagner. It was an important and valuable work, but Veblen (1901) argued that this conservative historical economics was bereft of theory and hence not economics at all. The other branch was represented by Schmoller and was the wellspring of the first generation of American economic historians.

In the UK, Alfred Marshall and Francis Edgeworth represented the antithesis of the "elder branch" and were on the forefront of a movement to incorporate formal, mathematical models into economics. It was the publication of Edgeworth's book, *New and Old Methods of Ethics*, in 1877 that prompted Marshall to write him and say "There seems to be a very close agreement between us as to the promise of mathematics in the sciences that relate to man's action."[15] Marshall (1897) viewed mathematics as a method of constructing absolutely true arguments. Whereas the

[15]Weintraub (2002), p. 21

historians called for facts and figures, Marshall stressed the danger of committing oneself to them before the theoretical foundations had been established.

The interest in economic history began to grow in the late nineteenth century. This led to the creation of exams, which necessitated teachers. The adoption of economic history for examination in the History Tripos at Cambridge in 1875 led to the publication of the first English language textbook in the subject by William Cunningham in 1882. The History Tripos produced its first fully fledged economic historian, John Harold Clapham, in 1898.[16]

Cunningham's two seminal contributions to economic history were his lifelong efforts to advance the subject through the further work on his textbook (1882), which had five editions and grew to three volumes, and his vigorous campaign to achieve public and scholarly recognition for the approach of economic history (1892). He was a candidate for the Chair in Political Economy at Cambridge that went to Marshall in 1885. The two were antagonists for the remainder of their lives, which did nothing to promote the discipline of economic history.

In Cunningham's view, the election of Marshall to the chair signified that Cambridge was favoring an antihistorical approach to economics. Marshall's triumph within his own field represented the nearly complete victory of the deductive over the inductive approach to economics on the eve of the twentieth century.

Economic history set its first serious footings in 1895 when the London School of Economics (LSE) opened its doors. It was founded in opposition to the tenets of orthodox economics. As a result, economic history was an important presence from the beginning. The first Director of LSE was a young economic historian named W.A.S. Hewins. In 1901, it became the first British university to offer a degree in economics, and economic history became a possible specialty. The first teachers of the subject were Hewins and Cunningham.

In France, the Annales School, focusing primarily on late medieval and early modern Europe, prevailed. It was developed by French historians to stress long-term social history. The school has been highly influential in the use of social scientific methods by historians, emphasizing social rather than political themes. Stoianovich (1976) and Forster (1978) credit the functional and structural approaches to history of the *Annales* School with moving the study of history from storytelling to problem solving.

At the dawn of the twentieth century, it appeared that the attempt of the historical school to replace deductive theory with inductive theory had failed. In fact, the economics discipline was moving toward a more deductive approach. The movement to turn economics into a science, which grew out of the rising stature of the natural sciences, gave way to a new understanding that for economics to take its place at the pinnacle of the social sciences, it needed to formalize and rely more on mathematical models.[17] This set in a period of waning of the historical movement and a historical low point in the discipline.

[16]See Tribe (2000).

[17]For a history of the mathematical movement in economics, see Weintraub (2002).

After WWI, economists became less theoretical and more statistical in their approach. The creation of the National Bureau of Economic Research, which is discussed below, is an example. This movement brought economists and historians a bit closer together. As an added benefit, it forced historians of all stripes to be less tolerant of loose, unsupported generalizations. The culmination was the creation of the first dedicated economic history society, the *Economic History Society*, organized in the UK in 1926, followed in 1927 by the first dedicated economic history journal, the *Economic History Review*.[18]

Economic History in America

American academics were from an early day interested in data. The *American Statistical Association* was launched in 1839, its membership consisting of individuals who paid serious attention to compiling time series data. By the late nineteenth century, numerous state and local historical societies as well as the *American Antiquarian Society* (founded in 1884) could boast of vigorous data accumulation efforts. The federal censuses had flourished from 1790 onward, with attention to economic measurements increasing after 1850. Among the earliest American publications in the subject of economic history along these lines included Freeman Hunt, *Lives of American Merchants* (1858); James L. Bishop, *History of American Manufactures from 1608 to 1860* (1861); and Thomas P. Kettell, *One Hundred Years' Progress of the United States* (1870). And even earlier, there were accumulations of quantitative data in time series form, such as Timothy Pitkin, *Statistical View of the Commerce of the United States* (1816), and Adam Seybert, *Statistical Annals* (1818).

There was no specialized outlet for the publication of research in economic history prior to WWI, but more mainstream economics journals did occasionally publish research in the field. Among the earliest economic history articles were Charles F. Dunbar's "Economic Science in America" in the *North American Review* in January 1876 and Guy Callender's (1903) *Quarterly Journal of Economics* article on early US transportation and banking.

Harvard was the incubator of economic history in the USA. Dunbar, professor of political economy – the first in the USA to be so titled – and founder of the Harvard economics department, along with his colleague Frank W. Taussig, taught courses titled "Financial History of the United States" and "The Tariff History of the Country." In 1882, J. Laurence Laughlin, who later would found the University of Chicago economics department, and Taussig combined to offer a course on US banking and financial legislation, and Laughlin taught a history of political economy course. The following year, Dunbar offered "Economic history of Europe and America since the 7 Years' War," and Taussig taught "The history of tariff legislation." In 1888, he published the first edition of his *Tariff History of the United States*.[19]

[18]See Barker (1977), Berg (1992), and Harte (2001) for a history of the *Economic History Society*.
[19]Mason (1982)

In 1892, Dunbar and Taussig were responsible for the hiring of William J. Ashley to the first chair of economic history in the world. Ashley's reputation as an economic historian was made with the publication of his history of the English woolen industry (1888).

Ashley studied under Arnold Toynbee, the Oxford-based scholar who coined the term "industrial revolution," and Schmoller at Berlin. In 1885, he left Oxford to accept the position of Professor of Political Economy and Constitutional History at the University of Toronto and published his great work, *An Introduction to English Economic History and Theory.* Volume two came out in 1893, the year after he moved to Harvard, where he remained until 1901. Ashley (1927) argued for a course in economic history alongside the general economic theory (i.e., political economy) course. Later in his career, he promoted statistics, which he felt would become an integral part of every important economics department.

Ashley was strongly influenced by German scholarship, as was his Harvard successor, Edwin F. Gay. Gay went to Germany in 1890 to do graduate work in medieval and ecclesiastical history at Leipzig and then Berlin, where he attended the Schmoller economic history seminar in 1893 and became a convert. He wrote little but imparted the standards and techniques of the German academy – the methodological principle of sticking to the facts, of telling history as it really was – on his colleagues and students. Gay used a multidisciplinary approach when teaching. It was the same principle he learned from Schmoller, who was famous for his saying: "Aber, meine Herren, es ist alles so unendlich compliziert," to convey his insistence that the big picture always had to be kept in mind. To account for the complexity, Gay taught his students that hypotheses had to reflect several approaches, including social, political, international, and psychological, as well as economic. Dunbar, Ashley, and Gay had brought over the German concept of stages in development, the notion of a particularly important "take-off" era which Toynbee (1884) had labeled the "industrial revolution," and even many of the criticisms of the industrial system – a particular focus of Toynbee's writings, which were soon to energize the "muckrakers" and subsequent social reformers.

Gay produced a noteworthy assemblage of doctoral candidates including Chester Wright, Norman S. B. Gras, Abbott Usher, Julius Klein, and Earl J. Hamilton, all of whom manifested in one way or another their perception of economic (or later business) history as an adjunct of economic theories. Wright (1941) attempted to carry the relationship farthest as in his *Economic History of the United States*, as did Gras (1962) in his efforts to extend the Germanic scheme of economic stages to capitalism. But it is Frederick J. Turner (1893) of Wisconsin who may be credited with the first serious American contribution to economic history with his work on the American frontier.

In the first decades of the twentieth century, economic history spread across departments, if not in influence within the discipline. Chairs in economic history were created at many leading institutions, but the discipline had difficulty gaining traction due to the lack of a dedicated journal or society to promote its research. Contributing to the problem was the growing fascination with the scientific method and its potential applications to economics, exemplified by the theoretical approach

espoused by Marshall in the UK and soundly rejected by economic historians. In the USA, this manifested itself in the growth of economic forecasting. As Friedman (2014) details, this eventually led to the creation of the *National Bureau of Economic Research* (NBER).

The NBER

Wesley C. Mitchell believed that economic theories were not immutable laws, but rather that they depended on context and evolved over time. He was interested in developing the field of economics into one that took into account what human beings actually did. This was the influence of his mentor at Chicago, Thorstein Veblen. His *Business Cycles* (1913) was an assemblage of business data and his comments on the various series, which seemed to forecast a new theory of business cycle movements. Arthur Burns considered it the key economics text between Marshall's *Principles of Economics* (1890) and Keynes's *General Theory* (1936).[20]

New areas of exploration gave evidence of continued advance in research techniques after WWI. The business cycle provided a field exciting by reason of its relative novelty. Arthur Cole (1930) attempted to extend this analysis backward using antebellum time series data as early specimens of Warren Persons's (1919) A, B, and C curves. At Columbia's Council for Research in the Social Sciences, Gayer et al. (1953) collaborated on a somewhat comparable study using British data from 1790 to 1850. American economic historians had thus made considerable strides in the handling of statistical apparatus.

During his service to the US government during WWI, Edwin Gay became convinced of the need for better economic statistics. He and Mitchell headed the Central Bureau of Planning and Statistics, responsible for the gathering and reporting of statistical data. Together they helped found the NBER to stimulate the collection and interpretation of historical statistics.

Mitchell served as research director at the NBER from its founding in February of 1921 until 1945. He gathered tremendous amounts of empirical economic data in order to draw inductive generalizations from it. His vision was to improve society through the use of expert analysis and statistical investigation. He believed that disseminating scientifically objective data and improving knowledge about business cycles could aid government and business leaders in enacting countercyclical policy that would mute the business cycle.

He combined his historical approach to understanding cycles, which he saw as a global phenomenon, with an urgent call for more data collection from around the world. The NBER was central to this data collection effort and served as a sort of haven for statistical economists. The mission of the NBER was to gather empirical information of many kinds about the American economy in order to create a robust foundation for theoretical generalizations.

[20]Friedman (2014), p. 174

After WWI, this expansion and increased proficiency in the use of statistical materials took attention and resources away from economic history, and it began to lose resources and graduate students to "applied" fields such as international finance, statistics, and the business cycle. The Great Depression only made things worse. Enrollment in economic history courses held steady since major universities required a semester of it in their graduate programs, but writing it as a field declined. Norman Gras (1931) gloomily summarized the state of economic history as being neglected by universities, who regarded it as a very special subject, but one suffering a lack of intellectual resilience.

The NBER ultimately served as a catalyst for the change in emphasis from narrative to quantitative studies in economic history. Mitchell, Simon Kuznets, Arthur Burns, Solomon Fabricant, and Harold Barger produced a series of quantitative descriptions of American economic growth while at the NBER that measured growth as far back as the 1870s. The culmination of this quantitative approach to descriptive economic history was the *Historical Statistics of the United States* (1960) produced by a committee of scholars and sponsored by the Census Bureau.

Over time, economic history presented itself as empirical and multidisciplinary. Empirical in that it dealt with the facts of the past. The facts could be quantitative, as the NBER emphasized, or qualitative (as the German school believed was the responsibility of economic historians). It was also empirical in that economic historians saw history as a laboratory where they could test economic hypotheses.

Business History

The post WWI era also saw the blossoming of the field of business history. Wallace B. Donham initiated the study of business history at the Harvard Business School when he succeeded Edwin Gay as dean in 1919. Gay had encouraged some of his students to pursue the subject. Donham was more ambitious than merely directing graduate students toward the subject. He helped create the *Business History Society* in the early 1920s and raised funds for the endowment of a chair in business history that was filled by Norman S. B. Gras and oversaw the publication of the *Journal of Economic and Business History*, the first American journal dedicated to economic history and the first in the world to combine it with business history. A falling out between Gras and Gay eventually led to Gras's isolation from economic history, largely populated by Gay's progeny, and the gradual drift of business history into a separate field of study.

The differences between business history and economic history are many. Cole discusses them (1945) and Gras (1962) enumerates seven of them, most prominently that economic history comes from economic theory, whereas business history uses economic theory, but also psychology, politics, and sociology, among other disciplines, and none is more important than any other.

Gras, in true Schmoller fashion, conducted detailed research in the archives of corporations; and under his leadership, the genre of business history took shape as a narrative form. His colleague at Harvard, Arthur H. Cole, undertook to sponsor

research on the role of the entrepreneur in economic history, about which more will be said later.

Like his mentor Gay, who trained the first generation of American economic historians, Gras was responsible for training a generation of business historians. He and his followers believed that firms mattered because they were different (i.e., heterogenous) and not the homogenous profit maximizing entity modeled by economists. He defined the subject matter and approach that research in the discipline would take and wrote the first general treatise in the field (1939). He edited the *Harvard Studies in Business History* and served as editor of the *Bulletin of the Business Historical Society* from 1926 to 1953. In 1954, it was renamed the *Business History Review.*

The Depression was not kind to the *Business History Society.* Funding evaporated and the Harvard Business School had to curtail activities to the bare minimum. Business history switched from a general study to one of company histories and individual biographies of businessmen, for which funding was easier to obtain from private sources.

Another major contribution of business history was its focus on entrepreneurship. The *Research Center in Entrepreneurial History* (1948–1958) at Harvard was led by Arthur Cole and supported by a grant from the Rockefeller Foundation as part of the foundation's drive to support and encourage the study of economic history. The center was multidisciplinary in its approach and brought together sociologists, economists, and business historians including luminaries such as Joseph Schumpeter, Thomas Cochran, David Landes, and Alfred D. Chandler. The Center was distinguished by its willingness to address big issues related to explaining the role of entrepreneurship in economic development.

Cole focused on entrepreneurs as the unifying theme under which all issues (growth, change, development, etc.) could be understood. From the beginning, the focus on the center's study of entrepreneurship faced the problem of identifying just what entrepreneurship was. This problem would plague the center for its entire existence. The Center's grants dried up and it ceased to exist in 1958. Before it did, it launched *Explorations in Entrepreneurial History*, which was originally conceived in 1949 as an in-house organ and was published as such until 1958. It was reborn as a "second series" in 1963, renumbering with volume 1, number 1, and eventually renamed *Explorations in Economic History* in 1969.[21]

The *Committee on Research in Economic History* (CREH)[22] was launched in 1941 with the intellectual promotion and financial aid of the Rockefeller Foundation, which seeded it with a $300,000, 4-year grant. The CREH members were united in their worry that mathematical, technical economics would take over the discipline. Their primary concern was that perspective would be lost and current problems would lose their historical context. The CREH introduced and gained nearly

[21]Hugh Aitken (1965) edited a volume of some of the best work appearing in *Explorations in Entrepreneurial History.*

[22]See Cole (1953, 1970) for a history of the CREH.

universal support for an examination of the role of government, especially state government, in the period before 1860. It also underwrote the research for the Census Bureau's volume of *Historical Statistics of the United States*.

The *CREH* lacked a unifying theme until Cole introduced entrepreneurship as a field of potential interest. The eclectic and disjointed nature of the research carried out under the grant was frustrating to Rockefeller Foundation committee members Kuznets and Robert Warren. In 1942, Kuznets resigned over the issue, but was talked into staying until the end of the war. Warren was more proactive, lobbying against renewal of the grant in 1945, going so far as to question whether there was a justification for maintaining economic history as a field separate from economics. Despite such protestations, the grant was approved for a 5-year extension. Ultimately, the *CREH* was not refinanced, but instead the funds were given to the *Center for Entrepreneurial History*, headquartered at Harvard under the direction of Cole.

Founding of the EHA

The first hint of a move to create an American economic history society came in a letter from Earl J. Hamilton to Anne Bezanson urging her to raise the issue of the formation of an American *Economic History Association* with her mentor, Edwin Gay, widely regarded as the most influential American economic historian of the first half of the century.[23] Gay, who would ultimately become the first president of the *EHA*, was a well-respected figure in the field. He had retired from Harvard in 1936, where he had trained many of the current crop of economic historians, and was now located at the Huntington Library in Santa Monica, CA. Despite his distant location on the West Coast and his retirement from academia proper, he was still a dynamic force, widely considered to be the keystone to the creation of an American economic history organization. In his letter to Bezanson in May of 1937, Hamilton said, "... you and I know that he is the one man who would have a good chance to succeed in this difficult undertaking."[24]

The formation of a US economic history society was spurred in part by fear. Edwin Gay's students, who dominated the American field of economic history, had learned the empirical, inductive approach to economic history, and when it was threatened with extinction by the growing mathematical approach, they sought a refuge. Hamilton, a Gay protégé, was the first to attempt a rescue. In 1937, he tried to rally colleagues to create an economic history association in the USA. He feared that the *American Economic Association* (AEA) was planning to eliminate economic history sessions from their annual meetings. The endeavor failed, in part due to the concern that it would cannibalize the UK *Economic History Society* and result in two weak sisters. A renewed attempt succeeded a few years later.

[23]There are several histories of the EHA, among them Aitken (1963, 1975), Clough (1970), Cole (1968, 1974), de Rouvray (2004a), Haupert (2005), and Heaton (1941, 1965a, b).

[24]EHA archives

The outbreak of WWII, which was expected to lead to a decrease in scientific exchanges between the USA and Europe, was the factor that finally led to the formation of an American economic history society. At the *American Historical Association* (AHA) meetings in Washington in 1939, Herbert A. Kellar gathered a group of interested scholars and decided to form the *Industrial History Society*. That same month in Philadelphia at the AEA meetings, Hamilton convened a steering committee chaired by A. H. Cole, including Herbert Heaton (vice chair), Hamilton, and Anne Bezanson (secretary). They were charged with forming an organization independent of any existing society, cooperating with existing organizations, enrolling members, and planning for the publication of a journal.

The group was cautious in its approach, fearful of encroaching upon the membership and damaging the existing societies of mutual interest. Their first objectives included the arrangement of meetings in collaboration with the historians in New York and of the economists in New Orleans in December 1940 and a survey aimed at gauging interest in an *Economic History Association*. Bezanson wrote to more than 500 potential members, receiving positive responses from more than 400. In response, Hamilton arranged to organize sessions in New Orleans, while Heaton would do the same in New York.

On December 27, 1940, the *EHA* debuted at a joint session with the *American Historical Association* in New York City with a session on "The Business Cycle and the Historian," chaired by Herb Feis. The following day, they conducted their first solo session with Professor A.P. Usher chairing "The Next Decade in Economic Historiography." A business meeting followed during which the steps to form the Association were formalized. Edwin Gay was named its first president and Shepard B. Clough secretary-treasurer, and arrangements were made to secure publishers for the new journal. About a month later, E. A. J. Johnson was named editor, Clough associate editor, and Winifred Carroll assistant editor of the new *Journal of Economic History*. The *JEH* debuted in 1941, barely 4 months after the naming of the editor. Harold Innis was the chair of the first stand-alone *EHA* meeting, held in the fall of 1941 at Princeton. On the 30th, in New Orleans, there was a joint session with the *American Economic Association* followed by a luncheon and business meeting, which endorsed the actions of the steering committee. Thus, the Association was born – in two places, over a period of 5 days.

Gay reluctantly agreed to serve as the first president of the *EHA*. He clearly had the skills to do the job, having previously served as president of the *National Bureau of Economic Research* from 1919 to 1933, the *American Economic Association* in 1929, and the *Agricultural History Society* (AHS) in 1934. His organizational skills, which were so eagerly sought, were well known. He was cofounder of both the NBER and the Harvard Graduate School of Business Administration, serving as its first dean. His academic career began with an appointment to the economics faculty at Harvard University in 1902. He went on to become chair of the department and, more importantly for the future of economic history, a mentor to an entire generation of economic historians. His reluctance came from the fact that he had retired to California for the express purpose of reducing his administrative responsibilities in order to concentrate on research.

At the first stand-alone *EHA* conference, John Nef (1941) took on the lofty duty of describing the responsibility of economic history, noting that the creation of the EHA at such a critical time came with obligations as well as privileges. First and foremost, the association had the duty of considering its objectives, if, as seemed probable at the time, Western Civilization had reached the end of an epoch.

The *Economic History Association* became a trendsetter in 1941 when it held its first annual conference in September. The usual pattern was for academic societies to hold their conferences the week after Christmas. The steering committee wanted to avoid the prospect of competition with its potential members, many of whom held memberships with either the AHS or the AHA, both of which met during the traditional Christmas break period. In addition, most members were also members of the AEA, which regularly met over the break. The perfect solution seemed to be to move the *EHA* meeting to another timeslot. Early September was chosen because it was before classes started at most universities, and it would avoid competing with related societies and the glut of holiday meetings already crowding the calendar.

By 1941, Gay felt that the work of the historical economists had not been able to displace the "theoretical school," but did modify it. By then, the use of the deductive method had become more guarded, and the practitioners of this "dark art" had increased the range and depth of their contemporary observations, and their viewpoint had expanded to become less individualistic and more social. In conclusion, he called for the reunification of economic history and theory, noting that the economic historians knew a great deal about the long trends of productive energies and social pressures leading to economic growth, which could be combined with the tools of the theorist to lend greater insight into the growth process. Far from incompatible, he felt that true philosophical objectives and the careful assembling of data were complementary.

E. A. J. Johnson (1941) fretted that while the number of tools available to economic historians was increasing, there was still too much work in economic history that was a haphazard gathering of facts with little appraisal of whether they actually shed any light on economic development. With so much to do to have a more complete understanding of the past, he felt economists should focus only on the most important tasks, such as productivity, capital formation, changes in income, regulation, consumption, and its effect on the entire structure of the economy. All of which, he argued, could be advanced by employing the most efficient theoretical tools at the disposal of the economic historian. He cited Leo Rogin's (1931) work on farm productivity as an example of measuring productivity (in a nonstatistical age), and how its changes, brought about by evolving technology, could be measured.

Cochran (1943) saw the use of limited and modest economic hypotheses, such as monopolistic competition or location theory, as more useful tools for practical research than the sweeping assumptions of the historian. He felt that specific limited propositions could be the first steps in applying to the data of social science a logical technique, similar to that developed in the natural sciences for stating and testing hypotheses.

So as the EHA was in its infancy, formed in part as a defense against the encroaching "mathematicization" of the discipline, the seeds of the cliometric

movement were being sown. It would be the next generation of economic historians who propelled that movement forward.

The New Economic History Movement

Arguing against those who cliometricians would later label "old" economic historians (the likes of Anne Bezanson, Arthur Cole, Edwin Gay, Harold Innis, and Earl Hamilton, the founders of the EHA), Kuznets claimed that little would be gained from a study of the past unless it was systematic and quantitative. According to him, this was the only way to weigh the relative effects of factors and events. The reason for the small quantity of quantitative work in economic history was due to the extraordinary effort necessary before the computer to sift and classify quantitative information and the relatively recent development of statistical theory and techniques capable of handling these problems.

After WWII, with the American economy booming, economists gained cachet. Economics with its rigorous models, tested from an abundance of numerical data by use of advanced, mathematically expressed formulae, came to be regarded as the paradigm of the social sciences. William Parker (1986) quipped that if economics was the queen of the social sciences, then economic theory was the queen of economics, and its handmaiden was econometrics.

At the same time as this increasingly technical focus, economists were increasingly interested in the determinants of economic growth and what they saw as the widening gap between the so-called developed and underdeveloped regions of the world. They saw the study of economic history as a source of insight into the issues of economic growth and economic development and the new quantitative methods as the ideal tools for analysis.

Norman Gras (1962) had a different take on economic history. He believed that it was showing its old age and declining in influence while business history was in its ascendency. His primary evidence for this claim was the decline in Germany, the incubator for the discipline, where he thought economic history had lost prestige at the expense of general history. Time would prove that Gras had a point. The rise of the cliometric movement in the USA was not mirrored in Europe, and when it did finally begin to make headway, it was in the UK before the continent.[25]

The generation of economists who were trained in the postwar decades found ways to mesh mathematics and economics, although the idea that economics should appropriate ideas from mathematics was itself contested, especially by economic historians. By the 1960s, the battle was over and the results were clear: economics was a "science," constructing, testing, and applying technically sophisticated models. Econometrics was on the rise and economic historians were divided

[25]Cliometrics did not dominate the European scene as early or as completely as it did in North America. See Tilly (2001) for an overview of German clio, Grantham (1997) and Crouzet and Lescent-Gille (1998) for France, and Floud (2001) for the UK.

between those who abhorred it, and those who embraced it. The former faded in influence and their followers retreated to history departments.

The "new" economic history can be dated to the 1957 joint meeting of the *EHA* (founded in 1940 by "old" economic historians like Gay and Cole) and the Conference on Research in Income and Wealth (under the guidance of the NBER). In particular, two joint papers by Alfred Conrad and John Meyer (1958) constituted the manifesto for the new era. The first paper, on methodology, explained what scientific method was really all about and how it applied to economic historians. Parker (1980) cites the second paper as one of the most influential in the evolution of economic history. It added enormous force to the methodological prescription by claiming to follow it in an analysis of the profitability of slavery on the eve of the civil war. The analytical method, the data, the economic and accounting framework, and the choice of slavery as a subject were to have vast consequences for the next generation of economic historians. The meeting produced a volume edited by Parker (1960), which included such path-breaking work as Robert Gallman's estimates of commodity output, the farm gross product and investment series produced by Marvin Towne and Wayne Rasmussen, Douglass North's balance of payment estimates, and Stanley Lebergott's wage series.

Goldin (1995) noted that economic historians who came before the cliometric revolution distinguished themselves by mastering a wide array of facts and knowledge of institutions. But without the rigor of theory and econometrics, they could not avoid the occasional faulty reasoning. Important data were overlooked without the ability to properly test theories.

de Rouvray (2004b) argues that the timing of the cliometric movement corresponded to the success of Kuznets's quantitative growth studies; a reflection of the infatuation economists had developed for the national accounting approach. This predisposed them to view the past through this same lens and altered their definition of historical evidence. Fogel (1965) agreed, crediting his mentor Kuznets as the primary inspiration for the work of the new economic history.

But cliometrics is not identical to the Kuznets approach. Cliometricians are eager to apply neoclassical models to even marginal historical issues, which would not have been a priority of Kuznets, who was focused on the bigger issue of economic growth. But the emphasis on quantification and measurement and the decreased reliance on qualitative measures were certainly in synch with the Kuznets methodology.

Kuznets may have inspired the cliometric movement, but it was Robert Fogel who reunified economics and history. He used the latest techniques of modern economics and gathered reams of historical data to reinterpret American economic growth in sectors as diverse as railroads, slavery, and nutrition. Rather than conjecture about the causes of growth, he carefully measured them. He pioneered the use of large-scale cross-sectional and longitudinal data sets harvested from original sources to examine policy issues. McCloskey (1992) credited his contributions with opening new ways to the past.

Fogel's breakthrough work was *Railroads and American Economic Growth* (1964a). At the time of its publication, economists believed they had established

that modern economic growth was due to certain important industries having played a vital role in development. Fogel set out to measure this impact, which he did with extraordinary precision. He constructed a counterfactual to highlight the contributions of the railways to the growth of the American economy. The result was not what economists or historians expected. He famously found that the railroad was not absolutely necessary in explaining economic development and that its effect on the growth of GNP was minimal. Few books on the subject of economic history have made such an impression as Fogel's. His use of counterfactual arguments and cost-benefit analysis made him an innovator of economic historical methodology, but not universally loved. Fritz Redlich (1965), for example, accused him of "fictitious quasi-history" for his emphasis on the counterfactual. He acknowledged the value of counterfactual analysis, but thought it was social science research, not historical.[26]

This approach formed his major works on slavery and demography as well.[27] Fogel recognized early in his career that to answer such questions much greater use had to be made of quantitative evidence, so he mastered the most advanced analytical and statistical methods available and successfully employed them in his research. Herein was the difference between the "old" economic history and the "new:" the use of newly created data series and cutting edge techniques – made more useful, applicable, powerful, and easy to replicate and reconsider, with the growth of computing power, to bring a finely focused eye on a problem.

Fogel was not the first to use a form of identifying opportunity costs known as counterfactual analysis, but he was the most extensive user of it and became famous (infamous?) for his use of the technique in his landmark railroad study. Counterfactual analysis is the idea of determining the impact of an event or factor by considering what would have happened in its absence. Before Fogel, the concept was proposed by Fritz Machlup (1952), Meyer and Conrad (1957) and Conrad and Meyer (1958).

Like Fogel, Douglass North made his initial impact with research on the American economy. However, whereas Fogel disputed the importance of one sector of the economy in explaining economic growth, North focused on the impact that individual sectors could have in explaining economic outcomes. He sought to explain the causes of growth in the antebellum American economy. Starting with an export-based model he had previously formulated, he showed how one sector (the cotton industry) could stimulate development in other branches, ultimately leading to specialization and interregional trade.

North also focused on quantification early on, measuring the impact of decreased transoceanic shipping costs. His surprising finding was not that shipping costs decreased, which was widely recognized at the time, but that it was not technology, so much as institutional changes, such as a decrease in piracy and faster turnaround times in port, that was the source of the decreased costs. This focus on institutions would become North's mantra for the remainder of his career.

[26]For a different view of counterfactuals, see Engerman (1980).

[27]See Fogel and Engerman (1974) and Fogel (2000), for example.

Goldin (1995) notes that the cliometric revolution pitted young Turks, outsiders, "theorists" as they were called by the old timers, against those "old" economic historians who were more likely to be historians and less likely to rely on quantitative methods. They accused the newcomers of bringing economic theory to history without a proper understanding of the facts (a familiar battle cry). Cochran (1969) characterized the disagreement as one about the choice of models. The old guard claimed that realistic models had to be too highly generalized or too complex to allow the assumption of mathematical relationships. The "new" economic historians, however, were primarily interested in applying operative models to economic data. There was a difference in method between new and old economic historians that could not be ignored. The models preferred by the new economic historians were quantitative and mathematical, while those used by "sociological economic historians" tended to be narrative.

The schism was not just about methodology, but also orthodoxy. Cliometricians were using their new tools to overturn some long-held beliefs. Among the accepted wisdom they overturned was that railroads were indispensable to economic growth (Fogel 1964a), that they were built ahead of demand (Fishlow 1965), that President Jackson caused the financial panics of the 1830s (Temin 1969), and that slavery was unprofitable (Conrad and Meyer 1958).

Andreano (1970) collected a series of articles originally published in *Explorations in Entrepreneurial History, Second Series* that he felt reflected dialogue that had been taking place during the 1960s between economists and historians on the methodology of the "new" economic history. But the first attempts to bring together a body of work representative of the "new" economic history were the publication in 1971 of *The Reinterpretation of American Economic History*, a collection of essays edited by Fogel and Engerman, and Davis et al.'s *American Economic Growth: An Economist's History of the United States* (1972).

The reception of the "new" economic history was chilly by some due its perceived threat to traditional historical methods, but warmly welcomed by others for the possibilities it promised. Hughes and Reiter compared the computational effort it took them in their steamships paper (1958) to that of Newmarch (1857), who compiled more than 13,000 individual pieces of information and then performed a mere three arithmetical calculations, but all by hand. His efforts represented a lifetime of work, while the steamship paper was but one of many "big data" projects cliometricians would explore with the power of new techniques and technology.[28] The steamship study had a total of nearly twice as many observations (as the Newmarch data set) on 1945 punch cards, but the computer then did all of the computational work.

[28]For example, they cited four additional data-processing studies in economic history carried out at Purdue in the late 1950s that had developed entirely new statistical series and could not have been conducted without the latest technology or mathematical models: Lance Davis's textile studies (1957, 1958, 1960) and the Davis and Hughes exchange rate study (1960).

Cliometrics got the platform it needed to take off when North and Parker were named editors of the *Journal of Economic History* in 1960. Robert Whaples (1991) found that the journal led the *EHA* meetings (a selection of whose papers were represented in the *Tasks* issue) in the new cliometric methods. From 1956 to 1960, 10% of the papers were "clio," but only 6% of the *Tasks* articles featured cliometrics. From 1961 to 1965, the numbers were 16% and 15%; from 1966 to 1970, 43% and 18%, respectively; and from 1971 to 1975, they skyrocketed to 72% in the journal and 40% at the conference. This reflects the difference in editorship of the journal (North and Parker, proponents of the "new" economic history) and leadership of the *EHA*, whose presidents were of an older, less quantitatively, and decidedly not "new" economic history background.

The Shortcomings of Clio

Clio has not had an uncheckered history. Its rise has led to a rift between economists who practice cliometrics and historians who practice economic history without the use of the formal models, which they argue miss the context of the problem and have become too enamored of statistical significance at the cost of contextual relevance. Boldizzoni (2011) famously attacked cliometrics, focusing his sharpest criticism on the quantification of history at the perceived expense of its humanity. On the other side, cliometrics has lost some of its significance with economists, who do not see it as anything more than another application of economic theory. While applied economics is not seen as a bad thing, cliometrics is not seen as anything special, just applying theory and the latest quantitative techniques to old data instead of contemporary data.

As early as 1986, Parker observed that what was lost in the move to theory and econometric emphasis was the humane interest of the old British political economy and social welfare and the idealistic German historical economist's concern for the whole society – i.e., the Schmoller perspective. At the same time, Alex Field (1987) cited problems from another flank. Whereas the "new" economic historians had to fight to prove their technical skills belonged in the study of history, by the late 1980s, there were no more "old" economic historians left to challenge. Instead, the challenge came from the other side, where economic theorists questioned what value cliometricians added to departments strapped for resources. Most economists possess the same or even more sophisticated technical skills, which can be applied to any data set, contemporary or historical.

Even within the cliometric camp, there were those who cautioned against the over reliance on technique. In the early days of the cliometric movement, Jonathan Hughes (1966) warned that cliometrics is unkind to those who confuse ends and means in the pursuit of historical understanding. And Lance Davis (1968), though praising the new economic history for its contributions to both economics and history, criticized indiscriminate uses of theory applied to history. He argued that the greatest failure of the new economic history was the rush by some to apply any theory, even if irrelevant, to a historical issue or, even worse, a handy data set,

without understanding the context of the historical situation. And North (1965) warned that too much of the new economic history was dull and unimaginative because there was too much emphasis on econometric techniques as a substitute for theory and imagination.

Clio's Accomplishments

Clio's moment in the spotlight, or 15 min of fame, as Sam Williamson (1994) coined it, came at the 1964 AEA meetings. William Parker organized a session on "Economic History: It's Contribution to Economic Education, Research, and Policy," featuring papers by Douglass North (1965), Robert Fogel (1965), Barry Supple (1965), Richard Easterlin (1965), Robert Gallman (1965), and Rondo Cameron (1965), with comments by Evsey Domar and R. A. Gordon (1965). The session drew a crowd estimated at 200, generated lively discussion, and put cliometrics in a national spotlight that it had never previously experienced.

Fogel (1964b) highlighted the changes in economic history that justified its being "new." It was not a change in subject; they still remained interested in the description and explanation of economic growth. It was the approach to measurement and theory that was new. Economic history always had a quantitative dimension. But much of the past work had been limited to the simple organization of data contained in government and business records. While continuing this pursuit, the new economic history placed its primary emphasis on reconstructing measurements and organizing primary data in a manner allowing them to obtain measurements that were never before possible. It thus followed that the most critical issue in the work of the new economic historians was the logical and empirical validity of the theories on which their measurements were based.

The new economic historians made use of the whole gamut of economic theory and statistical models, and the measurements they obtain yielded considerably more precise information than previously available. The perfect example of this was Fogel's railroad study.

The publication of *Railroads* "represented a very major milestone – it was as if we now had proof that we had left the bumpy and unpaved dirt road of the first few years and could see ahead a straight and well-paved highway into the future," says Lance Davis (2014) in his review as part of Project 2000. The publication of Fogel's railroad study generated an entire subdiscipline of parallel studies and, more importantly, provided a methodological foundation for the systematic study of economic history and long-term economic growth.

Railroads showed how well economic history could benefit from the careful application of theory and econometrics. The work immediately generated substantial controversy, and even today some quibbling over minor details occurs. However, time has failed to overturn Fogel's major conclusions: that per capita income growth would have been set back only a few months had the railroads never been invented, and there was no other industry that was likely to have been more important than the

railroads. Since its publication, the great majority of economic history has been written by scholars employing those basic economic and econometric tools.

Basman (1970) and Field (1987) defended the growing reliance of economic historians on quantitative methods. Cliometrics advocates replacing imprecise qualitative judgments common in narrative history with more precise quantitative estimates. In this way, it does a great service to economic history and economics in general by taking a closer and better informed interest in the formulation and testing of explanatory economic models. They also tried, where possible, to move beyond simple description and informal explanation in historical scholarship to the investigation of causal relationships linking exogenous and endogenous variables. Cliometricians shifted attention from documentary to statistical primary source material and emphasized the use of statistical techniques to test posited relationships among variables.

It is the lack of relevant data more than the lack of relevant theory that is often the greater problem in research. In this way, economic historians have made some of the greatest contributions to the fields of economics and history by discovering and compiling new data sets that can then be used by future researchers to better understand the evolution and growth of economies over time.[29]

Perhaps, the most influential book to come from the new economic history is North's *Economic Growth of the United States, 1790–1860* (1961). What it lacked in thorough empirical research, it more than made up in the way it clearly demonstrated how an economic model, theoretically sophisticated yet nonmathematical, could be employed to explain the organization and evolution of the various regions of the American economy over several decades.

In North's early work (1961, 1966), he focused on the standard neoclassical explanations for economic growth (technology, human capital, technological change). But when he began to study European economic history, he concluded that the neoclassical model was not able to explain the kind of fundamental societal change that had characterized European economies for the past 500 years. This led him down the path of what would become the new institutional economics, making him an early proponent of two different revolutionary schools of economic practice: cliometrics and new institutional economics.[30]

In a number of books, beginning with *Institutional Change and American Economic Growth* (1971, with Lance Davis), North demonstrated the importance of the role played by institutions (including property rights) on economic development. In *Institutions, Institutional Change and Economic Performance* (1990), he posed the fundamental question of why some countries are rich and others poor. His conclusion was that institutions are a major determinant in the profitability and feasibility of economic activity. The greater the institutional uncertainty, the greater the transaction costs and the greater the drag on economic growth and development.

[29]The listing of all such databases publicly available is massive; for an example of the size and scope of such endeavors, see the list of databases on eh.net.

[30]See Basu et al (1987), Galiani and Sened (2014), and Menard and Shirley (2014) for discussions of North's role in the new institutional economics movement.

These views were a novel approach in both the history and development fields. Typical economic growth models focused on technological change and capital accumulation, assuming zero transactions costs and ignoring institutions altogether. He maintained that new institutions arise when groups in society see a possibility of profiting that is impossible under prevailing institutional conditions. If external factors make an increase in income possible, but institutional factors prevent it, then new institutional arrangements are likely to develop. Other pioneering work emphasizing the importance of institutions included R. C. O. Matthews (1986) and Oliver Williamson (1985).

The crown jewel of Clio's accomplishments came in 1993 when the Nobel Prize in economics was awarded to Robert Fogel and Douglass North. The Royal Swedish Academy of Sciences announced the award of the Bank of Sweden Prize in Economic Sciences in Memory of Alfred Nobel jointly to Professors Robert W. Fogel and Douglass C. North "for having renewed research in economic history by applying economic theory and quantitative methods in order to explain economic and institutional change."[31] As the committee pointed out, both men were leading figures within the field of "new economic history," which is now known as cliometrics.

Conclusion

Economic historians have contributed to the development of economics in many ways, combining theory with quantitative methods, constructing and revising databases, and discovering and creating entirely new ones. This has made it possible to question and reassess earlier findings, thus increasing our knowledge, refining earlier conclusions, and correcting mistakes. In addition, this field has added greatly to our understanding of economic growth and development, affording the economic historian the valuable element of time as a variable, which the traditional theorist does not enjoy. The use of history to examine economic theory has deepened our knowledge and understanding within fundamental areas of research as to how, why, and when economic change occurs. It is perhaps in this area where the greatest contributions of economic historians have appeared.

By merging economic history with modern techniques, cliometricians have not ended economic history but elevated it. The continuing evolution of technology has made a tremendous impact on the ability of cliometricians to handle ever larger data sets, share them with a wider audience, and access new data sets that previously took a lifetime to collate. In conjunction with the greater facility current economic historians have with econometrics, the future seems limitless. But as any good historian knows, predicting it is fraught with perils.[32]

The Contributions of Robert Fogel to Cliometrics

David Mitch

Contents

Abstract

Robert Fogel was one of the earliest and most forceful advocates for the use of quantitative methods and economic theory in the study of economic history and long-term economic change. He demonstrated through his work on the economic impact of the railroads and the economic history of US slavery that the cliometric approach had the potential to challenge and overturn long-standing views based on narrative approaches to economic history. The volume he edited with Stanley Engerman, *The Reinterpretation of American Economic History*, published in 1971 provided an early manifestation to economists and historians alike of the wide range of applications the cliometric approach could offer to various fields of economic history. Throughout his career, Fogel advocated for the cliometric approach to history more generally, not just to economic history.

C. Diebolt, M. Haupert (eds.), *Handbook of Cliometrics*,
https://doi.org/10.1007/978-3-030-00181-0_49

His contributions were recognized when he was jointly awarded the Nobel Prize in Economics with Douglass North in 1993. In the subsequent 20 years until his death in 2013, Fogel pursued an interdisciplinary research project focused on long-run changes in the interaction between technological advance, nutrition, human health, and mortality culminating in *The Changing Body* (co-authored with Roderick Floud, Bernard Harris, and Sok Chul Hong).

Introduction: Robert Fogel as a Pioneer of Cliometrics

Robert Fogel was one of the earliest and most forceful advocates for the use of quantitative methods and economic theory in the study of economic history and long-term economic change. He demonstrated through his work on the economic impact of the railroads and the economic history of US slavery that the cliometric approach had the potential to challenge and overturn long-standing views based on narrative approaches to economic history. The volume he edited with Stanley Engerman, *The Reinterpretation of American Economic History* (1971), provided an early manifestation to economists and historians alike of the wide range of applications the cliometric approach could offer to various fields of economic history. He had a penchant for framing his conclusions in a provocative way which generated controversy but also sustained interest in his research areas. And throughout his career, Fogel advocated for the cliometric approach to history more generally, not just to economic history. Moreover, he had a major organizational impact on the practice of economic history through his establishment of a prominent university-based workshop in economic history, his training of a number of students who have gone on to prominent careers in economic history in their own right, and his establishment of the Development of the American Economy project through the National Bureau of Economic Research. His contributions were recognized when he was jointly awarded the Nobel Prize in Economics with Douglass North in 1993.

Fogel's own intellectual evolution presents a striking contrast with North. Both started out as Marxists. Both wrote dissertations focusing on business enterprise, in the case of Fogel, his M.A. thesis on the Union Pacific Railroad, in the case of North, large life insurance companies. However, throughout his scholarly career, Fogel's scholarship was strongly grounded in empirical data and evidence. He was the consummate miner of data and continued to seek new empirical sources throughout. His work maintained clear grounding in economic theory and he served as President of the American Economic Association. In contrast, North was much more conceptually oriented. Increasingly, he reached out to other social science disciplines and had major influences in political science and historical sociology. North never served as president of the AEA, and while some of his early work had empirical grounding,

he was not reliant on archival resources and large data bases as a major component of his scholarship.

Fogel shared with North the view that economic processes were fundamentally historical, but his views as to why this was the case put less emphasis on the role of institutions and political processes and more on the role of technology and biological processes. North, to a greater degree than Fogel, saw economic history as a requisite for improving the discipline of economics, while Fogel put more emphasis on how the tools of economics could remake the field of history. Fogel interestingly identified North as an economic theorist perhaps as much, if not more than, as an economic historian.

Throughout his scholarly career, Fogel saw economic history, and more specifically cliometrics, as inextricably tied to the study of economic growth. His first major impact on the study of economic growth was a response to the claims of W.W. Rostow about the role of leading sectors, such as the railroad, in processes of economic growth. It is sometimes overlooked that his work on slavery began with an attempt to explain the sources of relatively laggard economic growth in the US South. It was this pursuit that led Fogel to investigate the importance of the retarding effects of slavery on growth. His work on anthropometrics was part of longer-run views of the relationship between growth and human physiological development.

Fogel's work often responded to issues of the day. The Civil Rights movement and urban racial unrest in the 1960s, for example, seems to have been a major motivating factor behind his decision to pursue the cliometric study of antebellum Southern slavery.

Fogel's own intellectual interests changed considerably over his scholarly career. While he maintained an interest in what could be labeled the Kuznets tradition of examining long-term economic change, the focus of his research by the time he returned to the University of Chicago in 1981 increasingly focused on what he termed biodemography and health economics.

Robert Fogel's Biography and His Students

Robert William Fogel was born on July 1, 1926 in New York City to parents who were refugees from the Russian Revolution. He attended public school in New York City and then began undergraduate studies in electrical engineering at Cornell University. He changed his major to history with a minor in economics due to his growing awareness of the problems of unemployment in capitalist economies, graduating from Cornell in 1948. During the early 1950s, Fogel was a Communist Party organizer.

Fogel commenced graduate work in economic history at Columbia University in 1956 in order to pursue his interests in the great Marxian questions regarding the nature of long-term economic change. At Columbia, he completed a master's degree under the supervision of Carter Goodrich with a thesis on the Union Pacific as a case of premature enterprise. He also did course work in economics with George Stigler. At Goodrich's encouragement, Fogel enrolled in the doctoral program in economics

at Johns Hopkins University to study quantitative approaches to economic growth under the supervision of Simon Kuznets. He served as an instructor at Johns Hopkins in 1958 and then obtained an appointment as assistant professor of economics at the University of Rochester in 1960. In 1963, he obtained an appointment at the University of Chicago, first as Ford Foundation visiting research professor, completing his dissertation on the railroads and economic growth at Johns Hopkins in 1963.

The Chicago school of Economics associated with the Department of Economics at the University of Chicago is often depicted as ahistorical in its emphasis on rational choice and market processes. In fact by the time Fogel joined that department in 1963, it had a tradition of economic history going back to its founding in 1892. Chester Wright joined the faculty in 1907, John Nef in 1929, and then, to replace Wright, Chicago hired Earl Hamilton in 1947. Fogel was ultimately hired as the replacement for Hamilton, who had receded into the intellectual background of the department by 1963 and was no longer actively teaching economic history. Fogel was recruited both to teach economic history, a requirement for graduate students, and for his work on economic growth and development, an area of increasing interest at Chicago. But more importantly, a number of prominent members of the Department shared the view that economic history was a fundamental part of economics and were eager to recruit someone who would provide it with a more active presence. Fogel was invited to visit the department for the 1963–1964 academic year as the Ford Foundation visiting research professor. In the Fall of 1963, he was offered a tenured appointment as associate professor, and he joined the department on a permanent basis in 1964. According to Milton Friedman, the department was aware of the cliometric approach Fogel took to economic history and this was considered as a plus, less because of a definite commitment to hiring a cliometrician than because it demonstrated Fogel's originality and his promise for being a leader in the field of economic history.

The 1960s was a period of buoyant demand for new faculty with the marked expansion of higher education in the United States. In addition, there was particularly active demand in leading economics departments at this time for practitioners of the new economic history given its recent emergence. Thus, it is no surprise that Fogel was the frequent recipient of offers from other institutions. Coupled with Chicago's recognition that Fogel was one of the leading practitioners of an innovative approach to a field in economics that the department was particularly eager to promote at this time, he was promoted to full professor in 1965, just a year after joining the department as an associate professor. And he was able to command not only an attractive salary but also extensive research support. This included funding to establish the economic history workshop that began to meet in the fall of 1964. Further indication of the department's commitment to economic history at this time was its pursuit of Albert Fishlow, who twice spurned their offers to remain at Berkeley. Fogel's choice of Fishlow as a colleague, despite the potential rivalry given their common dissertation topics and specialties in US economic history, suggests both his high regard for Fishlow and his emphasis on intellectual merit over other considerations in choosing colleagues.

From 1975 to 1976, he was Pitt Professor of American Institutions at Cambridge University and then spent 1976–1981 on the faculty at Harvard. During this time, he played a central role in establishing the Development of the American Economy program affiliated with the National Bureau of Economic Research.

In 1981, he returned to the University of Chicago to succeed George Stigler as Walgreen Professor of American Institutions in the Graduate School of Business, where he established the Center for Population Economics. He also had an affiliation with the Committee on Social Thought at Chicago. In 1993, he was awarded the Nobel Memorial Prize in Economics (shared with Douglass North) for the development of quantitative and theoretical tools for the study of economic history. He never retired from his faculty position and continued to publish until his death in 2013.

At both Chicago and Harvard, Fogel had numerous students who went on to prominent careers in economic history in their own right. Examples include Alice Hanson Jones, Larry Wimmer, Peter Hill, Jacob Metzer, Clayne Pope, Claudia Goldin, Hugh Rockoff, Michael Bordo, Joseph Reid, Frank Lewis, Richard Steckel, David Galenson, Robert Margo, Kenneth Sokoloff, Jonathan Pritchett, Jenny Bourne Wahl, John Moen, John Komlos, Jonathan Pritchett, Dora Costa, and Joseph Ferrie.

The New Economic History: The Role of Theory and Quantification

Robert Fogel is commonly regarded as one of the pioneers of cliometrics (alternatively labeled the new economic history and sometimes referred to as econometric history or historical economics). Indeed, this is mentioned in the Royal Swedish Academy of Sciences press release (1993). In fact, the establishment of cliometrics is commonly dated to a conference in Williamstown, Massachusetts, in September of 1957 jointly sponsored by the Economic History Association and the National Bureau of Economic Research. At the time, Fogel was just starting his doctoral studies at Johns Hopkins. Fogel himself traces the origins of cliometrics even earlier, to advances in history, the social sciences, and mathematics underway before the Second World War (Fogel 1995). One general definition of cliometrics is the study of history using quantitative methods and social science perspectives. Definitions that have been offered of cliometrics have varied since the term was first coined in the early 1960s.[1] While Cliometrics is commonly distinguished from traditional approaches to economic history by the emphasis of the former on quantification and theoretical analysis, other basic distinctions seem to have been at stake in clashes between old and new economic historians. Indeed as has been noted above, pre-cliometric history frequently made extensive use of quantification. At least three

[1]See for example Sutch (1982), McCloskey (1978, 1987), and Williamson (1991). Fogel and Elton (1983), footnote 17 on p. 24 provides an extensive bibliography of pieces surveying the nature of cliometrics as do McCloskey and Hersh (1990). Histories of cliometrics include Williamson (1991) and Drukker (2006).

other basic contrasts, including one by Fogel, have been noted. The first is an emphasis on narration and description in traditional history versus an emphasis on causal explanation and application of formal models in the new economic history (Cochrane 1969; Hacker 1966). The second is a focus on institutions in traditional economic history versus one on processes in the new economic history (Redlich 1965). And the third, suggested by Fogel and Elton (1983, p. 29) is a focus on "specific individuals, on particular institutions, on particular ideas, and on non-repetitive occurrences" in traditional history versus a focus on "collections of individuals, on categories of institutions, and on repetitive occurrences" by cliometricians practicing scientific history.

Initially, in the late 1950s and early 1960s, the history to be studied by cliometrics was perhaps most obviously economic history and the social science perspective most clearly associated with the term was that of economics. However, during this same period, the use of quantitative methods and social science models was becoming more widespread in other fields of history as well. Thus, in 1962, the American Historical Association created an "Ad Hoc Committee to Collect the Basic Quantitative Data of American Political History" (Swierenga 1970). And in 1964, the Mathematical Social Science Board (MSSB) was formed with the joint sponsorship of the Social Science Research Council and the Center for Advanced Study in the Behavioral Sciences. Its stated purpose was "to foster advanced research and training in the application of mathematical methods in the social sciences" (Aydelotte et al. 1972, p. vii). The MSSB took an early interest in applications to history and in 1965 established a Committee on Mathematical and Statistical Methods in History. This Committee was chaired by Robert Fogel and also included Lionel McKenzie (a mathematical economist), Frederick Mosteller (a statistician), William O. Aydelotte (a political historian), Oscar Handlin (an American Historian), and Allan G. Bogue (a political and agricultural historian) (Bogue 1968). One of Fogel's aims in chairing this committee was to show the applicability of mathematical and statistical methods to a variety of historical issues, not just economic history. In a letter to Frederick Mosteller regarding the agenda of an early meeting of the Committee, Fogel stated:

> I view General History Project I as the most important of our potential undertakings . . .For I hope that out of this project will emerge a set of papers that could demonstrate to historians the full range of mathematical and statistical methods—from very simple statistical concepts to highly complex multi-equation systems—that are available for the analysis of historical issues as well as the variety of situations and ways in which such models are applied.[2]

The view that mathematical, statistical, and social science analysis could be applied to a broad range of historical issues was manifested in the establishment in 1975 of the Social Science History Association. That Fogel subscribed to such a broad, social science conception of cliometrics is suggested by his efforts in the early

[2]Letter from Robert W. Fogel to Frederick Mosteller dated April 9, 1965 located in Robert W. Fogel papers, Box 161, in Frederick Mosteller file.

1970s to establish a major graduate program in quantitative and social science history at the University of Chicago, to be called "Committee on Mathematical Methods in History."[3] It is also evident in his statements on cliometrics, which he more broadly termed scientific history (Fogel 1995; Fogel and Elton 1983).

Fogel conceived of the application of quantitative methods to history as entailing not only statistical analysis of empirical data but also the use of formal mathematics. Fogel (1995, p. 54) cites a 1982 American Heritage Dictionary definition of cliometrics as "The study of history using advanced mathematical methods of data processing and analysis." The committee on history that Fogel chaired for the Mathematical Social Science Board, as its title given above suggests, considered the application of mathematical as well as statistical methods to the study of history. In his 1973 letter to Frederick Mosteller regarding an early conference of the committee on history that Fogel organized, summarizes:

> The central objective of the conference then, as I see it, is the presentation of a set of papers which will dispel the notion that mathematical models are a straight-jacket; which will demonstrate that, when properly employed, mathematical models not only provide great flexibility, but greatly extend the range of opportunity for historical analysis.

And his proposed program at Chicago in applying social science and quantitative methods to history was entitled "Committee on Mathematical Methods in History," suggesting that he was prepared to take on board the use of mathematics generally as one of the hallmarks of cliometrics.

In considering what is distinctive about the use of quantification and perspectives from economic theory in the cliometric approach, Fogel emphasized the interrelationship between theory and measurement. He viewed theory as an aid to more effective measurement. Fogel (1966, pp. 7–8) observed:

> The methodological hallmarks of the new economic history are its emphasis on measurement and its recognition of the intimate relationship between measurement and theory. Economic history has always had a quantitative orientation. But much of the past numerical work was limited to the location and simple classification of data contained in business and government records. . .. The pioneers of the massive statistical reconstructions embodied in national income accounts were not economic historians but empirical economists, such as Simon Kuznets in the United States,. . .. While economic historians made considerable use of national income measures, they did not immediately attempt to extend the process of statistical reconstruction to the vast array of issues in their domain.

If in earlier statements Fogel (1964b) put more emphasis on theory rather than measurement as the distinctive trademark of cliometrics, he also conveyed in those statements that the contribution of theory was in enhancing the effectiveness of measurement.

[3]See memor from Fogel to Robert McAdams dated August 13, 1973, re: "A Proposal to establish a Committee on Mathematical Methods in History at the University of Chicago" located in Robert W. Fogel Papers, Box 145, Robert McAdams folder.

While Fogel has been one of the most forceful and persistent advocates for the use of quantification and social science perspectives in the study of history, as has already been noted, he was certainly not the first to do so. Indeed, he was awarded the Nobel Prize jointly with Douglass North, although the two of them were never direct collaborators. This suggests that cliometrics emerged from the efforts of various scholars. However, one tool of the cliometric approach that has been distinctively associated with Fogel is the employment of counter-factual analysis. The basic principle of counter-factual analysis is that in order to determine the impact of some factor, one must consider what would have occurred in the absence of that factor. Applying this principle to historical economic development, Fogel (1967, p. 285) states:

> one cannot determine the economic effects—negative or positive –of the tariff, slavery, the corporation, railroads, the Bessemer converter, the reaper, the telegraph, the Homestead Act, or interregional trade without considering how the economy would have developed in the absence of such institutions, processes, and artifacts. Obviously these counterfactual patterns of American development were not observed and are not recorded in historical documents. In order to determine what would have happened in the absence of a given institution, the economic historian needs a set of general statements that will allow him to deduce a counterfactual situation from institutions and relationships that actually existed.

Fogel did not originate the application of counterfactual analysis to economic history. This was proposed in Conrad and Meyer's methodological essay (1957). And Fogel (1967) himself acknowledged not only the influence of the Conrad and Meyer essay but also noted Fritz Machlup's (1952) discussion of counterfactual reasoning. Following Machlup, one can view counterfactual analysis as no more than systematic analytical reasoning. Or as John Meyer put it in a 40th anniversary retrospective on the 1957 Williamstown conference, "All policy proposals and advocacies are almost by their nature counterfactuals; what would have happened if a proposed policy had been adopted rather than rejected or overlooked" (Meyer 1997, p. 410). Fogel also points to the importance of Hempel's (1942) discussion of the role of general laws in history.

The employment of counterfactual analysis by Fogel in his study of the impact of the railroad on American economic growth provoked accusations by the traditional economic historian, Fritz Redlich, that Fogel's work was "fictitious" and "quasi history" (Redlich 1965, p. 486). And in a later version of his essay, Redlich states his "refusal to consider research based on counterfactual assumptions as genuinely historical research" (Redlich 1968 reprinted in Andreano 1970, p. 92). However, Redlich, in the same passage in this essay, also acknowledges the value of counter-factual analysis. However, he thinks that it should be classified as part of social science research rather than historical analysis: "I do not want to be misunderstood. I do not take a stand against this kind of research per se, nor do I consider it worthless; I only want to have it recognized as part and parcel of the social sciences and to stress its tool character as far as history is concerned" (Redlich 1968 [1970], p. 92).

Fogel has argued in response that not only is counterfactual analysis a useful tool in historical analysis, it is unavoidable if one wants to do any sort of causal analysis

or appeal to general principles. And he states that historians have actually quite frequently employed counterfactuals; they just have not acknowledged it or very fully examined the assumptions entailed in their use (Fogel and Engerman 1971, p. 10; also see Davis 1968, 1970).

Other new economic historians have frequently employed counterfactual analysis. Yet part of the reason why Fogel's work was singled out for attention and criticism was not just his explicit methodological employment of counterfactuals but the degree to which he pursued it in his work on the impact of the railroads. This is suggested by comparing his approach with that of Albert Fishlow's on the same topic. Fishlow also undertook the counterfactual comparison of what transportation costs would have been by water transport in the absence of railways; but in contrast to Fogel, Fishlow based his analysis on the existing canal system in 1859. Fogel instead argued in his analysis of the 1890 situation that in the absence of the railroad there would have been a considerable expansion of the nation's canal system. He then proceeded to propose a hypothetical canal system that might have been constructed by 1890 in the absence of the railway. He found that the presence of such an extended canal system substantially lowered his estimate of the social saving attributable to the railway. Fogel (1979) argues that Fishlow's employment of existing canal systems for his counterfactual analysis was just as hypothetical as Fogel's consideration of a hypothetical extended canal system. It is likely that developing such an elaborate counterfactual canal system earned Fogel's work the title of "figments" from his critic, Fritz Redlich (1965, 1968).

It has sometimes been suggested that the conflict between traditional and new economic history was at least partly generational, reflecting the brashness of "young turk" new economic historians (McCloskey 1985). Simon Kuznets, as Robert Fogel's dissertation supervisor, at times admonished his student for not showing sufficient respect for more traditional economic historians. This is of interest not only for exhibiting generational tensions, and the related ones between student and mentor, but also for highlighting Kuznets's distinctive role as a bridge between traditional and cliometric approaches. Thus, Kuznets wrote to Fogel in a letter dated August 17, 1962 of one passage in a dissertation draft:

> it conveys the unfortunate impression that so many of the traditional economic historians are men of limited understanding and imagination. In revising the text for the final version, I would urge you to go over the text with a fine tooth comb to try to eliminate this impression as much as possible.[4]

And in a letter to Fogel dated May 15, 1963, Kuznets says he wants to:

> repeat my urging to you to. . .edit out some of the statements which impress me as likely to irritate people and only make it more difficult for them to appreciate the value of your analysis. I am referring to statements that contain a generally high claim for the value of econometric analysis and by implication set a low value on more traditional economic

[4]Located in Robert W. Fogel papers, Box 157, Simon Kuznets folder.

> history. . .In general, it is best to let the analysis speak for itself, and err on the side of understating the possible general validity of the approach that you follow.[5]

In a reply to Kuznets dated June 5, 1963, Fogel writes:

> I do agree with you on the need to further edit my manuscript for statements which appear to implicitly repudiate the more traditional economic history. This was not my intention. I think that in history quantitative and qualitative methods of analysis supplement and reinforce each other. I do not view the increasing emphasis being put on the more rigorous use of theory and statistics by younger economic historians as a break with the past; I consider it a further development of a long existing trend in the discipline. At the same time I do not want to weaken my criticism of what I believe has been a serious underestimation of the opportunity that exists for extending quantitative methods worked out in other fields of economics to the domain of history. I also want to emphasize the same point with respect to theory. I realize that my methodological discussions lean heavily on standard principles of economics and statistics. I'm particularly conscious of the fact that many of my arguments are elaboration of points that you have made in various essays and lectures. However, I feel that when linked with specific applications to history, the methodological arguments become more meaningful to those who have previously misunderstood their import.
>
> I have tried to make these points without unduly offending those inclined to loose intuitive methods; but I realize that I have not been entirely successful in this effort.[6]

That Fogel saw continuity between traditional economic history and the new economic history becomes evident when considering his formulation of the contribution of economic history to the discipline of Economics.

The Reinterpretation of American Economic History

An important landmark in the development of cliometrics was the volume edited by Fogel and Engerman and published in 1971, *The Reinterpretation of American Economic History*. The volume consists of 36 essays, including a number by scholars who would not be regarded as economic historians. Among them are Zvi Griliches' article on the diffusion of hybrid corn, of T.W. Schultz on education as capital formation, and Simon Kuznets on the contribution of immigration to labor force growth. It also includes essays by scholars who might be regarded primarily as historians, including James Henretta and Allan and Margaret Bogue. The preface outlines three functions of the volume. Interestingly, the first is "to help teachers of undergraduate courses in American history introduce students to the quantitative revolution in historiography and the far-reaching substantive revisions produced by the new methodology" (Fogel and Engerman 1971, p. xv). The second is to give teachers of undergraduate economics courses materials to demonstrate the real world relevance of economic principles, while providing material for teachers of economic history is only third on the list. The volume opens with a piece by historian Daniel

[5]Located in Robert W. Fogel papers, Box 157, Simon Kuznets folder.

[6]Located in Robert W. Fogel papers, Box 157, Simon Kuznets folder.

Boorstin on "Expanding the historian's vocabulary." The volume perhaps had most impact on teachers of economic history. A projected second edition in 1976 was never realized.

Economic History as the Study of Economic Growth

As previously noted, one likely reason for the Chicago Department's keen interest in economic history during the late 1950s and early 1960s was a serious interest in the determinants of economic growth. Indeed, although Earl Hamilton's own research focused primarily on monetary issues, the research group he headed had the stated topic of the history of growth and development. While the workshop established by Robert Fogel had the more generally stated topic of economic history, Fogel's own research agenda in the mid-1960s saw economic history as primarily focusing on the determinants of economic growth. His work on the economic impact of the railroads was motivated by an interest in the contribution of a generally perceived key innovation to economic growth.

In the early 1960s, the study of economic growth was a common focus of cliometric activity (Drukker 2006). Both Douglass North's 1961 monograph, *The Economic Growth of the U.S.,* and his 1966 textbook survey, *Growth and Welfare in the American Past, A New Economic History,* featured growth in their titles. And North's students, Lance Davis and Jonathan Hughes, along with Duncan McDougall, focused on economic growth in their textbook first published in 1961. Indeed, Davis et al. (1961) discuss at some length in their introduction how, in contrast to the chronological focus typical of most textbooks in American Economic History, theirs is organized thematically, with sections and chapters focusing on key determinants of economic growth. A similar organizational format was featured in the textbook edited by Davis et al. in 1972, *American Economic Growth. An Economist's History of the United States*, which consisted of survey essays on key sectors and dimensions of the American economy.

Fogel began graduate work in economic history with an interest in the determinants of economic growth (Fogel 1994a). While in the midst of work on his dissertation on the railroads in the early 1960s, he had projected both a textbook on American economic history "within the framework of growth economics" and a research monograph entitled *Strategic Factors in American Economic Growth*.[7] Fogel appears to have had a definite conception behind the phrase "strategic factors" and for many years he offered courses alternatively entitled "Strategic Factors in American Economic Development" and "Strategic factors in American Economic Growth." In a memo to Lionel McKenzie, then chair of the Economics department at

[7]See Letter from Fogel to Kuznets dated August 28, 1961, pp. 3–4 located in Robert W. Fogel papers, Box 157, Simon Kuznets folder and Letter to Harold Barger dated July 15, 1963 located in Robert W. Fogel papers, Box 146, Harold Barger folder.

Rochester, dated Feb.1, 1961, Fogel described his view of the nature of strategic factors in economic growth:

> I would like to have the title of Economics 227 changed from Major Factors in American Economic Development to Strategic Factors in American Economic Development. The latter title is the one I originally submitted.
>
> My course attempts to single out and analyse those factors upon which the course of American economic growth depended; i.e., those factors whose absence would have fundamentally altered the record of development. The word "major" means "superior in quality or position"; it connotes only an ordering of importance. A major event need not be one which is capable of altering the design of a given pattern; it can have limited consequences. The development of cheap inland water transportation and the decision not to renew the charter of the bank of the Second Bank of the United States are both generally considered major events in American Economic history. The first was a necessary condition for economic growth during the first half of the nineteenth century; the second was not. The first had strategic consequences on the location of economic activity and the rate of growth; the second did not.[8]

Fogel saw economic history as contributing to an understanding of economic growth and he saw this as the traditional aim of economic history. He did emphasize the importance of using cliometric tools to come up with new answers to traditional questions; he thought that the fruitfulness of the new methods would depend ultimately on whether they led to and supported new interpretations (Fogel and Engerman 1971, p. 2).

Economic history as the study of continuity and change in economic activity can well be seen as entailing far more than just the study of economic growth. Fogel (1965, p. 94) explicitly conflates economic change with economic growth. In citing the historical school economic historian William Ashley, he suggests that Ashley thought that conflict between economics and economic history was avoidable because in Ashley's view "economics proper and economic history focused on different problems: the former on the static properties of modern economies; the latter on the evolution of economic societies – or as we now call it – economic growth."

However, Fogel's teacher at Columbia, Carter Goodrich (1960b, p. 536) noted that "there remain certain points to be considered before economic historians can agree to abdicate in favor of the new discipline of Economic Growth." He argued that "economic historians cannot accept its limitations as to time or to subject matter." He goes on to state that economic life in primitive societies and "issues involving human values and other effects of economic changes" have also been "central themes for economic historians in the past." And Paul David, a leading practitioner of cliometrics, appears to have shared Goodrich's concern when he noted in a letter on Fogel's 1965 reunification article that "it is important, I think, to preserve the distinction which recognizes 'growth problems' as a subset of the problems of secular change."[9]

[8]Located in Robert W. Fogel papers, Box 159, Lionel McKenzie folder.

[9]Letter from Paul David to Robert Fogel dated December 4, 1964 located in Robert W. Fogel papers, Box 149, Paul David folder.

In a 1971 evaluation of quantitative economic history co-authored with Albert Fishlow, Fogel himself acknowledges that the new economic history had emphasized issues of growth and development at the expense of distributional and welfare issues. Fogel lists, among other deficiencies of the new economic history, a focus on growth at the expense of equity and welfare issues (Fishlow and Fogel 1971). However, Fogel also argues for continuing work by economic historians on issues related to economic growth, while acknowledging the importance of other issues in economic history.

Robert Fogel's Substantive Contributions

Robert Fogel made major contributions in three basic areas: (a) estimates of the contribution of the railroad to American economic growth, (b) an examination of various dimensions of the antebellum US southern slave economy, and (c) anthromopetrics and technophysio evolution. Each of these contributions and their legacy on subsequent cliometric research illustrate different aspects of the power of cliometric research. Fogel's project first involved developing an innovative conceptual tool: social savings, and applying it with considerable skill and diligence. The social savings approach, as well as offshoots and reactions to it, have been applied to a wide range of other countries and historical settings. And recent research on the economic impact of the railroads and transportation more generally have employed new conceptual and computational tools to revisit the findings of the social savings approach. While Fogel's second project on slavery began with a focus on estimating the relative efficiency of slave versus free agriculture in the antebellum USA, it expanded into a quite wide-ranging examination of not only the economics of slavery but also of slave society and demography. And while this research made extensive use of the basic theoretical and quantitative tools of economics, narrative accounts, especially in Fogel's second book on slavery, *Without Consent or Contract* (1989), featured prominently as well. Fogel's final project was marked by its interdisciplinary character using methods and concepts from physical anthropology, nutrition, and related health science disciplines.

The Economic History of the US Railroad

Union Pacific as Premature Enterprise

Fogel's first published book on the railroads was *The Union Pacific Railroad: A Case in Premature Enterprise*. It appeared in 1960 and was based on his master's thesis at Columbia, written under the supervision of Carter Goodrich. The book is particularly relevant for understanding cliometrics because it represents a bridge between the "old" and "new" (i.e., cliometric) approaches to economic history. Fogel indicates in the preface that the topic for the book was suggested to him by Carter Goodrich. Goodrich was a more institutionally oriented economist who had serious interests in history and was president of the Economic History Association, but also

was active in various international labor organizations. He also wrote extensively on the role of government in the economy and one of his major books was *Government Promotion of American Canals and Railroads*. Thus, Fogel's book, as a study of a major American business enterprise reflecting a combined role for the government and private enterprise, clearly reflected long-standing interests of Goodrich (See Goodrich 1960a). The term in the book's subtitle, "premature enterprise," was the central one in the book. It has resonance, but contrasts with a parallel term, "building ahead of demand," articulated in Albert Fishlow's study of the antebellum railroad, published around the same time (Fishlow 1965).

The preface of the book indicates both continuities and differences with previous approaches to the history of the Union Pacific by previous historians. He outlines four differences, the first three of which pertain to issues raised by previous historians including (a) indicating that Congressional legislation on the Union Pacific reflected not a flight from a role for government in such enterprises, but instead a persistent commitment to them; (b) new material bearing on the difficulty of raising funds for the enterprise as reflected in new estimates of the market evaluation of the likelihood of failure; and (c) evaluating the wisdom of government involvement by providing new estimates of the social rate of return of the enterprise.

He then describes the fourth difference:

> ". . .it draws on formal economic theory in the determination and analysis of historical facts. Interest theory is combined with the theory of a 'fair game' to deduce, from the market price of the railroad's first mortgage bonds, the market's evaluation of the probability that the Union Pacific would fail. The theory of rent forms the basis for the estimation of the social rate of return on the capital invested in the railroad. The concept of present value is used in the determination of the relative efficiency of the various proposals that were put forth for the financing and construction of a Pacific road." He then goes on to defend the use of counterfactual analysis as articulated by Fritz Machlup (in advance of his 1964 book usually associated with this). He goes on to defend the role of theory "as helpful in the determination of facts as it can be in the explanation of them." (Fogel 1960, pp. 10–11)

Previous historians of the Union Pacific had claimed that the government subsidies of the construction of the railroad in the 1860s resulted in the corruption and excessive profits that characterized the "Gilded Age" more generally. In this study, Fogel undertook to construct detailed accounting measures of the profits earned by the railroad based on primary source material. He employed information related to bond prices to construct estimates of the expected "risk of failure" during the period of construction of the railroad. He then made adjustments in his measured accounting profits for the large measured risk premium his failure risk estimates implied. He thus concluded that claims of exorbitant profits were overstated, while also arguing that the actual mix of public and private sources of finance for the Union Pacific may not have been the most desirable choice. An important contribution of this work in applying economic theory to historical analysis was its utilization of financial models to estimate market risk premiums.

Another important contribution that he was to use more fully in his subsequent book on the railways and economic growth was his use of land rents. He used these

to measure the social benefit of the railroad not captured in the private rate of return to investors. This then allowed him to calculate the excess of the social rate of return to the railroad over and above the private rate of return.

Railroads and American Economic Growth

His doctoral dissertation, and the subsequent book *Railroads and American Economic Growth: Essays in Econometric History* (1964a), challenged the prevailing view that the railroad had a decisive influence on the growth of the American economy. He calculated how much higher the costs would have been to the US economy in 1890 of providing the same level of transportation services with alternative modes of water and land transportation. Fogel's counterfactual methodology proposed a hypothetical canal system that would have been built in the absence of railroads. His estimated "social saving" of the railroad was less than 5% of 1890 US gross national product. His findings spawned numerous challenges by other scholars. Fogel responded by arguing that, for the case of the United States, any plausible allowance for factors raised by critics (such as scale effects and problems of measuring freight rates on rail vs. water traffic) would still imply a modest rather than indispensable contribution to economic growth. However, Fogel also acknowledged that for other economies – such as Mexico, with its more limited access to water transport – the impact of the railroad on growth may well have been substantially larger. His counterfactual methodology generated considerable controversy among historians, with some stating that it was fundamentally ahistorical and fictive. Fogel replied that an analytical and causal approach to economic history inevitably requires the posing of counterfactual questions.

Some of Fogel's findings regarding the impact of the railroad involve relatively straightforward applications of basic price theory. Thus, one of his striking findings concerned the quite small, and by initial crude measures negative, impact of inter-regional railroads on transportation social savings. This was due to direct transport costs by water that were actually lower than rail costs given access to water routes for inter-regional transportation. When allowance is made to seasonal obstacles to water transportation and to the advantages of speed of the railroad over water, the contribution of the railroad increases, but not markedly.

However, his further striking finding was the greater contribution of intra-regional savings from the railroad. He uses two approaches for this calculation. His alpha estimates entail direct cost-savings. However, to allow for spillover effects, as in his Union Pacific study, he goes on to construct beta estimates that use changes in land rents due to railroad access.

Fogel's work initially generated lots of controversy over various dimensions. These include McClelland's (1968) critique of Fogel's (and Fishlow's) empirical evidence and David's (1969) critique of the book's analytical framework. A reprise can be found in Atack and Passell (1994) and Fogel (1979). Fogel (1979, p. 51) notes "some observers of the debate [over the social savings of the railroad] . . .have interpreted the sharp disagreements among the cliometricians as evidence of the failure of social science methodology, and particularly of quantitative methods, in history. There is in this view a confusion between artistic and scientific

processes. . .Scientific creations. . .are usually protracted over long periods, approach perfection quite gradually, and involve the efforts of a large number of investigators. . .[In the case of the social savings controversy] The results of the interaction between the investigators and the critics have been a gradual deepening of the analysis, an improvement of estimating procedures, and the searching out of additional, or more reliable, bodies of evidence bearing on the points at issue. Rather than being a sign of the failure of the cliometric method, the controversy is a sign that the method is working."

Although Fogel's basic work on this topic had been completed by the mid-1960s, his reprise of the controversies and his replies to critics formed his Economic History Association Presidential Address, delivered in 1978 and published in 1979. Over the few decades since, there has been renewed interest in returning to the impact of the railroad. One issue concerns examining the impact of the railroad in a wider range of countries than those considered in the first wave of railroad impact studies. Herranz-Loncan (2006) provides a quite useful survey. Summerhill's (2003, 2005) estimates of the social savings of the railroad for Brazil and Argentina in 1913 are of the same order of magnitude as Coatsworth's (1979) findings of 25% or more for Mexico in 1910. However, a further issue concerns using both considerably enhanced data bases, geographic information system techniques, and more sophisticated modeling tools based on general equilibrium theory to examine the impact of the railroad (Atack 2013; Atack et al. 2010; Donaldson and Hornbeck 2016).

The Study of Industrial Expansion: Antebellum US Iron and Steel

In the spirit of applying neoclassical tools to the study of economic growth, Fogel and his frequent co-author Stan Engerman (Fogel and Engerman 1969) developed a model of the USA's nineteenth-century iron and steel industry to consider the factors behind the ups and downs in its antebellum expansion. In particular, they sought to distinguish between the role of technological advance and tariff protection in influencing the expansion of the industry. They estimated a basic supply and demand model and a Cobb-Douglas production function to assess the relative importance of tariff protection and technological advance in influencing the relative fates of the charcoal and anthracite sectors of the industry. They argue that tariff protection would have facilitated ongoing expansion of the anthracite sector, which was sustained by growth in demand for its relatively crude metal products, such as rails, while this sector received only a modest boost from technological advance. However, they also argue that growing domestic demand would have been sufficient to boost domestic expansion even in the face of foreign competition. In contrast, the more refined charcoal iron sector would have declined in relative terms given the relatively slow growth in demand for its products, even in the face of tariff protection. Fogel and Engerman had anticipated continued work on this project extending the analysis to later time periods and the rise of the US steel industry but abandoned these plans in order to focus on the cliometrics of slavery (Fogel 1996).

The Cliometrics of Slavery

Time on the Cross and Without Consent or Contract

By the late 1960s, Fogel's attention was increasingly dominated by the cliometrics of slavery. Active interest in applying cliometric methods to the economic history of slavery predates Fogel and can be dated to the 1957 conference jointly sponsored by the Economic History Association and the National Bureau of Economic Research. At that conference, Alfred Conrad and John Meyer presented a paper on "The Economics of Slavery in the Ante-Bellum South" in which they found that rates of return on slave plantations throughout the deep South equaled or exceeded that for northern manufacturing industries. Conrad and Meyer's research was published in the *Journal of Political Economy* in 1958 (Conrad and Meyer 1958), and as Fogel notes in biographical memoirs, it was the focus of sustained debate among faculty and students in the Economics Department at Johns Hopkins University when he was a doctoral student there.

Fogel (1975c, p. 667) noted that he and Engerman made the decision in 1968 to conclude the iron industry project described above and "to throw our full energies into the study of slavery" after being struck by the anomalous result that Conrad and Meyer found that slave agriculture was more efficient than free agriculture. This research effort can be situated in both a long-standing historiography on slavery as such, and a long-standing historiography on the extent to which slavery contributed to Southern economic stagnation. With the latter issue, there was continuity with Fogel's previous focus on economic growth.

Fogel and Engerman initially decided in 1968 that a cliometric approach could contribute the most to ongoing debates about slavery among mainstream historians by estimating the relative efficiency of slave versus free agriculture, bypassing previous work on the profitability of slavery, or questions of paternalistic masters, the psychological impact of slavery on blacks, or the role of slavery in dismantling slave family life. Their preliminary efforts using total factor productivity measures to compare the relative efficiency of Southern slave agriculture with Northern free family agriculture yielded the result that slave agriculture was 6% more efficient than Northern free agriculture. They found this result quite surprising, given the presumption of many commentators that slave labor was inherently inefficient. Further adjustments to refine their measure actually increased the relative advantage of slave agriculture to almost 40% (as summarized in Fogel 1996). Subsequent research by Fogel and Engerman (1977) and others (Schaefer and Schmitz 1979; Field-Hendry 1995) considered the role of economies of scale in producing this outcome. Fogel and Engerman (1974, 1977) also focused on the role of the gang system in achieving high levels of labor productivity. They suggest that the gang system achieved high levels of productivity by setting a pace of work that forced all members of the gang to keep up with the most active members.[10] Although their initial calculations were

[10]Also see Toman (2005). For critical discussion of Fogel and Engerman's work see Wright (1979). For more recent surveys of the literature on the efficiency of slavery see Wright (2006) and Sutch's chapter on "African-American Slavery and the Cliometric Revolution" in this volume.

based on the Parker-Gallman sample of slave farms, they subsequently extended the data base and recruited James Faust and Fred Bateman to collect and code a sample of 20,000 Northern farms. As their data collection effort expanded, so did the research questions they considered, including slave demography and the material treatment of slaves.

Their efforts unearthed considerable amounts of new data sources to address a wide range of issues concerning slavery. It also generated considerable amounts of controversy both among cliometricians (see David et al. 1976) and between mainstream historians and cliometricians. The sources of controversy included technical issues, such as in the interpretation of their relative productivity measures of slave versus free agriculture. The controversy extended to the larger narrative about the slave system and imputations that they were defending slavery as a moral system. Further elements of controversy concerned their decision to publish a volume for the general reader accompanied by a volume of supporting technical findings, the speed with which the general volume was produced, and the lack of time allowed for feedback from other scholarly specialists.

After the publication of *Time on the Cross* in 1974, Fogel continued follow-up work addressing critics, and Engerman has continued with wide ranging scholarship covering slavery in a variety of countries. This culminated in Fogel's *Without Consent or Contract: The Rise and Fall of American Slavery,* published in 1989, with several volumes of supporting technical material. Two features noteworthy of this second volume are the 29 page "Afterward" on "the Moral Problem of Slavery," and the extended, almost 200 page, narrative account in Part II on "The Ideological and Political Campaign Against Slavery."

Much of the impetus for the interest in slavery in the late 1960s in the USA stemmed from the civil rights movement of the 1960s. Indeed, Fogel and Engerman (1974, Vol. 2, p. 17), in one of the appendices to *Time and the Cross,* mention "the national tension over race relations" as one reason why discussion became so angry in a 1967 session on "Slavery as an obstacle to Economic Growth." "It must be remembered," they continued, "that 1967 marked the third successive summer in which race riots engulfed American cities with arson, violence, and death." The implicit shift in Fogel's research to a historical topic that resonated with current events may have been of some consequence for the subsequent direction of cliometric work. It implied a shift away from studying the determinants of long-run growth, a topic that would seem to provide strong grounds for incorporating historical analysis into economics. In a 2005 interview with the author, Fogel emphasized that long-run change has always been the focus of his work and that he has never lost that interest. He said that he turned to the issue of slavery in order to understand how institutions affect economic growth (Mitch 2005).

In any event, Fogel certainly saw slavery as an important area for applying the tools of cliometrics and for stating with greater precision the issues formulated by previous historians of slavery.

The Decision to Aim at a Broad Public Audience

However, in his work on slavery, Fogel also sought to reach a much broader public audience than professional economists. Other economists associated with Chicago, including Friedrich Hayek and Milton Friedman, published work aimed at broad audiences. Fogel may have been distinctive for the more focused nature of the work he was trying to bring to public attention. He discussed this decision at some length in three articles published in 1975 (Fogel 1975a, b, c). He notes that recent research on slavery had increasingly touched on larger issues than those of narrow profitability and efficiency on which Conrad and Meyer's initial cliometric research had focused. Fogel explains that ongoing collection of plantation and probate records expanded the scope of issues beyond "such purely economic problems as profitability and efficiency. . .It became clear that our monograph should be broadened to cover such topics as the skill-composition of the slave labour force, the slave family, slave mortality, and slave morbidity" (1975c, p. 670). And "the principle feature of the third phase of cliometric research on slavery is the shift of emphasis from how the slave system worked to the recovery of black history. The onset of the third phase has not brought the second to an end. Rather the two phases coexist, each giving vitality to the other" (Fogel 1975b, p. 42). Finally, he explains his decision to reach out to a larger audience (Fogel 1975c, p. 670):

> We also decided to bring the cumulative findings of more than a decade and a half of cliometric work on slavery to public attention and to do so without waiting for the completion of the research in progress. The decision to write a book for the general public was not an easy one nor a sudden one. . .But it was only when we began to sift through the new data from plantation and probate records that we became convinced that the cumulative weight of cliometric research had reached a critical level. . .Since we viewed the interpretive volume as *initiating* a new debate rather than closing an old one, such a publication schedule seemed reasonable [italics in original]. Naturally, our colleagues would reserve the right to disagree with our findings until they had an opportunity to scrutinize thoroughly the technical procedures. . .Although most comments on our publishing strategy were quite positive, we encountered some sharply negative reactions. . .Still another reader, more perturbed than any of the others with the decision to publish technical findings in such popular form, warned that we were flirting with professional suicide. Stick to the monograph and the technical papers, he advised, adding that if we could not resist the urge to bring our findings to the public, we should write an article for *Scientific American*.

The Fallout from the Slavery Controversy

Nevertheless, to some in the economics profession the intensity of the debate over slavery raised doubts about the credibility of cliometrics (see Heckman 1997). And when Fogel was under consideration for the Walgreen Professorship in 1979, his predecessor in the chair, George Stigler, made a point of sending letters to a number of prominent economic historians both in the USA and England inquiring whether the controversy over *Time on the Cross* had seriously tainted Fogel's scholarly reputation. Their response was an unequivocal no, and that they still regarded Fogel as one of the preeminent economic historians in the world. However, John

Hope Franklin, the prominent African American historian in Chicago's history department, did have some reservations based on the arguments of some of Fogel's cliometric critics. He also noted Fogel's lack of engagement with Chicago's History Department, though he mentioned that he got along well with Fogel personally.

In summing up some two decades of work on slavery, Fogel (1989, p. 13) states:

> I began it like many other cliometricians, not because I was especially interested in the history of American slavery, but because an accident of scholarship made the economics of slavery a major testing ground for the application of cliometric methods. Once drawn into the subject, however, it was the substance of the issues that maintained my interest. Although my principal professional expertise was, and is, in the areas of economics and demography, I found myself led down a road that forced me to grapple with the work of colleagues in cultural, political, and religious history. . .

He concludes that book with an afterward on "The Moral Problem of Slavery" a point to which he returned in a series of published lectures (Fogel 2003, see especially, pp. 45–48; also see Fogel 1994b). Thus, Fogel acknowledges moral considerations that transcend and shape the interpretation of his economic findings, or might be implied by a narrowly defined "Chicago" approach employing rational, maximizing behavior. This interest in moral and social issues that transcend economic considerations comes to the fore in Fogel's 2000 qualitative exposition, *The Fourth Great Awakening and the Future of Egalitarianism*.

Fogel, in an epiphany reminiscent of John Nef, thus came to appreciate that work on the relatively restricted topic of the economics of American slavery had led him to pursue wide ranging cultural, ethical, and political issues. And one of Fogel's faculty appointments at the University of Chicago at the end of his career was with the Committee on Social Thought, established by John Nef. But if Fogel's work on slavery had resulted in a detour from his work on economic growth, it was also to lead to his return to the study of long-run economic change.

Demography, Anthropometrics and Technophysio Evolution

One major aspect of Fogel's research into slavery focused on demographic issues. Fertility and mortality measures provided key indices of the material conditions of slave life and of slave family patterns. A related element focused on nutrition. After publication of *Time on the Cross,* Fogel became aware that international public health specialists were using anthropometric measures (including not only measures of height but also weight and body mass index or BMI – a measure of weight controlled for height) to measure nutritional status of populations in less developed nations. Fogel and his collaborators realized that a variety of the sources they had collected, including, for example, coastal shipping manifests of slaves, reported information on slave heights and could be used for comparing heights of southern slaves with other populations, which in turn could provide evidence bearing on relative nutritional status.

Fogel spent much of his time as Pitt Professor of American Institutions at Cambridge in 1975–1976, reading demography. At this time, he became interested in more fully documenting trends in mortality in North America, with a view to resolving current uncertainty about demographic historians over whether trends in mortality rates during the eighteenth and nineteenth centuries in North America were increasing, decreasing, or level. He thus began a project with the working title "the Economics of Mortality in North America, 1650–1919." His commitment to demographic issues was evident when, upon his return to the University of Chicago in 1981 as the Walgreen Professor of American Institutions, he also established and became Director of the Center for Population Economics. Through his work on mortality, he became increasingly aware of the potential insights that anthropometric measures could provide on nutritional status and the health of populations. This led Fogel to initiate a second large-scale project he called "Secular Trends in Nutrition, Labor Welfare, and Labor Productivity," which aimed to collect numerous data sets on stature, mortality, and related measures for hundreds of thousands of people in North America and Europe. This, in turn, has generated a burgeoning literature using anthropometric measures to examine spatiotemporal patterns in nutrition and its relation to biological well-being and health status. Among other interesting findings generated by this research were the observations of cycles in nutrition as evidenced by cycles in median heights in populations (see Craig 2016 for survey).

Fogel's initial major source for his work on the USA was the pension records of the Civil War Union Army that provides very detailed medical histories of these veterans from the Civil War into the Twentieth century.

During his American Economic Association presidential address, Fogel (1999, p. 2) put forward the concept of "technophysio evolution," which he defined as "the existence of a synergism between technological and physiological improvements that has produced a form of human evolution that is biological but not genetic, rapid, culturally transmitted, and not necessarily stable." Floud et al. (2011, p. 3) set forth the following five building block mechanisms contributing to technophysio evolution:

1. The nutritional status of a generation – shown by the size and shape of their bodies – determines how long that generation will live and how much work its members will be able to do.
2. The work of a generation, measured both in hours, days, and weeks of work and in work intensity, when combined with the available technology, determines the output of that generation in terms of goods and services.
3. The output of a generation is partly determined by its inheritance from past generations; it also determines its standard of living and its distribution and wealth, together with the investment it makes in technology.
4. The standard of living of a generation determines, through its fertility and the distribution of income and wealth, the nutritional status of the next generation.
5. And so on ad infinitum.

What this translates into in long-run trends is that in the last few centuries, the human body has become taller and heavier per unit inch in response to

improvements in the food supply. This in turn led to substantial increases in effective labor supply as improved nutrition provided additional energy for the population to work intensively for many hours per day on average throughout the year.

One important exposition of the implications of this was *The Escape from Hunger and Premature Death, 1700–2100*, *Europe, America, and the Third World* (2004), which argued for nutritional improvements as a key driver of economic growth and improvements in health and declining mortality. Fogel's last major book, co-authored with Roderick Floud, Bernard Harris, and Suk Chul Hong, *The Changing Body. Health, Nutrition, and Human Development in the Western World since 1700* (2011) provides a survey and synthesis of evidence on how the five building block mechanisms interacted and played out in the cases of Britain, Continental Europe, and North America. It has been observed (Margo 2012, p. 542) that while richly interdisciplinary, incorporating work by medical doctors, nutritionists, demographers, statisticians, and historians, economic analysis plays "a supporting role" with not much coverage of "behavioral incentives, or market equilibrium, or the economics of the underlying institutions of food processing and distribution."

Conclusion: Fogel, Kuznets, and the Empirical Tradition in Economics

During his stay at Harvard, Fogel also became involved with the reorganization of the National Bureau of Economic Research and was influential in its Development of the American Economy (DAE) project. Both the DAE project and his work on demography and nutrition implied a focus on long-run change, arguably the basis for integrating economics and economic history. In this way, he followed in the footsteps of his mentor, Simon Kuznets. Kuznets did not define himself as an economic historian (see de Rouvray 2004). Fogel's own subsequent work has focused more on long-run trends in demography than economic history as such. He described his research areas as the bio-demography of aging and health economics rather than economic history (Mitch 2005); all the same, his influence on economic history continues through his students. His pursuit of the inter-relationships between nutrition, health, and human heights was a major impetus behind the rise of the field of historical anthropometrics (Meisel and Vega 2006).

In a 1978 interview with Simon Kuznets, Fogel observed "even though it [NBER project] started out being called the program in Economic History, my own conception of it is as a program in American economic development, with emphasis on trying to get a better picture of the long-term trends that have influenced the development of the economy – to determine whether or not these trends are still at work and what they are."[11]

[11]Travscript of interview located in Robert W. Fogel papers Box 84, NBER program folder, quote is from p. 4, 3/13/78 interview of Robert Fogel with Simon Kuznets.

While teaching at Harvard in the late 1970s, Fogel had continued to label his economic history course "Strategic Factors in American Economic Growth." But on returning to Chicago in the Fall of 1981, he offered a course entitled "Long-term factors in American Economic Growth." He indicates in his lecture notes that in the Winter 1982 Quarter, he would offer a course entitled "Problems in the development of American Economy," aimed at those intending to do research in economic history. The "Long-term factors" course was intended "to provide students interested in issues of current economic policy – interested in the policy issues of the 1980s, with the empirical background they need to adequately assess those issues." He goes on to elaborate, "I have placed an emphasis on long-term factors that affect current policy in order to emphasize that many issues that are today treated as of recent origin are quite long-standing and may not yield to treatment aimed at quick cures."[12]

A defining feature of his modus operandi on his return to Chicago was the research team. Fogel (1975c) noted that cliometrics had "ushered in a new style" featuring the research team made necessary by the large-scale collection and analysis of quantitative data. And he notes at the end of this article (p. 670) that:

> Interaction and cooperation among scholars is not new but it is now being practised on a new scale. The use of numerical evidence was always a feature of historical analysis, but earlier investigators did not have the large grants needed to finance the massive collection of data, nor the hardware required to process them.

And in his 1983 essay on traditional versus scientific history, Fogel notes that "large-scale, collaborative research. . ..[is] a hallmark of cliometric work (Fogel and Elton 1983, p. 61)." His work since the mid-1970s on long-run trends and determinants of nutrition, health, and mortality has featured the utilization of very large data bases, such as Union Army pension records, which has necessarily required large research teams. The theme of big data and use of population level sources was taken up by Fogel's student, Richard Steckel, in his SSHA presidential address (Steckel 2007).

Fogel had already employed a large research team for his work on slavery. His collaborative work with frequent co-author, Stanley Engerman, date back to the 1960s.[13]

Although Fogel achieved renown for his application of economics and quantitative methods to the study of history, throughout his career his research was informed by the view that economic history is indispensable for understanding economic processes and current economic issues. He believed, to quote Schumpeter (1954, p. 12), "the subject matter of economics is essentially a unique process in historic time" (Mitch 2005). His work on the railroads was intended to address a key issue regarding economic growth. His work on slavery was motivated by a desire to use an understanding of the past to inform contemporary social issues. His work

[12]Syllabus and Lecture notes for this course located in Robert W. Fogel papers Box 59.

[13]For Engerman's perspective on this collaboration see Engerman (1992).

on nutrition and mortality focused on the centrality of long-run change (2004). And his presidential address to the American Economic Association argued that the discipline of economics requires historical perspective to come to grips with the problem of accelerating technological change (Fogel 1999).

Fogel's overall assessment was an optimistic one in the tradition of Kuznets. He viewed technological change as a long-run driver of human improvement, which, with interactions with the human body itself, has led to dramatic improvements in life expectancy and well-being. In this he contrasts with North's underlying pessimism, or at least cynicism, about prospects for improvement given inherent difficulties with human institutions. Nevertheless, Fogel did have concerns about spiritual aspects of human experience, considered at length in his 2000 book *The Fourth Great Reawakening,* and one that he returned to in his final volume on the legacy of Fogel et al. (2013). In sum, Robert Fogel's remarkable career and contributions point to both the power and the challenges of pursuing cliometrics.

Douglass North and Cliometrics

Abstract

Douglass North (1920–2015) was one of the founders of the disciplines of cliometrics and the New Institutional Economics. He spent over six decades teaching economics and economic history at the University of Washington (1950–1981) and Washington University in St. Louis (1983–2015). In the 1950s and 1960s, North applied neoclassical economic models and quantitative techniques to major problems in US economic history and made significant advances on such topics as interregional trade, ocean shipping productivity, the US balance of payments, and sources of US growth. Switching his attention to European economic history from the late 1960s, North became convinced that economic historians needed to adopt a broader approach to analyzing long-run economic change that explicitly accounted for how economies were embedded in political, economic, and cultural institutions. After the publication of two major books using his new approach, *Structure and Change in Economic History* and *Institutions, Institutional Change and Economic Performance*, North and Robert Fogel were

awarded the 1993 Nobel Memorial Prize in Economics. Over the next 22 years, North's frame of analysis continued to expand. In his 2005 book, *Understanding the Process of Economic Change*, he argued that economists needed to draw from the sciences of human cognition and social psychology to understand why institutions form and how they change. In his last book, *Violence and Social Orders* (co-authored with John Wallis and Barry Weingast), North made the case that institutions arise in most societies to control the use of violence and are capable of supporting an open political order only in limited circumstances.

Introduction

Douglass Cecil North was born on November 5, 1920, in Cambridge, Massachusetts. His childhood was spent in Canada, England, France, Switzerland, and Connecticut. He graduated from the prestigious Choate private school in Wallingford, Connecticut. His father worked in the insurance industry and would become the president of MedLife, a West Coast insurance company. North graduated with a B.A. from the University of California, Berkeley, where he became a Marxist. A conscientious objector during World War II, he spent the war years as a navigator with the Merchant Marine. After the war, he returned to Berkeley to study economics and worked with Professor M. M. Knight, the brother of the well-known University of Chicago professor, Frank Knight. His dissertation, a study of the history of the life insurance industry in the United States, was completed in 1952. North joined the Department of Economics at the University of Washington in 1950 as an acting assistant professor and would continue as a faculty member in the department through 1983. In 1983, North moved to St. Louis, Missouri, becoming the Henry R. Luce Professor of Law and Liberty in the Department of Economics at Washington University in St. Louis. In 1993, North and Robert Fogel were awarded the Sveriges Riksbank Prize in Economic Sciences in Memory of Alfred Nobel. He was a founder of the International Society for the New Institutional Economics (now the Society for Institutional & Organizational Economics) and became its second president in 1998. North was a Senior Fellow at the Hoover Institution, which he visited regularly. Many summers were spent in Benzonia, Michigan, and North and his wife, Elizabeth Case, moved there year-round in 2014. He passed on November 23, 2015.

Douglass North's long and creative career was aptly summed up by the Royal Swedish Academy of Sciences when it awarded the 1993 Nobel Prize in Economics to Robert Fogel and North "for having renewed research in economic history by applying economic theory and quantitative methods in order to explain economic and institutional change." The Academy then caught the essence of both the man and the economic historian by praising him as "an inspirer, a producer of ideas, who

identifies new problems and shows how economists can solve the old ones more effectively" (Royal Swedish Academy of Sciences 1993).

North's influence on the field of economic history was primarily due to his path-breaking research on institutional change but also to the large number of economic historians who he mentored, taught, and inspired at the University of Washington (UW) and Washington University in St. Louis (WUSTL). UW students who were supervised or strongly influenced by North include three undergraduates who became prominent economic historians – Lance Davis, Jonathan Hughes, and Richard Sutch – and numerous Ph.D. students, including Terry Anderson, Lee Alston, Ben Baack, Richard Bean, Gordon Bjork, Philip Coelho, Rodgers Taylor Dennen, Price Fishback, Gerald Gunderson, Sumner La Croix, Robert McGuire, Lloyd Mercer, Ramon Myers, Roger Ransom, Clyde Reed, Gaston Rimlinger, James Shepherd, John Tomaske, Richard Tretheway, Irwin Unger, John Joseph Wallis, Gary Walton, and Robert Willis. A comparable list for WUSTL Ph.D. students includes Lorena Alcazar, Eliana Balla, Mary Ann Boose, Art Carden, Hugo Eyzaguirre, Tawni Hunt Ferrarini, Daniel C. Giedeman, Peter Z. Grossman, Bradley Hansen, Michael Haupert, Shawn Humphrey, Mansor Haji Ibrahim, Iacovos Ioannou, Shilpi Kapur, Philip Keefer, Janice Rye Kinghorn, Jeanine Koenig, Felix Kwan, Noel Johnson, Ruey-Hua Liu, Jeremy Meiners, Michael Munger, Randall Nielsen, Michael J. Orlando, Brian Roberts, Andrew Rutten, Werner Troesken, Mark David Vaughan, and Timothy Yeager.

In an ode to North's graduate teaching, Jonathan Hughes wryly observed that "the charisma emanating from North's lectern was slight indeed" yet then described his graduate seminar as a "place of excitement" (Hughes 1982: 11). Hughes attributed North's effectiveness as a teacher to his constant quest for new ideas and to his instillation of an attitude in his students to strive to be original. Hughes (1982: 10) noted that North always said "something like this" to each of his graduate students:

> If you are one of those who can be original, then it is your duty to the profession to write and publish. Do your work and *never look back*. Don't listen to critics until you've finished. Everyone can criticize; very few can produce new ideas. We must have new ideas; without them the field will die.

And while North constantly challenged students with his critical attitude, Hughes (1982: 11) noted that "[h]e also handed his students a sense of fun and life . . . You were his student, so you were worth something in the world by right."

North's career as a teacher and scholar saw prodigious accomplishments but was also marked by a relentless and restless search for a better analytical framework to analyze long-term change in economies and institutions. In the late1950s, he was one of a small group of economic historians who started the theoretical and quantitative revolution known as "cliometrics," a movement that brought the analytical tools of neoclassical economics and econometrics to economic history. From the mid-1950s to the early 1970s, North used the analytical engine of neoclassical economics to write two books on American economic history (*The Economic Growth of the United States, 1790–1860* and *Institutional Change and American Economic Growth*) and one book on European economic history (*The Rise of the Western*

World). His brilliance is perhaps best seen in his willingness to announce that neoclassical economics would not suffice to understand the issues posed by historical economies and that its analytical tools needed to be augmented with insights from the emerging field of transaction cost economics. In his seminal 1981 book, *Structure and Change in Economic History*, North again challenged economic historians to further broaden the scope of their analytical framework by incorporating explicit theories of the state and ideology. His 1991 book, *Institutions, Institutional Change and Economic Performance*, followed up by providing a more lucid development of specific theoretical concepts and new applications to American and European history. Despite the successful application of his expanded analytical framework, North came to the realization during the 1990s that it was impossible for economic historians and other social scientists to understand processes of economic, political, and social change until they explicitly considered how individuals form their beliefs about the physical and human world. In his 2005 book, *Understanding the Process of Economic Change*, North urged social scientists studying institutions to incorporate insights from evolutionary biology and cognitive science into their models. North's last book (co-authored with John Wallis and Barry Weingast), *Violence and Social Orders*, is unique in that it makes no new calls for an expanded analytical framework yet is strikingly original in its attempts to consider fundamental relationships between violence and the formation of states.

North's Early Career as a Neoclassical Economist and Cliometrician

North's early career at the University of Washington was marked by innovative research in which he staked out bold theoretical positions regarding US growth and assembled important data series critical to understanding US economic growth. Consider four articles published in leading economics and economic history journals between 1955 and 1960. His 1955 article, "Location Theory and Regional Economic Growth," set forth an original explanation of the differential pattern of growth, education, and inequality across the South, Northeast, and Midwest regions (discussed further below). The article was widely read and cited (45 times) by economists and economic historians in the 1950s and cited 1,550 times by 2017. His 1959 article, "Agriculture and Regional Economic Growth," used the framework developed in the "Location Theory" article to criticize arguments put forth by J. Kenneth Galbraith (1951), Theodore Schultz (1953), and Walter Rostow (1956). In North's words, all contended that "[g]rowth is associated with industrialization and stagnation with agriculture." North (1959: 950–951) countered that:

> this misses the whole problem of economic change and reflects a basic misreading of the economic history of the past two centuries. Involvement in the larger market economies, despite the evident hazards entailed, has been the classic way by which regional economies have expanded. It has resulted in specialization, external economies, the development of residentiary industry, and the growth of vertical "dis-integration" as a result of the widening of the market . . .

> . . . the relevant problems of regional economic development revolve around the issues raised in the main body of this paper. They are not issues of agriculture versus industrialization but rather revolve around a region's ability to become integrated into the larger markets of the world through exports, and of the resultant structure of the regional economy which will influence its ability to achieve sustained growth and a diversified pattern of economic activity.

North (1959: 951) then boldly stated that regional development theories predicated on the necessity of achieving industrialization fail to explain "the 19th century economic history of the Midwest from 1815–1860, the Pacific Northwest from 1880–1920, or even California from 1848–1900 . . ."

North's 1958 article on ocean freight rates over the 1790–1913 period provided a short preview of what was to come in his 1968 article on the same topic. He presented a quick look at new data on ocean freight rates for wheat and timber that revealed a long secular decline in rates over the period, interrupted sporadically by increases due to war and capacity bottlenecks. A major contribution of the article was its conjecture that the secular decline in freight costs was due not just to technological change in ship construction but also to external economies that accompanied expansion of particular export markets, to better capacity utilization from the rise of immigration from Europe to the Americas, and to the overall expansion of global trade.

North's 1960 article, "The United States Balance of Payments 1790–1860," was a fundamental contribution to the construction of historical national accounts for the United States. Earlier estimates had presented 12-to-30-year aggregates of the balance of payments, whereas North (1960: 573) was able to construct annual series from 1820 and 5-year moving averages from 1790 through 1819. North (1960: 573) coordinated his "methods and procedures" with Matthew Simon who was conducting a similar project for the US balance of payment series from 1860 to 1900. The publication of both studies in 1960 "provided a consistent and continuous series for the entire period of 110 years" (North 1960: 573; Simon 1960). The new series were anchored in reliable estimates of the merchandise trade balance. Invisible items in the payment calculations were dominated by shipping earnings which after 1815 failed to rise as fast as the expansion in US trade primarily because of falling ocean freight rates. Calculation of the balance of payment series also enabled calculation of an aggregate US foreign debt series. This provided a robustness check for the project as its estimate of US foreign debt compared well with careful estimates of the foreign debt made for particular years (North 1960: 183–184).

North's first book, *The Economic Growth of the United States, 1790–1860*, brought together several themes developed in his earlier articles. He made a point in the preface of emphasizing the role of markets in US growth and downplaying the role of institutions (North 1961: vii): "Institutional and political policies have certainly been influential . . . But they have modified rather than replaced the underlying forces of a market economy." To a modern reader, the book is an intense blizzard of tables and graphs, but they served the purpose of providing basic empirical foundations for North's new ideas regarding patterns of regional growth in the antebellum economy. Two important theses were developed at some length in the book. One thesis was that a necessary (but not sufficient) condition for

regional economic growth to emerge is for an export sector to experience strong growth. A single export sector can suffice to jump-start regional growth, but regional diversification into multiple export sectors provides the path to long-term regional growth. North used this idea to explain why the South's reliance on a single export crop, cotton, led to stagnation of growth vis-à-vis the Northeast and Midwest which had multiple export sectors experiencing strong growth. North's ideas on the contribution of exports to regional economic growth drew heavily from Richard Baldwin's (1956) seminal article on the same topic which, notably, also triggered a decades-long debate among development and trade economists over the same topic.

North's second and more important thesis was that the different types of organizations used in agriculture in the North, Midwest, and South provided the foundations underpinning the different patterns of trade flows, educational achievement, income inequality, and innovation across these regions. Claudia Goldin (1995: 199) aptly summarized this thesis:

> According to Douglass North, the roots of southern stagnation are to be found in the geographic patterns of trade in the antebellum period. The South, using slave labor, grew cotton and exported it to the American North and to Britain. With the receipts from its northern shipments it purchased foodstuffs from the Midwest and industrial goods from the North. With its receipts from European shipments, it purchased luxury items and other industrial wares. Little was ploughed back into the South as internal improvements. Schooling was denied slaves and was poorly provided to southerners in general. Cities, those generators of agglomeration economies, were rare in the South. Innovation was thereby stifled.
>
> The North ran a very different ship. With far more equality of income and wealth, northerners purchased goods produced by local tradesmen and local firms. Its funds were ploughed back into local industry and internal improvements. Its people were the best educated in the world. The North established institutions that served an egalitarian society and that furthered an industrial and growing region. The South had norms that reinforced a caste and race-based society and that inhibited growth at the service of a master class. Such institutions have long lives.

Some scholars have questioned particulars of North's regional trade narrative, noting, for example, that most Southern farms were self-sufficient in food and that Southern purchases of food from the Midwest were probably smaller than depicted by North (Goldin 1995: 199). The overall story told by North still resonates with economic historians, and its straightforward analysis of the different conditions and institutions that emerge from large plantations and small family farms provided the basis for its later elaboration and generalization to the global stage by Stanley Engerman and Kenneth Sokoloff (2000).

Doug North was among the economic historians using cliometric methods who met in 1960 at Purdue University, and annual cliometric conferences quickly became a forum for interchange and discussion of ideas and methods by rising younger scholars and established senior scholars. North and William Parker became co-editors of *The Journal of Economic History* in 1960, and subsequently each issue of the *Journal* began to include one paper that used cliometric methods (Diebolt

and Haupert 2017). The supply of cliometric papers grew in the early 1960s, and North trumpeted this trend in his 1963 *American Economic Review* article that announced the new movement to the broader economics profession. North would continue to be an advocate for cliometrics throughout his career and encouraged those who used cliometric methods to continue to expand the scope of the questions they addressed and to incorporate learning from other disciplines (Libecap et al. 2008).

In 1966, North published a collection of essays, *Growth and Welfare in the American Past: A New Economic History*, which he thought showcased the new economic history. Richard Sutch (1982: 24–25) observed that the essays were designed to introduce both economic history teachers and students to the new economic history. He found that "[i]n each essay, North used simple economic theory and the tabular presentation of quantitative data to challenge views that were widely held at the time . . . On topic after topic North demonstrated how the most elementary economic theory could be used to cast doubt upon venerable interpretations of the past." Perhaps the major contribution of the book was that it stimulated economic historians to think further about the hypotheses put forth on the burden of the Navigation Acts, income growth in the South between 1840 and 1860, public land policies toward railroads, and agrarian discontent, among others. As Sutch (1982: 27) succinctly put it, "*Growth and Welfar*e sent more than a few hares off and running," and "a host of newly converted New Economic Historians enthusiastically gave chase."

The expansion of North's frame of analysis from an economist focused on historical markets to one focused on historical institutions and markets first came into focus with his 1968 publication, "Sources of Productivity Change in Ocean Shipping 1600–1850," in the influential *Journal of Political Economy*. Deidre McCloskey (2010) praised this article as North's "best scientific work," noting its careful attention to how productivity in this industry was improved by reducing transaction costs. The article used state-of-the-art methods to estimate change in productivity for ocean shipping, and it revealed big increases over the period. What was notable about this finding was that most of the gains in productivity were not due to technical changes in shipping and ship construction but rather to "a decline in piracy and an improvement in economic organization." The use of bigger ships increased load factors, the time spent in port declined, and the amount of armament and manpower per average ton of ship declined. North attributed the adjustment in the last factor to the big decline in piracy that occurred over this period. Knick Harley's (1988: 868–869) study of ocean shipping rates took issue with North's findings. He found that declines in shipping rates pre-1850 were primarily due to the integration of a "relatively young American economy" into "the wider European economy" and productivity advances in shipping cotton, while declines in shipping rates after 1850 were primarily due to changes in "mechanical and metallurgical technology" that reduced the costs of constructing and operating ships.

North's focus in his ocean shipping research was ultimately on how improvements in the institutional environment reduced the risk of piracy which, in turn, allowed organizations in the industry to make changes in their structure and operate more efficiently. This research was a harbinger of a recurrent theme in his work, that

institutional change led to changes in the structure and variety of organizations operating in the market and that these organizations often had incentives to effect institutional change to further their own objectives. From the mid-1960s through the early 1970s, North's research agenda focused on how changes in market prices could induce both efficient changes within organizations operating within the market and efficient institutional change. For North, this phase of his research would be relatively short-lived, yet the books that emerged from this agenda would prove to be long-lived, highly influential, and very controversial.

From Cliometrics to Neoclassical Theories of Institutional Change

From the mid-1960s to the mid-1970s, North's research refocused on the role of institutions in retarding or stimulating economic growth. North collaborated with fellow cliometrician Lance Davis to investigate how tools of neoclassical economics could be used to understand long-term institutional change in the American economy. The result was a 1971 book, *Institutional Change and American Economic Growth*, which showed how changes in relative prices had induced efficient changes in the American institutional framework. The late 1960s also marked a switch in North's research interests toward historical European economies. In 1973, North and his University of Washington colleague, Robert Paul Thomas, published a 158-page book, *The Rise of the Western World: A New Economic History*, which provided a panoramic view of 800 years of European history.

The book by Davis and North built upon their earlier co-authored article (Davis and North 1970), "Institutional Change and American Economic Growth: A First Step Towards a Theory of Institutional Change." The centerpiece of this line of research is their theory of efficient institutional change. Efficient institutional change is triggered when an "action group," which could be an organization, a group of organizations, or even an individual, perceives that a change in a particular institution would not only generate gains for them and others but that the aggregate gains would exceed the costs borne by other organizations and individuals. Whether action groups take on the task of advocating and organizing institutional change depends upon how burdensome existing arrangements and laws are, the society's current technology, and the degree of novelty involved in the proposed changes. An effective action group would need to devise arrangements that provide losing groups with some type of compensation for their losses. Compensation reduces opposition to the proposed changes and increases the likelihood that efficient institutional changes are realized. As these changes culminate over time, the result is sustained economic growth.

In the 1971 book, Davis and North apply their theory to central topics in American economic history. Topics covered include land policy and agriculture, organization and reorganization in financial markets, transportation developments and economic growth, economies of scale and unsuccessful cartelization in manufacturing, institutional change in the service industries, organization and education of the labor force, and the changing public-private mix of economic activities. Davis and North were remarkably humble in evaluating their applications, noting

in the introduction that "the explanation at times [are] incredibly simplistic" while proclaiming that the book "represents a first step towards a useful theory of economic growth." Richard Sutch (1982: 34–35) pointed out that Davis and North were themselves aware that their theory could not explain the timing of many institutional changes analyzed in the book (Davis and North 1971: 263). In his review of their book, Alan Bogue (1972: 962) also drew attention to the authors' own perceptions of "the inadequacies" of their theory:

> In their eyes these include among others: the static nature of the model, the problem of tracing inter-sectoral relationships, the fact that profit maximization may be less adequate as an explanation of institutional change than in other aspects of economic process, the paucity of our knowledge about information flows, the fact that redistributive potential may stimulate arrangements of a different nature than the theory would at first suggest and that aspects of the political process are not completely compatible with the model.

Inadequacies aside, North had enough confidence in the theory's explanatory power to showcase it again in his 1973 book with Robert Thomas, *The Rise of the Western World*. In the book's preface, North and Thomas announced that "this is intended to be a revolutionary book" in that they "have developed a comprehensive analytical framework to examine and explain the rise of the Western World; a framework consistent with and complementary to standard neo-classical theory" (North and Thomas 1973: vii). Their analysis of changes in economies and institutions over eight centuries focuses on how population change led to changes in the relative price of land and labor, which, in turn, led to institutional change.

The book "steps into history" in the tenth century "when feudalism and manorialism shaped the society of much of Western Europe" (North and Thomas 1973: 9). Consider now a very brief synopsis of their brief synopsis of eight centuries of complex history. With the breakdown of the order provided by the Carolingian Empire, North and Thomas contended that the institution of the manor arose to cope with the most basic social problem, the control of violence. In their model, fleshed out more fully in an earlier article (North and Thomas 1971), the lord offered to the tenant the protection of the castle as well as land to farm in common fields in exchange for the tenant's fealty. Over the course of the next three centuries, security improved, population slowly increased, and settlement expanded in the frontier areas between villages. In Southern Europe and parts of Northern Europe, cities grew, and as trade increased, new trade networks emerged, along with institutional structures designed to support trade. As European populations expanded, the bargaining power of lords improved. Wages fell, rents increased, and the change in factor prices induced institutional changes that favored lords. A series of famines and epidemics in the fourteenth century culminated with the Black Death and substantially reduced population in Britain and across the continent. The drastic declines in populations led to increases in wages and declines in land rents. Competition among lords for tenants led to gradual changes in manorial institutions that would eventually end serfdom in Western Europe. Declining population also reduced trade, and cities adopted institutional arrangements that were "more 'defensive' in nature." "By the

time population began to grow in the last half of the fifteenth century, the basic structure of a feudal society had given way." Better ships and navigational methods led to the discovery of the new world at the end of the fifteenth century, and the flood of treasure from the new world lubricated the emerging trade between Western Europe with "its centers of skilled trades and manufactures" and Eastern Europe where lands "were still abundant relative to population." Over the next two centuries, changes in military technology occurred that increased the "optimal size of the most efficient military unit." For the larger political units, they needed to raise revenue, and this typically meant that they encouraged trade, as it could be taxed by the ruler. North and Thomas concluded that the search for revenue by emerging nation states led countries down different paths. In France and Spain, monarchs were able to develop a system of taxation that effectively raised revenues while depressing economic growth. By contrast, in Holland, an "oligarchy of merchants" rose to power, while in England, the Glorious Revolution established "the ascendancy of parliament over the crown." In both countries a body of property rights emerged "which promoted institutional arrangements, leading to fee-simple absolute ownership in land, free labor, the protection of privately owned goods, patent laws . . . and a host of institutional arrangements to reduce market imperfections in product and capital markets" (North and Thomas 1973: 17–18).

Criticism of the narratives relayed in *The Rise of the Western World* came from many quarters. Stefano Fenoaltea (1975) presented a trenchant critique of North and Thomas's model of the English medieval manor, a model that provides the foundation for much of North and Thomas's analysis of the tenth-to-thirteenth centuries. In particular, Fenoaltea focused on North and Thomas's argument that "[s]erfdom in Western Europe was essentially a contractual arrangement where labor services were exchanged for the public good of protection and justice" (North and Thomas 1971: 778). Fenoaltea (1975: 387) characterized their "ingenious interpretation" as "empirically unacceptable," noting that their argument "is contradicted by a variety of facts, from the pattern of manorial organization to the technology of medieval warfare." Moreover, "[t]he argument that the 'classic' manorial arrangement of labor services minimized transaction costs also seems erroneous, since North and Thomas appear to misspecify the feasible alternatives (which in fact included indirect barter and market exchange) and misrank the alternatives they consider (as even rents in kind appear superior to labor dues)" (Fenoaltea 1975: 408).

Herman van der Wee's (1975) review of *The Rise of the Western World* extolled the book as offering "precious reward" while criticizing their model of institutional change as far too reductionist: "The reduction of the institutional framework to the problem of property rights in land and man seems to me too narrowly juridical and should be tempered by social, economic, geographical, and cultural points of view" (van der Wee 1975: 238). Van der Wee praised North and Thomas for criticizing the singular emphasis in the Marxist model on the role of technological change in generating institutional change and then sent the same criticism to them for their singular emphasis on population change in generating institutional change. Without explicit discussions of the interdependence of these factors, "both explanations are . . . one-sided" (van der Wee 1975: 238).

Alexander Field (1981) criticized the North-Thomas research agenda for using neoclassical economic principles to explain endogenous institutional variation. Field argued that neoclassical theory is built upon a central assumption that certain elements in a general equilibrium model are exogenous, e.g., "endowments, technologies, preferences, and rules" (Field 1981: 184). He noted that in *The Rise of the Western World*, North and Thomas treat all of the usually exogenous elements as endogenous variables to be explained within their model. Field then argues that "some subset of institutional structures or rules needs to be treated as parametric" in a model of institutional change or the model will not be able to identify all of the phenomena that it attempts to explain.

Despite the extensive criticism, *The Rise of the Western World* was successful in one big way: it refocused the attention of many economic historians on the role of institutions in generating sustained economic growth over long historical horizons. The criticisms and the difficulty in putting together the two books on the European and US economies also forced North to recognize that neoclassical economics was inadequate to the task of explaining institutional change and to explicitly acknowledge that institutional change has not always proceeded efficiently. North's 1978 article, "Structure and Performance: The Task of Economic History," in the *Journal of Economic Literature* was influential because it rejected the idea, used in his 1971 and 1973 books, that the standard tools of neoclassical economics could provide sufficient foundations to explain why institutions arise and how they change over time. North (1978: 963) criticized economic historians for failing to support a historical framework that would enable economists to place contemporary problems in perspective. He admonished that the "[f]ailure of economists to appreciate the transitory character of the assumed constraints and to understand the source and direction of these changing constraints is a fundamental handicap to further development of economic theory." North (1978: 974) then appealed to economists to "go beyond the traditional boundaries of economics to explore political behavior, the growth and application of scientific knowledge, and demographic change." A hint at the direction that North's future research would take came with his call in the article for economic historians to integrate transaction costs into the economic framework used to analyze historical institutions (North 1978: 974–975).

North's subsequent incorporation of transaction cost considerations into his research was partly due to his search for an expanded set of economic tools that could be applied to historical materials and partly due to the intellectual atmosphere in the economics department at the University of Washington that supported vigorous discussion of the role of transaction costs in understanding how markets, firms, and governments were organized. Two colleagues, Yoram Barzel and Steven N.S. Cheung, had both spent time at the University of Chicago and had been influenced by Ronald Coase's use of transaction costs to explain how actual markets and firms were organized. As their stimulating work unfolded during the 1970s, North saw that incorporating transaction costs into his analysis of institutions provided a vehicle for understanding why economic institutions did not always change promptly or efficiently, and from the late 1970s, his research explicitly incorporated transaction cost economics.

In 1982 North and his former doctoral student, John Wallis, published an influential short article that criticized "crude predatory theor[ies] of the state in which government is simply a gigantic transfer mechanism for redistributing wealth and income" (North and Wallis 1982: 336). They emphasized instead that the "wedding of science and technology in the late nineteenth century made possible a technology of production whose potential was only realizable with an enormous increase in the resources devoted to political and economic organization – the transactions sector of the economy. A substantial part of this increase has occurred in the market and through voluntary organization, and a substantial share has also been undertaken by government" (North and Wallis 1982: 336). North and Wallis examined their thesis by dividing government expenditures for 15 OECD countries over the 1953–1974 period into two categories, transfers and transaction services. During this period of strong economic growth, they found that the share of transaction services grew faster than GDP and was relatively stable across countries (North and Wallis 1982: 338).

In a 1986 article, Wallis and North conduct a more in-depth breakdown of the transaction cost components of private and public sectors of the US economy from 1870 to 1970. Because many components of transaction costs are not easily measured, they focused their analysis on measuring transaction services provided by particular industries and by particular occupations (Wallis and North 1986: 103). Banking, insurance, finance, real estate, wholesale services, and retail services are identified as the primary industries providing transaction services, and all of their revenues are counted as transaction services. Occupations such as lawyers, accountants, judges, notaries, police, guards, managers, foremen, inspectors, sales workers, clerical workers, and personnel and labor relations workers are identified as providing transaction services, and wages of these employees in firms outside the transaction service industries are counted as transaction services (Wallis and North 1986: 105–106). Their central finding is that the percent of GNP accounted for by transaction services rose from about 25% in 1870 to over 50% in 1970 (Wallis and North 1986: 120). They identify a number of reasons potentially responsible for the increase: "[I]ncreasing specialization and division of labor; technological change in production and transportation accompanied by increasing firm size; and the augmented role of government in relationship to the private sector" (Wallis and North 1986: 123). They conclude that the main contribution of this line of research is its identification of the "sheer volume" of resources devoted to supporting transactions in US markets.

In a third short article, Wallis and North consider whether the treatment of transaction service sectors in US GNP accounts biases its calculation. They find that excluding final goods in the transaction service sector from GNP reduced the level of GNP in both 1870 and 1970 but had little effect on GNP growth rates (Wallis and North 1988: 653). Their transaction cost quartet concludes in 1994 with a paper examining a classic proposition drawn from Ronald Coase's research: given the existence of a specific technology, firms will choose institutions to minimize transaction costs. North and Wallis expand the inquiry to ask whether Coase's proposition still holds when firms simultaneously choose institutions and technologies. In this broader context, they show that it "is demonstrably false. Institutions will be chosen

that minimize total costs, the sum of transformation and transaction costs, given the level of output" (North and Wallis 1994: 610). The distinction is important because the broader proposition allows for institutional change within a firm to be a vehicle for implementing technical change and "also allows for institutional change to be an important and independent source of growth" (North and Wallis 1994: 610–611).

Expanding the Frame of Institutional Economics

North's 1981 book, *Structure and Change in Economic History*, was completed when he was 60 years old, and it represents a watershed for his research, as it sets forth an agenda for research in global economic history and institutional change that he would pursue for more than three decades. North identified four new elements as necessary building blocks for any viable theory of institutional change. First, he urged economic historians modeling institutional change to reconsider their reliance on models based on neoclassical economics and instead use models that explicitly blended considerations of transaction costs with neoclassical economics. Once this broader framework became North's engine of analysis, then a central implication of earlier models based on neoclassical economics – that institutional change leads to more efficient outcomes – no longer holds. This was a critical change in perspective as it allowed North's new theory of institutional change to encompass a broader range of economic and political outcomes seen in Africa, Asia, and South America as well as a much longer range of human history. Second, North contended that a theory of institutions must be built upon a theory of property rights, but, third, for a theory of property rights to make sense, it needs to be grounded in a theory of the state. A theory of ideology was the fourth new element set forth by North, and it is a necessary element because it is a critical building block in understanding how "different perceptions of reality" lead individuals to respond differently to common changes in the objective environment.

North's model of the state has been highly influential in the social sciences, and this is due in part to its simple definition of a state: "[A]n organization with a comparative advantage in violence, extending over a geographic area whose boundaries are determined by its power to tax constituents" (North 1981: 21). "The basic services that the state provides are the underlying rules of the game" (North 1981: 24). To raise tax revenue, the ruler specifies property rights in man and land that will be at least partly enforced by the state. Typically, there is a trade-off between adoption of more efficient institutions and the ruler's interests, such as raising additional revenue (North 1981: Chap. 3). One of the model's well-known implications is that "the property rights structure that will maximize rents to the ruler (or the ruling class) is in conflict with that that would produce economic growth," and this produces tensions between the interests of powerful groups and the ruler (North 1981: 28).

North was emphatic that institutional change can only be understood when models take into account how ideology frames people's perceptions of reality. Models of institutional change derive rules that govern actions taken by individuals, but which maximizing individuals have incentives to disobey in some situations, i.e.,

to free ride. North (1981: 45–46) pointed out that in other situations, individuals stick to the rules even in instances when they could violate them with little fear of punishment. North then argued that ideology, defined as "intellectual efforts to rationalize the behavioral patterns of individuals and groups," accounts for much of these deviations, as it provides an "economizing device" to simplify decision-making in a complex environment. Ideology "is intrinsically interwoven with moral and ethical judgments about the fairness of the world the individual perceives," and individual ideologies tend to change when "their experiences are inconsistent with their ideology" (North 1981: 48–49). Most importantly, theories of institutional change that fail to incorporate a theory of ideology will flounder in explaining participation of individuals and organizations in politics as well as decision-making by politicians.

North's application of *Structure and Change*'s theory to historical institutions runs just 130 pages and sweeps over 10,000 years of human history, beginning with a model of the transition from hunting and gathering to agriculture and ending with an analysis of the progressive movement in the United States during the early twentieth century. Chapter 7, "The First Economic Revolution," provides a simple theory of the transition to agriculture that uses population pressure to induce simultaneous declines in the populations of migratory animals hunted by competing bands and increases in the formation of private property rights (enforced against outsiders) in land farmed by members of a band. Chapter 8, "The Organizational Consequences of the First Economic Revolution," considers the 8,000 years of the ancient era and focuses on the institutional changes required for societies to make the transition from hunting and gathering to agriculture, the rise of small states, and their consolidation into regional empires. Chapter 9, "Economic Change and Decline in the Ancient World," covers the decline of regional empires and the chaos that enveloped Europe until the end of the first millennium AD, while Chaps. 10 ("The Rise and Decline of Feudalism") and 11 ("Structure and Change in Early Modern Europe") provide a very short (34 pages), somewhat revised rendition of institutional change over the same centuries (900–1700) covered in *The Rise of the Western World*. Chapter 12, "The Industrial Revolution Reconsidered," provides a reinterpretation of the nature and causes of the industrial revolution, while Chapter 13, "The Second Economic Revolution and its Consequences," argues that the scientific advances of the "Second Economic Revolution" enabled the creation of "an elastic supply curve of new knowledge which built economic growth into the system" (North 1981: 171). North concluded that "at the heart of the modern problems of political and economic performance" is the "on-going tension between the gains from specialization and the costs arising from specialization . . ." (North 1981: 209).

Structure and Change was received much more favorably by social scientists and historians than *The Rise of the Western World*, which covered many of the same topics. For example, David Galenson (1983: 189) concluded that "North makes a significant departure from orthodoxy in arguing that a theory of ideology is needed to explain both how collective action can occur in many instances, in spite of the obstacles to it posed by the free-rider problem, and why societies invest resources in

establishing their political legitimacy." Jack Goldstone (1982) and Walter Rostow (1982) applauded the expansion of North's theories and range of historical analysis to cover "a broader canvas," though Rostow concluded that North's "failures all stem from the same source: his lack of a reasonably coherent view of the individual human being." Gordon Tullock (1983) criticized specifics of North's applications but called the book a "rich collection of new and stimulating ideas and perspectives [that] deserve a good deal more space." An outlier in this wave of good feeling was the review by Frederic Pryor (1982: 986–989) in *The Journal of Economic History* who found that North's applications of his theories were often wrong and otherwise were "at such a high level of abstraction that the textures of the economic systems of the past are lost."

North joined with political scientist Barry Weingast to study England's "Glorious Revolution," and the resulting article, "Constitutions and Commitment: The Evolution of Institutions Governing Public Choice in Seventeenth-Century England," is the most highly cited article ever published in *The Journal of Economic History.* This pathbreaking case study changed how a generation of historians and social scientists approached this signal historical event and, more generally, how they analyzed government institutions designed to restrain the power of the executive. North and Weingast argued that the 1688 Glorious Revolution in England was a watershed in the country's institutional history, as it enabled a set of political institutions to be put in place that allowed the revolutionaries:

> to solve the problem of controlling the Crown's exercise of arbitrary and confiscatory power. Parliamentary supremacy, central (parliamentary) control in financial matters, curtailment of royal prerogative powers, independence of the judiciary (at least from the Crown), and the supremacy of the common law courts were established. A major consequence was an increased security of property rights. (as summarized in North 1991: 139)

North and Weingast then argued that the reforms allowed England's capital markets and institutions supporting capital markets, such as the Bank of England, to develop. The government's ability to borrow funds in capital markets was a critical factor in the country's success in two wars with France during the 25 years after the Glorious Revolution. North (1991: 139) later concluded that "[t]he security of property rights and the development of the public and private capital market were instrumental factors not only in England's subsequent rapid economic development, but in its political hegemony and ultimate dominance of the world."

Scholars have questioned the North-Weingast interpretation of the Glorious Revolution, with some asking whether the particular mechanisms that induced Britain's revolution in public finance were correctly identified and others challenging whether their overall interpretation captures the essence of the conflict underlying the Glorious Revolution. Steven Pincus (2009) in his magisterial history, *1688: The First Modern Revolution*, forcefully argued that North and Weingast totally misunderstood the context of the Glorious Revolution. Rather than a battle between forces supporting the monarch's prerogatives and forces supporting a Parliament intent on restraining the monarch and reinforcing individual rights to property and liberty, the

Glorious Revolution should instead be viewed as a battle between two modernizing forces, each with different visions of the polity, society, and economy that would allow Britain to compete effectively with Louis XIV's France (See also Pincus and Robinson 2014).

Others have focused on whether it was the Glorious Revolution that precipitated a financial revolution in Britain or the postrevolutionary threats to William and Mary from the deposed king. John Wells and Douglas Wills (2000: 419) argued that it was the threat from the followers of James II (and later his son) to overturn the Glorious Revolution that "better explains *why* the state introduced these institutional changes than do" North and Weingast. They concluded that much better institutions were required, because the Jacobite threat "exacerbated" the Crown's credibility problems and "both Parliament and the Crown had to develop new institutional arrangements to overcome these credibility problems" (Wells and Wills 2000: 419). Bruce Carruthers (1990: 697) argued that it was James II's "Catholicism more than his absolutism that turned his subjects against him. The wealth holders of England who engineered the Glorious Revolution were more concerned with popery than with property." Carruthers also maintained that it was not just the constitutional changes of the Revolution that enabled Parliament to assert itself more effectively but also the emergence of organized competition between the Tory and Whig parties in Parliament and the influence of a decision by the House of Lords in the Bankers Case, which contested a default of crown debt under Charles II.

North and Weingast then joined with Paul Milgrom on a project that provided a second more extensive case study of the theories outlined in *Structure and Change*. In their 1989 article, they present a formal game-theoretic model that provides theoretic foundations underpinning the "Law Merchant," an institution used by participants in the European Champagne fairs of the early medieval period to enforce contracts made at the fairs. Their analysis considers this essential question: How, "even if no pair of traders come together frequently" at the fairs, can their reputations provide a bond to ensure that the seller provides the promised quality and the buyer pays for the product? Their model finds that "if each individual trades frequently enough within the community of traders, then transferable reputations for honesty can serve as an adequate bond for honest behavior *if members of the trading community can be kept informed about each other's past behavior*" (Milgrom et al. 1990: 3). This article is important, as it served to provide formal game-theoretic foundations for North's early informal theorizing about the linkage between growth in European trade in the eleventh and twelfth centuries and the rise of specific institutions to support the trade.

North's 1990 book, *Institutions, Institutional Change and Economic Performance*, is a short, clearly written volume focused on fleshing out his theoretical framework in a way that could be understood by a wider audience of social scientists and historians. This book is by far the most widely cited of North's works, with Google Scholar listing 57,734 citations as of February 2018. The volume contains relatively little history, although it neatly illustrates various chapters with a fresh set of applications to European and American history. Besides outlining a theory of institutional change, the book also explains "how the past influences the present

and the future, the way incremental institutional change affects the choice set at a moment of time, and the nature of path dependence" (North 1990: 3). Achieving "an understanding of the differential performance of economies through time" is portrayed as the book's "primary objective."

One of the contributions of the book to North's overall analytical framework is that he draws a clear distinction between organizations and institutions. Organizations are defined as "groups of individuals bound by some common purpose to achieve objectives" (North 1990: 5). They will be "designed to further the objectives of their creators," and their structure and actions will be determined by technology, preferences, transaction costs, relative prices, and institutional constraints. North emphasizes that "in the course of attempts to accomplish their objectives," organizations can become "a major agent of institutional change." This can occur because of incremental alteration of the informal constraints as a by-product of maximizing activities of organizations, because organizations become directly involved in the process of institutional change, and because they acquire knowledge that changes costs and benefits associated with existing institutions.

North (1990: 7) draws the reader's attention to his 1984 book, *Structure and Change*, where his adoption of an economic model incorporating transaction costs had led to the abandonment of the proposition that institutions would necessarily evolve efficiently over time. In his 1990 book, he further expands on this idea by identifying more explicit pathways down which institutional change could go awry. His main focus is on organizations that are created to take advantage of opportunities within the institutional framework and then directly or indirectly alter that framework. North (1990: 7–8) hypothesizes that "the symbiotic relationship between institutions and the organizations that have evolved" can lead to lock-in, as these organizations depend on the institutional framework for their profitability. Suppose, however, that "entrepreneurs within economic and political organizations" perceive that they could do better by altering the institutional structure. If transaction costs were zero, only efficient choices would be taken. But transaction costs of changing institutions are positive, and, moreover, "actors frequently must act on incomplete information and process the information that they do receive through mental constructs that can result in persistently inefficient paths." Given this setup, it is easy to find examples of some countries – the United States in the late nineteenth century – where efficient institutional change was undertaken and other countries, England in the early seventeenth century, where institutional change that favored redistributive activities was undertaken.

North (1990: Chap. 11) further develops these ideas in a chapter that emphasizes Paul David's (1985) newly developed concept of path dependence. The basic idea is that "if the process by which we arrive at today's institutions is relevant and constrains future choices, then not only does history matter but persistent poor performance" can be locked in (North 1990: 93). This is most likely when the choice of an institution leads to increasing returns (from a variety of sources) as organizations take advantage of the institution's incentives. The situation that develops is complex, because "ideological beliefs influence the subjective construction of the models that determine choices" (North 1990: 103). Informal institutional constraints,

rooted in a society's culture, can also serve to lock-in institutional choices. North (1990: 140) concludes that "[w]e need to know much more about culturally derived norms of behavior and how they interact with formal rules to get better answers" to questions pertaining to institutional change and persistence.

David Galenson's review (1993: 419–422) in *Economic Development and Cultural Change* finds that the book "provides a synthesis of much of the best of [North's recent work] and serves to point up both its strengths and weaknesses. Much of the most successful work has focused on the political economy of processes by which institutions are formed, and here considerable progress is evident. Much less progress has been made in evaluating the consequences of institutional design." By contrast, Walter Neale (1993: 422), in a review in the same journal, calls it "a strange book, even a sad one." This is because North:

> views institutions as essentially limiting: they are 'the humanly devised *constraints* that shape human interaction' and 'define and *limit* the set of choices of individuals' [North 1991: 3–4; emphasis added by Neale] … One wishes that he had seen his way to adopting the idea that institutions are always and everywhere essential to almost all of human life. Language, rules for raising and sustaining children, drawing a contract, buying a tomato, … are all patterns that we call institutions. Institutions do indeed forbid many activities but … they are always and everywhere liberating as well as limiting. (Neale 1993: 423)

Neale also points out, as did Fredric Pryor in his earlier review of *Structure and Change*, that historical materials used to develop North's grand theories were typically limited to the Americas and Europe, with historical materials from Africa, Asia, and the Pacific often ignored.

Expanding the Horizons of Economists: From Cognitive Science to Political Orders

In his 2005 book, *Understanding the Process of Economic Change*, North begins by forcefully criticizing the rationality assumption of neoclassical economics, arguing that "the uncritical acceptance of the rationality assumption is devastating for most of the major issues confronting social scientists and is a major stumbling block in the path of future progress." To understand how "we perceive the world and construct our explanations about that world requires that we delve into how the mind and brain work – the subject matter of cognitive science" (North 2005: 5). North believes that cognitive science has lessons to teach economic historians about "how humans respond to uncertainty and particularly the uncertainty arising from the changing human landscape, the nature of human learning, the relationship between human learning and belief systems, and the implications of consciousness and human intentionality for the structure that humans impose on their environment" (North 2005: 5–6).

One place to begin incorporating such considerations is to take a close look at "the genetic architecture that evolved in the several million years that humans

evolved as hunters and gatherers. Innate cooperative behavior among small groups does appear to be a genetic trait," and there is some experimental evidence in support (North 2005: 45). We observe, however, that various groups in different societies display substantial variation in the extent and forms of cooperative behavior. North (2005: 47) speculates that these differences may stem from variations in the processes by which individuals learn. They could be due to "(1) the way in which a given belief system filters the information derived from experiences, and (2) the different experiences confronting individuals and societies at different times." North argues that one of the factors affecting individual learning is that many of the important decisions that individuals and groups need to make are in response to novel "non-ergodic" situations, in which important stochastic processes relevant to the decision are unstable. In these "non-ergodic" situations, there is little that decision-makers can learn from past decisions, and this opens the door for players to use nonrational beliefs to make their decisions.

North (2005: viii) emphasizes, however, that "[h]uman learning is more than the accumulation of the experiences of an individual over a lifetime. It is also the cumulative experiences of past generations" which are "embodied in language, human memory, and symbol storage systems [which include] beliefs, myths, [and] ways of doing things." Because every society's culture changes slowly, this affects how successful changes in the formal institutional rules of a society can be in fixing social problems and grasping new opportunities.

The rest of the book sketches out applications of these ideas and many others (e.g., the importance of human intentionality for understanding evolution of institutions) presented in the book to traditional Northian topics, e.g., *The Rise of the Western World*, and new topics, e.g., *The Rise and Fall of the Soviet Union*. North (2005: 169) concludes by observing that "[all] societies throughout history have eventually decayed and disappeared." Substantial evidence suggests that "flexible, adaptively efficient" institutions have been key to the persistence of successful societies, yet he worries that "[t]he ubiquity of economic decline of civilizations in the past suggests that adaptive efficiency may have its limits."

Masahiko Aoki (2010: 139) considers North's 2005 book to be a watershed for research in institutional economics and praises its "dynamic perspective" as "original and comprehensive." Aoki views North as following in a long line of other social scientists who conceived of institutions as "rules of the game" and sees North's originality as following from "the particular attention paid to the crucial importance of enforcement of the rules." Aoki (2010: 241) agrees with North that "the 'normative/ideological beliefs' of political entrepreneurs . . . can be a driving force of institutional change, as such beliefs make a certain direction of change in the human landscape a 'focal orientation.' But it is one thing to say this and another to understand how such beliefs in fact become shared behavioral beliefs . . ." Aoki then attempts to clarify these issues by translating North's informal game-theoretic ideas into the formal language of game theory. Perhaps his most important insight was that while the different economic, political, and social games in which organizations and individuals participate are intrinsically linked, the types of games played in each domain are different, and this limits our attempts to understand their linkages until

we understand each type of game. Aoki (2010: 145) echoes North in his observation that "it is still at an unsatisfactory stage for us to formulate social and political games, if not so much economic games . . . To understand the nature of interactions of play across different domains of games, we first need to be clear about what makes one type of domain essentially distinct from another." Once that is clarified, then in order to understand the process of institutional change, bi-directional relationships between the ways strategic play of the political and economic games are coordinated by people and organizations need to be explored. These relationships may be amenable to explicit game-theoretic analysis in terms of dynamic strategic complementarities, and this would allow a flourishing interdisciplinary field of analysis to emerge.

North's 2009 book, *Violence and Social Orders*, is a creative and ambitious attempt to develop an analytical framework for examining transitions between political orders over a broad range of societies and historical periods. Co-authored with long-time collaborators John Wallis and Barry Weingast, the North-Wallis-Weingast (NWW) team identifies the control of violence as the critical challenge faced by every society. The basic insight is that it is impossible for people in a society to achieve a high level of welfare if they live in an atmosphere charged with frequent outbreaks of violence. If violence reigns, then, in the immortal words of Thomas Hobbes, "life is nasty, brutish, and short." While no society can ever eliminate violence, a society can only prosper if violence is "controlled and managed" (North et al. 2009: 13). Societies living in the shadow of violence try to solve this fundamental problem by devising social arrangements to "deter the use of violence by creating incentives for powerful individuals [and their supporters] to coordinate rather than fight." In the NWW conceptual framework, there are two general ways in which societies can be *ordered* to control violence. In a *limited access order*, violence is primarily controlled by devising formal rules that limit people's rights to form new organizations which could compete with established organizations. In an *open access order*, violence has been largely restricted to the military and police, which are controlled by well-established lines of authority in the government. Political institutions support open entry of new organizations to compete in economic and political markets with organizations run for and by established interests (North et al. 2009: 4).

What is the mechanism used in a limited access order to control the use of violence (North et al. 2009: 4)? Leaders of powerful groups and powerful individuals first agree to form a "dominant coalition" whose members divide up resources and opportunities among themselves and agree to maintain each other's privileged access to those resources. Such privileges generate economic rents (defined as a premium above and beyond the normal returns to an activity) and will, if incentives are properly structured, ensure that each leader and their group keep the peace rather than fight. Because self-enforcing agreements between the members of the dominant coalition often break down, the dominant coalition acts to provide an "organization of organizations" – often called "the state" – which provides third-party enforcement of privileges. If individuals or groups inside or outside the dominant coalition fail to respect member privileges, then individual members of the coalition and the state

have incentives to take action to enforce member rights. In fact, to maintain their exclusive access to economic rents, the key action that members of the dominant coalition must take is "to *limit* the possibility for others to start rival organizations."

How are the economic rents created by the dominant coalition distributed to its members? Distribution is heavily influenced both by the violence potential of powerful individuals and organizations and by established networks of unique personal, family, and group relationships. Networks are important for rent distribution because most of the relationships between elites in the dominant coalition are personal, not impersonal. Because important relationships among elites are personal in nature, enforcement of agreements between members of the elite depends on the identity and status of the particular member of the elite rather than impersonal rules of law. Use of impersonal rules to enforce agreements between people of different status is impossible, and this means that agreements requiring high levels of trust can only be concluded by people from the same social group.

NWW spend the rest of the book elaborating on their theory of social orders and providing particular examples of different types of limited access and open access orders. Additional chapters cover the emergence of three different types of limited access orders, namely fragile, basic, and mature natural states; the development of English land law; institutions, beliefs, and incentives supporting open access orders; doorstep conditions underpinning the transition to an open access order; and examples of successful transitions in Britain, France, and the United States. In their reviews of *Violence and Social Orders*, Robert Margo (2009) and Robert Bates (2010) praise the book for its originality and criticize it as being too devoted to providing taxonomic classifications of social orders rather than providing deeper micro-foundations of their origins, operation, and evolution. Margo identifies the book's most important and profound idea as "the notion that one cannot simply 'get rid' of the superficial exterior of natural states and thereby uncover the beating heart of an open access order yearning to be free . . ."

In 2012, the NWW team (with Stephen Webb) edited a second volume, *In the Shadow of Violence*, that provides case studies of economic and institutional change in ten developing countries using the analytical framework developed in *Violence and Social Orders*. Critics of North have noted his reliance on evidence from Europe and the Americas to illustrate his theories, and the NWW team commissioned this second volume to show the broad range of historical experiences that could be analyzed with their analytical framework.

Do Institutions Matter? North and His Critics

Critics of North have come at him for a variety of sins. Economists with ties to the Wisconsin version of institutionalism, pioneered in the writings of John Commons (1934) and Thorstein Veblen (1899; 1904), have viewed North's work as fatally flawed because his theoretical framework, however suitably modified to incorporate transaction costs, continued to have one foot in the silo of dysfunctional neoclassical economics. Ben Fine and Dimitris Milonakis (2003: 568) take a slightly different

tack, with their criticism of North stemming from his continued reliance on methodological individualism. They conclude that "North's own intellectual voyage, despite setting out under the mast of individualism, eventually leads him to the troubled waters of collectivities, power, and conflict" which his theories accommodate poorly.

North's definition of an institution, "the rules of the game in a society or, more formally, . . . the human-devised constraints that shape human interaction," and his emphasis on the importance of institutional change in generating economic growth have been criticized by several prominent economic historians and theorists, including Avner Greif, Deidre McCloskey, Joel Mokyr, and Gregory Clark. Brief summaries of their critiques follow.

In a series of pathbreaking studies analyzing institutions with the tools of game theory, Avner Greif (2006) contends that institutions are best defined as the expectations of individuals regarding "the regularity of others' behavior." Greif and Christopher Kingston (2011: 25) summarize "the institutions-as-equilibria approach" as follows:

> The core idea in the institutions-as-equilibria approach is that it is ultimately the behavior and the expected behavior of others rather than prescriptive rules of behavior that induce people to behave (or not to behave) in a particular way. The aggregated expected behavior of all the individuals in society, which is beyond any one individual's control, constitutes and creates a structure that influences each individual's behavior. A social situation is 'institutionalized' when this structure motivates each individual to follow a regularity of behavior in that social situation and to act in a manner contributing to the perpetuation of that structure.

Greif's definition and analysis of institutions differ from North's approach, but both economic historians view institutions as fundamental to understanding how economies change and why some have been able to generate sustained growth. Several prominent economic historians have, however, tried to make the case that better institutions were *not* the main factor behind the surge of economic growth in the nineteenth and twentieth centuries.

In Volume II of her three-volume opus, *Bourgeois Dignity: Why Economics Can't Explain the Modern World*, Deidre McCloskey (2010) takes several chapters to criticize both the methodological underpinnings and the usefulness of North's scholarship. McCloskey contends that despite the expanding frame of analysis embraced by North over his career, his analysis remains burdened by continued reliance on outdated concepts from neoclassical economics – profit maximization by firms subject to constraints and utility maximization by consumers subject to constraints. North is accused of being fixated on constraints and failing to understand how noneconomic dimensions of culture, religion, and politics affect human behavior. Within the terms of North's own analytical framework, McCloskey criticizes North's narratives explaining how changes in institutions in Britain and other countries triggered modern economic growth. She argues that the actual timing of changes in institutions and changes in economic growth is poorly aligned with North's theoretical predictions. North's emphasis on the emergence of a more credible commitment to property rights in Great Britain after the Glorious Revolution is dismissed, with

McCloskey arguing that strong property rights had been well established in Britain for several centuries and that, in any case, the English Civil War was more important for the development of modern British institutions than the Glorious Revolution. McCloskey then contends that the last two centuries of economic growth were made possible by the development of bourgeois values and the rising respect gained for those values during the seventeenth and eighteenth centuries.

Joel Mokyr (2017: 5) observes that "much of the literature in economic history that is trying to explain differences in economic performance and living standards . . . has accepted in one way or another Douglass North's call for the integration of institutions into our narrative of economic growth . . .." Mokyr (2017: 5) agrees that better institutions "can be credited with many positive economic developments in the past" and yet "better markets, more cooperative behavior, and more efficient allocations do not in themselves account for modern economic growth." He concludes that the Industrial Revolution "[a]t first blush does not seem to have been a response to any obvious institutional stimulus." Rather it "was made possible by cultural changes" that affected man's "attitudes towards the natural world" and made possible institutions that "stimulated and supported the accumulation and diffusion of 'useful knowledge'" (Mokyr 2017: 6–7).

Gregory Clark (2007) argues that neither institutions nor geography nor exploitation of colonies can explain the last two centuries of economic growth. Rather, the long-established culture of a society combines with demographic forces and chance to determine long-term economic growth. From Clark's perspective, institutions are relatively unimportant because they are endogenously determined. "Thus institutions vary across time and places mainly because differences in technology, relative prices, and people's consumption desires make different social arrangement efficient" (Clark 2007: 212). Clark sees a close correspondence between his view of institutions and the neoclassical theory of institutions espoused by North and Thomas in *The Rise of the Western World*, where changes in relative prices and other economic factors drive institutional change and institutions tend, over a long horizon, to be efficient.

North's Legacy

For Doug North, longevity and creativity paid off. Some of his impact was due to an unusually long and extremely productive career that spanned 65 years. The rest was due to a creative mind that challenged economic historians to address questions that were typically out of their comfort zone. The entire range of human history was within the scope of his research, and by the end of his career, he had completely changed how economic historians perceived their mission and vastly expanded the analytical framework used to analyze long-term change in economies and institutions.

From the early 1990s, North had become increasingly interested in how different people could have different perceptions of the same reality. In this context it is notable that different scholars perceive North and his work very differently. Oliver

Williamson (2000: 600), one of the founders of the New Institutional Economics and the recipient of the 2009 Nobel Prize in Economics, identifies North as one of the key people whose work and organizational activities led to the founding of the New Institutional Economics, standing alongside other Nobel Laureates such as Ronald Coase, Kenneth Arrow, Friedrich Hayek, Gunnar Myrdal, and Herbert Simon. Many economic historians see North, along with Robert Fogel, John Meyer, Robert Gallman, William Parker, and Lance Davis, as one of the founders of cliometrics, the theoretical and quantitative movement that transformed research in economic history. Other economists perceive North as a scholar who constantly hectored them to escape from the narrow silo of neoclassical economics and to consider how their analysis could be enhanced by incorporating insights from other disciplines.

Perhaps the most perceptive views of North come from scholars who recognize how radically he revised his views on institutional change over the course of his more than six-decade career. A look at his first book provides an extremely different view of economic change than a look at his last book, which focuses on the foundations of social orders and how they change. Claude Menard and Mary Shirley (2014: 3) perceive that his big achievement was to change "many economists' view of development from a process of growth spurred by new technology and capital accumulation to a dynamic process of institutional change." And John Wallis (2014: 48) concludes that "North's genius is figuring out what to ask next, which often comes as an answer to the question of what cannot be explained with the current conceptual framework." Asking new questions and developing new ways to answer them lie at the heart of all scientific inquiry, and posing new, extremely challenging questions may well prove to be North's fundamental contribution to history and the social sciences.

Economic History and Economic Development: New Economic History in Retrospect and Prospect

Peter Temin

Abstract

I argue in this chapter for more interaction between economic history and economic development. Both subfields study economic development; the difference is that economic history focuses on high-wage countries while economic development focuses on low-wage economies. My argument is based on recent research by Robert Allen, Joachim Voth and their colleagues. Voth demonstrated that Western Europe became a high-wage economy in the fourteenth century, using the European Marriage Pattern stimulated by the effects of the Black Death. This created economic conditions that led eventually to the Industrial Revolution in the eighteenth century. Allen found that the Industrial Revolution resulted from high wages and low power costs. He showed that the technology of industrialization was adapted to these factor prices and is not profitable in low-wage economies. The cross-over to economic development suggests that demography affects destiny now as in the past, and that lessons from economic history can inform current policy decisions. This argument is framed by a description of the origins of the New Economic History, also known as Cliometrics, and a non-random survey of recent research emphasizing the emerging methodology of the New Economic History.

Prepared for the 2014 annual BETA-Workshop in Historical Economics hosted by the University of Strasbourg from 9 to 10 May, and organized in association with the Bureau d'Economie Théorique et Appliquée (BETA, http://www.beta-umr7522.fr), the University of Strasbourg Institute for Advanced Study (USIAS, http://www.usias.fr/en/), the Association Française de Cliométrie (AFC, http://www.cliometrie.org) and Cliometrica (Springer Verlag, http://www.springer.com/journal/11698).

The New Economic History was born about 50 years ago. As economics changed after the Second World War, economic history changed as well. The New Economic History started in the 1960s as a part of economic history and has grown to become the dominant strain in economic history today. I survey this progress and think about the future of economic history in three stages. The first stage recalls some of the early days of the New Economic History, its origins and early development. The second stage reflects on the achievements of the New Economic History as shown in recent publications by Robert Allen and Joachim Voth. Taken together, these contributions build on a half-century of research and suggest promising areas for the future. The third stage surveys some other contributions to the New Economic history in a partial and idiosyncratic way and distils implications for the future.

Paul Samuelson arrived at MIT in 1940. Receiving his PhD from Harvard in that year, he was snatched up by MIT when Harvard failed to make him a faculty appointment (Keller and Keller 2001, pp. 81–82). From this event came both the birth of the MIT economics department, and a revolution of economics itself. Samuelson's PhD thesis, published as *The Foundations of Economic Analysis* (1947), championed the use of mathematics in economics. He was not the first economist to use math, but he showed how math could be systematically employed to reformulate familiar and unfamiliar economic arguments. He was like Adam Smith, organizing various strands of existing economics into a new coherent synthesis.

The MIT economics department started its graduate program after the war. It was constructed like a three-legged stool, resting on required courses in economic theory, econometrics, and economic history. But while the legs of a stable stool are equal, these required courses were not. Economic theory and measurement were in their ascendancy, and economic history needed to find a way to coexist with the new theories and econometrics to survive. As in older economics departments, economic history had been taught before the Samuelsonian revolution, but it had been more like history than what we now think of as economics.

One effect of the change in the focus of economics was to change the main mode of reasoning from inductive to deductive. This meant that papers in economics changed from being primarily narrative to starting with a model. New economics papers progressed from a model to data and then hypothesis tests. Economic historians responded to this change in economics by embracing the new tools of economic theory and measurement in what became known as the New Economic History.

This movement was led by the two recipients of the 1993 Nobel Prize in Economics, Douglass North and Robert Fogel. North was editor of *The Journal of Economic History* with William Parker in the 1960s with the conscious aim of attracting papers using formal economics in their analysis. He gained most fame

by stimulating the growth of the New Institutional Economics through his many publications. Fogel burst into this scene with publications first on the social savings of American railroads and then, with Stanley Engerman, on American slavery. These contributions were showcased first at annual meetings of what would come to be called cliometricians held in the 1960s at Purdue University in the dead of winter.

The New Economic Historians threw their lot in with the econometricians. They turned to the collection of historical data and their use in testing hypotheses about economic activity. In this way, the New Economic History brought itself into the mainstream of economics as it was developing, but it caused a growing problem for economic history as economics departments turned their face toward the new theories championed by Samuelson and Solow.

The economic history paper was central to one of the legs of the three-legged stool supporting the MIT economics department. The paper requirement began soon after the war when most field courses had term papers. It was only a remnant of this pedagogical approach to graduate studies by the beginning of the twenty-first century. The two surviving papers, the remnants of the omnipresent term papers in most courses in the 1950s and 1960s, shared several characteristics. Students had to select a question to answer or a hypothesis to test, drawing on their course work or their general knowledge. They had to answer their question or test their hypothesis with using evidence from empirical data. And they had to write this up in the form of an article for an economics journal. They were, in short, two variants of an assignment in applied economics. In fact they were hard to distinguish at the margin and sometimes overlapped.

The two papers also differed in important respects. The history paper drew from economic history – defined loosely to follow the economics convention of focusing on events a quarter-century or more past – for its questions and hypotheses. The aim was for the students to analyze events in a different institutional setting or with unfamiliar relative prices. Given the scarcity of historical data for many interesting historical questions, particularly those about foreign countries, many different quantitative techniques were used. The econometrics paper by contrast was focused on the econometric methodology being used and less on the context in which it was used. And the history paper came in the first year of graduate work, while the econometrics paper was a feature of the second year.

I began to teach economic history at MIT in 1965, and I attended the cliometrics conferences at that time. The dominant memory I have of the conferences was the attention to data. An econometrics professor at MIT had remarked to me that when he could not find data for 1800 that he needed for a regression, he used data from 1900 instead. This was not the culture at the cliometrics conferences. Great attention was taken to the collection and interpretation of data, and disagreements were as often concerned with these issues as with the arguments and hypotheses built on the data.

I presented a paper at one of my first cliometrics conferences on the American iron industry, the topic of my thesis. As I recall, I found the ante-bellum iron data hard to reconcile with my hypotheses, and I proposed what I thought was a reasonable revision of the data for future use. The conferees thought this was a

terrible idea, and there was a lot of critical commentary demonstrating to me that the worlds of economic historians and econometricians had drifted apart. Bob Fogel came up to me after the session, asking how I could remain so calm under the fire I had just sustained. I remarked that the criticism was directed at my paper, not at me. Bob shook his head and rejected that distinction. We went on from there to become friends who often disagreed with each other.

There was palpable excitement among New Economic Historians during the next two decades. Two well-known and controversial books from that time can help us remember this excitement. *A Monetary History of the United States, 1867–1960* by Milton Friedman and Anna J. Schwartz appeared in 1963. They offered a new interpretation of fluctuations in the United States for the previous century and promoted the view that changes in the stock of money were the prime determinants of economic activity. Their claims and Friedman's awesome debating skills made this book a *cause célèbre* among economists and economic historians alike. Their data continue to be used, and their point of view is relevant to current debates. Ben Bernanke, Chairman of the Federal Reserve Board, once said to Friedman that he would not repeat the mistakes Friedman claimed the Fed made in the 1930s.

Time on the Cross by Robert W. Fogel and Stanley L. Engerman (1974) appeared a decade later. It too became famous and controversial, albeit more among historians and economic historians than among economists. They offered a new interpretation of American slavery as a more benign institution than previous authors and in which the rate of exploitation of slaves was markedly lower than previously thought. It is interesting that they derived this latter result by assuming that slaves had to pay for their own upbringing. This approach has returned today as college students increasingly have to pay for their own education as public support for state universities has declined. The growth of student debt is analogous to the debts Fogel and Engerman asserted slaves owed to their owners.

A measure of this intellectual enterprise was taken at the annual meeting of the American Economic Association in 1984. The papers presented in this session were published in the annual *Papers and Proceedings of the American Economic Association*, and the whole session was published in *Economic History and the Modern Economist* (1986), edited by William N. Parker. The session consisted of two papers by economic historians and two by Nobel-laureate economists. The economists took it upon themselves to discuss the place of the New Economics in economics as a whole.

Kenneth Arrow concluded his essay by saying, "In an ideal theory, perhaps, the whole influence of the past would be summed up in observations on the present. But such a theory cannot be stated in any complex uncontrolled system, not even for the Earth, as we have seen. It will always be true that practical understanding of the present will require knowledge of the past (Parker 1986, pp. 19–20).

Robert Solow made essentially the same argument in different words:

> The economist is concerned with making and testing models of the economic world as it now is, or as we think it is. The economic historian can ask whether this or that story rings true when applied in earlier times or other places, and, if not, why not. So the economic historian

> can use the tools provided by the economist but will need, in addition, the ability to imagine how things might have been before they became as they now are. . . . It was once suggested—by my kind of economist—that the division of labor is limited by the extent of the market. Perhaps what I have just been doing can be thought of as suggesting that economists extend their market and accept the specialized services that, in a more capacious market, the historians as well as other scholars, can provide. (Parker 1986, pp. 28–29)

These eminent economists gave good advice. The New Economic History has endeavored to follow it by examining questions drawn from a wide range of places and times, ranging from prehistory to recent events and all around the world. Anywhere there are data or information that can be construed to text hypotheses is fair game.

Three techniques have emerged as particularly useful in these wide-ranging explorations. The first is modern econometrics. New Economic Historians of the first generation used simple econometrics, which were a new way to learn from data in the historical literature. In its new approach to economic history as economics, however, simple econometrics looked like undergraduate econometrics. The use of econometrics was enough to get the first generation employed at good universities, but it was not sufficient for the next generation.

Fortunately, these students had been educated in modern econometrics, and they began to use it in their research. Younger scholars interested in economic history consequently have been able to get jobs at good universities and their articles published in top economics journals. For example, compare my experience at MIT with my younger colleague, Dora Costa. I published largely in economic-history journals and used simple regressions in my work. (I cannot resist noting that my use of even a simple regression about trade in ancient Rome sent ancient historians into a tizzy.) Costa by contrast used cutting-edge econometrics in her work, published regularly in major economic journals and taught econometrics at MIT.

The second technique utilizes the ideas behind event studies to examine the effects of turning points and decisions in economic history. Discontinuities provide information on the structure of economic systems that may not be apparent from their smooth operation in normal times. Legal boundaries provide discontinuities over space, and events ranging from crises to discoveries provide discontinuities over time. These important historical events clarify the structure of economic activity and provide evidence to test preconceived ideas about economic history.

The third useful technique is to examine events over several generations, an opportunity given to economic historians and students of economic development that distinguishes them from some other fields of economics. We can study the effects of demography and education that often are simply held constant in current economic analyses. These two approaches run into each other as we go further back in the past, as we sometimes find the effects of dramatic events in the fortunes of people over several generations. As usual among economists, we distinguish ideal types to think about processes that can be seen as a continuum from another point of view.

The big events of economic history are the Black Death of the fourteenth century, the European discovery of America in the sixteenth century and the Industrial

Revolution in the eighteenth century. We keep going back over these dramatic and far-reaching events to learn more about the path from the slow-moving economies before them to the fast-moving ones today. We know more about the most recent of these events, and it has overshadowed studies of the earlier ones. I want to return to the first of them to illustrate how the New Economic History is reshaping our conception of this transition and to illustrate how much we have gained from this collective activity we call the New Economic History.

When I started teaching these events, we saw the Black Death in very simple ways. It was a demographic shock that sharply reduced the supply of labor while leaving the supply of land intact. The result was a dramatic rise in the real wage, chronicled for England by Phelps Brown and Hopkins (1962) and revised and explored further by Clark (2005, 2007). The English data were extended to continental Europe by two less well-known contributions. The first one was the discovery of what Hajnal (1965) called the European Marriage Pattern. This pattern, as I recall teaching it long ago, had three components. The age of female marriage was high, in their twenties; many women did not marry at all, and married women did not automatically join the household of their husbands. According to Hajnal, this contrasted with an Asian marriage pattern where almost all women married at menarche and moved into extended households of their husbands' families. Hajnal observed this pattern in the early modern period, but he offered no clues where it came from.

The second contribution came from Brenner (1976), who argued that the effects of the demographic changes generated by the Black Death were modified by social and political structures. In the West, that is, England, the monarchy was strong and the aristocracy weak. This left room for workers to take advantage of their relative scarcity and bid up their wages. In the East, vaguely identified as continental Europe, the aristocracy was strong, and it prevented workers from moving to better jobs. This reduced the bargaining power of labor, and wages in the East did not rise after the Black Death. Serfdom decreased in Western Europe and increased in Eastern Europe. Brenner's argument was more controversial than Hajnal's views, and it gave rise to extensive debate – although not to explicit hypotheses testing.

The Brenner debate took place largely outside economics, but it can be seen as an application of North's emphasis on the role of institutions (North 1990). This view gave rise to the New Institutional Economics, a group of economists and economic historians who emphasize the role of institutions in shaping economic affairs. Brenner's ideas can be rephrased as a hypothesis about the role of institutions in shaping responses to the Black Death. The difference between strong monarchies in the west and strong aristocracies in the east was the key to the treatment of labor in this view.

The New Institutional Economics has spread beyond the bounds of standard economic history. It motivates a new view of the economic history of the Greco-Roman world (Scheidel et al. 2007). The editors of this volume tried to move away from the traditional opposition of primitivists and modernists in the study of ancient history into what they considered a more fruitful approach. They found inspiration in North's work and employed the New Institutional Economics to explain differences

among provinces of the Roman Empire, providing insights which other ancient and economic historians have expanded (Temin 2013).

This welter of seemingly unrelated contributions has now been clarified and reformulated by the New Economic History. Voitländer and Voth (2013) argue that the Black Death gave rise to the European Marriage Pattern and set in motion a process that led to the Industrial Revolution. This is a large claim, and it leads to a sharp revision of Western economic history. It needs some explanation to be understood.

Voitländer and Voth argue that the scarcity of labor after the Black Death led to a change in agricultural technology. Moving along the wage-rental isoproductivity line, farmers changed from growing crops to tending animals, from arable farming to husbandry. In other words, movement along a smooth production-possibility curve was a sharp change in the underlying technology. Sir Thomas More expressed it most colorfully over a century after the Black Death in his *Utopia* (2012 [1516]): "Your sheep that were wont to be so meek and tame, and so small eaters, now, as I hear say, have become so great devourers and so wild, that they eat up and swallow down the very men themselves. They consume, destroy, and devour whole fields, houses and cities."

The result of this adaptation of agricultural technology changed the role of women in Medieval society. Switching from crops to husbandry reduced the demand for strength to push plows and expanded the scope of work that women could do. The result was a change in the status of women in society that Alesina et al. (2013) observed at other times and places as well. The reduction in plowing reduced the demand for men's labor and increased it for women's labor. Women's wages rose and their opportunity for work expanded. They delayed marriage, entered service and became more independent. This in turn led to the European Marriage Pattern and the family pattern described by Laslett (1965). It was a massive change in the structure of society, but at the household level analyzed by Hajnal rather than the societal level described by Brenner.

The opportunities open to women delayed their marriage and reduced the rate of population growth. The result was the birth of the high-wage economies of England and a few neighboring countries. Voitländer and Voth test this theory in two ways. They use unpublished data from Broadberry et al. (2011) to estimate that the share of pastoral production in English agricultural output rose dramatically from 47% to 70% between 1270 and 1450. And they show by regressions that the age of first marriage after 1600 – when data become available – was dependent on both the share of pastoral production and its increase since the Black Death in English counties. They conclude that the extensive use of pastoral production increased the age of female marriage by more than 4 years.

The rise in wages as a result of the Black Death was sustained by a shift in marriage patterns that increased the age of women's marriage and reduced the rate of population increase. The adaptation to the initial shock led to a durable rise in people's income. This in turn led to a demand for more meat in their diet, which of course was accommodated by more husbandry. The whole pattern fit together with the Black Death as a shock that shifted households and the economy from one equilibrium to another.

This all fits in with Allen's view of the Industrial Revolution being the result of a high-wage economy. In fact, Voitländer and Voth probably were inspired at least in part by Allen's work. Allen (2009a) argued that the initial innovations of the Industrial Revolution emerged from tinkering by producers to reduce the costs of expensive labor and reap the benefits of cheap power. In response to the awareness from other work by Allen et al. (2005) that wages were high generally in Western Europe, Allen went to some lengths to show that the marginal gains from these initial innovations were not large enough to be profitable in either France or the Netherlands (Allen 2009a, b).

Allen (2013) argues in more recent work that wages and energy prices in North America were close enough to the British pattern for policy initiatives like tariffs, education and infrastructure investments to create conditions hospitable to industrialization. This clearly was true of countries in Western Europe that also followed the British pattern once industrial productivity advanced from its initial level. These countries did not have the factor prices to make the initial innovations of the Industrial Revolution profitable, but further development of these innovations rendered them profitable at factor prices close to those in Britain. And, as Allen noted, policy changes helped industrialization along as it spread.

But this was all within the high-wage area described by Voitländer and Voth. They noted that the European Marriage Pattern extended only from the Atlantic to a line from St. Petersburg to Trieste. Other countries in Asia or Africa were low-wage economies subject to Malthusian pressure on wages, and their factor prices were not close to English prices. Small changes in economic policies were not sufficient to make industrialization profitable in India or Egypt. The story that links the Black Death to the Industrial Revolution therefore is also a story why Europe has industrialized most easily in the past two centuries.

This synthesis reveals that these specific papers extend and unify a generation of contributions to the New Economic History. One strand has been to look at real wages in many times and places, finding evidence where none was suspected before. Another strand has extended financial history back to agrarian economies to reveal a very different index of how economies operated. And a third strand has been insights about odd and interesting facets of economic history that seem at first glance to be only isolated curiosities, but which later turn up as parts of arguments about how all of these strands can be woven together.

Three implications emerge from these recent contributions by the New Economic History. First, they rewrite Western history from soon after the end of the Roman Empire to today. Second, they provide a guide to the role of economic history in economics departments. And third, they call out for a change in publication strategy. I consider these implications in turn.

David Landes (1998) began his magisterial economic history of the West from the discovery of America. The expansion of Europe was an important event, but we now know it was hardly the beginning of the high-wage story. High wages in Western Europe could have resulted from the rise in the ratio of land to labor by the opening up of American land. But we now realize that the start of the high-wage economy

came from the rise in the ratio of land to labor that resulted centuries earlier from the Black Death. The growth of commerce to the New World was helped by British and Dutch shipping and services, and the resulting prosperity kept wages in London and Amsterdam particularly high. The expansion of Europe is an important part of the story, but not the beginning.

Another part of the development of Western Europe was the invention of the printing press in the interval between the Black Death and the expansion of Europe. Printing clearly was a labor-saving innovation, and it is tempting to see it as the result of high wages. Dittmar (2011) however, argued that the spread of printing was related more to the distance from Mainz, where it was introduced, than to factor prices. In terms of this discussion, Dittmar argued that printing was not a marginal innovation like the spinning jenny, but rather a discontinuous change in costs that spread with knowledge. This can only be true in part, as printing spread for the first century or so only within the areas of the European Marriage Pattern.

This single example reveals a more complex story beneath the outline given here. We have to fill in the blanks to provide a new history that reveals the combination of shocks that produced Western history. And while this story is based on simple economics, it requires some modification of the simple Malthusian story. For the high-wage economies of Western Europe were not simply fluctuations around a pre-existing norm; they were a new equilibrium around which population fluctuated. The Malthusian model needs to be expanded to encompass important changes in production and distribution like those that followed the Black Death. The Industrial revolution was not the first escape from the dismal conclusion that real wages could not long stay above subsistence.

This is an important story; how does it fit in modern economics departments? I propose that economic history and economic development should both be considered relevant to modern economic growth. The difference is that economic history traditionally directs its attention to the high-wage economies just discussed, while economic development focuses on the low-wage economies outside Europe. These two inquiries are closely related. They both analyze the growth of economies with new technologies, and they both are concerned with the incentives people have to adopt new innovations.

There is now a large gap between the technologies being used in high-wage and low-wage economies which mirror the large gap between real wages in these two types of economies. If we want to bring the low-wage economies to the level of high-wage economies, we have to modify either the technology being used in the high-wage economies or change the factor prices in the low-wage economies. These are two different directions of research and policy, and they are complementary to each other. If the education and employment of women lead to population control, this will lead to higher wages in poor countries that will make modern technology more appropriate. And if technological innovations like cell phones broaden the factor prices at which they are useful, this too will promote economic development.

Once economic history and economic development are seen as two sides of the same coin, there should be interesting cross fertilization between economic historians and development economists. One interesting factor is the time involved in

economic change. The world appears to be moving rapidly today, but the story of Europe now stretches from the fourteenth to the eighteenth. It is an interesting question how an interaction between these two fields might suggest ways to make a faster transition.

This brings us to the third implication of the New Economic History of Europe. We have to change our publication strategy. Voitländer and Voth published their contribution to European history in the *American Economic Review*, while Allen published his views on economic development in the *Journal of Economic History*. The papers are written for their respective journals, and there would be little point in simply reversing their position – should that even be possible. Instead, we need to think how to get the message across to the relevant audiences. How can we get historians to understand that they must start the story of modern Europe from the Black Death? And how can we get economists to understand that they must start analyzing policy interventions with a consideration of factor prices?

I hesitate to suggest how to do this to these established and prolific economic historians, but I do so to illustrate the paradoxical position of the New Economic History. And just as these contributions build on the work of many New Economic Historians, the job of communicating these results to the appropriate audiences probably would be most effective as a group effort.

Voitländer and Voth need to change from presenting a hypothesis test – the hallmark of the New Economic History – to presenting a narrative that historians will appreciate. They need to place their test in a narrative of Western European history that distinguishes the areas that adopted the European Marriage Pattern from those areas that did not. I have suggested some of the writings that should be included in the intellectual background, but the narrative should focus on telling a persasive story of a critical time in European history.

Allen needs to move in the opposite direction, to extract hypothesis tests from his impressive manuscript that can appear in a good economics journal. He might anchor his tests in a theory like that in Acemoglu and Zilibotti (2001) to provide a bridge between economic growth and economic history. He might incorporate his test of the suitability of the spinning jenny (2009b) or the graphs in his recent survey, but the paper must stand as a test of the overall proposition he made in his presidential address (2013). And it of course needs to have the bells and whistles that current economic articles now sport.

These suggestions of course can be safely ignored. They do however illustrate the paradox of the New Economic History. New economic historians have turned their back on traditional historians and sought their place among economists. This has provided good jobs for many scholars, but the acceptance by economists is still incomplete. We therefore have two challenges ahead of ourselves. The first is to argue that economic development can only be fully understood if we understand the divergent histories of high-wage and low-wage economies. And the other big challenge is to translate our economic findings into historical lessons that historians will want to read. These challenges come from our place between economics and history, and both are important for the future of the New Economic History.

These papers signal the achievements of the New Economic History, but not its breadth. I therefore conclude this paper with a very partial and highly idiosyncratic review of varied contributions to the New Economic History. It should become clear that the list deals mostly with people in and around Cambridge, MA, or that I know personally in other locations.

The first papers deal with the expansion of Europe, but from a different point of view. The Black Death changed Europe, but not at the expense of other people. The expansion of Europe a few centuries later was not as big an event in the economic history of Europe – if you believe the story I have just recounted – but it had repercussions outside Europe that have had lasting effects.

Melissa Dell (2010) investigated the effects of the Spanish silver mines in South America that led to the great European inflation of the sixteenth century. The Potosi and Huancavelica mines that yielded silver and the mercury to refine it were operated by indigenous labor under a *mita* system. Between 1573 and 1812, villages located near the mines in the Andes Mountains were required to provide one-seventh of their adult males as rotating laborers. Dell revealed the effects of this labor system by comparing current conditions in villages under the *mita* with adjacent villages.

Using all three of the techniques listed above, Dell found that the effects of the mita were apparent today, five centuries after the expansion of Europe. She used a "regression discontinuity approach," examining conditions at the edges of the *mita* area. Given the length of time involved and the complex geography, this was not an easy task. Dell exploited both the Spanish preference for workers close to the mines and from the Andean highlands and modern mapping techniques showing altitude for any location. She found that the long-run effect of the *mita* reduced household consumption by one-quarter, resulting at these low income levels in significant stunting of children.

This dramatic finding raised an obvious question: how could it be that the costs of the Spanish exploitation could last over several centuries? Dell organized her explanation around haciendas, rural estates with attached labor force reminiscent of medieval manors. The Spaniards discouraged the growth of haciendas in the *mita* area to preserve their unimpeded access to their labor force. Here we see an inversion of the Brenner thesis that local aristocrats oppressed workers after the Black Death by limiting the extent of the labor market; haciendas would have limited the exploitation of workers by the central, Spanish government by limiting its access to the labor market.

The haciendas were a mixed bag. On the one hand, they expanded after the end of the *mita* by coercive activity ranging from using legal rules to physical violence. On the other hand, they built roads connecting the highlands to lowland urban markets. Access to markets was a critical factor in the history of the high-wage economies of early-modern Europe and North America; it appears to have had similar effects in the low-wage economy of South America. It is worth noting that haciendas cannot be the source of future progress. They were abolished in 1969.

Nathan Nunn (2008) looked at more labor-market effects of the expansion of Europe, this time in Africa. The effects of American slavery in the New World have been the subject of myriad research projects. Nunn inverted this question to ask

about the effects of the slave trade on Africa. In other words, Nunn did not look at slaves and their descendants, but at the people who escaped this fate. Like Dell, he found persistent deleterious effects.

The Atlantic slave trade ended two centuries ago, but Nunn found that African countries that had more slaves per square mile taken from them have lower per capita GDP today. Like the *mita*, the slave trade is gone, but its effects linger on. Nunn made sure that the direction of causation was from trade to economic development, rather than vice versa, or that some other cause was to blame. One demonstration was that slaves were not taken from previously well-organized areas, but rather the reverse. It was the most organized areas that exported the most slaves.

The explanation for this reversal of fortune is that slaves were obtained for export by villages or states raiding each other. The lure of the profits to be gained from slave exports discouraged the expansion of village federations and the growth of ethnic identities. Suspicion and distrust impeded state formation. It is a truism of current development research that the multitudinous ethnic divisions in Africa impede economic growth. Nunn provides at least a partial explanation why there are so many ethnicities in Africa.

This idea can be generalized. Dasgupta (2007) argued that trust is the basis of economic prosperity. He devoted a short summary of economics to this single proposition. Revealing for this discussion, Dasgupta started his discussion by contrasting the conditions of a young girl in the United States with one in Ethiopia, one of Nunn's observations. This rather esoteric exploration into the durable effects of a defunct activity has led directly into the center of economics.

I stated earlier that the New Economic History focused on high-wage economies, yet this survey started with two important papers about low-wage economies. They illustrate how economic history and economic development work together to construct full pictures of poor economies in the world that can lead to productive economic policies. These papers are significant contributions to both economic history and economic development.

Turning now to contributions to American economic history, I start with *Time on the Cross*, mentioned earlier. This innovational study combined the use of massive new data and explicit economic reasoning to reach surprising conclusions. It was not only controversial; it became emblematic of both the advantages and some possible drawbacks of the New Economic History. Its conclusions were contested by both other economic historians and more widely (David et al. 1976).

One aspect of that discussion is unexpectedly relevant today. Fogel and Engerman measured what they called the exploitation of slaves by assuming that slaves were responsible for the costs of their own upbringing. In contrast to the more usual family pattern where parents support children in an intergenerational transfer, they assumed that slaves were isolated individuals who needed to "borrow" from slave owners to eat before they could work. The low earnings of adult slaves then was interpreted more as repayment of these loans than exploitation.

This argument appeared strange to their critics as a description of the nineteenth century, but it seems accurate for the twenty-first century. Slavery is long gone, of course, but its influence remains strong. Margo (1990) described the poor

educational opportunities open to free slaves in the late nineteenth century, and education in urban areas today exhibits a similar pattern of purposeful neglect. Childhood and education have become longer as time has gone on, and a decent education today includes college.

Poor students in the second half of the twentieth century could get low-cost education in state universities where the costs were subsidized by their parents' generation in taxes in an extension of public schools. But as states were strapped for funds at the end of the century and more recent years, it has been the path of least resistance for states to reduce their spending for state universities. State universities are largely private now with state funds accounting for only a minor part of their costs. The universities have raised tuition in an effort to offset this loss of revenue, returning young Americans to the position Fogel and Engerman assumed for slaves.

Wise men and politicians are telling us that the federal debt will burden our children and must be reduced. But the real burden on young people is educational debt caused by state educational policies. Our children have been made responsible for their own college education, which has become an important part of their preparation for work. They are graduating college with overwhelming debts of $100,000 or more, and even those who fail to graduate still leave college with ample college debts. College debt has surpassed credit-card debt, and the President and Congress have wrangled about the interest rate to charge.

This is a historical parallel of some interest and another reason to integrate the New Economic History with current economics. The discussion could even extend to macroeconomics, as the high debt of many young people will depress their consumption in coming years. The analog of slaves presumed repayments to their owners is the low consumption of debt-ridden young people today. The large amount of student debt outstanding suggests that this low consumption may be a drag on the American recovery from the global financial crisis.

Costa and Kahn (2008) examined social debts in a study of Civil War soldiers. They looked at the interactions of soldiers in war and captivity to see the effects of friends and comrades. They found that some soldiers were willing to risk their lives for others (heroes) while others were more like the *homo economicus* of elementary economics (cowards). They reach out to other social sciences for other concerns about the effects of community ties and suggest a variety of hypotheses to be considered. Their research also recalls Adam Smith, using tools derived from *The Wealth of Nations* to raise questions about the topics of *The Theory of Moral Sentiments*.

Hornbeck (2012) extended our understanding of long-run effects of economic changes to natural disasters. The Great Depression is thought of as a macroeconomic event, but the dust bowl of the 1930s was an important part of the national experience. Hornbeck used the same kind of regression discontinuity as Dell to separate the effects of soil depletion and other factors. Land values fell 30% in high-erosion counties.

Hornbeck looked for the kind of substitution in production that Voitländer and Voth found after the Black Death, but found little movement along relevant cost curves. Instead, he found that people migrated out of the dust-bowl area rather

than adjust their agricultural practice to the new conditions. The Okies, as the migrants to California were called, revealed another path of adjustment to change. As Hornbeck noted, this geographical adjustment is typical of recent American labor-force adjustments to other changes in employment opportunities (Blanchard and Katz 1992).

The fall in land prices in the dust bowl is similar to the fall in house prices at the end of the recent housing boom. Many mortgage holders have found themselves "under water" with the value of their loans exceeding the value of the houses. Various forms of relief have been tried, but the banks have resisted writing down their loans. The result is that many people are unable to spend as they would like or move because of their outstanding mortgages. This then has macroeconomic effects as noted already for educational loans. Consumption is down and geographical mobility as an adjustment to labor-market difficulties is not available. The New Economic History of the United States reveals that some of the factors that enabled us to recover from natural and man-made disasters are not available to us now.

Finally, the New Economic History has informed us of recent demographic events other than the Black Death. The "baby boom" in the United States was created by the return of soldiers from the Second World War after a long depression that depressed birth rates. Easterlin (1987) studied how the baby boomers fared in subsequent years. He found crowded schools and increased labor-force competition. The important new observation was the persistence of the effects of the demographic shock. As baby boomers aged, their problems aged with them in age-appropriate ways. For example, as the baby boomers have reached retirement age, politicians are worrying how the Social Security System will be able to handle them. A presidential commission increased the normal retirement from 65 to 67 over many years to prepare for this shock. More changes are under discussion. Urban economists are now even asking if the postwar American growth of suburbs that accommodated all those children is now outmoded. Cause and effect are unclear at this point, but a lower birth rate and shifting technology have begun to have their effects of living patterns. The New Economic History does not have much to say about historical processes just beginning, but the history Easterlin studied is relevant to the work of economists who analyze these movements.

Let us now turn our attention to good fortunes that have been illuminated by the New Economic History. Even if economics is the dismal science, economic history need not be. The largest favorable shock that has been illuminated by the New Economic History has already been mentioned. The Industrial Revolution was a major change whose effects are all around us still. Allen (2009a) used the tools of the New Economic History to show that the Industrial Revolution emerged from the combination of high wages and low energy prices. As already noted, this was such a large historical event that the literature about is immense and ongoing. I can only allude to it here.

Instead, I focus on the good analog of the persistent damage done to people damaged in economic transitions. Clark (2014) has used the extensive data characteristic of the New Economic History to show that half of the variation in overall status of individuals is determined by their lineage. Clark and his colleagues showed

that this is true from the United States to China and Japan, and from Sweden to India. Regression to the mean is apparent in their data, but the process takes hundreds of years.

The methodology was to use surnames to identify descendants. Instead of relying on scarce censuses and family records, Clark and his colleagues identified unusual names characteristic of prosperity at some historical time. They then looked at more recent data on prosperity and social standing to see if these names were over represented. Surprisingly, they were, in many countries and over long periods of time.

This view of durable status has been reinforced recently by Ferrie, long a student of population mobility in the United States (Ferrie 1999). Using the more familiar approach of identifying families in censuses, Long and Ferrie (2014) extended the normal two-generation study of social mobility to three generations in a recent paper. They found more persistence over three generations than over two generations. Clearly, there is a great deal of noise in the mobility of individuals and in any single generation. But extending the length of study provides evidence of greater stability.

Goldin and Katz (2008) used a different approach to analyze the relative fortunes of different groups in America during the twentieth century. Their focus was on education and the difference between educated – and therefore skilled – workers and uneducated and unskilled workers. The progress of technology sets the demand for labor, and the interaction of supply and demand was characterized as a race between education and technology. This colorful metaphor drastically simplifies the many determinants of both education and technology. Their book goes into these complications in great detail.

This contribution is particularly relevant today. Economists examining the distribution of jobs have found that the progress of computers has hollowed out the demand for labor. There are demands for low-wage jobs and quite high-paying jobs, but the demand for factory jobs that were the mainstay of growing employment after the Second World War is down. This has created a need to rethink the simple macroeconomics of labor, since different aspects of technology have effects on different segments of the labor supply. The New Economic History provides a historical background that suggests several important lessons. The nature of technology has been exerting pressure on the wages structure for many generations before this one. Both progress in education (supply) and technology (demand) must be considered when trying to discover effective policies in this area. And, as Goldin (1990) observed in the history of women's work, participants in these sorts of changes cannot predict where they will end up.

Let me abandon this romp through economic history now and try to think more broadly about the future of the New Economic History. I do not like cherry picking in the work of others; I cannot imagine it is informative in much beyond methodology here. The brief sampling of work here does not lead directly to substantive conclusions; it rather suggests the scope of the New Economic History. The subject matter ranges over time from early history to recent events, and over space across continents. If there is one safe prediction, it is that the discovery of new data and of new ways to use existing data will encourage this wide geographical and temporal spread.

As suggested earlier, two aspects of the New Economic History are keys to the growth of scholarship in this area. One is the focus on institutions as carriers of economic structures across generations and sometimes centuries. The other is the focus on causality through imaginative use of identification strategies.

The importance of institutions is undeniable, but its role in research is problematical. The tradition takes its cues from North (1990) and the support of the New Institutional Economics that carries on this tradition. As I have described, the New Economic History often appeals to the role of institutions in the long-term effects of various short-run changes. But while the econometrics are fine in these studies, the accounts of institutional change often are less fully analyzed. Greif (2006) tried to clarify the issues involved, but his concern with theory of institutions may have made the empirical task of finding changes in institutions harder. One issue is that the evidence on institutions frequently is qualitative instead of quantitative. Ways need to be found to quantify what before was not considered quantifiable. In addition, institutions often change only infrequently or very slowly. Finally, it is not always clear how to define the institutions in question. Have morals declined in the United States? Are morals even considered an institutional framework? These are the kind of questions that need more research.

The other characteristic of the New Economic History is the attention given to causality. This typically involves a strong identification strategy to disentangle the motives of different parties to a decision. As shown in the brief selection of work above, the New Economic Historians are aware of this issue and devote a lot of thought to the process of identifying supply or demand influences. Voitländer and Voth went to great lengths to show that the Black Death was in fact the cause of the demographic transition in Western Europe, and Allen has supported his explanation of the Industrial Revolution by comparing factor prices in many other countries. Dell and Hornbeck used geographic boundaries to identify causal elements in their stories.

Let me illustrate these claims with two final examples, one from a young New Economic Historian and one from an old member of our tribe, one from far away and one from long ago. They both involve the consequences of plagues.

The first example is by Dan Li, a Chinese economic historian (Li and Li 2014). She and her coauthor are part of a geographical expansion of the New Economic History to Asia. A recent paper summarized the literature on the history of Chinese economic institutions and macroeconomics for a millennium (Brandt et al. 2014). The paper argues that economic history illuminates choices today – as I have stressed for issues in more familiar venues. Li examined migration from China to Manchuria in the early twentieth century, shortly after a plague that hit the destination of the migrants. The plague reduced population more strongly in some areas than in others. Migrants to areas where the plague hit hard fared better in future years than those to other areas. The question is why did migrants settle there. In other words, was this good fortune determined by design or by luck?

There are no records of individual choices being made, no questionnaires about why a specific destination was chosen. Instead Li and Li (2014) use their data to

distinguish migrants to different areas in the data we have. They found that migrants with higher socioeconomic status avoided plague-hit villages. Migrants to these areas were the least likely to do well in Manchuria.

The second example originated in a conference on quantification in the ancient world. My first reaction was that ancient data was an oxymoron. But my second reaction was that qualitative data – even if only the opinions of modern ancient historians – could be quantified. The process was made manageable by choosing only to quantify the data only in the binary way so typical of our modern electronic devices. By this metric, inflation was either present or not, and political instability was either present or not. American economic historians will recognize this approach as the technique used by Romer (1986) to compare the severity of business cycles throughout the twentieth century. She had to degrade the recent data to make it comparable to the older data. I had to simplify the desired information to quantify at all.

The quantification allowed a decision on timing. The empirical result was that both switches turned on at the same time. This suggested joint causation, and a third possible cause was likely. I looked for a plausible exogenous variable that could have set an interactive process of inflation and instability off together and argued that the preceding Antonine Plague was the cause of both inflation and instability. I commend you to my book for details of the change from the Early Roman Empire to the Late Roman Empire, an important institutional change in world history (Temin 2013).

These two final examples are presented only to highlight the extension of familiar techniques to new fields of inquiry and the opportunities open to the New Economic History. If there is a theme that runs through this survey of where we were, where we are, and where we might go, it is that the fields of economic history and economic growth have much to learn from their interaction.

Economic History as Humanomics

The Scientific Branch of Economics

Deirdre Nansen McCloskey

Contents

Abstract

Essays in any field of the intellect about "whither the future of X" have a deep intellectual problem of an economic character. The future is coming, whether we like it or not, and our bets on its outcome will determine how we personally do. But if good predictions were achievable by studying econometrics or by following Warren Buffett, we would all be above average, as in Lake Wobegon. And we are not. So in sober truth, such sessions are actually about "What Do I Want Economic History to Become." Herewith, I am therefore to be allowed to make unrealistic "predictions."

Introduction

Essays in any field of the intellect about "whither the future of X" have a deep intellectual problem of an economic character. The problem is that if you or I were so smart as to know the answer, then you or I would be rich. If anyone could predict the future of, say, mathematics, she could arbitrage between the present and the future. As the satirical song writer Tom Lehrer put it long ago, she would "publish first." She would achieve riches in a coin relevant to her preferences, namely immortal fame. She would be the Euler of the twenty-first century.

The principle is identical to the more obviously economic one that predictions of the stock market or housing prices or hem lines of skirts are useless. As they say in Hollywood, nobody knows anything. That *Rocky* was a hit doesn't mean that *Rocky 2* or *3* or *N* will be. We have to make predictions, of course, and necessarily we place bets on them. The future is coming, whether we like it or not, and our bets as producers of movies or of mathematics will determine how we personally do. But if good predictions – better than what the average punter makes with his bookie or in the forward markets – were achievable by studying econometrics or by following Warren Buffett, we would all be above average, as in Lake Wobegon. It ain't happenin'.

So in sober truth such sessions are actually about "What Do I *Want* Economic History to Become." I am therefore to be allowed to make unrealistic "predictions."

What Economic History Has Become

I actually think, to be realistic for a moment, that it is probable that economic history will continue for the next decade or so to be dominated by Scientism, quite different from actual science. Scientism is the belief that you are only scientific if you follow a method of science laid down by an amateur philosopher fifty or a hundred or two hundred years ago. In cliometrics, everything is supposed to be quantitative, because then we are Scientists. (I once believed this, so I know.) In science, generally the method is supposed to be Baconian, expressed by Sherlock Holmes in "A Study in Scarlet" as "it is a capital mistake to theorize before you have all the evidence. It biases the judgment." In history, the method comes from Leopold von Ranke's first book, in 1824, in the form of *wie es eigentlich gewesen*, "as [the past] actually was," and in American history from the 1880s to the present in the form of "that noble dream" of an objective historical science.[1] In economics, the method comes from Lionel Robbins (1935) in the 1930s, influenced by Austrian logical positivism already by then under devastating attack by actual philosophers. Nonetheless, the illogical method of logical positivism was enthusiastically seconded by Samuelson (1947) in the 1940s and Friedman (1953) in the 1950s.

[1]Novick 1988 on American history. Novick argues that *eigentlich* should actually be translated "essentially," which gives the phrase a less naively Baconian essence.

The method eventuated in the official constitution of Samuelsonian economics, drafted by Tjalling Koopmans in 1957, *Three Essays on the State of Economic Science.* Koopmans (whose name, by the way, means "salesman") recommended a theoretical/empirical specialization. He recommended that theorists spend their time gathering a "card file" of *qualitative* theorems attaching a sequence of axioms *A', A", A"'*, etc. to a sequence of conclusions *C′, C″, C‴*, etc., *separated from* the empirical work, "for the protection [note the word, you students of free trade] of both," both the theorist and the empiricist. Then the empirical econometricians down in the basement will get to work to see if in the actual world A' leads to C′ or to C″'.

The official method would be fine if the theorems were not merely *qualitative*, the way Samuelson in *Foundations* had laid down they could be. If they took instead the *quantitative* form of the math used by physicists or geologists, in contrast to the on/off existence theorems that mathematicians and economists so love, good. Then the duller wits like McCloskey, the economic historian, could be assigned to mere observation, filling in the blanks in the theory. But *there are no blanks to fill in*, no How-Much questions asked, in the sort of theory that economists admire and that absorbs much of their waking hours (in recent years a little less, I am glad to acknowledge, in favor of quantitative simulation, praise the Lord).

I am here to tell you that the Samuelson-Friedman-Koopmans method will go on being used in economic history for a while, until economic historians realize that whatever its prestige in economics, and its power to overawe in history, it is bankrupt.

In its theoretical branch, the excess of liabilities over assets in the method is well illustrated by non-cooperative game theory. For one thing, experimental economics has shown over and over again that the premise of noncooperation is factually mistaken in humans. For another, finite games unravel, and infinite games have infinite numbers of solutions. In Yiddish syntax, some theory. No one of sense is against theory, if it means economic ideas. Informational asymmetry. Computational general equilibrium. Good. But if all we have is Koopmans' card file of qualitative theorems out to A^{100}', none tested, even in the empty set of ones that can be, what do we have, scientifically speaking?

Ah, but you will reply, we *do* test, with that econometrician down in the basement. No we don't. Name the important factual economic proposition since the Second World War that has been rejected or accepted by an econometric test. Robert Fogel subtitled his book of 1964 on railroads *Essays in Econometric History.* But Bob did not use econometrics, even by the definition of 1964. He used simulation. Rich Weisskoff and I were the RAs for John Meyer about that same time, incompetently helping to edit his essays with Alfred Conrad for a book entitled *The Economics of Slavery: And Other Studies in Econometric History* (also 1964). John and Alf in fact used simulation and accounting and economic ideas. One of Meyer's simulations, an input-output study of British growth in the late nineteenth century, led me out of using the idea of Keynesian aggregate demand for the long run, when I realized that John had done so and that it did not make a lot of sense, in view of the opportunity cost of resources (Kain and Meyer 1968).

Three terms of econometrics, such as I took (with Meyer in one course and Guy Orcutt, that pioneering simulator, for the rest), with no graduate training in other empirical methods – such as simulation, archival research, experiment, surveys, graphing, national income accounting – makes modern PhDs into savants of tests of statistical significance. Test, test, test says David Hendry. The trouble is that such tests are themselves bankrupt, as, for example, Kenneth Arrow (1960) noted a few years after Koopmans' constitution.

You will not believe, I realize, that null hypothesis testing without substantive judgment of magnitudes is bankrupt. Perhaps, though, you can come to believe by reading the report in 2016 of an official committee of the American Statistical Association (ASA 2016). I'll make a prediction. Someday, if you are young and scholarly and intellectually flexible enough, you will get it, and will give up mechanical tests of statistical significance at the 0.05 level and will start doing real science.

On the side of theory and Koopmans' card file, I worry in economic history about "analytical narratives," which seem to be popular with neo-institutionalists of the Northian tendency. Certainly, the contribution of economic history to economics consists in part in a "narrativizing" of economic behavior, a moving picture as against the more usual snapshot. The trouble again is the lack of meaningful quantitative testing. Quantification doesn't seem to happen in neo-institutionalism to a high standard. If the analysis is "consistent with" some little piece of economic history, all is said to be fine. What one would like to see is quantitative oomph, or else the humanist's substitute for quantity, serious comparative histories. Either or both would do.

I hesitate to cast the first stone, because I am not without sin. True, as the men caught in the #MeToo movement nowadays often say in extenuation, the sinning was a long time ago. Still, by confessing my own sins here and now I can avoid the impoliteness of naming particular works by my beloved colleagues in economic history that routinely misuse analytic narratives – that is, existence theorems, weakly "consistent" with the data, and not comparative, either. It would be easy to name them. It would be even easier to name colleagues who use tests of statistical significance – also weakly "consistent" with the data, at low power, and anyway usually irrelevant to the economic and historical question at issue, which is almost always not fit, but coefficient size, substantive oomph. But I won't.

So, bless me, father, for I have sinned. It has been half a century since my last confession.

In 1971, I gave a paper to the meetings of the Economic History Association, published the next March in the *Journal of Economic History* as "The Enclosure of Open Fields: Preface to a Study of Its Impact on the Efficiency of English Agriculture in the Eighteenth Century (McCloskey 1972)." Sounds swell, eh? But I remember uneasily that my commentator in the session at the meetings, the law professor, and student of environmental law and economics, Earl Finbar Murphy, complained that I had not shown in the paper that my very clever analytical narrative had actual quantitative oomph. I was distressed at the complaint, and, in the way of young scholars, even angry at Murphy. But I must have taken his complaint to heart,

because the next time I ventured into the open fields and their enclosures, I made sure to provide the quantitative goods, in a paper in 1976 called "English Open Fields as Behavior Towards Risk (McCloskey 1976)."

My friend Stefano Fenoaltea (1970) challenged the argument that scattering of plots was behavior towards risk with another analytic narrative, also as in my original 1971 paper not tested for oomph. Uncharacteristically for Stefano, his paper did *not* provide the quantitative goods. So in reply I wrote with a student at Chicago, John Nash, a paper actually measuring the oomph of Stefano's suggestion of storage of grain as insurance alternative to scattering of plots (McCloskey and Nash 1984). Oomph. Good on me, even at age 42.

And in that paper with John, to speak of econometrics, in order to isolate the cost of storage per month, including interest, we regressed changes in the prices of grain in any particular location against the number of months the change was measured over. The slope is what mattered. We had the good sense not to use tests of significance to "test" what any economist already knows, that prices rise after a harvest by the full cost per month of storage. They have to, for elementary reasons of arbitrage. Our R^2s were derisory. But so what? We were filling in the factual blanks in a quantitatively specified theory.

And again in the same era (the light was dawning in me slowly, slowly) I wrote a paper with J. Richard Zecher on "How the Gold Standard Worked" (1976), which used regression analysis to articulate a quantitative standard of what "one market" means. We did not do what studies of market integration routinely do down to the present, which is to "test" against a 0.05 standard of significance "whether or not" separate markets were integrated. Such a test is meaningless. There is no sense, Dick persuaded me, in which on/off, yes/no is a scientific standard. One has to have a comparative standard, such as within-USA integration of the market in bricks compared with international integration, USA vs. UK, for example. It's true in physics and it's true in economic history.

What Economic History Could Be

Enough of reality. What do I *want* economic history to become? What are my unrealistic predictions? In brief: I want it to continue to be the scientific part of economics and of history, but to get even more scientific than it is now.

Many economic historians trained as economists lack self-confidence in the face of their proud if ignorant colleagues in theory and econometrics, and therefore do not realize that economic history is the Darwinian-scientific part of economics. Peter Temin, my first teacher of cliometrics in the first year he gave the course, has recently lamented the decline of economic history in economics departments, such as his own at MIT, in favor of more appointments in theory and econometrics (Temin 2016). One wonders why in his long career at MIT he did not arrange for succession, though I have to admit that at Chicago I did not either. Two months after I left the University of Chicago in 1980, the department abolished the requirement in the graduate

program of a course in economic history. Now PhDs from Chicago, as from MIT, know nothing of the past of the economy.

Economic historians trained in other fields, such as sociology or history itself, or in departments of economic history in the Old World, are less inclined than their cliometric colleagues in the United States to whore after the latest "insight" alleged to matter factually from the theorists, or the latest "technique" of the econometricians identifying the number of angels on the head of a pin. But anyway, I say again, with pride at my colleagues' accomplishments worldwide, economic history is the almost completely *scientific* portion of economics and of history. It just needs more.

Realize, though, that the word "science" is a big problem in English, and is misleading economic historians to try to imitate what they imagine happens in physics. In all other languages, from French to Tamil and back, the local science word means merely "systematic inquiry," as distinct from, say, casual journalism or unsupported opinion. In German for example *Geisteswissenschaften,* which means literally in English a spooky sounding "spirit sciences," is the normal German word for what American academics call the "humanities," the British "arts." The Dutch to this day speak of *kunstwetenschap,* "art science," which English speakers now would call "art history" or "theory of art" and place firmly in the humanities arrayed against Science. In Italy, a proud mother of a 12-year old girl who is doing well at school speaks of *mia scienziata,* which sounds strange indeed in recent English, "my scientist."

In earlier English, *Wissenschaft* or *wetenschap* or *scienza* is what "science" also meant in English. Thus Alexander Pope in 1711: "While from the bounded level of our mind/Short views we take, nor see the lengths behind: /But more advanced, behold with strange surprise/New distant scenes of endless science rise!" (Pope 1711, *Essay on Criticism*, lines 221–224). Then in the mid-nineteenth century, as a result of disputes over chairs of chemistry in Oxford and Cambridge, the word was specialized to the systematic study of the physical world. In the *Oxford English Dictionary,* the new meaning, slowly adopted from the 1860s on (Alfred Marshall never did adopt it, but by the time of Keynes everyone had), became sense 5b, the dominant sense now, the lexicographers of Oxford inform us, in ordinary usage.

The usage of the last century and a half makes for endless yet silly disputes about whether economics is a Science, and gives natural scientists permission to issue lofty sneers about social *science*. Yet what would it matter to the practice if after learned dispute we decided that economics or economic history were *not* Sciences? I suppose we would be banished from the National Science Foundation or the National Academy of Science, which would be sad and unprofitable. But would the banishment change the actual practice of economic or historical science?

In actual practice, indeed, the sort of categorical issues that occupy *humanistic* sciences are an essential step in any systematic inquiry, whether of physical or social or conceptual matters. The humanities – such as literary criticism in the Department of Literature, and number theory in the Department of Mathematics, and transcendent meaning in the Department of Theology – study categories, such as good/bad, lyric/epic, 12-tone/melodic, red giant/white dwarf, hominid/*Homo sapiens*, prime/not, consciousness/not, God/gods, exist/not. The crucial and neglected point in the

battle of the Two Cultures is that such humanistic and human categorization is a *necessary initial step in any scientific argument*. You have to know what your categories *are* by well-considered definitions, such as *Homo sapiens sapiens*/*Homo sapiens neanderthalensis*, before you can *count* their members. This is obvious – though not to the anti-humanistic George Stiglers or Michael C. Jensens or Murray Rothbards of economics.

For example, economic theory is entirely humanistic, dealing in definitions and their relations, sometimes called "theorems" or, more usefully for an empirical science, "derivations." Theory makes remarks about categories – as Coase did: Transactions costs may be important here, and this is how they should be defined. Or, as Irving Fisher and Milton Friedman said, MV = PT. Or, as Edgeworth and Samuelson said, $(dU/dx)/(dU/dy) = P_x/P_y$. Or, as the Austrian economists say, markets may be more about events out of equilibrium than about equilibrium. Or, as Israel Kirzner and now D. N. McCloskey might put it, discovery may be more important for human progress than is routine accumulation or routine maximization of known functions.

At the level of economic theorizing, such folk are humanists, dealing in categories and derivations, in advance of and sometimes in lieu of examining the history of actual markets. I recently spent some time browsing through 2014 Nobel laureate Jean Tirole's textbook on the theory of finance (2006). The book gathers some hundreds of theories, with no shred of evidence supplied about which of the theories might apply to actual financial markets. For good or bad, it is as much an exercise in humanism as is Kant's *Critique of Pure Reason* (2008) or Ramunajan's notebooks on number theory (Ramanujan et al. 2000).

Some definitions and their corresponding theorems are wise and helpful, some stupid and misleading. The humanities, and the humanistic steps in any science, study such questions, offering more or less sensible arguments for a proposed category being wise or stupid, before counting or comparison or other factual inquiry into the world. The humanities study the human mind and its curious products, as for example, John Milton's *Paradise Lost* or Mozart's Flute and Harp Concerto in C (K. 299) or the set of all prime pairs or the definition of GDP. The studies depend on categories, such as enjambed/run-on lines or single/double concerti or prime/not-prime or marketed/unmarketed, such as we humans use.

In the early twentieth century, for example, many economists and other scientists such as the great statistician Karl Pearson believed that the category "Aryan race" was wise and helpful for thinking about the economy and the society.[2] Around then the American Progressives, and especially the leading economists among them, believed passionately in racism. They advocated policies such as immigration restrictions (later passed into law with the assistance of the KKK) and the minimum

[2]A late example of his views is Pearson and Moul 1925, "Taken on the average, and regarding both sexes, this alien Jewish population is somewhat inferior physically and mentally to the native population." And an early one is Pearson 1882 (1900), pp. 26–28, "From a bad stock can come only bad offspring. . . ."

wage (now adopted by modern Progressives) and compelled sterilizations ("Three generations of imbeciles are enough") to achieve eugenic results in favor of the perfection of the Aryan race (Leonard 2016). Later we decided, after some truly disturbing experiences and more reflection, that "race" aside from *Homo sapiens* was actually a stupid and misleading and even evil category. The decision itself depended on reflections on the humanistic categories of helpful/misleading, wise/stupid, good/evil.

The necessity of the humanistic first step, note well, applies to physical and biological sciences as much as to *les sciences humaines* or *die Geisteswissenschaften.* Meaning is scientific, because scientists are humans asking questions interesting to them about the meaning of β decay. Such is the main conclusion of science studies since Thomas Kuhn. The Danish physicist Niels Bohr wrote in 1927, that "It is wrong to think that the task of physics is to find out what the world is. Physics concerns what we can *say* about it."[3] We. Humans. Say. With words. About such *geisteswissenschaftliche* categories the German-American poet Rose Äuslander (2014) wrote, "In the beginning/was the word/and the word was with God/And God gave us the word/and we lived in the word. /And the word is our dream/and the dream is our life."[4]

We dream of categories, in our metaphors and stories, and with them make our models and our economic histories and our lives, especially our scientific lives, saying the world. The poet Wallace Stevens (2011) exclaims to his companion, walking on a beach in Key West, "Oh! Blessed rage for order, pale Ramon, /The maker's rage to order words of the sea," the human arrangement of words imposing order on the world. Of the woman they had heard singing, Stevens sang, "when she sang, the sea, /Whatever self it had, became the self/That was her song, for she was the maker."

There is nothing scary or crazy or French or postmodern or nihilistic about such an idea. The "hardest" sciences rely on human categories, and therefore on human rhetoric and hermeneutics, the speaking and the listening sides of human conversation in the sciences. The category of "capital accumulation," for example, can be defined in an aggregate, Smithian-Keynesian way. Or it can be defined in a disaggregated, action-specific Austrian way. It matters to the science, changing what we then proceed to measure and to recommend by way of policy. The humanistic job of economic theory is to ponder the categories, to see their internal logic, to criticize and refine them, just as in the departments of English and of physics.

But the humanistic step – though I am saying it is quite necessary for scientific thought – is of course not in a factual or policy science like economics the whole

[3]Quoted in *Niels Bohr: Reflections on Subject and Object* (2001) by Paul McEvoy, p. 291. The provenance of the remark is a little hazy, but it is well known. In Danish, the philosopher Hans Siggaard Jensen informs me, it was something like "*Fysik er ikke om hvordan verden er, men om hvad vi kan sige om den*."

[4]*Am Anfang/war das Wort/und das Wort/war bei Gott/Und Gott gab uns das Wort/und wir wohnten/im Wort/Und das Wort ist unser Traum/und der Traum ist unser Leben*.

scientific job. The point is one that economists regularly miss in their fascination with the blessed rage for order. Theory is not science *tout court.* One could have a theory of epics or concerti that never applied to any actual epic or concerto, and indeed foolishly misrepresented them as they are in the actual human world. Specializing in humanistic theorizing of the sort that Kenneth Arrow or Frank Hahn did is dandy, but it does not do the entire scientific job unless it is at some point firmly attached to experiment or observation or other serious tests against the world, as much of the work of these two brilliant men never was. The philosopher and economist Arthur Diamond looked into the empirical uses down in the empirical basement of abstract general equilibrium theory such as Arrow and Hahn practiced, and found that there was none.[5] If you are making a quantitative point, as must happen in a policy science like economics or in a world-speaking science like physics or in the glorious systematic inquiry into the past of the business of ordinary life called economic history, then after the humanistic step you must proceed to the actual count or the testing comparison. Count the deaths from plague in the 1340s or compare its impact in China, from whence it came.

Too often in economics the count or comparison does not happen, because economists think, as I have said, that theorems offer factual "insight," and believe that statistical significance "tests" the theory against facts. The two sides, theory, and econometrics, they say, can therefore specialize and specialize and specialize. Never trade. Such a procedure believes it imitates physics but does not inquire into how physics actually works. Physicists, even theorists, as one can see in the lives and writings of Enrico Fermi and Richard Feynman, spend much of their time studying the physical equivalent of the *Journal of Economic History.*

Conclusion

So what? Here's what. Economic history should become as humanistic as it is now foolishly anti-humanistic. It will become so if we overcome our anxiety that we might not be worthy of the white coats of the Scientists, sense 5b.

The word is "humanomics," coined by the indubitably scientific experimental economist Bart Wilson and embodied now in a book in progress by Bart and the Nobel laureate and founder and first president in 1986 of the Economic Science Association, Vernon Smith (Smith and Wilson 2017). I quarreled with Vernon at the time about the appropriation of the word "science" for what is mainly an association of laboratory experimenters. By now, he and I thoroughly agree that "science" covers more than misinformed imitations of physical sciences. Humanomics does not abandon what we can learn from such imitations, and is certainly not against mathematics or statistics. That is what is disastrously wrong with the complaints of, say, Francesco Boldizzone against cliometrics (Boldizzone 2011; McCloskey 2013).

[5]Diamond 1988, though Leland Yeager noted correctly that it does provide a useful "integrating factor of the whole body of economic theory" (Yeager 1999, p. 28).

There is much of value in the old German Historical School and the old American Institutionalists, but their ignorant hostility to what they called "English economics" is not it.

A properly scientific economic history invites the methods of the humanities into economic science. Bart and Vernon and colleagues, for example, are increasingly studying the meaning that their experimental subjects attach to their actions, as revealed by the humanistic techniques of textual analysis of what the subjects say to each other during the experiment. It has been known for decades in experimental economics that letting the subjects speak to each other can radically change the results. The study of human meaning casts light on the ordinary business of life.

We in economic history are well placed to take advantage of humanomics, as for example, merging business and economic history. But to do so, clearly, we need to set aside our anxieties about the National Academy of Science, and listen to *all* the evidence about the economy, whether it comes in the form of statistics of exports or the letters of one businessperson to another or the themes of contemporary drama. That last, for example, is one piece of evidence that attitudes towards business were radically changing in England in the first decades of the eighteenth century (McCloskey 2016).

Our colleagues in economics are trudging in the other direction, with a behavioral economics that ignores human meaning in favor of insisting, in the manner of 1930s psychology, that all that matters is external behavior; or, more extremely anti-humanistic, neuro-economics, which studies the brain but ignores the mind, as though we could understand Jascha Heifetz' fiddle playing by a closer and closer study of his muscles.

The solution is not either to run after the latest declared crisis in the environment or the latest "current policy issue" in the labor market, though admittedly the temptation among young scholars cowed by their present-minded colleagues to do so is great. The TV and newspaper and present politics are not good guides to what is permanently important in the study of the nature and causes of the wealth of nations. Bob Fogel once said that his principle in choosing topics for research was to do nothing that would not matter in 50 years. It is why early in the 1970s he abandoned some tentative research on the history of federal land policy in the United States. What will still matter in 50 years in economic history is poverty and its ending, and in political history tyranny and its ending. If poverty and tyranny are ended, the rest will follow. Better stick to the important issues.

I do not wish merely to preach (although come to think of it there's nothing wrong with preaching the gospel of scientific common sense). So let me give a concrete example of the scientific payoff of humanomics. Somewhat embarrassingly, the example is my own recent work in economic history, my trilogy on The Bourgeois Era (2006, 2010, 2016). Forgive me, mother, for I have sinned.

The Great Enrichment per capita in real terms by a factor of 20 or 30 or much, much more since 1800 is the most astounding economic change since the domestication of plants and animals. Historians, economists, and economic historians have been trying to explain it since Smith. Recently some have come to concentrate on the role of ideas, as in the work of the economic historians Joel Mokyr (2016) and Eric

Jones (2003), the historian Margaret Jacob, the historical sociologist Jack Goldstone, the anthropologist Alan MacFarlane or the economist Richard Langlois, or myself (2006, 2010, 2016), among a courageous handful of others.

The Great Enrichment has usually been explained by material causes, such as expanding trade or rising saving rates or the exploitation of the poor or changes in the rules of the legal game. The trouble is that such events happened earlier and in other places. For example, any organized society from hunter-gatherers to the United States of America has private property and the rule of law, or else it is not a society but a war of all against all, contra North and Weingast (1989). For another example, foreign trade is ubiquitous in human history, and is not about power, contra Findlay and O'Rourke (2007). Such points in criticism of the instinctive materialism of economic scholars after 1890 or so is itself a use of the humanist's substitute for quantification, comparison. Such material events as legal change and foreign trade cannot therefore explain the Industrial Revolution (which in fact has earlier parallels, usually a mere doubling of incomes). Especially they cannot explain its astounding continuation in the Great Enrichment of 3000 percent per capita. One can show in considerable detail (McCloskey 2010) that the material causes we study in economics do not work. One can also show (McCloskey 2016) how attitudes towards the bourgeoisie began to change in the seventeenth century, first in Holland and then in an England with a new Dutch king and new Dutch institutions. And one can show that the Bourgeois Revaluation was not ethically corrupting (McCloskey 2006).

One hypothesis is that if the social position of the bourgeoisie had *not* been raised in the way people spoke of it, then the aristocrats and their governments, or the bourgeoisie itself in guilds and mercantilism, would have crushed innovation, by regulation or by tax, as they had always done. And the *bourgeois gentilhomme* himself would not have turned inventor, but would have continued attempting to rise into the gentle classes. Yet if the material methods of production had not thereby been transformed, especially after 1800, the social position of the bourgeoisie would not have continued to rise. One could put it shortly: without spoken honor to the bourgeoisie, no modern economic growth. (This last was in essence of Milton Friedman's Thesis.) And without modern economic growth, no spoken honor to the bourgeoisie. (This last is in essence of Benjamin Friedman's Thesis.) The two (unrelated) Friedmans capture the essence of poor men, and women and slaves and colonial people and all the others freed by the development of admiration for the bourgeois virtues.

The causes were liberalism (McCloskey 2016), the scientific revolution (Mokyr 2002; not, however, in science's direct technological effects, which were postponed largely until the twentieth century), and above all a change in the rhetoric of social conversations in Holland and then in England and Scotland and British North America about having a go. The change in rhetoric was in turn a result of accidents of politics and society in northwestern Europe from the Reformation to the French Revolution that made people bold. By happenstance in the other advanced societies at the time such as China or the Mughal and Ottoman empires, boldness in the economy was not encouraged, as it had been in those places earlier, and in many

other ways, such as always in military technology. Europe "won" the war of civilian betterment by accident.

You can ask how an explicitly and persuasive bourgeois *ideology* emerged after 1700 from a highly aristocratic and Christian Europe, a Europe entirely hostile – as some of our clerisy still are – to the very idea of bourgeois virtues beneficial to the poor. In 1946 Schumpeter declared that "a society is called capitalist if it entrusts its economic process to the guidance of the private businessman" (Schumpeter 1946). It is the best short definition of that essentially contested concept, and highly misleading word, "capitalism." (Misleading because it invites us to focus on aggregate capital accumulation rather than on the particular and Austrian discovery of ideas for betterment that actually made the modern world.) "Entrusting" the economy to businesspeople, Schumpeter explained, entails private property, private profit, and private credit. (In such terms, you can see the rockiness of the transition to capitalism in present-day Russia, say, where agricultural land is still not private, and where private profit from actual enterprise, as against extortion and theft, is still subject to prosecution by the state, the jailing of billionaires, the cutting down of tall poppies.)

Yet what Schumpeter leaves aside in the definition, though his life's work embodied it, is that the society – or at any rate the people who run it – must *admire* businesspeople. Schumpeter, as Richard Langlois (2014) has noted, had no sociological theory. People must come sociologically to think the bourgeoisie capable of virtue. It's this admiring of the bourgeois virtues that Russia lacks, and has always lacked, whether ruled by boyars or tsars or commissars or Putin and his friends, ever since Muscovy long ago fended off the Mongols, at the sacrifice of the commercial model of Novgorod.

Attributing great historical events to ideas was not popular in professional history for a long time, 1890–1980. A hardnosed calculation of interest was supposed to explain all. Men and women of the left believed in historical materialism, and so strong was the belief that many liberals or conservatives were embarrassed to claim otherwise. But such a result of the "dream of objectivity" hasn't worked out all that well. Actual interest – as against imagined and often enough fantasized material interest – did not cause World War I. The Pals Brigades did not go over the top at the Somme because it was in their prudent interest to do so. Non-slave-holding whites did not constitute the bulk of the Confederate armies for economic reasons. Nor had abolition become a motivating cause because it was good for capitalism. And on and on, back to Achilles and Abraham pursuing their honor and their faith.

We do well therefore as economic historians to watch for cognitive-moral revolutions, and not simply to assume that Matter Rules, every time. A showing that ideas matter is not so unusual nowadays among historians. But it is another project to show that the material base itself is determined by habits of the lip and mind – *that* conclusion evokes angry words among most people on the economistic side of the social sciences, and often enough from historical materialists in the humanities.

In short, the Great Enrichment is a world-historical example of the force of language in the economy – its linguistic embeddedness as the sociologists would put it. In the economy the force of language is not to be ignored. (Or that it *is* to be

ignored: if the research is genuine the possibility must be lively that the hypothesis turns out to be wrong.)

Thus "humanomics." Ignoring the burden of art and literature and philosophy in thinking about the economy is bizarrely unscientific. It throws away, under orders from an unargued and demonstrably silly Method, a good deal of the evidence of our human lives. I do not mean that "findings" are to be handed over from novels and philosophies like canapés at a cocktail party. I mean that the exploration of human meaning from the Greeks and Confucians down to Wittgenstein and *Citizen Kane* casts light on profane affairs, too. A human with a set of virtues and vices, beyond the monster of interest focusing on Prudence Only, characterizes our economies, if not our economics.

And so (the hypothesis goes) an economic history without meaning is incapable of understanding economic growth, business cycles, or many other of our mysteries. A humanomic economic history would extend but also to some degree call into question the techniques of modern economics, and the numerous other social sciences from law to sociology now influenced by an exclusively Max *U* theory.

Economic history, that is, can embrace the humanities, without forsaking measurement, and become more, not less, scientific.

Cliometrics and the Study of Canadian Economic History

Ian Keay and Frank D. Lewis

This chapter is dedicated to the memory of Frank Lewis, my co-author, colleague, and friend. I.K.

Contents

Abstract

The long-run development of the Canadian economy has been marked by discontinuities in policy, structure, technology, and performance. By applying cliometric tools and techniques, our understanding of these discontinuities has evolved well beyond the narratives that traditionally documented Canadian economic history. The theoretical foundations and quantitative rigor of cliometric analysis allow us to describe the Canadian experience relative to contemporary and international parallels. In this chapter we illustrate the transformative effect cliometrics has had on the study of Canadian economic history through a survey

of the key contributing factors and episodes that affected Canadian development. These factors include the role of resource-led growth, including the impact of the fur trade and western wheat production; the relationship between policy and performance, including the adoption of trade protection, the subsidization of infrastructure, and the impact of immigration; and the connections between economic policy and entrepreneurial decision-making.

Keywords
Canadian economic history · Resource-intensive development · Fur trade · Wheat boom · Trade policy and growth · Immigration policy · Railway building · Technological choice · Entrepreneurial failure

Introduction

Canada is a big place, but its aggregate economy has always looked rather small relative to its main trading partners. The Canadian land mass is over 23% larger than the lower 48 US states, but both total population and GDP in Canada have consistently been no more than about one tenth that of the aggregate American economy. The extraction and processing of natural resources have been, and continue to be, a considerably larger share of the Canadian economy than in the USA. Urquhart (1993), and domestic manufacturing establishments during the late nineteenth- and early twentieth-century industrialization phase differed substantially from US establishments in the same industries, located in northern border counties. Specifically, Canadian establishments were smaller, more rural, more seasonal, and more resource and labor-intensive, and there were fewer factories using less steam power (Inwood and Keay 2008). There is a natural tendency to compare Canadian economic performance to that of the USA, particularly in a historical, long-run development context. As these stylized facts suggest, this often leads to an unflattering portrayal of the Canadian experience, and traditional narratives typically reflect a decidedly pessimistic perspective (Bliss 1990).

Despite the negative depictions in much of the traditional historiography, there is some evidence supporting a more favorable view of Canadian development. For example, from as early as the 1870s, relative to global averages, Canadian growth was strong, nearly matching US and even British industrial production per person between 1870 and 1913 (Urquhart 1993). Compared to other "new world" economies, including the USA, Canada has also been relatively urban, with a disproportionately large share of its population living in dense, albeit geographically disparate, cities and towns. Canadian total factor productivity (TFP) levels and growth rates have been comparable to the global leaders since the 1870s, and real GDP per capita growth between 1880 and 1913 was faster even than growth in the USA (Harris, et al. 2015). Canada's interactions with the global economy during the first era of globalization support this more optimistic characterization of Canadian performance, with large and growing volumes of net immigration, particularly after the mid-1890s, significant net capital inflows amounting to nearly 10% of GDP, and rapidly expanding trade flows, notably into the US market.

Canadian development defies overly deterministic descriptions, and in its complexity, we can find close parallels over time and across a wide range of countries. The long-run industrial and economic development of the Canadian economy may not have been as obviously and unambiguously exceptional as the US experience, but this marks Canada as more representative of a wide range of countries in, for example, Scandinavia, Australasia, South America, and among currently developing, resource-rich, strongly globalized economies. Added to these features of Canadian growth are the fact that the country is unusually well endowed with high-quality historical evidence from business archives, tax, court, and probate records, trade reports, and census manuscripts and that there was exceptionally rich policy, geographic, institutional, and sectoral variation available for identification, and we can see why the union of complexity, common experience, and evidence allows us to draw broad lessons from the study of Canadian economic history. It also helps to explain why the Canadian experience is unusually well suited to the application of cliometric tools and techniques.

Traditional narrative approaches struggle to identify the causal factors at work in economic environments that are characterized by fluid, rapidly evolving, and endogenously determined forces. The careful use of economic theory and statistical rigor helps us to sort, categorize, and weigh these forces. This chapter provides a survey of some of the fundamental questions and debates within Canadian economic history that have been the subject of cliometric study. More specifically, we review the role of resource-led growth, focusing on the fur trade, the resource curse, and the wheat boom, and the relationship between policy and performance, focusing on the adoption of trade protection, the subsidization of infrastructure building, the impact of immigration and immigration policies, and the impact of policy choice on entrepreneurial decision-making. From our survey we learn that the cliometric study of Canadian economic history has had a transformative effect on our understanding of some of the key contributing factors and episodes affecting Canadian development. The traditional narratives are not necessarily or unequivocally overturned in every case, but the confidence that cliometric tools bring to our analyses clearly illustrates the value of a quantitative, transparent, and structured approach to the study of Canadian economic history.

Resource-Led Growth: Curse or Blessing

Canada has long been a resource-intensive economy, with nearly 20% of domestic GDP originating in resource extraction and processing industries between 1900 and 1999 (Keay 2007). The threat of a "resource curse," therefore, has been significant in a Canadian development context. Using a standard growth equation, with a panel comprised of 69 countries spanning the years 1970–1989, Jeffrey Sachs and Andrew Warner (2001) identify a strongly significant negative relationship between the natural resource intensity of countries' exports and their real per capita income growth. Sachs and Warner famously dubbed this relationship the "curse of natural resources," and although the finding has been the subject of study across a wide

range of countries and time periods, it has proven to be remarkably robust (Auty 2001, Lederman and Maloney 2007). The causal channels through which the curse is supposed to operate are broadly associated with the fear that the pursuit of resource rent draws productive factors away from more growth-enhancing economic activities. Resource rent is considered undesirable as a source of growth due to its association with corruption, weak institutions – particularly with respect to property rights – and poor policy and entrepreneurial decisions (Lederman and Maloney 2007). More generally, resource extraction and processing are not viewed as growth enhancing because these activities are perceived to be relatively low-skill labor-intensive, low-technology capital-intensive, and, therefore, low-productivity. In addition to these structural shortcomings, international prices for resource-intensive products are considered to be inherently more volatile than more elastically supplied, less resource-intensive traded goods, and the Prebisch-Singer hypothesis suggests that the terms of trade for resource exporting nations have been in long-run decline since early in the twentieth century (Cuddington et al. 2007). If we combine these factors with the threat of currency appreciation and input price inflation associated with "Dutch disease," there appears to be ample reason to be concerned about the long-run growth effects of resource specialization.

Sachs and Warner recognize that there is a problem reconciling their contemporary evidence of a curse with the experience of early industrializing nations, such as the USA, the Scandinavian countries, Australia, and, of course, Canada. These nations were strongly resource intensive in production and trade during the late nineteenth and early twentieth centuries (Bhattacharyya and Williamson 2011; Keay 2007). Sachs and Warner (2001) suggest that perhaps these nations were less reliant on resource extraction and processing than more contemporary developing economies or the combination of high transport costs and energy using technological biases around the turn of the twentieth century may have mitigated the worst effects of the curse. Cliometricians have challenged the universality of the curse by integrating resource and growth theories and by working to accumulate a body of quantitative historical evidence, particularly for Canada, that calls into question the causal determinants and predictive capacity of the resource curse narrative.

Cliometric tools have helped to document the Canadian historical experience as a clear case of successful and persistent resource-led industrial development and diversification. W.A. Mackintosh (1923) originally articulated the "staples thesis" as a model describing how globalization and inter-industry externalities foster industrial development and diversification in an initially resource-rich but labor- and capital-poor economy. Export demand and the pursuit of resource rent draw foreign capital into infrastructure projects and resource extraction and processing industries. These industries and projects generate rents, which raise domestic income levels and expand domestic demand for less resource-intensive manufacturing, construction, and service sector industries. Transport cost advantages shift local supply curves for raw material inputs, providing an additional boost to geographically proximate resource using manufacturing industries. The aggregate impact of the resource sectors' direct and indirect contributions to the intensive and extensive

growth and diversification of an economy can be both large and persistent in this model, even as stock depletion occurs.

Keay (2007) uses a four-equation vector autoregressive system, with industry-level price and output data from 1900 to 1999, to test for long-run chronological patterns in Canadian resource output, raw material prices, non-resource-intensive manufacturing output, and service sector output. He finds that increases in domestic resource extraction and processing "Granger caused" reductions in Canadian raw material prices and increases in non-resource-intensive manufacturing and service sector output. Although these results do not provide structural evidence that the staples thesis was operating in Canada through the twentieth century, they are fully consistent with the chronological patterns predicted by the model. Measures of the aggregate economic value of these indirect inter-industry externalities over the 1900–1999 period, and the calculation of annual industry and stage-of-production-specific resource rents, reveal that resource specialization just slightly reduced real GNP/capita growth rates in Canada over the twentieth century (from 2.1% per year to 2.0%) but average income levels were nearly 18% higher as a result of the extraction and processing of Canada's resource endowments (Keay 2007).

The weakly negative impact of resource specialization on Canadian twentieth-century growth is not inconsistent with the more contemporary, panel data evidence of a resource curse, but the strongly positive effect of resource specialization on income levels is not at all what is implied by Sachs and Warner's curse. Again, cliometric tools can help us resolve this apparent inconsistency. Boyce and Emery (2011) augment a basic exogenous macro-growth environment by incorporating key aspects of Hotelling's (1931) optimal extraction model. They show that in panel data, under some reasonable assumptions about relative productivity differences (namely, that non-resource-intensive manufacturing productivity is higher than resource industries' TFP), it is theoretically consistent to suggest that resource specialization will be associated with slightly slower income growth rates but considerably higher income levels. In their model, accumulated resource rents raise income levels, but optimal extraction paths in a hotelling environment reflect a trade-off between rising resource rents (increasing scarcity) and the rate of return on other assets. As a result, initially resource-intensive economies will shift factors of production out of resource industries and into more productive alternate industries more slowly than economies with initially low levels of resource intensity. Thus, in the presence of optimal decision-making, resource specialization may be associated with slower income growth rates, just as the curse literature finds in the contemporary data, but higher income levels, just as Keay finds for Canada over the twentieth century.

Imposing a little economic structure, and the collection of long-run evidence with careful empirical identification, does not necessarily undermine the universality of the resource curse in a modern context, but it does help to reconcile the historical experience of Canada and other early industrializers with the results derived from contemporary panel data. Resource-led growth may be slightly slower than growth in less resource-intensive economies, but over the long run, the average person in a

resource-rich economy will be significantly better off than the average person in a resource poor economy.

Indigenous Peoples and the Fur Trade: Market Signals, Demography, and Depletion

Canada was engaged in resource-intensive activities long before 1900. Our understanding of the early interactions that occurred between the indigenous population of North America and Europeans engaged in the fur trade affects our perceptions of First Nations people and the nature of their relationship with commercial markets. The application of economic theory and statistical analysis to the substantial body of evidence left by French trading companies and, more importantly, by the Hudson's Bay Company, are transforming long-held views and traditional narratives (Ray and Freeman 1978). During the eighteenth century, the Hudson's Bay Company traded for a variety of animal pelts throughout the Hudson's Bay drainage basin, but their primary trade target was beaver fur, which they acquired in exchange for more than 60 distinct European products. Using the annual trade accounts from individual trading posts, which report trade volumes and the rates of exchange between pelts and European goods, Ann Carlos and Frank Lewis (2010) develop a price index for furs. This information about the value of fur earned by trappers over time and across trading posts reveals that the indigenous participants in the recorded trades were more like the "industrious workers" of the emerging Industrial Revolution, rather than the "docile peasants" of pre-modern Europe.

As the price of furs traded at the Hudson's Bay posts steadily increased through the eighteenth century, indigenous trappers dramatically increased their purchases of luxury goods, including cloth, jewelry, and tobacco while maintaining their purchases of necessities. Purchases of alcohol also rose during this period, but they were insignificant relative to the value of the overall trade, and the total volume purchased undermines any suggestion that alcohol had more than a minimal impact on indigenous societies during this era. Carlos and Lewis (1999) combine their evidence on the value of the various furs brought to the posts with a simple logistic stock depletion model for beaver. They show that indigenous trappers were increasing and redistributing their effort in response to changing relative fur prices and rising depletion rates.

The records of the Hudson's Bay Company, and other quantitative evidence, have also been used to re-examine the impact of European traders' introduction of smallpox into the indigenous population in northwestern Canada. Carlos and Lewis (2012) focus on one example of a particular smallpox epidemic that swept through the Hudson Bay region in the early 1780s. Narrative accounts put the death rate among the indigenous population as high as 60–90%. Carlos and Lewis trace the volume of trade in furs during the pre- and post-epidemic years, finding only small reductions and limited price movements. They then estimate total mortality from eye-witness accounts of company men and indigenous traders who visited the affected trading posts, and they reconstruct pre-epidemic indigenous population

levels by calculating the human population that might have been supported by the moose, bison, and other resources in the region. As a final assessment, they appeal to the medical evidence on smallpox mortality rates from other more recent, better documented epidemics. According to Carlos and Lewis, all the quantitative evidence suggests that indigenous mortality, while devastating, was likely closer to 10–20%, rather than 60–90%. This surprising result, like much of the growing body of quantitative, cliometric evidence on the economic lives of First Nations populations in Canada, is shifting and refining our views on the role played by indigenous peoples in long-run growth and resource-led development.

The Wheat Boom: Time Series Analysis and the Identification of Structural Breaks

Shifting our focus from beavers in the eighteenth century to wheat at the very end of the nineteenth, we again see a prominent role attributed to Canada's resource endowment. Between 1896 and Canada's declaration of war against Germany on August 5, 1914, the population of the country grew from just over five million to nearly eight million, GDP in 1900 dollars increased from $655 million to nearly $1.8 billion, and annual gross immigration increased from just over 17 thousand to 400 thousand (Urquhart 1993). This period of historically unprecedented income and population growth has become known as the "wheat boom," in no small part because even the most casual of observers at the time recognized that although growth was clearly accelerating in the aggregate economy, the three western prairie provinces – Manitoba, Saskatchewan, and Alberta – were being fundamentally transformed. Wheat exports increased by more than an order of magnitude between 1896 and 1913; new railroad track, which was being added almost entirely west of Ontario, nearly doubled the national total to just over 29 thousand miles in 1913; and the population of the prairie provinces alone rose from approximately 330 thousand in the early 1890s to more than 1.3 million by 1913.

More recently, cliometric analyses have begun to reveal that Canadian growth during the wheat boom was not as unbalanced as the accounts from the period and the broad national aggregates and proxies seem to suggest. Green and Urquhart (1994) provide a detailed investigation of the macroeconomic evidence from this period. They suggest that growth in Canada did discontinuously increase after the mid-1890s, but this expansion was not necessarily narrowly based on the production and export of wheat alone. Wheat exports from the prairie provinces did begin to rise in the early 1890s following the completion of Canada's transcontinental rail line, the Canadian Pacific Railway, and an increase in the relative price of wheat and flour on international markets, but the largest increases in wheat production came later, in the 1910s and early 1920s. More closely coincident with the boom in income per capita was a dramatic increase in the accumulation of fixed capital, particularly infrastructure and social capital, and a relatively balanced expansion in both the urban-industrial and agricultural sectors. Between 1896 and 1913, the value of gross fixed capital increased from just over 10% of GDP to more than 30%, domestic

saving rates more than doubled, and foreign capital inflows more than tripled. Over the same period, manufacturing maintained its GDP share at approximately 25%, while agriculture's share actually dropped slightly, from approximately 25% to just over 20% (Green and Urquhart 1994).

Looking at migrants' intended destinations upon arrival, Green and Green (1993) find that balanced growth also characterized the labor market during this boom. Their figures show that the urban share of the population increased after 1890, in part because the large inflow of new migrants ended up fairly evenly distributed between central Canadian urban centers and the prairie provinces. The cliometric evidence, therefore, suggests that Canada's wheat boom may in fact be more accurately described as a complex expansion in investment, geographically balanced population growth, terms of trade, and exports. Cliometricians have sought to map out the connections among these macro-variables, documenting the implied structural transformation of the Canadian economy during the late nineteenth and early twentieth centuries. The most common tools applied in this effort have been a range of time series econometric techniques.

Inwood and Stengos (1991), for example, test for the presence of a unit root in Canadian aggregate GNP and gross investment between 1870 and 1985. The presence of unit roots in the macro time series indicates that the series are not trend stationary, which suggests that some shocks, or deviations from the long-run trend, were not transitory. These shocks, therefore, permanently affected the underlying determinants of trend growth in Canada over this period. Inwood and Stengos cannot reject the presence of a unit root over the full 1870–1985 period, but when they impose structural breaks in 1896, 1914, and 1939, essentially segmenting the series into sub-periods and allowing for period-specific trends, unit roots can be safely rejected for both GNP and investment. The implication of this finding is that the start of the wheat boom in 1896, World War I in 1914, and World War II in 1939, all marked permanent breaks in Canada's underlying macroeconomic growth trends. Inwood and Stengos argue that all other shocks to the economy, including the collapse of Canada's terms of trade in the early 1920s, the Great Depression, the post-World War II baby boom, and the oil shocks during the 1970s, were transitory – meaning that growth returned to its underlying, stable trend following the dissipation of these shocks.

This is a powerful result that clearly marks the wheat boom as a transformative episode in the long-run development of the Canadian economy. However, the nature of the underlying growth determinants is not explicitly modeled by Inwood and Stengos, and their discretionary imposition of structural breaks is, in effect, based only on their reading of the historiography on Canadian development. Evans and Quigley (1995) argue that the use of univariate time series models does not allow for tests of the exogeneity of any particular structural break or series of breaks. They also show that trend segments imposed in 1896, 1914, and 1939 are not necessarily the only breaks that lead to the rejection of a unit root in the Canadian GNP and gross investment series. Alternate breaks imposed in chronologically proximate years, and the imposition of additional breaks in, for example, 1920, 1929, 1949, and 1973, can also support the confident rejection of the presence of permanent shocks affecting Canadian growth. In a rejoinder, Inwood and Stengos (1995) respond to Evans and Quigley's critiques of their methodological approach and their choice of 1896, 1914,

and 1939 as the unique set of exogenous structural breaks affecting trend growth in Canada. They demonstrate the importance of segment-specific critical values for their unit root testing procedure, while probing the statistical strength of their unique 1896, 1914, and 1939 break points, and they argue for the a priori exogeneity of the technological, climatic, and international demand shocks that triggers the expansion of wheat production and exports in 1896 and the strictly international origins of the two world wars.

Green and Sparks' (1999) contribution to the wheat boom literature also employs time series techniques to study shifts in the underlying trend determinants of Canadian macroeconomic growth. However, rather than relying on univariate models of GNP and gross investment in isolation, they use a dynamic vector autoregressive (VAR) system, which models the time series connections linking population, real investment, terms of trade, real exports, and aggregate real income in Canada over the period 1870–1939. After establishing stationarity and estimating the cointegrating relationships among their five macro-variables, impulse response functions parameterized from the estimation of their VAR model allow them to map out the dissemination of shocks through their system of equations. They find that the cointegrating coefficients among their five variables, which reflect the long-run equilibrium relationships among them, were distinct during the 1896–1913 period, suggesting that the wheat boom was, in fact, a structural discontinuity in trend growth in Canada. The relative size of the impulse responses reveals the substantial impact that exogenous export market shocks had on real Canadian GNP between 1896 and 1913, the endogenous origins of the real investment shocks, and the key role played by deviations from trend growth in population. Green and Sparks (1999: 57) report that, "(t)he most striking result is the substantial contribution coming from innovations in population. . .(which). . . shifted up the growth path of per capita income by 5.7%."

The value of these time series analyses of the late nineteenth- and early twentieth-century Canadian growth experience, and, more specifically, the adoption of a dynamic, multivariate approach, comes from the confident distinction that can be made among possible sources for the structural discontinuity in the underlying trends. We can not only see that the wheat boom marked a significant structural break – fundamentally transforming the Canadian macroeconomy – but we can quantify the importance of the exogenous shocks to the immigrant inflow into Canada (population growth) and, to a lesser extent, the exogenous shocks to foreign demand for Canadian export products (wheat and flour). These findings not only reveal much about this episode in Canadian development, but we also learn more general lessons about resource-led growth that can be applied in other export-oriented, resource-rich countries.

The Adoption of Protectionism: General Equilibrium and "New Trade" Models

Resource-led growth in a labor and capital-scarce economy is only feasible if international market access can be assured, and Canada's interactions on international markets have been largely determined by the structure of domestic trade

policy. Policy choices in general, and trade policy in particular, have played a key role in Canadian development. For Canada, the impact of policy choice can be identified due to the presence of sharp discontinuities.

Through the 1870s, inter- and intracontinental transport costs were falling sharply, capital and labor flows were rising, and international trade, particularly in industrial products and raw material inputs used in industrial production, was expanding rapidly. In the USA, a deeply divided, Republican-controlled Congress raised average tariff rates from 15% in 1859 to 45% in 1870, and although there were some selective reductions, US rates were maintained at or slightly above 30% for the next two decades (Irwin 2010). In Canada, John A. Macdonald's Conservative Party campaigned in the 1878 national election on a platform that promoted a new "National Policy," which included support for European immigration into the Canadian west, subsidization of a transcontinental rail line entirely within Canadian territory, and the adoption of explicitly protectionist trade policy objectives. The Conservatives won the election, and in their first budget, brought before Parliament in 1879, virtually the entire Canadian tariff schedule was rewritten. Tariff rates averaged over all imports rose from just under 14% to 21%, and there were further tariff increases in 1884 and 1887. Through the 1890s and early 1900s, average rates slowly slid back, but on the eve of Word War I in 1913, the average weighted tariff (AWT) in Canada remained at 18%. Protectionism remained a primary objective for Canadian trade policy until the signing of the free trade agreement with the USA in 1988.

Traditionally, economic historians have characterized the National Policy as a "necessary evil" (Easterbrook and Aitken 1956). The standard narrative recognized that trade protection likely resulted in market power and economic profits for domestic manufacturers, earned at the expense of consumers who faced higher prices as a result of the increased tariff rates, but any negative consequences were thought to have been offset by the positive effects of infant industry protection. Higher tariffs were considered necessary to support import substitution, increase the scale of domestic production, and provide investment incentives for Canadian industries that were struggling against rising imports and closing international (particularly USA) markets.

A revisionist literature shifted the focus away from infant industry arguments, toward static welfare losses in a neoclassical Ricardian trade setting (Easton et al. 1988). The revisionist view concluded that the National Policy tariffs reduced competitive pressures in the Canadian economy, allowing manufacturers to charge prices in excess of their marginal costs, which resulted in reductions in consumer surplus and, therefore, lower social welfare. The size of the estimated static, partial equilibrium welfare losses resulting from the move to protectionism in 1879 varies from approximately 4% of Canadian GDP to 0.6% (Pomfret 1993, Beaulieu and Cherniwchan 2014, Alexander and Keay 2018a). The differences in the size of the measured effects depend critically on the trade elasticity estimates used in the deadweight loss calculations. In general, greater substitutability between domestic and foreign-produced goods leads to greater deadweight losses. Reliable estimation of the required elasticities is problematic in a historical setting due to the need for

highly disaggregated price information, controls for multilateral resistance, and a recognition of potentially endogenous prices (Alexander and Keay 2018a).

Recently, the digitization of the Canadian trade tables from as early as 1867 has encouraged a reinvestigation of the impact of the National Policy tariffs based on cliometric approaches that use the newly available, highly granular, product-specific import, export and tariff data, and new trade models that allow for deviations from the standard partial equilibrium, neoclassical environment. Both the traditional and revisionist literature on Canada's adoption of protectionist policy objectives in 1879 rely on measures of tariff rates averaged over broad categories of products or all import products. Beaulieu and Cherniwchan (2014) were the first to use newly digitized trade data to document the highly selective nature of the tariff changes that were applied by Macdonald's Conservative government. The initial round of tariff increases was characterized by a narrow targeting of manufactured import products destined for final consumption. Non-manufactured raw material products, and products used primarily as intermediate inputs, faced significantly smaller tariff increases. Alexander and Keay (2018b) use theory-consistent specifications derived from Grossman and Helpman's (1994) protection-for-sale model to show that products produced by establishments with the most potential political influence also enjoyed particularly large increases in their protection. Beaulieu and Cherniwchan (2014) derive trade restrictiveness indexes which reveal a tendency, particularly with the 1884 and 1887 revisions of the tariff schedule, to target import products with relatively close domestic substitutes, thereby promoting import substitution, strongly increasing the restrictiveness of Canadian tariffs, and increasing the welfare cost of protection.

Keay (2018) relies on estimating equations based on models of optimal tariff setting in the presence of infant industries with strong learning-by-doing effects, to show that the piecemeal reductions in Canadian tariff rates that occurred after 1890 were just as selective as the tariff increases during the 1880s. The post-1890 tariff cuts appear to have targeted products that showed signs of maturation during the first decade following the initial adoption of protectionism. Maturing products are defined as those with rising net exports, and therefore falling learning potential, from 1880 to 1889. Cutting tariffs on products with lower learning potential reduced deadweight losses due to Canadian trade policy by approximately 0.4% of GDP per year between 1890 and 1913.

As these examples from the literature illustrate, more finely disaggregated trade data not only allow us to get a better sense of the complexity of late nineteenth- and early twentieth-century Canadian trade policy, but they also allow us to assess the impact of protective tariffs with more sophisticated modeling approaches. To derive partial equilibrium, static measures of deadweight loss in a Ricardian trade model, the standard neoclassical assumptions must hold, including perfect competition, market clearing, no externalities, and constant returns to scale. However, the "new trade" models that were developed in the 1980s and 1990s allowed for the assessment of the impact of trade restrictions in economic environments that do not satisfy these standard assumptions (Melitz and Trefler 2012).

Harris et al. (2015) rely on predictions derived from two new trade models to interpret the results from a series of difference-in-differences and treatment intensity specifications that use the newly digitized Canadian trade data from 5-year intervals, spanning the period 1870–1910. The first of these models relaxes the assumption of perfect competition by treating the domestic manufacturing sector as a Cournot oligopoly. In this environment, a tariff can promote a dynamic growth response through the reduction in markups and the exploitation of internal scale economies. The second model focuses on the impact that tariff protection has on the accumulation of experience and the productivity advantages of learning by doing. Treating the imposition of the National Policy as a "natural experiment" in which some producers received larger tariff increases than others, they find that the products with the largest tariff increases in 1879 experienced disproportionately rapid output growth, productivity improvement, and output price reductions between 1890 and 1913. These dynamic growth effects are consistent with the theoretical predictions from the new trade models. Namely, tariff protection allowed domestic output to grow more rapidly, which facilitated a movement down producers' long-run average cost curves, and up their learning curves, such that productivity improvement accelerated and, eventually, output prices fell.

The impact of output expansion, and longer-run productivity and price effects, cannot be captured in static, partial equilibrium measures of the National Policy's impact on the Canadian economy. The employment of new trade models provide us with a new perspective on Canada's early adoption of protectionist objectives. Another new perspective opens when we move away from partial equilibrium models, toward a general equilibrium approach to welfare measurement. Alexander and Keay's (2018a) static, general equilibrium trade model with multiple industries reveals that, even for small open economies like Canada in the late nineteenth century, increases in tariff protection do not necessarily lead to lower aggregate welfare. In a general equilibrium setting, tariff increases do trigger partial equilibrium price distortions, and hence deadweight loss, but they also increase government revenues and positively impact domestic terms of trade. The net effect on welfare need not be negative. Alexander and Keay (2018a) use product-specific trade data from Canada, the USA, and Britain, to show that although the general equilibrium welfare effect of the tariff increases imposed under the National Policy is sensitive to the choice among alternate estimates of historical trade elasticities for Canada, under most reasonable specifications, Canadian welfare likely rose by as much as 0.16% of domestic GDP between 1877 and 1880 as a result of its unilateral adoption of protectionism. Of course, they also show that welfare would have increased substantially more had Canada and its trade partners pursued multilateral free trade during the late nineteenth century, rather than unilateral protectionism.

As the findings in these studies illustrate, our understanding of the sophistication of Canadian trade policy, and the impact of the adoption of protectionism in 1879, has recently undergone a transformation as a result of the accumulation of highly disaggregated import, export, and tariff data, which in turn has facilitated the application of more flexible modeling approaches. The reliance on quantitative evidence analyzed through a cliometric lens and interpreted with theory-consistent

methods has changed the way we view Canadian industrial development and the impact that domestic trade policy had on that development.

Transport Costs: Intracontinental Shipping and the Subsidization of Railways

Canada's adoption of protectionism in 1879 was, at least in part, a response to the pressures associated with falling trade costs and rapid globalization. Trade costs are a function of tariff rates, but transport costs are another key contributing factor. Depending on the route and product being shipped, between 1870 and the start of World War I, global trans-oceanic freight rates fell by between 35% and 85% (Jacks and Pendakar 2010; Mohammed and Williamson 2004). In addition to these reductions in freight rates, there were equally sharp reductions in insurance, wharfage, and brokerage fees (Inwood and Keay 2015). For a trade-dependent nation like Canada, which consistently had gross import and export values totalling approximately 40% of GDP between 1870 and 1913, the economic impact of falling transport costs and rapidly integrating intercontinental goods markets was potentially dramatic.

Inwood and Keay (2015) explore the connection between trade volumes and transport costs in Canada by focussing on a product that has become a key indicator of industrial development during the late nineteenth and early twentieth centuries – pig iron. Between 1870 and 1913, the total cost to move one net ton of pig iron from the docks in Liverpool to the port of Montreal fell from $6.71 to $4.10. What is surprising is that this nearly 40% reduction in trans-oceanic shipping costs did not coincide with an expansion in British exports as a share of the Canadian market. Britain's share of Canadian pig iron consumption fell from 30% in 1870 to less than 5% in 1913. Using an instrumental variable approach to control for the endogenous relationships between transport costs, domestic pig iron prices, and British pig iron shipments, Inwood and Keay estimate flexible, log-linear Armington import demand specifications. Their results reveal that falling trans-Atlantic transport costs did increase British trade in pig iron, but the effect of falling ocean freight rates was swamped by rising tariff rates in Canada and, even more importantly, declining inland water and rail transport costs.

The primary inputs used in the production of pig iron are iron ore and coal. Most Canadian blast furnaces imported iron ore from northern Michigan and coal from Pennsylvania. The transport cost share of Canadian producers' coal and iron ore input prices fell from over 45% in 1870 to just 26% in 1913. The collapsing transport costs that characterize the first era of globalization were a greater benefit to the Canadian pig iron producers trying to compete against British exporters in their home market, than they were to British exporters shipping pig iron across the Atlantic. Inwood and Keay's study of a specific trading relationship illustrates how a detailed, theoretically founded, but narrowly focused analysis can help resolve more general, broadly applicable historical questions. Their findings highlight the key role played by intracontinental railway and inland shipping costs during this period of rapid industrial development and global market integration.

Given the geographic dispersion of Canadian economic activity and the importance of intracontinental transport costs, it is not surprising that railways have long held a prominent position in the study of domestic development in Canada (Lewis and MacKinnon 1987, Carlos and Lewis 1995). The largest and longest continuously operating railway in Canada, the Canadian Pacific Railway (CPR), completed its transcontinental trunk line in 1885. The building of a railway across Canada, entirely on Canadian soil, was one of the three pillars of John A. Macdonald's National Policy. The transcontinental line was a formidable technological achievement that helped to integrate an east-west market to rival the pull of US markets south of the border. The rail link has come to be recognized as a cornerstone of early Canadian economic development. However, the role of Macdonald's Conservative government in the building of the railway has been controversial almost from the birth of the company.

The federal government gave the CPR a vast area of prime agricultural land in the prairie provinces, a large cash grant, unfettered access to construction materials along the line, and a long list of other benefits. Whether or not these subsidies were inefficient and excessive was first addressed by Peter George (1968) and Lloyd Mercer (1973), who used the company's financial reports to make "ex post" rate-of-return calculations. Both authors show that the CPR's private investors ultimately earned significantly more than the opportunity cost of their investment funds. Emery and McKenzie (1996) point out, however, that the decision facing the government and the investors at the time was in fact an "ex ante" one. There was considerable uncertainty surrounding the future of the CPR, and more generally, late-nineteenth-century railway investments were prone to highly volatile, unpredictable returns. Based on a recognition that construction of the new transcontinental line precluded the benefit of waiting for more information, and the resulting resolution of uncertainty, Emery and McKenzie employ a financial options model that captures the impact of both ex ante uncertainty and the irreversible nature of the decision to build. Emery and McKenzie use reasonable assumptions about the ex ante uncertainty faced by private investors, determined by measuring the volatility in the returns earned on comparable US railway investments. They find that the subsidies received by the CPR were not only necessary to get the project started, but they were in fact quite modest, at least in light of the risks associated with the commitment to privately fund such a massive infrastructure project. The National Policy's railway subsidization, therefore, was probably just adequate to spur the private construction of the railway, which contributed to the integration of the widely dispersed domestic market, lowered intracontinental shipping costs, and, as a result, promoted industrial development. As this finding suggests, with respect to the National Policy's tariff and railway building objectives, the exoneration of government decision-makers and the longer-run development consequences of their policy choices have become clear only with the application of cliometric tools in micro-level studies of narrowly identified industries (pig iron) and individual firms (the CPR).

Immigration: Self-Selection and Assimilation

The third and final pillar of John A. Macdonald's National Policy was the promotion of immigration into Canada. Nearly as many migrants moved south across the open border to the USA as arrived from Europe, so through most of the late-nineteenth-century, Canadian net migration was near zero. On average, between 1870 and 1895, for example, over 55,000 new arrivals were registered at Canadian ports and overland border crossing points in each year. However, 60,000 left the country annually over the same period. This net loss of population and human capital to the USA came to an abrupt end not with the passage of the National Policy in 1879 but with the start of the wheat boom in 1896. Gross immigration increased by more than 18% per year between 1896 and World War I, while net immigration became strongly positive, with new immigrants outnumbering emigrants in each year by more than 50,000 over this period (Green and Urquhart 1994). Although net immigrant flows fell slightly during the interwar period, between 1896 and 1930, immigration played a key role in boosting Canada's population by more than a factor of two, to just over ten million. This period of growth transformed Canadian labor markets and the demographic characteristics of the population as a whole.

Traditional narratives focus on the role played by the National Policy's direct subsidization of transport costs and the maintenance of open immigration rules in encouraging Ukrainian, Russian, Scandinavian, and more generally eastern European farmers and agricultural laborers destined for the wheat fields in the newly settled prairie provinces. Alan Green and David Green (1993) use both census data and micro-data drawn from ship manifests, which includes detailed information on the characteristics and intended destinations of individual migrants and their families, to explore how new arrivals in 1912 were distributing their human capital across Canadian labor markets. A multinomial logit model links the probability of migrants' intended destinations to their personal and family characteristics and the characteristics of their destination labor markets. Green and Green (1993) find that the new arrivals did not disproportionately favor western or agricultural labor markets, but instead they sought locations and occupations that not only matched their skills but also satisfied sectoral and regional labor market demands. One implication of this result is that even the large inflows of migrant labor during the post-1896 period did not substantively impact Canadian wage distributions.

Green and Green (2016) confirm and extend this finding by using random samples from the population census manuscripts from 1911 through 1941 to estimate age-occupation-birth place-specific elasticities of substitution, derived from a nested CES production model. Again, they find that through some combination of self-selection, post-arrival redistribution, and general equilibrium wage effects, the market-specific human capital brought by migrants roughly matched the existing distribution of human capital across Canadian markets.

Of course, a balanced distribution of the new arrivals' human capital, and evidence of responsiveness to market signals, does not necessarily imply either

smooth or rapid assimilation of immigrants into the Canadian labor market. Alan Green and Mary MacKinnon (2001) use samples from the early twentieth-century population census manuscripts for Toronto and Montreal to probe the labor market experiences of the foreign-born relative to the native born. Their findings suggest that unemployment for the foreign born was both higher and more persistent during the Great Depression, and estimates from fully flexible age-earning profiles reveal very slow wage assimilation at the start of the twentieth century, in part due to the disproportionately low number of clerical positions held by the foreign born. Looking more narrowly at British and Irish immigrants, Dean and Dilmaghani (2016) employ a pseudo-cohort methodology with census manuscript samples from 1901 and 1911, which allow them to draw a distinction between entry and assimilation effects. They also find slow assimilation, and they can show that initial earnings as immigrants first entered Canadian labor markets fell over successive post-1896 immigrant waves. Inwood et al. (2016) extend the time series evidence on assimilation, again estimating age-earning profiles using census manuscript samples from 1911, 1921, and 1931. They find relatively rapid immigrant assimilation in 1911 and 1921 but a sharp reversal in 1931. Even among the cohorts who had immigrated many years earlier, earning declines during the Great Depression were much steeper for the foreign born than the native born. Again, these findings indicate the extent to which labor market adjustment and self-selection forces were at work in domestic markets.

Alex Armstrong and Frank Lewis (2012) rely on evidence from ships' passenger manifests to look more closely at the selection of migrants arriving in Canada during the 1920s. They note that average earning differences between Canadian labor markets and European home markets could be as high as 400%. This could be taken as evidence of strong self-selection from the very top of the human capital distribution in migrants' home countries. However, drawing insights from a life-cycle model in which a taste preference for the home country is introduced and borrowing is assumed to be constrained, Armstrong and Lewis show that large European-Canadian average earning differentials do not necessarily reflect strong self-selection tendencies. In their model, potential migrants must save for several years before acting on their decision to migrate, in part because the adjustment period upon arrival can be long and costly. New arrivals could face a decline in occupational status, especially those from poorer countries, and there will almost certainly be a loss of amenities associated with immigrants' home markets. Together, these factors suggest that market-specific characteristics and human capital are important, but very high earning differentials were required simply to trigger migration, without necessarily reflecting severe self-selection. These insights into immigrants' decisions to move, their experiences with assimilation, the role of policy, and their impact on Canadian labor markets and earning distributions are only revealed as a result of the careful application of theoretical and statistical cliometric tools, which in turn can only be used where reliable micro-data has been carefully compiled and digitized.

Entrepreneurial Failure: Measuring Productivity and Technological Change

M.C. Urquhart (1993) has provided us with income per capita estimates for Canada that extend from 1870 to 1926, the first year that official *Dominion Bureau of Statistics* GDP figures are available. As a result of Urquhart's monumental effort to produce these estimates, we have a continuous and consistent basis for comparing Canadian macroeconomic performance to a wide range of international benchmarks over virtually the entire span of industrial development in Canada. Geographic, cultural, historical, and institutional proximity makes the USA by far the most obvious and most common comparator. Over the very long run, Canadian GDP per capita has been consistently lower than American GDP per capita. Depending on exactly how prices are measured, the average income gap between Canada and the USA has been stubbornly stable at something between 10% and 30%, in favor of the USA, with convergence rates statistically indistinguishable from zero (Urquhart 1993).

Standard macroeconomic growth models tell us that income growth and convergence depend critically on the accumulation of physical capital, human capital, and technological development. At least since the mid-eighteenth century, most capital accumulation and technological change has originated from within industrial production processes. As a result of these considerations, economic nationalists have confidently blamed domestic industrialists for the development and persistence of Canada's income per capital shortfall relative to the USA (Williams 1994). The "industrial failure" narrative focuses on the perceived consequences of government trade, industrial, and migration policy decisions stretching back to the National Policy in 1879 (Eastman and Stykolt 1967). These policy choices are said to have led to a wide range of economic, political, and social ills, including excessive US ownership of Canadian capital and poor entrepreneurial decision-making. The evidence offered in support of this traditional view is typically anecdotal descriptions of "backward" or "parochial" technologies, drawn from business histories and biographies (Naylor 2006, Bliss 1990), or highly aggregated information on labor productivity, scale, and output prices (Baldwin and Gorecki 1986).

Problems with these claims of long-run, persistent industrial failure in Canada become evident when we interpret this view through a cliometric lens, employing the tools of microeconomic theory and careful quantitative analysis. Since the late nineteenth and early twentieth centuries, labor and power, more specifically electricity, have been relatively cheap in Canada compared to the USA, while capital has been expensive (Wylie 1990, Keay 2000a, Inwood and Keay 2008, Harris et al. 2015). Because these input price differences reflect differences in geographic endowments, institutional differences, and differences in policy, we can reasonably assume that they have been taken as given and hence considered exogenous by individual decision-makers within Canada's industrial establishments. Cost minimization in the presence of well-defined industrial technology suggests that optimal decision-making can lead to quite dramatically different input employment

combinations, technological choices, and output decisions when exogenous market conditions, particularly input market conditions, differ across production units. In other words, low labor productivity, low output levels, and the use of industrial technology deemed to be well below the technological frontier by business historians or economic nationalists, mainly because it differs from US technology, may not necessarily be evidence of poor decision-making and industrial failure. Better tests of industrial performance require the assessment of technological choice, input employment decisions, and the productivity of entire production processes, conditional on the presence of domestically unique input market conditions.

Tornqvist productivity indexes are geometric averages of relative labor, capital, and intermediate input partial factor productivities, with factor weights derived from cost shares (if we assume competitive market conditions) or econometrically estimated from flexible production function specifications. These total factor productivity indexes allow us to compare performance across production units – Canadian and US manufacturing industries, for example – and over time (Keay 2000b, Inwood and Keay 2008). Inwood and Keay (2008) construct these indexes for 1870, with carefully matched Canadian and US census manuscript micro-data on industrial establishments in Ontario and US border counties in New York, Ohio, Pennsylvania, and Michigan. They find that among establishments in the same industries, located along the Canada-US border, the average TFP difference favored US producers by less than 10%. This total factor productivity gap was so small despite clear evidence that in 1870 Canadian industrial establishments were producing nearly 28% less output per worker; they were smaller and more seasonal; they used less capital but more raw materials; they used less steam or water power; there were far fewer factories; and Canadian markets were considerably thinner than US border county markets (Inwood and Keay 2005).

The comparison of Canadian and US industrial productivity can only be extended over a longer time period for a much narrower cross section. Keay (2000b) draws firm-level evidence from *Moody's Industrial Manuals* for 78 firms representing 9 Canadian and US manufacturing industries. His productivity comparisons reveal remarkable persistence in the North American TFP gap, with an average difference of less than 10% through the decades from the 1910s until the 1990s. The industrial failure narrative in Canada is clearly not consistent with this evidence of near parity in Canadian and US TFP performance from as early as the 1870s until the very end of the twentieth century. Reconciling this evidence requires a detailed analysis of longer-run patterns in technological change and input employment.

Generalized Leontief and translog functional forms are flexible in the sense that they allow for the estimation and assessment of production technology that can evolve independently across production units and over time. Input employment, therefore, can be idiosyncratic, and technological change can be strongly non-neutral within these production and cost function specifications. This flexibility allows for the comparison of industrial performance – input employment decisions, technological choice, and total factor productivity – between production units that operate in widely varying economic environments, such as those characterized by Canadian and American input markets through the late nineteenth and twentieth centuries.

Wylie (1990) estimates systems of input demand functions for a sample of Canadian and US manufacturing industries derived from underlying translog production function specifications. They reveal that between 1900 and 1929, Canadian producers were using technologies that were strongly biased in favor of electricity use, and these biases were strongest relative to the USA, where Canadian electricity prices had fallen most steeply. Keay (2000a, b) finds the same tendency toward domestically unique technological biases that reflect relative input price differences, this time favoring labor use and capital saving among Canadian producers, when he estimates systems of input demand equations derived from generalized Leontief cost functions over the 1902–1990 period. Keay's input demand estimates also capture cross-border differences in input employment, with labor and raw material intensity rising among the Canadian establishments as the relative prices of these inputs declined, and capital intensity falling as relative capital costs in Canada increased over the twentieth century. Even cross-border differences in adoption patterns for new agricultural technologies during the first half of the twentieth century, including the tractor, can be confidently linked to changes in the price of fuel, labor, and capital in the Canadian prairie provinces relative to the US mid-western states (Lew and Cater 2018).

Guided by theoretical predictions of optimal decision-making under cost minimization, the estimation of flexible underlying production and cost function specifications, and the measurement of total factor productivity, a new understanding of the impact of policy choice on Canadian industrial performance has evolved that is at odds with the traditional economic nationalists' failure narrative. In response to idiosyncratic, potentially policy-induced price differences, manufacturers in Canada adopted and adapted their technologies, and employed their inputs in a way that favored relatively cheap labor and raw materials, while conserving on expensive capital. We cannot observe the impact of these decisions by looking narrowly at partial factor productivities or by relying on descriptive characterizations of "backward" technological choices. Cliometric tools allow us to search for evidence of sound decision-making and industrial success among Canadian manufacturers, and the evidence reveals that since at least 1870, technological and input employment choices fostered technical efficiency and total factor productivity growth that nearly matched the global technological leaders.

Concluding Remarks

Long-run economic and industrial development in Canada has been characterized by discontinuous changes in policy, technology, and industrial structure, which have triggered complex and often endogenously determined consequences. These discontinuities, combined with remarkably good historical evidence and the application of cliometric tools and techniques, allow us to ask a wide range of historical questions about the Canadian experience. The presence of close historical and contemporary parallels makes these questions broadly relevant across time and space. The coincidence of complexity, common experience, and exceptional evidence that characterizes Canadian economic history allows us to revisit accepted, long-held traditional

narratives. From the survey in this chapter, it is clear that the evidence, and economic theory, is often, but not always, inconsistent with these narratives.

Looking at resource-led development, we find that the presence of diversifying linkages can help to overcome the corrupting effects of resource rent and price volatility. In addition, the trade in beaver pelts reveals dynamic, responsive decision-making within indigenous peoples' commercial transactions, and population and export booms associated with the emergence of the prairie wheat economy triggered structural changes in Canada's underlying growth trends.

When we turn our attention to the impact of policy choice, we find that Canada's selective adoption of protectionism under the National Policy in 1879 was associated with dynamic productivity effects, infant industry protection, and possibly even welfare improvement. Overland transport costs played a key role in the first era of globalization's transport cost revolution, and the Canadian government's efforts to support domestic railway building appear to have been both effective and efficient. We can also see that the maintenance of a relatively open immigration policy into the twentieth century promoted the assimilation of foreign-born human capital into Canadian labor markets. Finally, the evidence suggests that there is little support for claims of policy-induced entrepreneurial failure among Canadian manufacturers.

While this review of the impact that cliometrics has had on Canadian economic history is admittedly incomplete, it does illustrate the value of structured analysis and the power of statistical rigor. By working to identify causal factors in the complex, fluid, and rapidly evolving economic environment that characterizes long-run Canadian development, cliometricians have transformed our understanding of Canada's economic history, which in turn has affected broader perspectives on development in resource-rich, rapidly globalizing economies.

Human Capital

Human Capital

Claudia Goldin

Contents

Abstract

Human capital is the stock of skills that the labor force possesses. The flow of these skills is forthcoming when the return to investment exceeds the cost (both direct and indirect). Returns to these skills are private in the sense that an individual's productive capacity increases with more of them. But there are

often externalities that increase the productive capacity of others when human capital is increased. This essay discusses these concepts historically and focuses on two major components of human capital: education and training, and health. The institutions that encourage human capital investment are discussed, as is the role of human capital in economic growth. The notion that the study of human capital is inherently historical is emphasized and defended.

Human Capital and History

For much of recorded history, income levels were low, lives were short, and there was little or no economic growth. We now have healthier, longer, richer, and hopefully happier lives. The regime shift involved increased knowledge and its diffusion, greater levels of training and education, improved health, more migration, fertility change, and the demographic transition. In short, the process involved advances in *human capital*.

What Is Human Capital?

Human capital is defined in the *Oxford English Dictionary* as "the skills the labor force possesses and is regarded as a resource or asset." It encompasses the notion that there are investments in people (e.g., education, training, health) and that these investments increase an individual's productivity.

We use the term today as if it were always part of our lingua franca. But it wasn't. Not that long ago, even economists scoffed at the notion of "*human* capital." As Theodore Schultz noted in his American Economic Association presidential address in 1961, many thought that free people were not to be equated with property and marketable assets (Schultz 1961). To them, that implied slavery.

But the concept of human capital goes back at least to Adam Smith. In his fourth definition of capital, he noted: "The acquisition of . . . talents during . . . education, study, or apprenticeship, costs a real expense, which is capital in [a] person. Those talents [are] part of his fortune [and] likewise that of society" (Smith 2003, orig. publ. 1776).

The earliest formal use of the term "human capital" in economics is probably by Irving Fisher in 1897.[1] It was later adopted by various writers but did not become a

[1]Fisher cites J.S. Nicholson, "The Living Capital of the United Kingdom," for the term "living capital" as opposed to "dead capital."

serious part of the economists' lingua franca until the late 1950s. It became considerably more popular after Jacob Mincer's 1958 *Journal of Political Economy* article "Investment in Human Capital and Personal Income Distribution." In Gary Becker's *Human Capital: A Theoretical and Empirical Analysis, with Special Reference to Education*, published in 1964 (and preceded by his 1962 *Journal of Political Economy* article, "Investment in Human Capital"), Becker notes that he hesitated to use the term "human capital" in the title of his book and employed a long subtitle to guard against criticism[2] (Becker 1962, 1964).

Schultz's article (1961) demonstrates the importance of the concept of human capital in explaining various economic anomalies. Some are easy to figure out, such as why both migrants and students are disproportionately young persons. Some are more difficult, such as why the ratio of capital to income has decreased over time, what explains the growth "residual," and why Europe recovered so rapidly after World War II. Some are even more difficult, such as why labor earnings have risen over time and why they did not for much of human history. As is clear from most of these issues, the study of human capital is inherently historical.

Why the Study of Human Capital Is Inherently Historical

Robert Solow's pioneering work on economic growth in the 1950s led to the formulation of growth accounting and the discovery (or uncovering) of the "residual."[3] Solow (1957), working with data from 1909 to 1949, demonstrated that the residual was 87.5% of total growth in per capita terms. The residual is that portion of economic growth that the researcher cannot explain by the increase in physical productive factors such as the capital stock, the number of workers, and their hours and weeks of work.

The size of the residual during much of the twentieth century relative to economic growth in per capita or per worker terms demonstrated that physical capital accumulation did not explain much of growth and that something else did. That something else is knowledge creation and the augmentation of the labor input through education and training. In other words, much of the residual was due to the increase in human capital.

Some researchers devised methods to close the "residual" gap by adding human capital growth to the Solow model (Mankiw et al. 1992). Others demonstrated that the growth of knowledge and other "non-rival" goods meant that some of the implications of the Solow model were violated (Jones and Romer 2010).

Among the most important findings regarding economic growth over the long run, and the one most relevant to the study of human capital in history, is that the

[2]A Google "N Gram" of the term "human capital" reveals that there was virtually no usage in the English language until the late 1950s. After the 1950s the usage of the term increased until today, with a somewhat greater uptick in the 1990s than previously.

[3]For an understanding of the "residual" in economic growth, see the original Solow (1957) article or an economic growth theory textbook such as Barro and Sala-i-Martin (2003).

residual has greatly increased over time. Physical capital accumulation and land clearing explain a substantial fraction of economic growth in the past. But they do far less well in the more modern era. As a fraction of the growth of income per capita in US history, the residual has increased from about 57% for the 1840–1900 period to around 85% for the 1900–1980s period.[4]

The residual can be reduced by about 20% for the 1900–1980s period by accounting for the growth in human capital embodied in individuals.[5] But growth in human capital does little to reduce the residual for the earlier period. In large measure the reason that human capital advances explain more economic growth in the twentieth century than the nineteenth century is because education advances were slower. That is, there simply was not a lot of human capital formation in the earlier period. Exactly why schooling levels advanced in the late nineteenth century is discussed in the section on education below. But another reason is because the productivity increase from higher levels of education was probably less.[6]

The inclusion of human capital in growth accounting treats increases in education as enhancing the productivity of individuals. Differential productivity is measured by how much higher earnings are for workers of different levels of education. That is, earning ratios by education (e.g., college/high school graduates) are held constant and the fractions of workers with different levels of education are allowed to change over time. These relative "prices" can be updated in the same way that prices are changed in chain-weighted prices for commodities.[7]

The impact of education would be considerably larger, and the residual smaller, if non-private aspects of human capital accumulation were included. These non-private aspects of human capital include spillovers across firms from increased knowledge, lower amounts of criminal activity in society, and greater innovation because there are more smart and informed people.

Another way in which the study of human capital is inherently historical concerns the origins of the "knowledge economy" (Mokyr 2004). Knowledge evolved historically beginning with observations about *natural phenomenon* – the elemental discoveries or the "what" of knowledge. These include "my headache goes away when I chew on the bark of the willow tree."[8] Knowledge then shifted from "*what* is it?" to answering "*how* does it work?" This knowledge involved generalizations and scientific findings. The willow tree contains (acetyl) salicylic acid, which is an anti-inflammatory and anticlotting drug. Aspirin was made out of this substance in the early 1900s. Knowledge then advanced to a deeper understanding of the "how" and

[4]See the calculations in Robert Gallman's chapter in Davis et al. (1972) and those in Denison (1962).

[5]The calculation is larger in Denison's work than in Goldin and Katz (2008). But both of these are a lower bound for a host of reasons including the endogenous nature of capital and, most importantly, the externalities from having a more educated workforce and population.

[6]The data needed to assess this point are very thin and consist of earnings for various occupations.

[7]See Goldin and Katz (2008, Table 1.3).

[8]Hippocrates left records of this finding.

only in 1971 did researchers figure out that the anti-inflammatory response occurred because of suppression of prostaglandins.

An important part of the creation of knowledge is diffusion of the initial "what." In premodern periods, the existence of large numbers of people living in close proximity was important to the maintenance of knowledge. Widely dispersed settlements, on the other hand, meant that chance discoveries would be less likely to spread and to be built upon. Later advances, such as the printing press, books, scholarly societies, and formal schools, helped preserve knowledge and spread discoveries. The notion that denser populations enhance the spread of knowledge and heighten innovation is important to understanding how humans escaped the Malthusian trap and why investments in human capital were worthwhile.

Human Capital and Economic Growth

Human Capital and Economic Performance in the Long Run: Escaping Malthus

According to many economic historians, real wages in Europe were stagnant from at least 1200 to about 1800 (Allen 2001; Clark 2005, 2007a, b). As can be seen in Fig. 1, real wages may have been stagnant, but they were not unchanging during those centuries. The real wages of both agricultural laborers and building craftsmen rose when population decreased, as during the Black Death (peaking around 1350), and they fell as populations rebounded. They varied, as well, due to agricultural vicissitudes. But, on average, they changed little. World population increased, but only slightly from around −5000 BC until around 1800 AD (see Fig. 2).

By and large, the data series in Figs. 1 and 2 point to a classic Malthusian equilibrium – stagnant real wages during long periods, small increases in population, and occasional periods of real wage growth followed by increased population and subsequent decreased wages. The Malthusian problem was twofold: a fixed amount of resources in the form of land and no fertility controls.

But sustained growth in real income per capita and in real wages is apparent in mid-nineteenth century Europe (see Figs. 2 and 3) and somewhat earlier in North America. Population growth had been extremely low but increased enormously in the period just after the "industrial revolution." The demographic transition set in at various moments in Europe and North America. It occurred in the United States and France in the early 1800s, in parts of Europe later in the nineteenth century, and in other parts of Europe as late as the early twentieth century.

By the nineteenth century many parts of Europe, the Western Hemisphere, and elsewhere had entered the modern era of economic growth and had escaped the Malthusian trap. How the regime change came about is one the most important issues in economic history. The answer mainly concerns technological change and the fertility transition. Underlying both of these transformations is the concept of human capital. Without knowledge embodied in people, there can be no

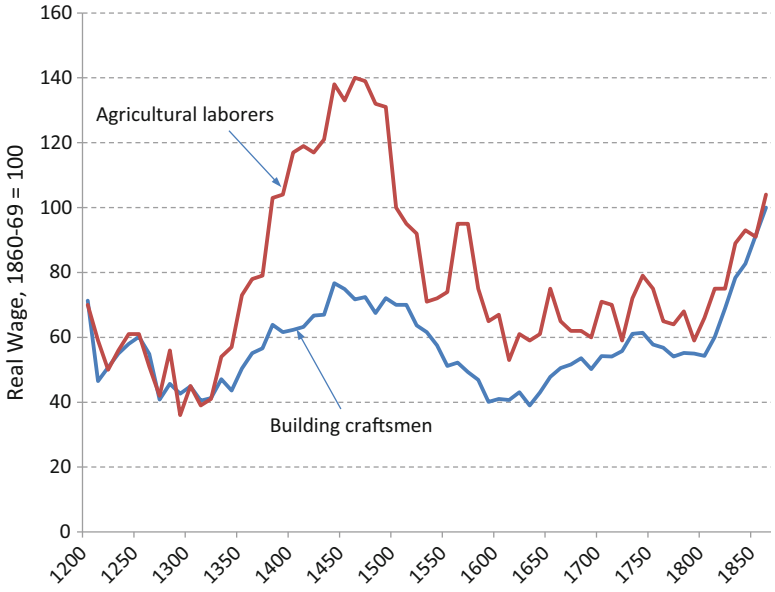

Fig. 1 English laborer's real wages, 1209–1865 (Sources and Notes: Clark (2007b), Table A2 for agricultural laborer real day wages and Clark (2005), Tables A2 for building craftsman real wages. Both series set 1860–69 = 100. The building craftsman series is for decades, the midpoint of which is used here. Agricultural wages are given at approximately annual intervals, and the midpoint numbers for the decades are used. The higher real wage for agricultural wages during much of the period shown may be due to the greater uncertainty during the year and the fact that these are daily wages)

technological change. Without an increase in the value of each child, parents will opt for quantity over quality.

One way of reconciling the historical facts is through an insightful endogenous growth model, pioneered by Galor and Weil (2000) and expanded in Galor (2011). Central to their model is the emerging role of human capital.

The model contains three regimes, and the decision makers are parents who determine how many kids to have and how much to invest in each. At the outset there are low levels of income, no schooling, no income growth, and a very low increase in population. As population increases, technology advances (recall that the "what" of knowledge diffuses with larger, denser populations). Even small levels of technological change increase incomes and induce parents to allocate some of their resources to school their children. Education increases, which in turn boosts technological change, income, and population. At some point intensive growth, a demographic transition, and sustained growth per capita, all become possible, and the world escapes the Malthusian trap.

Human capital is fundamental to the Galor-Weil model. A greater and denser population increases technological change because of the notions about knowledge creation, discussed above. Technology complements skill and increases the returns

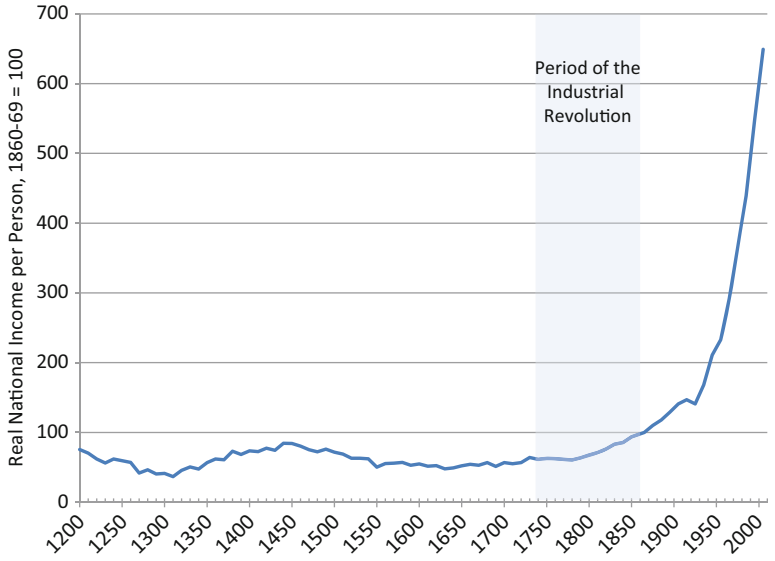

Fig. 3 Real national income per person, England: 1200–2000 (1860–69 = 100) (Source and Notes: Clark (2009), Table 28, column labeled Real National Income/N (PNDP) for 1200–1850, and Table 34 for 1860–2000, where the midpoint of the decade given is graphed. The approximate dating of the industrial revolution is from Clark (2007a), Fig. 10.2)

Table 1 Private versus public provision and funding of K-12 schooling

	Provision	
Funding	Public	Private
Public	Public schools (also called common schools, graded or grammar schools, high schools)	Vouchers (U.S., Sweden 21st century) Pauper schools (U.S. 19th century)
Private	Rate-bills (early to mid-19th century U.S.) Tuition bills (early 20th century)	Private schools (any century) Academies (U.S. 19th century)

to investments in education. Education, in turn, induces more technical change. Finally, families are induced to have fewer and more highly educated children than a greater number of lower-educated children, and the crucial demographic transition can eventually set in.

Human Capital, Institutions, and Economic Growth

The ability of nations to foster human capital accumulation depends on the existence of enabling institutions. One set of these enabling institutions is the legal and extralegal rules that define property rights in man. Another set includes a host of related institutions such as the franchise, form of government (due process, rule of law), and religion.

Optimal human capital investment depends on various factors such as the degree to which capital markets are well functioning and the level of certainty in the economy and polity. When political power is unequally held, human capital accumulation is likely to be suboptimal since groups cannot make credible, long-term commitments to the "elites." Even though everyone could be better off, one can get stuck in a bad equilibrium.

If the key to economic success is good institutions, then "why isn't the whole world developed?" as Richard Easterlin aptly questioned in his 1981 Economic History Association presidential address (Easterlin 1981). A compelling answer is provided in a series of papers.[9]

Acemoglu et al. (2002) reveal the origins of growth-dependent institutions in the colonized parts of the world. As Europeans arrived, places that were dense in existing populations and rich in resources were exploited and given "bad" institutions that allowed Europeans to tax and extract rents. The bleaker, poorer places, on the other hand, were given enabling institutions to encourage European migration.

[9]Mark Twain provides a similar answer in *A Connecticut Yankee in King Arthur's Court*.

These institutional differences persisted and produced "*reversals of fortune*." The poorer places, like North America, became richer and the richer places, like the Caribbean, stagnated.

Engerman and Sokoloff (2012) and Sokoloff and Engerman (2000) contain similar logic and underscore the fact that the same European powers that brought bad institutions to some places brought good institutions to others. The British settled much of North America, but they also settled parts of the Caribbean. Engerman and Sokoloff emphasize particular institutions such as those relating to property rights in man, educational institutions, and the franchise.

A spectrum of labor and human capital institutions has existed historically. Starting with the least free, these institutions include slavery, indentured servitude, labor contracts of various types including apprenticeships, and, ultimately, free labor with its associated educational institutions. If free labor is at one end of the spectrum, then slavery is at the other, and indentured servitude and contract labor are somewhere in between.

Slavery is an ancient labor system. Slaves are mentioned in the Bible, and the majority of Athenians were enslaved in some respects. But slavery in the New World was different. It was not a temporary state. Rather, it was in perpetuity. And in the Americas slavery was mainly based on *race*. Whites could be indentured servants and convict laborers, and they could be coerced and duped, but they could not be slaves.

The slave trade from Africa began in the 1500s with the vast majority brought to Brazil and the Caribbean (60%). Just 7% went to North America. Slaves in the Western Hemisphere were mainly used in tropical and warmer areas to produce sugar, rice, tobacco, indigo, and later (and most consequentially) cotton. But they also produced a large amount of the food consumed in the South. Slavery had once existed in many northern states but changed in the 1790s through a series of gradual and then immediate emancipation laws and state constitutions.[10]

After the US and British slave trade closed in 1808, the market for slaves, which had previously existed in various ways, rapidly developed into a market for hires (rentals) and a market for sales (prices). Slavery provides the most extreme form of the market for human capital. Human beings were rented and they were sold. But did this market mean that there was optimal human capital investment in slaves? Did masters have the right incentives to invest in formal schooling and training in various trades such as carpentry, shoemaking, and mechanics?

It would appear that slavery reduced two barriers to optimal human capital investment. The first concerns capital market constraints since most masters would have been wealthier than ordinary laborers. The second is having an employer invest in the general skills of his employee. In this case the employee was bound to the master. But two larger problems arose.

The first concerns the alignment of private incentives. If a master invested in his slave, would he be able to obtain optimal effort, and could the slave escape? In

[10]Fogel (1989) provides a definitive treatment of the subject.

antebellum southern towns and cities and even in the farm areas, slaves were often hired out.[11] Some of the more trusted and skilled slaves hired themselves out, and master and slave had an implicit or explicit contracts regarding how the income would be shared. These agreements, however, were not commonly found possibly because of issues of trust but most likely for another reason. That reason concerned the public sphere.

Reading and writing, it was believed, would provide slaves with a greater ability to communicate with each other and revolt. Around the 1820s all southern states made the teaching of slaves any literacy skills illegal. The second reason, therefore, is that endowing slaves with much human capital became prohibited.

Indentured servitude was another labor market form that existed to solve a capital market problem. Whereas slavery was for life and for all future generations, indentured servitude was for a given period to pay back a loan generally for passage to America but also to care for orphaned children (e.g., Oliver Twist). In the eighteenth century many who came to North America were "indentured servants" (Galenson 1984). Indentures appear to have enhanced capital markets and enabled geographic mobility. They declined as transport costs decreased and as incomes in the sending nations rose, thereby obviating the need for loans.

Producing Human Capital: Education and Training

The Rise of Formal Education and the Role of the State

A fundamental difference between humans and other species is the extensive transmission and preservation of knowledge among humans. This transmission and preservation is what had led to modern economic growth. But the transmission could not have been broad based and could not have reached the "masses" of people if not for institutions called schools.

Knowledge was, and still is, transmitted without a formal and extensive school system. Socrates taught Plato; Plato taught Aristotle; private tutors taught the Confucian classics to hundreds of thousands of Chinese from the Sung to the Qing so they could take part in the "exam system"; apprentices were taught skills by their masters; parents have always taught their children. But only with schools, in which training begins with young children, could the system reach large numbers of ordinary people.

Formal Schooling in Europe and America

The transition to mass primary education in much of Europe began sometime in the late nineteenth century but occurred much earlier in North America. According to

[11]See Goldin (1976) on slavery in US cities from 1820 to 1860.

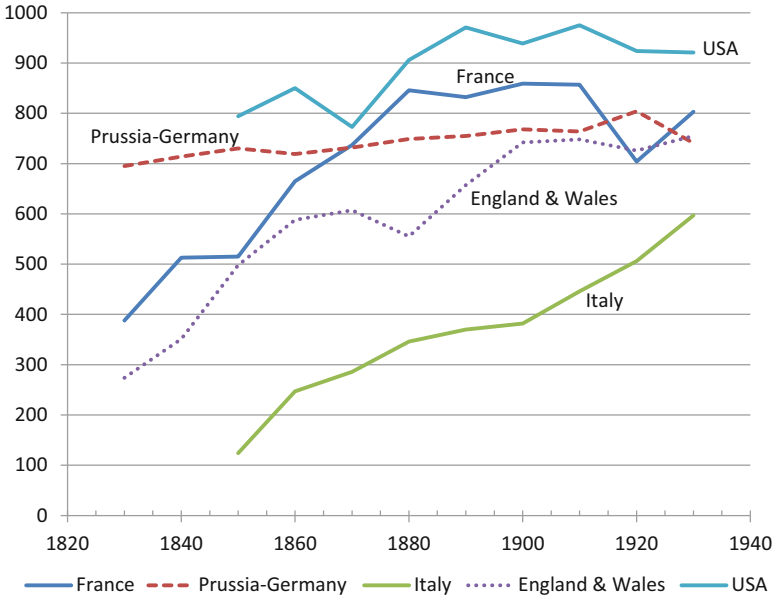

Fig. 4 Public and private primary school students per thousand 5- to 14-year-olds (Sources: All data other than United States, 1850–1870: Lindert (2004a), Table 5.1; Lindert (2004b), Table A1 contains the raw data for the numerator. United States 1850–1870: Carter et al. (2006) Bc 438–446 for enrollment rates and Aa 185–286 to convert 5- to 19-year-olds to 5- to 14-year-olds) (Notes: Data for Prussia after 1910 are extrapolated on Germany's data. Public and private schools are included for Prussia, but public only are reported for Germany. US data is listed in Lindert (2004a) as public and private for 1880–1930 and includes all races; 1850–1870 data are for whites only obtained from Carter et al. (2006) where the denominator is 5- to 19-year-olds and is converted to 5- to 14-year-olds using population data for whites. The 1850–1870 data are from the US Census rather than from administrative records. Lindert cites Carter et al. for 1880–1930, which are from census data and thus could not differentiate public from private enrollments)

the data in Fig. 4, the United States and Prussia, leading nations in education, had primary schooling rates of about 70% by 1860 for 5- to 14-year-olds.[12] The United States retained its lead and surpassed (unified) Germany in the late nineteenth century and had a primary schooling rate of exceeding 90%. But France, Germany, and Britain all had primary school rates in excess of 70% by the start of the twentieth century.

Although the main contours of educational change at the elementary level from around 1840 to 1940 in Europe and the United States are probably well captured in these data, they must be used with some caution. School data are often gleaned from census records and do not account for the number of months children are in school.

[12]The figure for the United States beginning with 1880 includes the South and all races. Thus, the underlying data are even higher for the white population and that outside the US South, which had and still has lower schooling rates than the North and the West.

Especially when school data come from administrative records, it is not always clear that the numerator is for youths between certain ages even though the denominator is. In many places where secondary schools did not yet exist, older youths attended the common or primary schools that held the elementary grades. Therefore the numerator could be inflated by the older children. Another difficulty is that comparisons across nations must account for a variety of institutional details since schools are almost always at least in part in the public sector.

The educational lead of the United States that is apparent in the primary school data for the nineteenth century expanded enormously in the twentieth century with the beginnings of the "high school movement." Although many of the richer nations of Europe had broad-based primary education for youth by the early part of the twentieth century, they did not have mass education at the secondary and tertiary levels. But the United States did.

The United States greatly increased the number of its youth graduating from secondary schools, as can be seen in Fig. 5, so that by the 1950s the median youth in the United States had graduated from a secondary school. In contrast, carefully assembled data comparing 13 OECD nations in the mid-1950s show that secondary school enrollment rates for teenagers in full-time general schools were low in all of Europe. Many of the nations in northern Europe had technical programs for teenaged youth. But even adding these, the enrollment numbers, as seen in Fig. 6, do not demonstrate a broad-based system of secondary education and thus not an open system for tertiary education.

Europe eventually caught up in mass education to the United States and has, in more recent decades, leaped ahead in terms of both the quantity of secondary

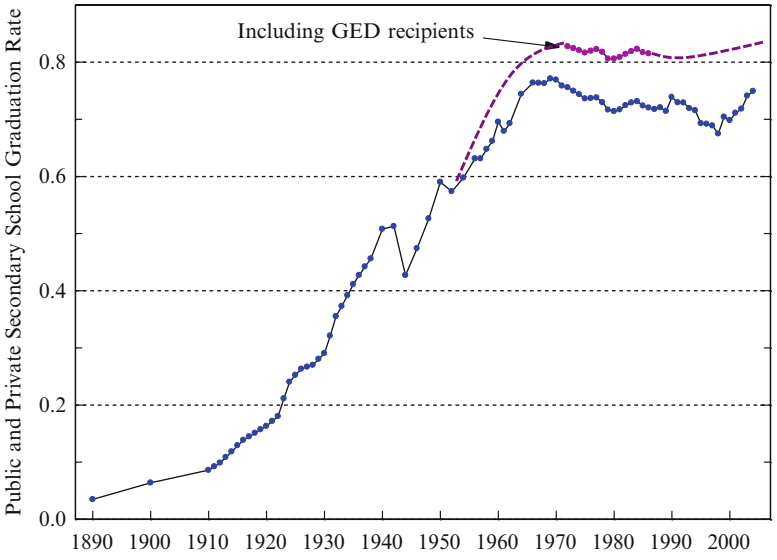

Fig. 5 Public and private secondary school enrollment and graduation rates: United States, 1890–2005 (Source: Goldin and Katz (2008), Fig. 9.2)

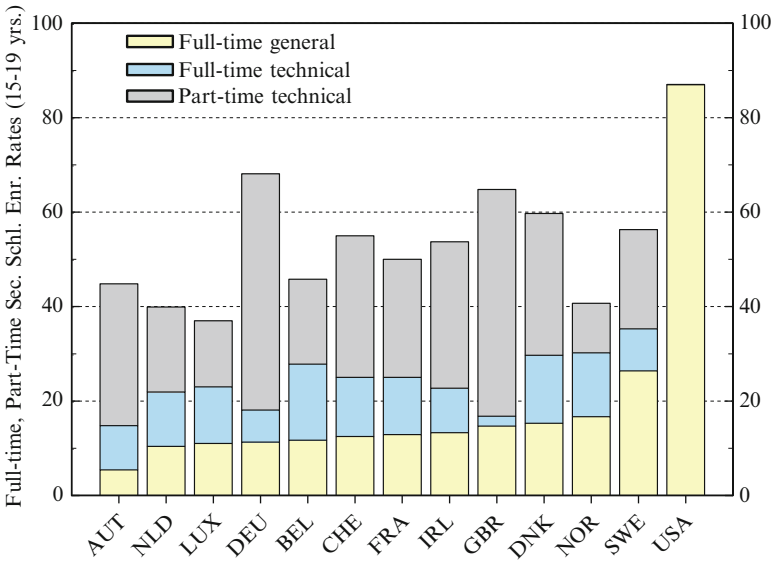

Fig. 6 Secondary school enrollment rates: OECD, 1955/56 (Source: Goldin and Katz (2008), Fig. 1.7)

schooling and its quality. But at this point it is instructive to understand why the United States took the initial lead and what roles were played by individual families and by local, state, and federal governments in terms of funding and regulations.

The twentieth century clearly became the human capital century. It began first in North America but later spread to the rest of the world. How and why did that occur? Mass education in the United States was achieved early because of several characteristics, emphasized in my previous writings (Goldin 2001; Goldin and Katz 2008). These characteristics were "virtuous" at the time and for some time after. Many remained in place, even as some lost their virtuous characteristics.

Education in the United States has generally been open and forgiving in nature. Openness means that schools, by and large, allowed all children to enter. The openness of US schools is related to that fact that ever since the mid-nineteenth century, elementary and secondary schools were (fully) publicly funded by local and state governments. Forgiving means that students who did poorly in one grade were generally allowed to advance to the next. The forgiving nature is related to the fact that until recently there were few standardized tests that were required by law.

The funding of schools, moreover, was provided by small, fiscally independent districts. Because the provision was largely by small districts, rather than the state or the federal government, it was difficult to impose uniform testing. Even more important to the issue of funding is that the districts were so small that there were thousands of them. At their peak in the 1920s, there were around 130,000 school

districts.[13] School districts could compete for families, and families could move to areas that had better schools or less expensive schools or different types of schools.

Another characteristic was that US education was academic, yet it was also practical. Unlike many European nations there were few "tracks" that shunted youth into industrial and vocational programs. All children were to be given the chance to advance to higher grades, even if financial and intellectual limitations often prevented that ideal.

Related to that ideal is that by the early part of the nineteenth century, most primary schools were gender neutral, and during the high school movement, the same was true of the nascent secondary schools. Colleges became gender neutral somewhat later although those in the public sector were generally coeducational from their initial opening (Goldin and Katz 2011a). US education was, as well, secular. Not only did the United States have no established religion (prohibited by the US Constitution Bill of Rights, Amendment 1); state constitutions in the nineteenth century were rewritten to forbid the use of state and municipal funds for religious schools.

These characteristics were virtuous because, in a variety of ways, they increased secondary school enrollment when it was low. The most obvious reason is that openness to most groups meant no exclusions. Small, fiscally independent districts allowed groups of families to determine the amount spent on and taxed for education. By not tracking children at young ages, all children had a chance to rise to the next level. By being forgiving, the errors of one's youth had less impact on one's future.

When levels of education are low, these characteristics are virtuous. Even if a small fraction of the districts want to increase taxes to fund a secondary school, they can do just that and do not have to wait until the majority in a state wants to do so. Families that want to increase public schooling expenditures can migrate to districts that have them, or they can send their children across school district borders and pay tuition.

But these characteristics are not necessarily virtuous in all times. They might increase the quantity of schooling but not necessarily the quality. When enrollment and graduation rates increase, quality not quantity becomes important. Small districts will increase quantity but may also lead to large differences in expenditures per pupil.

Exactly what these characteristics did manage to accomplish in the United States can be seen in Fig. 7 part A. Educational attainment rose by about 1 year per decade, a feat that could happen only with a broad-based educational system. Each generation could look forward to being more educated than its parents and to having children more educated than they.

Interestingly, females had more years of education than males until cohorts born around 1920, and they again did with cohorts born after 1950 when the female lead emerged because of their increase among college students. But after the cohorts born

[13] Although most were "common" school districts, a large fraction was fiscally independent. There are about 16,000 largely independent school districts today. See Goldin and Katz (2008), Chaps. 3 and 4.

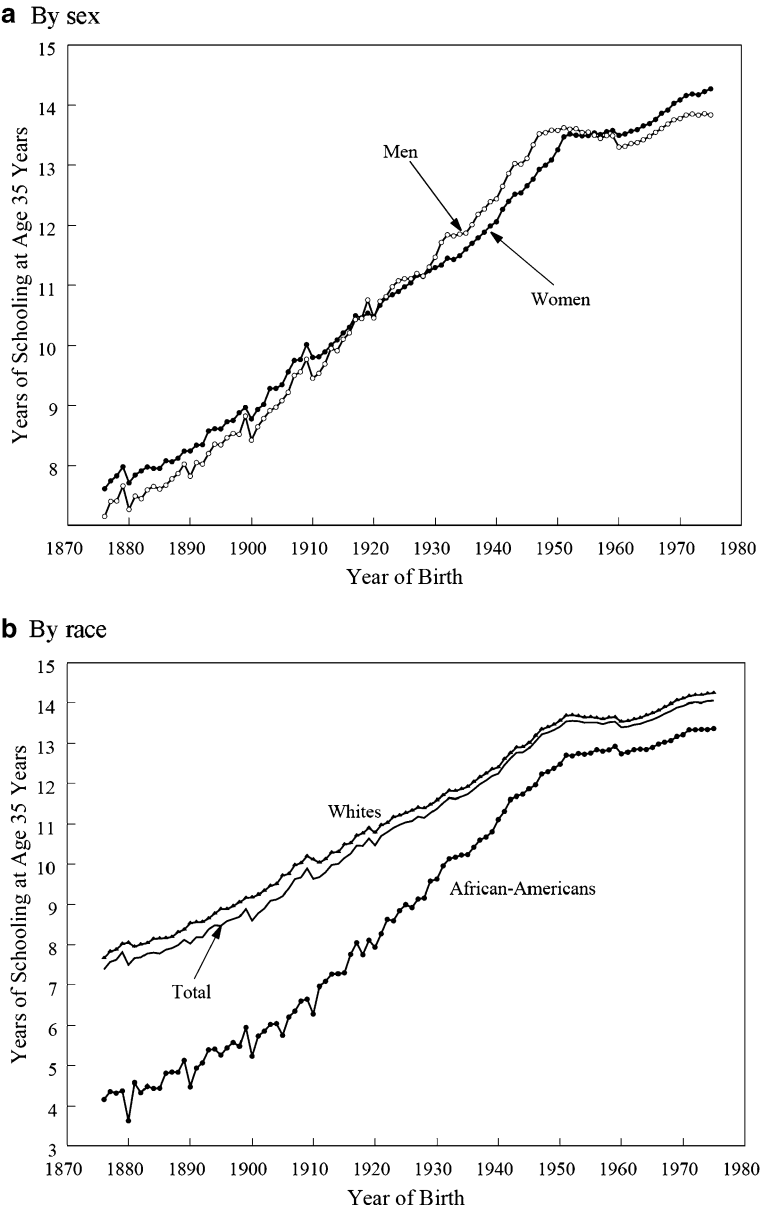

Fig. 7 Years of schooling at age 35 years by year of birth, US cohorts born 1875–1975 (Source: Goldin and Katz (2008), Figs. 1.5 and 1.6)

around 1950, a great slowdown ensued in educational attainment, which has only just begun to pick up again, especially for females.

African-Americans, as can be seen in Fig. 7 part B, had extremely low levels of education early in the twentieth century. Those born around 1880 would have

completed just 4 years of formal schooling, whereas the average white would have completed around 8 years. The quality of schooling for African-Americans was considerably worse than it was for whites, and the number of actual months attended was far less (Card and Krueger 1992a).[14] The levels increased considerably in the twentieth century but did not converge.

Why Invest in Education or Training?

The discussion of educational attainment has not confronted the most basic question in human capital. Why invest at all in education or training? Much can be learned from the simplest of frameworks. Assume a two-period model of human capital investment in which an individual can work or can invest in human capital during the first period. If work is chosen, then w_1 is the first period non-investment wage and w_2 is the second period non-investment wage. But if investment is chosen that costs C, then E_2 is the second period investment wage ($>w_2$). The individual can borrow at rate r. The individual should invest if and only if the following relationship holds,

$$\frac{\left({}^{E_2}/_{w_2}\right) - 1}{1 + r} > \frac{C + w_1}{w_2} \tag{1}$$

which is equivalent to saying that the individual should invest if the discounted returns, expressed as a fraction of the second period non-investment wage, exceed the costs (direct costs of C plus the opportunity cost of the first period non-investment wage, w_1), also expressed as a fraction of the second period non-investment wage.

The simple human capital investment model says that investments are more likely when the returns are higher, the costs are lower (possibly lower with economies of scale provided by schools), and the discount rate (possibly a function of parental income and greater certainty) is lower. But the simple framework does not address several important factors such as where the training takes place (school, on the job, at home), who provides for the training and pays for it, and what role the "state" or collective plays in these matters. These topics are addressed here.

First off, what determines where the training takes place? Does it occur in a formal school or as training on the job or informally at home? It is well known that America in the nineteenth century had far fewer formal apprenticeships than in England. What does this have to do with the investment decision? The answer is that when technological change is rapid and geographic mobility is high, a general, flexible education is more valuable than one that is specific to a particular occupation or place and is relatively inflexible. When the opposite is the case, specific training is

[14]On the quantity and quality of education for African-Americans and whites in US history, see Card and Krueger (1992a). A related article of theirs (Card and Krueger 1992b) shows that the quality of schools, as measured by pupil/teacher ratios, average term length, and teacher salaries, positively affects rates of return to education at the state level.

much better. America had greater geographic mobility and, for some time, greater technological dynamism than in Europe. Both factors made general, flexible education more valuable and occupation-specific apprenticeships and industrial training less valuable.

The second item that is omitted in the simple framework concerns who pays for human capital investment and the role played by the "state." By the "state" I mean a collective of individuals. The collective can be involved in the provision of schooling (e.g., capital investment in the building, hiring of teachers, and selection of curriculum), and it can also be involved in its funding. One can think of the possibilities as a two by two matrix, as in Table 1, where the horizontal headings are the provision (public, private) and the vertical headings are the funding (public, private).

From the nineteenth century to the present, there have been examples of each of the forms contained in the matrix. Cases along the main (positive) diagonal are the most common. They include privately provided schools that are privately funded and publicly provided schools that are publicly funded.

But the minor diagonal elements, which may seem like oddities, exist today and have existed historically. In the nineteenth century, many school districts had schools that were publicly provided but were privately funded. Families received rate bills, also known as tuition bills, for the attendance of their children. The rate bill in some places was for the full amount, but in other districts parents were assessed for the child's attendance only above some maximum number of days.

There are also cases of schools that are privately provided but publicly funded. In some cities in the early nineteenth century, schools were provided for the children of impoverished families by private groups, including religious orders, but were funded by the municipality. In more recent periods, the United States and Sweden, for example, have been using vouchers to fund private schools out of taxes. Therefore, there are a multitude of possibilities that history provides.

Another issue is whether individuals who invest in training have greater ability and, therefore, whether estimates of the return to education and training are biased upward because of selection. The best recent analysis of the magnitude of ability bias shows that it is not very large (Card 1999). For historical estimates of the return to years of schooling given below, because secondary schools in the early twentieth century were just spreading, youths who did not attend them were not necessarily less able than those who did.

Role of the State in Education

In almost all places and during most historical periods, education has been publicly provided and publicly funded. There have been times when the private sector has been larger, but the public sector has almost always increased in relative importance compared with the private sector. The reasons for the increasing government involvement in education are many.

The state has various interests in education that increase demand for schools and, in turn, lead the state to subsidize education. A main interest of the state is that

education provides public goods of various types including endowing citizens with a set of common values. The state also has interests in correcting market failures concerning schooling.

Democracies require literate citizens and educated leaders; nondemocratic governments often restrict education (see, e.g., Sokoloff and Engerman 2000). States have a multiplicity of needs for educated individuals including teachers, engineers, military personnel, clerical staff, and bureaucrats. Education creates positive externalities of many types, such as lower crime rates and better health. In places with low population density, schools are often natural monopolies, and state provision or regulation can be justified on efficiency grounds to increase the quantity available to the public and decrease the price.

Another reason for state involvement in education is that parents often face capital market constraints. Some parents may be insufficiently altruistic, and because children cannot write binding contracts with their parents, they cannot borrow against their future human capital. To increase efficiency, the state might want to lower the interest rate faced by parents and children. A customary way of doing this is to have the schools funded by communities as in an "overlapping generations" framework. Young families with children are subsidized by older families whose children have grown.

If parents are insufficiently altruistic, the state might want to compel them to send their children to schools. If children are too myopic, the state might want to compel them to attend school. Compulsory schooling and child labor laws often accomplish these goals. But these laws were not often binding in the United States (Goldin and Katz 2011b). The reason is that the United States was already providing schools for the masses. In consequence, few families and youths were constrained by the compulsory education and labor laws. In contrast, these laws were often binding in other countries, such as Britain and Ireland. The main reason is that they "compelled" the state to provide schools and pay for teachers for broad-based education.

Most of the reasons just provided for government interference in the production of educated individuals need not involve the provision of schools but would involve the financing of education. The involvement of government in the provision of schools and in the hiring of teachers is often because it is more convenient for the collective to provide these than for a private organization to do the same.

I had previously noted that the United States had an enormous number of independent school districts and that more districts allow the sorting of families by the demand for education and the ability to pay. In many other countries school districts are far fewer in number relative to population and centralization is more the norm. In France, for example, there is just one school district.

Because education is not a pure public good and can be purchased from the private sector, parents can opt out of the public system even though they are still taxed to pay for it. If the parents in a school district have a sufficiently wide distribution of demands for the quantity and quality of education, the public sector can be stymied by what is known as the "ends against the middle problem" (Epple and Romano 1996). Parents with low demand for education (or low income) will not

want to vote for high spending, and parents with high demand for education (or high income) will also not want to vote for high spending since they will, most likely, opt out and use the private sector. One solution is to have small districts that will better match school expenditures to parental demands and result in higher levels of schooling. One of the initial virtues of US education was the existence of a large number of small, fiscally independent districts.

Why Education Levels Increased

Education in the United States, and in most other nations, advanced to mass education across the three transformations that are the three parts of schooling: primary, secondary, and tertiary.[15] The precise number of years of each of these portions and the ages at which youth make each of the transitions varies somewhat across nations. But there is considerable uniformity probably relating to the biology of child development.

In the United States the first transformation to mass primary schools occurred before the twentieth century. Schools for primary school students were often called "common" schools, in part because youth had a shared experience but also because they were generally one-room school houses. In their graded form, they were called grammar schools. The schools were common in the sense of including everyone and common in the sense of being ordinary and abundant. They were operated, most often, by small communities and in their early days were funded by parents through "rate bills," which were charges based on the number of days children attended school. In the mid-nineteenth century, various social movements led to the ending of the rate bills, and by the 1870s primary schools were free to parents and their children. The same laws and judicial interpretation that made primary schools free of marginal charges to parents also made secondary schools free of tuition charges for those living in the school district.

In the late nineteenth century, another educational movement emerged, particularly in the eastern states. It led first to the establishment of private academies of various types that trained youth beyond the limited courses of the common schools. The private academies were generally small, ephemeral institutions, and not much is known about them. Some were later converted into the public high school after the community voted to fund one. The fact that academies were private institutions and almost always funded by individual parents demonstrates that the movement was grass roots in origin. The academy movement morphed into the "high school movement," one that is better known and was national in scope.

Both the academy and high school movements were spurred by the increased demand for skills so that young people could be better prepared to enter the burgeoning world of business and commerce and the more mechanized, electrified

[15]Many places have added two other transitions: preschool to kindergarten and middle school or junior high school to high school.

world of industry. But why did the high school movement begin and expand when it did, around 1910?

One way to assess this question is to look at the earnings of young people with skills valuable to commercial establishment relative to those without these skills. In the pre-1920s, these ratios were exceptionally high, pointing to high rates of return to secondary education just as the high school movement was spreading.[16] The evidence on whether these rates of return were also high in the nineteenth century is less clear (see Goldin and Katz 2008, Chap. 4).

The first national US Census to ask years of completed schooling was in 1940. A few state censuses contained questions on education, and the best of these was done in Iowa. The Iowa state census of 1915 contains rich information on education and earnings for the precise period when greater education was exceptionally valuable in the factory, the counting house, and even the farm.

A set of individual-level earning functions, as provided in Table 2, reveals that years of high school greatly mattered at the start of the high school movement. The pecuniary return to each year of high school, for 18- to 34 year-olds, was around 12%. The return to more education was experienced even within blue collar and farming occupations and was not just because of a shift in the educated population to the white collar sector.

In places that did not have public secondary schools, some youths remained in the common schools for more years. But additional years in the common schools was far less valuable than years in an actual secondary school that could provide instruction in a host of separate disciplines and that could endow youths with various skills.[17] Technological changes were occurring in many of the economy's sectors, and education was a complement to it in 1915, as it is today.

The virtues of education discussed earlier also impacted the spread of higher education in the United States. US higher education was academic yet practical. The enormous number of higher education institutions in the United States produced enormous variety and competition among schools for students and faculty. In 1900, England had just one-seventeenth the numbers of higher education institutions per capita. And even in 1950, England had one-eighth the numbers per capita that existed in the United States.

US higher education was relatively open and forgiving, just as was the case for the lower grades. Students who did not do well enough in high school to enter a university could go to a community college and then transfer to a better institution. The institutions of higher education were geographically close to the people, enabling even rural families to send their children to college. The outcome was that sometime in the twentieth century American colleges and universities became the finest in the world.[18]

[16]Goldin and Katz (2008), Chaps. 4 and 5

[17]This result is given in Goldin and Katz (2008), Table 2.5.

[18]For a discussion of higher education in the United States, see Goldin and Katz (1999, 2008).

Notes: Regressions also contain a quartic in potential experience, a race dummy, and a dummy variable for those missing "years in the United States." Potential experience is defined as min (age – 15, age – years of schooling – 7). Blue collar includes craft, operative, service, and laborer occupations. White collar includes professional, semiprofessional, managerial (but not farming), clerical, and sales occupations. Standard errors are given in parentheses below the coefficients

[a]Includes only unmarried women

Race Between Education and Technology

The rate of return to secondary school was high in the period just preceding the high school movement. As secondary school enrollment and graduation increased, the high school premium, meaning the return to graduating high school relative to eighth grade, plummeted.

Because the high school movement shifted some individuals into the college ranks and since there was some substitution of the skills of high school graduates for those of the college educated, the premium to college relative to high school also fell. By the 1950s the wage distribution was far more compressed than it was in the 1910s and 1920s (Goldin and Margo 1992).

But the relative demand for skilled and educated workers continued to advance. The college premium rose in the 1970s, and it has continued to increase. The premium to a year of education today, as seen in Fig. 8, is even somewhat higher than it was in 1910 at the dawn of the high school movement.

The point is that ever since the late nineteenth century at the latest, there has been a race between education, on the one hand, and technology, on the other. That is, there is a race between the supply of skills and the demand for skills with the return

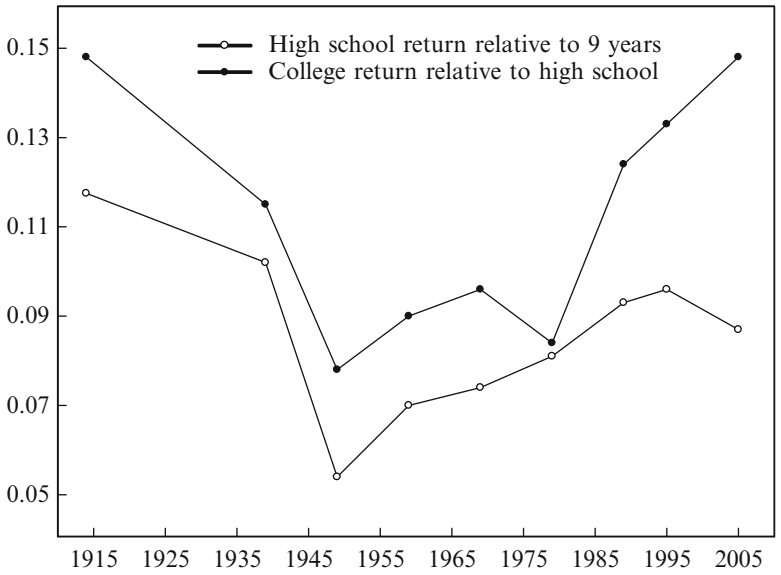

Fig. 8 Returns to a year of school for young men: 1914–2005 (Source: Goldin and Katz (2008), Fig. 2.9 and Table 2.7 for notes)

to education as the equilibrating price. When the return is high, the supply of new skills will be greater, and when it is low, the supply of new skills will be smaller.

New technologies increase the demand for superior skills. The technologies of the late nineteenth and early twentieth centuries increased the demand for workers who could read blueprints, knew a bit about electricity, and were numerate and sufficiently literate to type from scribbled notes and hastily dictated letters. Technological advances throughout the last century increased demands for yet more human capital.

The large increase in the rate of return to education and training in the United States during the last several decades occurred largely because the supply of human capital did not increase sufficiently not because the demand for skills accelerated (Goldin and Katz 2008). But the supply of human capital has recently begun to increase again.

Human Capital and Education: Concluding Remarks

Human capital, in the form of schooling embodied in the labor force, increased in the United States from the beginnings of the nation. It greatly changed in content as the demands for skills in the economy shifted. The increase in years of schooling from the nineteenth century was fairly continuous until the past three decades when it slowed down. The increase followed the three transformations and was often a grassroots movement with the cooperation of communities, states, and, at times,

the federal government. Compulsion had little effect in the United States but had a greater impact in other nations where it often constrained governments to build and maintain schools.

The several virtues of education discussed previously aided the spread of human capital in terms of years of education. But, in recent decades, these characteristics may have slowed progress particularly in terms of the quality of education. Publicly funded education by small, fiscally independent districts increased years of education but produced large differences in per student resources. An open and forgiving system helped spread education to the masses, but such a system often has few promotion and graduation standards at even the state level. Many of these defects of the initial virtues are currently being reassessed by states and by the federal government.[19]

Producing Human Capital: Health

Health Human Capital and Income

In 1650 Thomas Hobbes famously wrote in the *Leviathan* that life was "[solitary], nasty, brutish, and short." He meant that without strong government, civil society would disintegrate into war of every man against every man. But in 1650 life *was* "nasty, brutish, and short," with or without strong government. It was filled with infectious disease and pestilential maladies. And people really were "short." They were 5 in. shorter in Great Britain and France than today and 7 in. shorter in Denmark than currently.

People eventually became healthier and taller. They live a lot longer now and have less nasty lives with less pain and suffering. People now die mainly of chronic diseases, far less from infectious maladies. During the period from the 1600s to the present, the human body changed in a multitude of ways and in a time frame that defies the usual rules of Darwinian evolution.

Increased resources allow people to invest more in their health human capital. But, in addition, more health human capital allows people to be more productive. In the discussion that follows, the causation will mainly go from increased resources to advances in health human capital. There is also an important historical literature in which the causation goes from improvements in health to increases in income.

Improvements to health for most of history are the result of increased resources, not the cause. More resources allow people to consume more calories and protein and to eat more nutritious foods. Investments in improved nutrition enhance health human capital.

[19]For example, state equalization plans have restricted the degree to which separate districts can raise funds, and states have transferred resources to poorer districts. States have passed more stringent high school graduation standards, and "No Child Left Behind," passed in 2002, has forced states to have higher standards at all grades.

For the more recent historical period, however, health improvements have served to increase income. The channel is generally through improvements in health for the young that enable children to attend school for more days and to learn more. Bleakley (2007) shows the effect for hookworm eradication in the US South in the early twentieth century. Almond (2006) investigates the long-term consequences of the 1918 influenza epidemic for those in utero at the time. Health improvements also allow adults to work more days and years over their lifetime and to labor more intensively. The direction of causality here is from an exogenous improvement in health human capital to income.[20]

Measures of Health Human Capital

Mortality is the clearest indicator of health status and one that exists across long periods and for many places. A large number of related measures of health exist historically. Heights and weights for adults and for children during the growth spurt, infant weights, body mass index (BMI), and chronic and infectious disease rates also exist historically. Quality of life measures generally do not.

Expectation of life at birth is given in Fig. 9 for four European nations from the eighteenth century to the present and in Fig. 10 for white males and white females

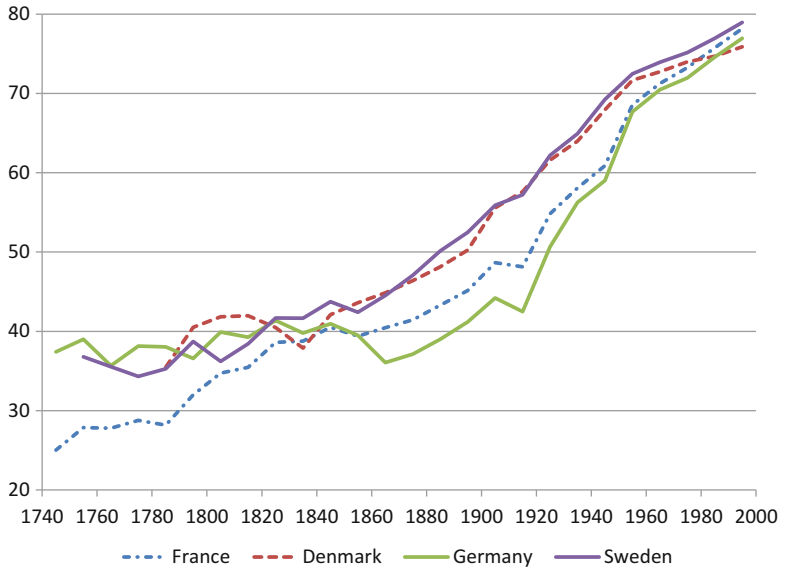

Fig. 9 Expectation of life at birth (period rates) for four European nations, 1745–1995 (Source: Floud et al. (2011), Table 5.1)

[20]See Weil (2007) for a clever way to separate the effects of health on income from the reverse causality.

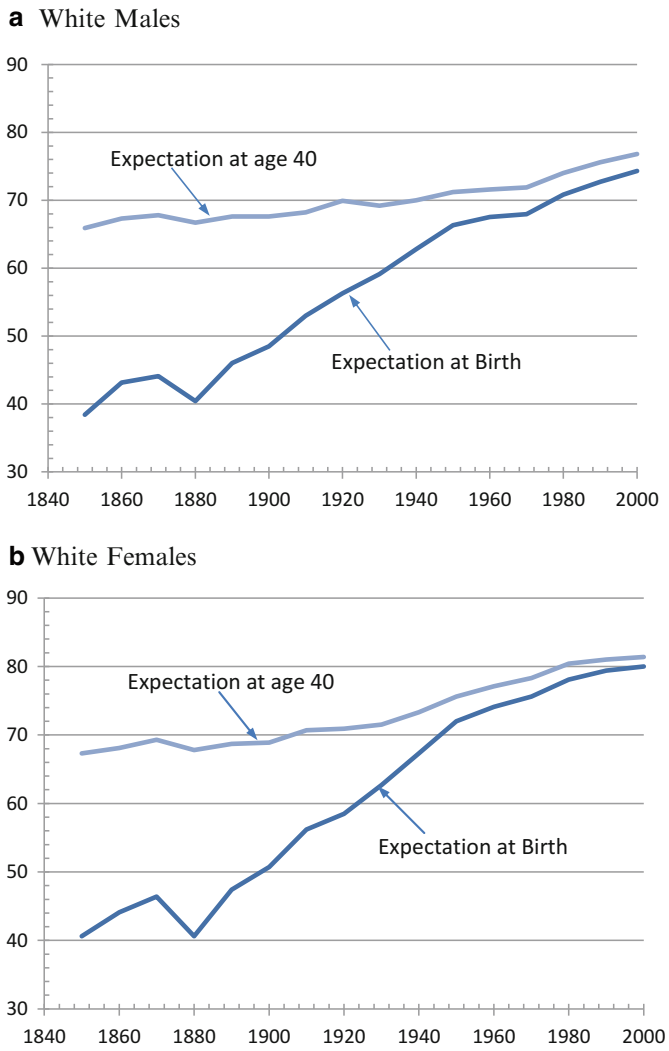

Fig. 10 Expectation of life at birth and at age 40 (period rates) for US whites by sex: 1850–2000 (Source: Carter et al. (2006), Tables Ab644-655)

separately for the United States from the mid-nineteenth century. Life spans at birth were not very long in much of Europe until the mid-twentieth century. The average citizen of France in the late eighteenth century had a life expectation that was less than 30 years at birth, and an individual in Sweden or Germany could expect a lifetime at birth of less than 40 years. Even by 1900 a German or French baby could expect to live to just 40 years or so and one in Sweden, Demark, or the United States to 50 years. But by 1980 all life expectations at birth converged to around 75–80 years old.

Much of the rise in life expectation to the mid-twentieth century in these nations was due to the decrease in infant and child mortality since life expectation conditional on reaching adulthood does not change much until fairly modern periods. That fact can be seen in Fig. 10 for white males and females in the United States. The largest decrease in infant and child mortality occurred from around 1880 to 1920s, although decreases continued.

Life expectation conditional on reaching age 40 changes little until the early twentieth century when it slowly begins to increase. But from the mid-twentieth century onward, the increase in life expectation was primarily from decreased mortality conditional on reaching adulthood. Expectation of life at age 40 increases, and the distance between it and life expectation at birth changes far less than it had up to that point.

Americans lived longer relative to those in other rich countries to mid-nineteenth century. Relative to the English, life expectation at birth before 1850 was better in the United States. But post-1850, life expectations for the two populations were about the same. Relative to France, the expectation of life at birth was better in the United States to around 1900. Americans were abundantly well nourished at least from the start of the nation and were the tallest people in the world to the mid- to late twentieth century (Floud et al. 2011).

In the United States from 1800 to 2000, there was a gain of about 35 years, 40–74 years for men and 44–80 for women. In England from 1750 to 2000, there was a gain of 38 years from 35 to 77 years. In France from 1750 to 2000, the gain in life expectation was 43 years, 25–78 years. The increase in life expectation in each of the countries can be divided into three phases. The first concerns improvements in nutrition, the second involves improvements in public health interventions, and the third phase encompasses a host of medical discoveries such as antibiotics.

Increased Life Expectation: The Three Historical Phases

Phase I: Improvements in Nutrition

Phase I, described by Fogel (2004) as the escape from hunger and malnutrition in Europe, occurred from 1700 to the late nineteenth century.[21] Fogel and his coauthors have emphasized that increased income produced better nutrition and that better health, as children and as adults, allowed the population to fight off infectious disease (Fogel 1997, 2004; Floud et al. 2011).

The notion that health status improved around 1700 because of a marked decrease in chronic malnutrition goes back to Thomas McKeown, a medical historian who wrote *The Modern Rise of Population* (1976). McKeown's goal was to eliminate from consideration two competing factors – public health and medical treatments.

Fogel extended McKeown and gave his ideas considerable force. Fogel noted that before 1700 chronic malnutrition, not crisis-year famine, was an ever-present

[21]The division among the three phases is the author's, not necessarily that of the various contributors to the literature.

problem that limited the health of the population. Sometime around 1700 the second agricultural revolution with its enclosures, plow, seed drill, threshing machine, crop rotation, and selective breeding, brought about a marked increase in caloric intake. In England, for example, calories per capita increased by 300 and in France by a whopping 1,000 in the century after 1750.

Nutrition not only allowed populations to be healthier. More calories also led, over generations, to changes in the human body. Greater food consumption first brought about heavier adults and then produced taller people. The upshot was a higher BMI, healthier individuals, and decreased mortality.

The interpretations offered by Fogel and McKeown have been criticized by Preston (1975, 1996) who notes that the disease environment worsened when urban populations polluted their drinking water, were more distant from food sources, and lived in packed quarters. Some of the overall gain in health status that would have been achieved from increased resources was clearly eaten away by increased population. But much remained that led to an increase in weights, heights, and life span.

Phase II: Public Health Interventions

The next period, Phase II, occurred from the late nineteenth century to the 1930s and was characterized by public health campaigns and interventions. The era could only have begun in the late nineteenth century because of the necessity for the "how" of disease to be discovered and for scientific discoveries concerning the germ theory of disease to be widely accepted.

Little could be accomplished before the understanding of the germ theory of disease. And even after the mechanism for infectious disease was known, water filtration, chlorination, proper sewage disposal, vaccination, quarantine, and food quality regulations had to await public measures and expenditures. Thus, greater public acceptance of the channel through which disease spread was essential. Without that municipalities could not have gained the support to spend large sums on projects to provide clean water and to separate sewage from drinking water.

The mode of disease transmission began to be discovered around 1850 by Semmelweiss who observed that puerperal fever decreased when physicians washed their hands using chlorinated lime. The precise causal agents were not known until around 1870s, first with anthrax, then typhoid and tuberculosis. Robert Koch's work on anthrax in the 1870s proved the germ theory. The foundations had been set by Leeuwenhoek (1600s) who first saw the germs, Pasteur (1860s) who discovered the bacterial basis of decay in foods and later the cause of disease in living organisms, and Lister (1860s, 1870s) who used carbolic acid as an antiseptic in surgery. The understanding of the causal agents was later advanced by Paul Ehrlich known for using salvarsan chemotherapy, also known as the "Magic Bullet," to treat syphilis.

In the case of the United States, Cutler and Miller (2005) have demonstrated the impact of cleaner water on the decrease in infectious disease, particularly typhoid. They estimate the "treatment" effect of filtration and chlorination for 13 cities using plausibly exogenous variation. According to their estimates, water filtration and chlorine treatment account for half of reduced urban mortality in the period.

Some cities (e.g., Philadelphia, Pittsburgh) experienced large effects, but the impacts were small or nonexistent in other cities. Across all cities, filtration and chlorination reduced typhoid fever mortality by 25%, total mortality by 13%, infant mortality by 46%, and child mortality by 50%. Since total mortality declined by 30%, clean water accounted for 43% of the total, 74% of the reduction in infant mortality, and the complete elimination of typhoid (all from 1900 to 1936). The rates of return to investments in clean water technologies were huge.

Life expectation in the United States during the period of public health interventions increased from 45 to 62 years or by 50% of the total change experienced from 1850 to 2000. No other period is as great. Most of the decrease in the period came from the reduction in infectious disease as a cause of death. The period also saw the elimination of the "urban health penalty."[22]

Phase III: The Age of Modern Medicine

The third phase began with the introduction of sulfa drugs in 1935. It was preceded by other medical advances such as the small pox vaccine and salvarsan, an arsenic compound to treat syphilis. The first antibiotics, penicillin in 1941 and streptomycin in 1944, were followed by a multitude of broad-spectrum drugs and antivirals.

Jayachandran et al. (2010) show that from 1937 to 1943, before the discovery and diffusion of penicillin, substantial decreases occurred in deaths from infectious diseases such as scarlet fever, pneumonia, and flu. Maternal mortality, in particular, decreased considerably. The reason for the decline in particular infectious diseases was because of the discovery of sulfa drugs, the precursor to antibiotics.

Infectious diseases were responsible in 1900 for 30% of all deaths in the United States but just 17.5% in 1936 and only 4% in 2000.[23] A combination of public health measures and modern medicines has all but eliminated infectious disease as a cause of death. Not only have life spans been lengthened, a host of modern medical procedures and medications have improved the quality of the years remaining.

In sum, the majority of the gains in longevity in the United States and elsewhere in the rich world came about before the spread of modern medicine. But modern medicine is probably responsible for most of the increase from 65 to 75 or 80 years in the expected age at death from 1936 to 2000 for US men and women. And because of modern medicines and treatments, chronic disease no longer incapacitates large numbers of individuals in their older years.

Human Capital: Summary

Human capital is the stock of productive skills, talents, health, and expertise of the labor force, just as physical capital is the stock of plant, equipment, machines, and tools. Within each type of capital, the performance, vintage, and efficiency can vary. The stocks of human and physical capital are produced through a set of investment

[22]On the changing relationship between health and economic development, see Preston (1975).

[23]See Cutler et al. (2006), Fig. 3 for US data and Floud et al. (2011), Fig. 4.5 for England and Wales.

decisions, where the investment is costly in terms of direct costs and, for human capital investment, in terms of the opportunity cost of the individual's time.

In this essay I have explored human capital in terms of its use and production. Human capital (E) enters the aggregate production function given by Eq. 2 by augmenting labor, which is a function of the level of population (P) and the aggregate labor force participation rate (λ). In practice, human capital is measured as an index of efficiency units of labor. Aggregate output (Q) is altered as well by other inputs such as the stock of capital (K), resources (X), and the level of technology (A).

$$Q = f(A, [E \cdot P\lambda], K, X) \tag{2}$$

This methodology was employed to understand how human capital affects income levels and economic growth. I mentioned that individual well-being could also be impacted in ways that do not necessarily get reflected in aggregate output. Quality of life measures, as they are called, have become an important research area but are difficult to produce historically.

This essay has discussed how human capital is augmented and the rules that are often employed in making human capital investment decisions. Two main types of human capital have been considered here – education and training and health. Both are produced in schools, families, firms, and a variety of other facilities. Both types of investments require good information. Knowledge regarding the cause of disease was important in making investments in health human capital, particularly expensive ones determined by governments, such as water purification. Information regarding the effectiveness of education is required for public investments in schools.

This essay has not emphasized the forces that alter population growth and labor force participation, both of which are related to aggregate measures of human capital. These subjects are covered in other essays, as is the effective use of human capital that can be hampered by discrimination and insufficient geographic mobility.

I have stressed that the subject of human capital is inherently historical. There is much that remains to be explored historically. Why do governments expand formal schooling, and why is informal training more important in certain places and during certain periods? What has been the interplay between grassroots demands for schooling and top-down provision of education? What is the interaction between education and health? Currently, more educated people are healthier. But has that always been the case? The history of schooling across the globe, particularly outside Europe and North America, is still in its infancy. The list of questions and topics in the study of human capital and history is long.

Labor Markets

Robert A. Margo

Contents

Abstract

This chapter presents a brief historical overview of labor and labor markets, using the United States as a case study. Topics include the concepts of the labor force and the labor market; sources of information for historical study; basic features of change over time in the size and composition of the labor force, hours worked, occupations, and skills; changes in real wages over time and in the structure of wages; the emergence of a national market for labor; and the evolution of racial differences.

Introduction

This chapter presents an overview of issues in the economic history of labor and labor markets, using the United States as a case study. My overview is highly selective in method and topics. In terms of method, I focus on research in the "cliometric" tradition. Cliometricians are economic historians who use the tools of modern academic economics – formal theoretical models of economic behavior and econometric models used to test and refine the theory – to study long-term economic development. In their use of the theoretical and statistical tools of modern economics, cliometricians are generally like other economists, and their work is judged by the same standards. However, cliometricians differ from other economists in two key respects.

First, a critical component of the cliometric research agenda is the documenting of long-term change. This requires the collection and analysis of primary historical economic data, often from archives and related sources. Second, when cliometricians use the tools of modern economics, it is primarily to contribute to scholarly understanding of an important issue in economic history, not to validate (or disprove) a particular economic theory (although this can also be a goal of the research). To do both properly – that is, the collection of primary historical data and their analysis – requires deep immersion in the historical context. Good cliometrics, in other words, requires good history, not just good economics.

Cliometricians have made fundamental and lasting contributions to scholarly understanding of the evolution of labor and labor markets. My chapter touches on many of these contributions, although it is far from a complete review. Broadly speaking, I focus on topics involving the measurement of aggregate economic quantities – for example, the unemployment rate – and the demand and supply of labor. The chapter begins by first discussing what economic historians mean by the "labor force" and by a "labor market." I then turn my attention to sources of information for historical study and to the basic features of historical change in the labor force – size, composition, the "intensive margin" (e.g., hours worked), occupations, and skills.

I follow the discussion of the labor force with a discussion of the price of labor – namely, the wage. I present terms, sources, and summarize change over time in real wages and in the "structure" of wages – for example, differences by education level. I also discuss how wages differed across regions in the United States historically and that changes in these differences over time speak to the emergence of an integrated, national market for labor. The chapter concludes with a brief road map of suggestions for further research.

Definition of the Labor Force

An organizing principle in modern economics is the aggregate production function:

$$Y = F(L, K, T) \quad (1)$$

In this equation, Y refers to some measure of aggregate output, L is the aggregate labor input, K is the capital, and T is natural resources ("land"). F is the production function or "technology" linking the use of productive factors (L, K, and T) to output. Output is a "flow" variable – that is, measured over some period of time – and the inputs are also flows over the same period.

Changes in Y between two time periods of production reflect changes in the use of inputs or in the technology (or both). Letting d(ln X)/dt represent the rate of change in a variable over time, we can summarize this point quantitatively in the following equation:

$$d(\ln Y)/dt = dA/dt + \alpha_L d(\ln L)/dT + \alpha_K d(\ln K)/dt + \alpha_T d(\ln T)/dt \quad (2)$$

The "α's" in the above equation are output elasticities – the percentage change in Y for a given percentage change in the relevant factor of production, holding other factors constant. For quantitative purposes, it is generally assumed that the sum of the output elasticities (all of which are positive by definition) is one and that, for computational purposes, each elasticity can be identified with its respective factor share.[1]

In terms of the above equation, L represents the total amount of labor supplied in the economy. Here "amount" has two components – the number of people supplying labor (the extensive margin) and how much time is spent working (the intensive margin).

To measure the first of these components, economists define the "labor force" to consist of individuals who are actively contributing their time and skills to the production of national income. If national income is defined broadly to include production in the home, the majority of the adult population would be in the labor force and the concept would not have much analytic usefulness.[2] But if we take a narrower view, that of market production, there have been significant changes over time in the size and composition of the labor force – that is, how many are working and who they are.

The fundamental source for long-run information on the labor force for the United States is the federal census. Historically the census provides the basis for two different definitions of the labor force. The first definition, used prior to 1940, relies on the "gainful worker" concept as a bright line – if a person reports a "gainful

[1]The assumption that the factor shares sum to one is equivalent to assuming that the aggregate production function is constant returns to scale. However, a strong case can be made for increasing returns in the aggregate – so-called endogenous growth; see PM Romer (1986). The output elasticities will equal their respective factor shares if the factor markets are competitive, so that each factor is paid the value of its marginal product.

[2]The distinction is important historically in the case of the United States because historically much production took place within households. Household production, however, declined as transportation costs fell and more economic activity took place within markets.

occupation" to the census, the individual was part of the labor force. Examples of gainful occupations include farmer, carpenter, domestic servant, and clerk.[3]

According to the second definition, in use today, a person is in the labor force depending on their activities during the census week – that is, a particular window of time. If the person has a job at which he/she is working or would be working except for a temporary hiatus (e.g., a vacation) or works for himself/herself (self-employed), the person is in the labor force. If he/she is without such work but is actively looking for it, he/she is unemployed and still considered part of the labor force. Although modern survey methods are sufficiently refined to measure job-seeking activity, the concept is still fuzzy in practice and especially so during economic downturns in which people turn into discouraged workers, convinced that there is no point looking for work because there is no work to be had.

What Is a Labor Market?

In an idealized market, the goods that are exchanged between buyers and sellers are assumed to be homogenous in quality, and one unit is equivalent as another as far as buyers are concerned – that is, the units are perfect substitutes. For better or worse, this off-the-shelf model is often applied to labor markets – that is, a market in which the good in question being exchanged is the quantity of labor services. Holding the supply curve fixed, an increase in demand will drive up the equilibrium wage and quantity of labor services. Conversely, holding constant the demand curve, an increase in the supply of labor will drive down the equilibrium wage (and increase the equilibrium quantity).

Most markets exist in geographic space, and this is certainly true of most (if not all) labor markets. In a typical labor market, buyers and sellers of labor services are located in physical proximity to each other, and the buyer commutes to her place of employment. This notion of commuting to the workplace gives rise to a fundamental geographic construct in the modern United States – the standard metropolitan statistical area, or SMSA. An SMSA is defined as a collection of counties such that the substantial majority of individuals living in the SMSA also work within its boundaries.

Given a set of labor markets that are geographically delineated, it is natural to ask if they operate distinctly from one another or else are linked together. Imagine that there are two such labor markets, A and B, and suppose that, at the moment, the equilibrium wage in A exceeds that in B. If the cost of migrating between A and B exceeds the difference in wages, there will be no tendency for the situation to change. However, in the long run, if the difference in wages is expected to persist, the net benefit of labor to migrate from B to A may be positive. If this occurs, the

[3]It is possible to adjust the figures to make the pre- and post-1940 figures comparable because information was collected at the time using both questions allowing adjustment factors to be computed; see Durand (1948).

supply of labor will increase relative to demand in A, causing the wage there to fall. Economists speak of this process as the integration of geographically separated labor markets and the narrowing of the wage gap as convergence in wages between A and B. Market integration of this sort occurs if the costs of transporting people between A and B were to fall due to technological change.[4] Alternatively, even if people are not free to migrate between A and B for some reason, the wage difference may narrow if the goods produced in both regions are traded between them; this is called "factor price convergence."

The view that a national market for labor eventually emerged in the United States as the knitting together of geographically distinct labor markets is one that is embraced by many economic historians (see, e.g., Rosenbloom 2002). Later in the chapter, I argue that this view has merit, but it must be supplemented by the consideration of the gradual extension of the frontier – in other words, labor markets expanded outward as the country was settled from east to west.

As noted above, the analogy between goods and labor markets is highly useful but presumes that each unit of labor services is a perfect substitute to one another. A more sophisticated approach to labor market equilibrium invokes the notion of hedonic prices (Rosen 1974). In this model, individuals arrive at the labor market with a set of characteristics which are valued by employers – for example, education or skill – and each employer also comes with a distinct set of characteristics. In this setting, there is not a single equilibrium wage but rather an equilibrium wage function that is comprised of a set of equilibrium prices for worker and employer characteristics. This model is highly useful, for example, in describing how wages vary with education or skill or employer characteristics such as plant safety or the likelihood of job termination or layoff.

Labor markets do not exist in a theoretical vacuum but rather in a specific historical and institutional context. Generally, modern economists have in mind a so-called "free" labor market in which individuals are presumed to have the right to sell their labor services to the highest bidder.[5] However, the model per se does not rest upon a particular set of property rights invested in individuals – the right to trade labor services could be allocated to a third party. Such was the case with indentured servitude and slavery.

In the case of indentured servitude, former individuals were willing to give up their freedom for a period of time in exchange for transit across the Atlantic. Indentured servitude made economic sense because transportation costs from Europe to the New World were very large relative to the productivity (in Europe) of potential servants, and there was no means by which servants could finance the

[4]It can also occur if information flows between A and B improve so that workers have more accurate knowledge of labor market conditions.

[5]That said, labor markets exist in a continuum between truly free labor and slave labor. Historically much labor was restricted in ways that limited labor mobility and even today labor markets are not truly free in the economic sense. For example, many workers in the United States today sign so-called "noncompete" clauses which prohibit them from working for a competitor for some period of time if they terminate their employment with their current employer.

journey themselves. Ship captains were middlemen in this market, arranging for transportation in Europe and then selling servant contracts in the New World. The length of indenture varied with the expected productivity of the servant – shorter, if productivity was higher, longer otherwise – and also with location characteristics. Servants who went to the Caribbean had shorter periods of indenture arguably because health conditions were very poor (Galenson 1984; Grubb 1985).

Chattel slavery, such as was practiced in the United States before the Civil War among other New World economies (e.g., Brazil), was very different from indentured servitude. Slaves did not willingly enter into a contract – they were forcibly abducted or were spoils of war and sold on an international market. The New World, including the United States, was an eager recipient of slave labor from Africa. In the case of the United States, the international slave trade was vigorously active until banned by the act of Congress in 1808. Within the United States, however, slaves were traded more or less freely, until the peculiar institution ended with the defeat of the Confederacy in the American Civil War. These were rental and asset markets – that is, markets in which individuals could transact for the use of slave labor for a specified period of time (rental) or for trading slaves as capital goods (asset). Because of this, there is substantial historical information on both asset and rental prices of slaves, which enables historians to quantitatively assess various key features of the workings of the slave economy (Fogel and Engerman 1974; Fogel 1989).[6]

Documenting the American Labor Force

The historical documentation of the American labor force rests fundamentally on the federal census of population. A census of population was mandated by the United States constitution to be taken every 10 years for the purpose of determining representation in Congress, with the first such census occurring in 1790.

The censuses taken during the first half of the nineteenth century contain relatively limited economic information (the 1840 census is an exception), but there are sufficient data such that, with judicious assumptions, reasonable accurate estimates of the labor force can be made. Starting in 1850, additional information was collected, most importantly on occupation. As the economy shifted out of agriculture and experienced occasional bouts of distress – "panics" in nineteenth-century parlance or business cycles today – "unemployed" workers made their appearance, and it became evident that this, too, became an economic outcome worth documenting, beginning with the 1880 census. States also got into the act of collecting information on the labor force. Starting with Massachusetts, state governments created divisions which monitored and, eventually, regulated various features of labor markets, such as maximum hours that children were permitted to work, or

[6]For example, because both asset and rental prices are known, it is possible to estimate the internal rate of return to owning a slave; see Fogel and Engerman (1974).

plant safety. Established in the late nineteenth century, the US Bureau of Labor Statistics (BLS) also monitored and surveyed the labor market, often at the request of Congress. Many of the documents prepared by the US BLS and its state counterparts in the late nineteenth and early twentieth centuries contain vast quantities of information on individual workers or establishment-level data. The technology to process the data did not exist much less the economic theory to interpret any findings, but the agencies still published the information anyway – perhaps with the belief that, in the not-too-distant future, both the theory and technology (i.e., computers) would be available.

Although the collection of economic data on labor increased steadily after 1900, it became obvious in the early years of the Great Depression that the information was neither comprehensive nor especially timely enough to be of use to policymakers. From the labor statistics point of view, the 1940 census marks a watershed moment – the census was the first to collect comprehensive national data on wages, week works, and educational attainment, all mainstays of modern labor market analysis. But this information was still taken too infrequently to be of use for short- or even medium-term policy.

Economic historians have used the available historical data to construct long-run statistics on the size and composition of the American labor force. The pioneering estimates were undertaken by Lebergott (1964). Lebergott's estimates for the nineteenth century have been revised and updated by Weiss (1992, 1999).

Although the census is indispensable for establishing long-run trends, it provides no evidence on short-run movements. To be useful, such information must be timely – quarterly, say – but the costs of taking a full census every 3 months are obviously prohibitive. Enter the Current Population Survey or CPS for short. The CPS was first taken in 1940 and again in 1944; in the late 1940s, it became a monthly survey. Today, government, business, and academic economists rely heavily on the CPS to give current information about earnings, employment, and unemployment. From time to time, the CPS includes additional questions in its survey, and these have proven invaluable in shedding light on specific topics of current interest.

Since the establishment of the CPS, there have been innumerable specialized surveys by government and private agencies aimed at eliciting labor market information. Of these surveys, arguably the most useful – and certainly the most frequently used – are the Panel Study of Income Dynamics (PSID) and the National Longitudinal Surveys (NLS). These surveys track individuals over time for many years and, indeed, across generations.

Most of the data described above is readily available to the general public via the Internet, such as the websites of the United States Census Bureau (2014) and BLS (United States Department of Labor and Labor Statistics 2014a). Some of the most useful data, such as the CPS or the more recent American Community Surveys (ACS), are samples of individual and household level information. A very convenient source for these samples is the IPUMS (Integrated Public Use Microdata Series) project at the University of Minnesota (Minnesota Population Data Center, University of Minnesota (2014)). The IPUMS site is regularly updated when new

samples become available; among the most interesting in recent years are those in which individuals are linked across census years forming a panel (such as 1880–1910).

The literature on methods for analyzing labor force data is vast and far too complex to discuss here. Excellent background information on survey methods, both historical and contemporary, can be found in the BLS *Handbook of Methods* (United States Department of Labor and Labor Statistics 2014b) (http://www.bls.gov/opub/hom/). The publishing firm Elsevier produces an economics handbook series in which distinguished authors survey the literature on topics of interest at a level useful for professional economists and graduate students; currently there are four volumes in their *Handbook of Labor Economics* series (Ashenfelter and Layard 1986a, b; Ashenfelter and Card 1999a, b, c; Ashenfelter and Card 2011a, b). For tables giving long-term time series on a wide array of labor statistics (e.g., the size of the labor force, unemployment, and so on), a very convenient source is the most recent edition of *Historical Statistics of the United States* (Carter et al. 2006).

Size and Composition of the American Labor Force

Table 1, taken from Margo (2015), displays the aggregate labor force and the labor force per capita (labor force divided by population) from 1800 to 2010. In 1800 there were 1.7 million workers in the labor force, or 320 per 1,000 persons – an aggregate labor force participation rate of 32%. By 1900 the labor force had grown by a factor of 17, and the aggregate labor force participation rate was 38%, 6 percentage points higher than in 1800. The labor force continued to grow in the twentieth century. In 2010, the latest year for which census data are available, there were 154 million workers in the American labor force, and the aggregate participation rate was 50%, 18 percentage points higher than in 1800. As the aggregate labor force participation rate increases in the long run, so does per capita income – implying that rising labor force participation has contributed to rising living standards over the past two centuries of American economic growth.

Changes in the aggregate size of the labor force and in per capita terms reflect complex shifts in population composition, as well as fundamental economic and social change driven by technology, economic growth and development, cultural norms, and government regulation. Children were much more likely to be in the labor force in the nineteenth century than in the twentieth century. The decline in child labor reflects a secular rise in the relative demand for educated workers coupled with the fact that investment in education is sensibly "front-loaded" – that is, undertaken by the young – in the life cycle. It also reflects, to a lesser extent, the passage of laws requiring that individuals remain in school until a certain age – compulsory schooling laws – or which restrict the employment of children – child labor laws (Margo and Finegan 1996). Another long-run trend of enormous importance is the rise of "retirement." Retirement refers to the phenomenon of individuals leaving the labor force at older ages, usually permanently. Retirement was uncommon in the nineteenth century but begins to be observed in the late nineteenth century and accelerates in the twentieth century with the advent of private pensions,

Table 1 The labor force in the United States, 1800–2010

	Labor force (in 1000s)	Per 1,000 population, all ages
1800	1,713	323
1810	2,337	323
1820	3,163	328
1830	4,272	332
1840	5,778	338
1850	8,193	353
1860	11,293	359
1870	13,752	345
1880	18,089	361
1890	23,701	376
1900	29,483	387
1910	37,873	411
1920	42,345	399
1930	49,343	401
1940	56,168	425
1950	62,208	411
1960	69,628	388
1970	82,771	405 [604]
1980	106,940	472 [638]
1990	125,840	506 [665]
2000	140,863	501 [671]
2010	153,889	497 [647]
Average annual rate of growth, 1800–2010	2.11%	0.21%
Average annual rate of growth, 1800–1900	2.88%	0.18%
Average annual rate of growth, 1900–2010	1.50%	0.24%

Social Security, and Medicare (Ransom and Sutch 1986; Costa 1998). For detailed discussions of these issues, see Margo (2000a) and Goldin (2000).

The shifts in child labor and labor force participation among the elderly tended to reduce the labor force per capita, and yet the ratio of workers to population rose substantially while these trends were occurring. Some of the upward trend can be attributed to immigration; historically, the foreign-born tend to have higher labor force participation than native-born Americans. But the primary trend offsetting decreases in child labor and older workers is the long term, very substantial rise in the labor force participation rate of married women. The long-term increase in participation among married women reflects shifts in the structure of the economy toward sectors in which women were closer substitutes for men; growth in the relative demand for educated labor, coupled with a largely gender-neutral education system; shifts in cultural norms that enabled women to enter occupations that were formerly closed to them, along with associated anti-discrimination legislation; and

improvements in contraceptive technology, which enabled younger women to more readily invest in schooling and other skills that paid off later in the life cycle (Goldin 1990).

The Intensive Margin

The number of people in the labor force is a very imprecise measure of the labor input into the aggregate production. Among the reasons for this imprecision are changes over time in hours worked. This refers to changes in hours among employed persons as well as, potentially, changes in the incidence and duration of unemployment.

It is frequently assumed that each hour worked by an employed worker is a perfect substitute for the other, so that hours in the aggregate is simply the sum across workers. However, this ignores much evidence that reducing hours per day but keeping days of work per week constant may have a different effect on output than holding hours per day constant but reducing days per week. My discussion below ignores such subtleties (see Atack et al. 2003; Sundstrom 2006).

For the nineteenth-century United States, most of what is known about hours worked pertains to the manufacturing sector. In the early 1830s, the average workweek in manufacturing was about 69 h; this declined to about 62 h on the eve of the Civil War. Weekly hours continued to trend downward for the remainder of the century but slowly – in 1900, the typical workweek was 59 h. This decrease occurred not because of fewer days of work per week but rather fewer hours per day, perhaps a fall of about 90 min per day from the early 1830s–1880s. The 1880 census provides detailed information on variation in hours worked; these data reveal substantial differences across industries and geography, as well as substantial seasonality (Atack and Bateman 1992).

It seems likely that the decrease in weekly hours was offset by an increase in annual weeks worked. Over time, an increasing share of manufacturing establishments operated on a full-year rather than part-year basis. The increase in full-year operation has a multitude of causes – improvements in indoor heating and lighting, enabling firms to operate continuously in colder climates; improvements in transportation networks, which lessened the frequency and severity of supply chain interruptions; and a greater use of fixed capital (machinery), which created incentives for more continuous production (for further discussion, see Atack and Bateman 1992 and Atack et al. 2002).

The decline in weekly hours continued after the turn of the twentieth century, falling from around 60 h per week in 1900 to about 50 h per week in 1920. Further decreases continued in the 1920s and, especially in the 1930s, when employers turned to so-called work sharing as an alternative to layoffs. Not surprisingly, weekly hours rose temporarily during World War Two, but resumed a modest decline after, settling eventually on the norm today, just shy of 40 h per week.[7]

[7]For additional analyses of historical data on the length of the work data, see Whaples (1990), Costa (2000), and Vandenbroucke (2009).

The long-run decline in hours is often interpreted using a simple labor-leisure choice model. In this model, individuals choose between time not spent working – leisure – and goods, which are purchased using the income from work. The outcome of this choice is a labor supply curve relating hours of work supplied to the real wage. If leisure is a normal good, that is, if the income elasticity of the demand for leisure is positive, it is possible for the labor supply curve to be "backward bending," that is, hours of labor supplied will be a negative function of the real wage. For workers who are highly attached to the labor force, it is generally believed that the wage elasticity of labor supply is close to zero; in this case, for a given increase in real wages, the income effect on leisure demand(fewer hours supplied) is just offset by the substitution effect – the worker substitutes away from leisure when its price relative to consumption goods increases. Although the model is useful, it abstracts from changes over time in preferences for leisure which may have been important (see Hunnicutt 1980; Maoz 2010).

As noted earlier, today's concept of the labor force includes individuals who are not currently employed but who are seeking work – the unemployed. In the early nineteenth century in which the majority of the labor force was engaged in self-employed agricultural production, the modern notion does not have much meaning. However, as development progressed in the nineteenth century, labor shifted out of agriculture, and workers increasingly became the employees of someone else.

An important feature of the evolution of labor markets has been the development of laws to deal with contractual relationships between employers and employees. Broadly speaking, in the United States, this evolution produced the notion of "employment at will." With few exceptions, employees are free to leave their job with little or no notice to the employer – that is, the employee is free to quit her job – and the employer has no legal recourse to prevent this from occurring. The flip side is that, again subject to restrictions (more on the employer in today's labor market than on the employee), employers can "divorce" their employees by terminating their jobs. The termination can be with the expectation of being recalled, a separation, or it can be permanent with no expectation of recall – a divorce. It is this two-sided freedom that accounts for two of the three ways in which an individual can enter the status of unemployment.

As noted earlier, unemployment was first recorded in the 1880 census but the data are poor in quality. Much better quality data was collected in 1900 and 1910; the individual level responses have been analyzed by Margo (1990) and reveal significant differences from patterns prevailing in the late twentieth century. Specifically, in the early twentieth century, the odds that a worker would enter into unemployment appear much higher than today (here I am speaking in comparison to similar points in the business cycle), but the length of unemployment was shorter. The labor market, in other words, of the early twentieth century seems closer to the proverbial spot market with more churning than was typical in the late twentieth century.

The time series characteristics of aggregate unemployment have been of central importance to macroeconomics because these are thought to reveal crucial features of the impact of policy. A tenet of post-World War Two macroeconomics for a long time was that policy was effective in taming the business cycle. This was allegedly

revealed by changes in the dynamics of aggregate unemployment – in particular, unemployment was supposedly less volatile once activist policy was adopted.

This tenet was challenged in a celebrated debate originating in Romer (1986a). Pre-1940 unemployment rates were constructed in an entirely different manner from postwar rates. In particular, the pre-1940 rates were inferred as residuals from estimates of the labor force and employment. Romer argued that the assumptions in this method tended to overstate true volatility relative to a time series in which unemployment was collected directly (as is the case after 1940 using the survey week method described earlier). When this bias is corrected, there is no clear evidence that unemployment after WW2 was less volatile than before. Since the publication of the original article, Romer (1999) modified her criticism somewhat, allowing for some dampening of volatility in the 1990s. However, the recent financial crisis may have changed this interpretation of the long run – the jury is still out.

While the debate continues over the second moment of the unemployment series (its variance), there has been little debate – again, excepting the recent period of financial crisis – that in the very long run the unemployment rate has shown little tendency to drift upward or downward. This belies, however, some stubborn cross-sectional differences. The most notable of these is a persistent racial gap in unemployment; this gap, along with associated differences in labor force participation overall, is addressed later in the chapter.

Occupations and Skills

The American labor force changed in the long run not just in terms of numbers or the amount of time spent laboring. There have also been vast changes in the type of work performed. A useful, if imperfect way, to capture these changes is to examine the structure of occupations.

In Table 2, I present estimates of the occupation distribution at 50-year intervals between 1850 and 2000. The distributions are derived initially from the IPUMS samples and subsequently adjusted to be as comprehensive as possible. The broad contours of change are adequately revealed by using so-called "one digit" categories as shown in the table. Details on the construction of the estimates can be found in appendix B of Katz and Margo (2013).

In the top half (Panel A) of Table 2, I show the percentages of the labor force in the various occupation categories. In terms of change, the most substantial are the secular decrease in the share in agriculture and the secular increase in the share in white collar. According to Weiss (1999), about three-quarters of the labor force was engaged in agriculture in 1800, so the long-term shift away from farming began quite early in American history.

The shift of labor out of agriculture can be readily explained by a standard two-sector general equilibrium model with specific factors, although for quantitative purposes more complex versions of the model would be required (Lewis 1979). In the standard two-sector model, agricultural output is a function of labor and land, and

Table 2 Occupation and skill distributions, the United States, 1850–2000

Panel A: by occupation				
	1850	1900	1950	2000
White collar	**6.9**%	**17.1**%	**37.5**%	**61.8**%
Professional-technical	2.3	4.3	8.9	23.4
Manager	3.1	5.7	9.0	14.2
Clerical/sales	1.5	7.2	19.6	24.2
Skilled blue collar	**11.6**	**11.0**	**14.0**	**9.8**
Operative/unskilled/service	**28.7**	**36.4**	**36.8**	**27.1**
Agriculture	**52.7**	**35.3**	**11.7**	**1.2**
Operator	23.9	20.0	7.7	0.6
Farm laborer	28.8	15.5	4.1	0.6
Panel B: by skill group				
	1850	1900	1950	2000
High skill (prof/tech/man)	5.4%	10.0%	17.9%	37.6%
Middle skill 2 (clerical/sales/farm operator/craft)	37.1	38.3	41.3	34.6
% Low skill (oper/unsk/serv/farm lab)	57.5	51.1	40.8	27.7

Source: Computed from Tables 4 and 6 of Katz and Margo (2013). See Katz and Margo (2013, Appendix B) for details on the construction of the figures in this table

nonagricultural output, a function of capital and labor. Labor is allocated between the two sectors so as to equate the value of its marginal product. If the demand for agricultural output is price and income inelastic, an increase in total-factor productivity in agriculture would "push" workers off the farm into the city (i.e., nonfarm occupations), whereas an increase in total-factor productivity in nonagriculture would "pull" workers into the nonfarm sector. It is clear that total-factor productivity increased in both agriculture and nonagriculture, so the effect of technical progress was to shift labor away from farming.

An interesting feature of the estimates is that the share of skilled blue-collar labor remained more or less constant over the nineteenth century, while the shares of white collar and of operative/unskilled/service workers increased. The rough stability in the blue-collar share is the outcome of competing forces. On the one hand, the economy experienced its own industrial revolution, leading to the emergence of a growing and highly productive manufacturing sector. A key feature of manufacturing development in the nineteenth-century United States is the growth of the factory system and the concomitant displacement of the artisan shop. Labor historians refer to this process as one of "de-skilling," in which the share of artisans in manufacturing decreased, while the shares of operatives/unskilled and white-collar workers increased – or as Katz and Margo (2013) put it, the occupation distribution in manufacturing "hollowed out." But manufacturing was more intensive in the use of artisans than the economy overall, and, in addition, demand for artisan labor increased because the construction sector expanded. De-skilling in manufacturing, therefore, reduced the demand for artisans, while manufacturing and construction growth overall increased the demand, leaving the overall share more or less constant (see also Chandler 2006).

During the first half of the twentieth century, there was a steady and substantial move out of agriculture, an equally steady and substantial increase in the share of white collar, stability in the unskilled/operative/service share, and a modest rise in the share of blue collar. Since World War Two, the rise in the white-collar share has been inexorable, while the other groups have declined. In the year 2000, slightly more than 1% of the American labor force was engaged in agriculture, a vast decline over the previous two centuries.

A somewhat different take on the same evidence is provided in Panel B, which classifies occupations by broad skill categories – high, middle, and low. Low-skill jobs require relatively little or no training or education; high-skill jobs require substantial (for the time period) human capital investment; middle-skill jobs are in between. The most salient changes in Panel B are the long-term rise in the share of high-skill jobs and corresponding decrease in low-skill jobs. Middle-skill jobs expanded their share from the late nineteenth century through the first half of the twentieth century but have decreased since 1950.

To make sense of these shifts, they need to be combined with shifts in the relative wages by job category. Based on the available wage data, Katz and Margo (2013) argue that the relative demand for high-skill jobs appears to have increased more or less continuously throughout American history. Here the basic idea is the complementarity between new technologies and skills: as technology advances, much of which is embodied in new capital goods, the demand for high-skilled workers increases relative to the other groups. The increase in relative demand can be met, or not, by shifts in relative supply, or what Goldin and Katz (2008) refer to as the "race" between technology and skills. In the nineteenth century, the relative wage data suggest that the demand for high-skill workers grew slightly faster than supply because the relative wage of high-skilled workers was slightly higher at the end of the century than ca. 1820. In the twentieth century, the relative wages of high-skill workers declined over the first half of the twentieth century but rose over the second half. Goldin and Katz (2008) show that these twentieth-century shifts are explained by shifts in relative supply – the relative supply of highly skilled (educated) workers increased faster than demand over the first half of the twentieth century, but the reverse was true over the second half. The rise in the relative wages of highly skilled workers in recent decades is an important component of increasing income inequality in the United States (see Goldin and Katz 2008).

Wages: The Price of Labor

The wage is the price of labor – a payment per some unit (e.g., per hour) for the rental of a person's labor services. This payment could be in money or "in kind" – for example, housing or food.

Economists distinguish between nominal and real wages. Nominal wages are expressed in terms of current monetary values, whereas real wages are adjusted to reflect changes in purchasing power over time. A real wage, in other words, needs to be deflated (divided) by an index of prices. The price index could be an index of producer prices, in which case the real wage is called the "product wage" and is

isomorphic (or dual) to an index of labor productivity. The price deflator could be an index of consumer prices, in which case the real wage measures the extent to which workers over time can command more goods and services for a given quantity of labor services provided to the market.

Real wages increase over time for two primary reasons. First, individuals may have more complementary inputs to work with – more capital per worker, say. Increases in complementary inputs per worker will raise labor productivity and therefore real wages as well. Second, the economy will experience technical progress, which will raise labor productivity even if there are no corresponding increases in complementary inputs per worker. Historically, both factors have been in play more or less continuously over the course of American economic history.

Sources of Information About Wages in American Economic History

At the start of the nineteenth century, the vast majority of workers were self-employed in agriculture and not working for wages. Information on wages for the colonial and early national period, therefore, tends to come from occasional transactions recorded in account books of farmers or craftsmen. As the nineteenth century progressed, more persons worked for wages and more information is available. For the census years 1850–1870, for example, the Federal Census of Social Statistics recorded average daily wages (with and without board) for common labor and carpenters, the weekly wages of female domestics, and the average monthly wages (with board) of farm labor. Extensive wage data survive for the construction and maintenance of the Erie Canal; company records provide evidence in certain industries, such as textiles. For a more extensive discussion of available sources, see Margo (2000b).

By far the most extensive (and comparable) data pertain to civilian employees of the US Army, who were hired by quartermasters at the various army posts throughout the nineteenth century in a wide array of unskilled, artisanal, and white-collar jobs. Margo (2000b) provides a comprehensive analysis of the extant data for the antebellum period for this source, which yields regional and aggregate time series for unskilled labor, artisans, and white-collar workers. After the Civil War, the available information increases sharply as governments at all levels began collecting wage information on a regular basis. In the late nineteenth century, the US Bureau of Labor Statistics became the primary federal source of routine information on wages, which continues to the present day, supplemented since 1940 by wage information collected by the US population censuses and the CPS. Generally speaking, the BLS data is collected from employers, whereas the census (and CPS) data derive from self-reports by individuals.

Long-Run Growth in Real Wages

Standard long-run series of nominal and real wages can be found in Margo (2006). A useful approximation is that, in the aggregate, real wages have increased at a long-

run rate of about 1.5% per year, implying a fourfold rise every century. There has been acceleration in real wage growth comparing the twentieth to the nineteenth century, and volatility – the standard deviation of the real wage – is also lower in the twentieth century.

The growth in the aggregate real wage, however, masks important and sometimes dramatic shifts in the structure of wages. Economists refer to wage structure as the measures of the distribution – for example, its variance or the difference between wages at the 10th and the 90th percentiles – or closely associated differences by level of skill, such as the difference in wages between white-collar and unskilled workers or the difference in wages between high school and college graduates.

Economic historians have worked hard to measure shifts in wage structure over the course of American history, with a fair degree of success at documentation. In the nineteenth century, these shifts appear to be relatively modest, tending to show that over the century the relative wages of white-collar workers increased compared with unskilled labor or artisans. In conjunction with the evidence on occupations discussed earlier, this suggests that the relative demand for white-collar skills grew more quickly in the nineteenth century than did relative supply, although any difference between two trends was fairly modest (Margo 2000b; Katz and Margo 2013).

In the twentieth century, measures of wage structure follow a U-shaped pattern (Goldin and Katz 2008). Specifically, the relative wage of skilled or educated workers appears to have decreased during the first half of the twentieth century but increased during the second half, leaving the level of the skill or education premium approximately the same. The U-shaped pattern was not due to shifts in the relative demand for skills – these appear to have been more or less constant across decades, with the exception of the 1940s (Goldin and Margo 1992). Rather, the shifts in wage structure are due to supply. During the first half of the twentieth century, the supply of skilled, or educated, workers increased relative to demand, whereas in the second half of the century, supply lagged significantly behind demand (Goldin and Katz 2008).

Regional Differences: The Emergence of a National Labor Market in the Nineteenth Century

A major theme in American economic history is the emergence of national markets in goods and mobile factors of production. This process began in the nineteenth century and occurred in conjunction with the settlement of the country from east to west (Rosenbloom 2002). The process was greatly facilitated by the so-called transportation revolution – canals, inland waterways, and, most importantly, railroads (Taylor 1951; Slaughter 1995; Atack et al. 2010).

The evolution of a national market in labor begins with a consideration of a paradox. In 1840, per capita income was highest in the Northeast and lower, on average, in the South than in the North. Within the North, per capita income was much higher in the Northeast than in the Midwest. The direction of population

movement within the North, however, was from east to west – that is, from the region where per capita income was highest to where it was lowest (Easterlin 1960).

A variety of explanations have been offered to explain east-west migration given the regional income gradient. One prominent hypothesis views the west as a "safety valve" for disaffected eastern labor. The idea here is that migration to the western frontier may have been selective – those who left the East were low-wage workers whose wages were in fact higher in the West than they were in the East but, on average, were still lower than average wages in the East. This would happen if migrants to the west were "negatively selected," but the extent of negative selection cannot fully resolve the paradox (Ferrie 1997).

A complementary explanation focuses on the possibility of capital gains to land (Galenson and Pope 1992). Migrants to the frontier could not immediately begin farming – the land had to undergo extensive improvement. Moreover, the value of the land was heavily dependent on its proximity to transportation, which itself was a function of settlement (Craig et al. 1998; Coffman and Gregson 1998; Atack and Margo 2011). Capital gains, nonetheless, did occur, and it is also worth noting that per capita incomes in the Midwest rose substantially relative to the Northeast between 1860 and 1880. The key point is that migration was expected to be permanent rather than transitory, implying that the present discounted value of migration is the relevant gross benefit of moving, not the current difference in income.

Another argument is that, for a variety of reasons, the per capita income estimates do not capture the actual geographic pattern of differences in the marginal product of labor. That is, the marginal product of labor may have been higher in the West than in the East, and yet measured per capita income was actually lower. The simplest models of labor market integration posit that labor should move from A to B if the value of the marginal product of labor is higher in B than in A, allowing for the costs of migration.

If the value of the marginal product of labor was higher on the frontier, this should be evident in real wages. Margo (2000b) provides annual time series of nominal and real wages for the United States from 1820 to 1860 for three occupations, common labor, skilled artisans, and clerks (i.e., white-collar workers), for four census regions – the Northeast, Midwest, South Atlantic, and South Central regions. In addition, he also provides regional estimates of the number of workers in three occupations over the same period.

Margo uses these data to study shifts in relative wages and employment before the Civil War. The first pattern that emerges is that, for all three occupations, real wages within the North and within the South were higher on the frontier – the Midwest in the case of the North and the South Central in the South – than in the settled region, the Northeast and the South Atlantic.

Second, within the North, there was a general tendency for the regional wage gap to decline over time. For example, in the case of common labor, Margo estimates that real wages were about 32% higher in the Midwest than in the Northeast in the 1820s, but the gap had fallen to 17% in the 1850s. Over the same period, the share of common labor in the North residing in the Midwest rose substantially – that is,

relative (Midwest-Northeast) wages moved inversely with relative employment. This suggests a process of market integration in which labor moved from east to west, increasing the relative supply of labor in the west and causing the relative wage to fall.

An analogous process of convergence also occurred for skilled artisans and white-collar workers in the North. Interestingly, the initial gap was much larger for skilled artisans and white-collar workers than for common labor, indicating a skill "shortage" and therefore a relatively high initial skill premium on the frontier. Again, skilled blue- and white-collar labor responded by moving from east to west, causing the wage gap to narrow over time.

Within the South, there is less evidence of regional convergence in wages, regardless of occupation. However, it is also the case that, in absolute terms, the regional gaps were generally smaller than in the North, suggesting the possibility that the southern labor markets before the Civil War may have been more efficient in terms of regional allocation than the northern labor market.

In addition to regional gaps, Margo (2000b) also provides evidence on wage convergence using data from the 1850 and 1860 censuses of social statistics. These censuses recorded the average daily wages of common labor and other occupations, with and without board, at the level of minor civil divisions, a geographic aggregate smaller than a county. It is possible to use these data to construct a proxy for real wages and, therefore, estimate a regression of the change in real wages between 1850 and 1860 on the initial level. Margo finds that the coefficient on the initial level is significantly negative, consistent with a market integration process in which labor migrated generally from low to high real wage areas.

If state dummy variables are added to Margo's regressions, these show that the extent of wage convergence was less complete across states rather than within. This is not surprising because the average distance within states between counties (the unit of observation in the regressions) is shorter than the average distance across states. We expect that distance will matter – less accurate information about job opportunities and wage differences and higher costs of migration.

Both because the shortest distance between two points is a straight line and because much human capital in agriculture in the nineteenth century was latitude-specific, the settlement process in nineteenth-century America was generally due West and, importantly, mostly incremental (Steckel 1983). Occasionally, however, vast amounts of intermediate settlement were sidetracked in favor of direct movement to a very distant location. This occurred because of very large "shocks" to labor demand in the distant locations, invariably in response to the discovery of natural resources.

By far the most famous example of such a discovery in the nineteenth century was the California Gold Rush. Close study of the Gold Rush reveals much of interest to the student of historical labor markets.

The Gold Rush commenced with the discovery of gold in California in January 1848 and was for all practical purposes complete by the middle of the 1850s. Although obviously part of the land mass of North America, it would be incorrect to call California part of the American economy in the early nineteenth

century – if anything, it was part of the Mexican economy. But American fur traders had arrived at the start of the nineteenth century, and Russia also had its eyes of California, establishing a fort in 1812 in the northern part of the region. Slowly, Americans began arriving, agreeing to become Mexican citizens in exchange for land grants. Conflicts between the settlers and the Mexican government escalated into war in 1846 which ended with California (and other lands) being ceded to the United States by treaty in 1848. Ironically, the 1848 treaty was signed shortly after gold was discovered. When the news of the discovery reached the east coast, it set off a frenzy of activity as "49ers" made their way arduously to the gold camps.

Margo (2000b) provides a model to assess the impact of the Gold Rush on the labor market in California at the time. The model is inspired by similar frameworks used to assess "Dutch disease" – so-called in reference to the effects of the discovery of oil on the Netherlands in the 1970s. In the model, there are two sectors, one of which is gold mining. The discovery dramatically increases the demand for labor in gold mining. Some labor responds by shifting out of the other sector, but this is not nearly enough to prevent wages in gold mining from rising. The increase in wages draws in migrants from the rest of the country, prompting wages to decline. If the Rush is fully temporary – that is, over when all the gold is mined – both labor supply and wages should return to their pre-gold equilibrium.

Based on archival wage data, Margo provides estimates of nominal and real wages for artisans, white-collar workers, and common laborers in California from 1847 to 1860. He finds, as the model predicts, a sharp rise in wages after gold is discovered, but the rise is abated and to some extent reversed as in-migration occurs. However, he also finds that real wages in California settle at a level that is significantly higher than before the Rush. Since not all of the labor returned, this suggests that what the discovery really did was speed up the exploration (and exploitation) of the Pacific coast. In fact, California entered the union as a state long before many of the other territories in the West, and to this day it remains far more settled than much of the land between it and the Midwest.

Diversity in the Labor Market: Racial Differences

Race is central to the economic history of the United States – one cannot truly understand American economic development without understanding the role of slavery, nor can one understand the post-Civil War history of the country without appreciation for the role of race. Race, too, plays a key role in the evolution of American labor markets and in the income distribution.

Comprehensive data on income by race for the nation as a whole are not available until after World War Two. For the years after the Civil War but prior to World War Two, race-specific information on earnings (income from wages) is available in the 1940 census. Prior to 1940 there are scattered surveys of wages by race and other information on income sufficient to allow economic historians to piece together a plausible timeline on racial income differences.

The earliest black-white income estimate in the aftermath of the Civil War is that by Robert Higgs (1977) for approximately 1870. The underlying data is more extensive and reliable for agriculture than for nonagriculture, but this is a good thing, because just after the Civil War, the vast majority of African-Americans were in the South, engaged in agriculture. Higgs' estimate of the black-white per capita income ratio in 1870 is 0.25 – for every dollar of income accruing to a white person, blacks received 25 cents. Higgs has also made an estimate for 1900, and here the ratio is 0.35. The implication is that racial convergence occurred in the three decades after the Civil War – the black-to-white income ratio increased.

There are several reasons to believe that the direction of change is plausible even if one quibbles about the magnitudes. In the aftermath of the Civil War, schools were set up for African-Americans in the South, and, for the vast majority, these were the first schools any had ever attended. As a consequence, the racial gap in literacy – a chasm in 1870 – had narrowed substantially by 1900. Literacy had an economic payoff in the postbellum south, and thus the narrowing literacy gap promoted convergence in incomes (Collins and Margo 2006).

A second reason to believe that convergence plausibly occurred is that there is evidence of convergence in wealth. The evidence comes in two forms. The first form refers to assessed wealth for tax purposes, which was reported by a number of southern states. These data show a narrowing of black-white differences in per capita wealth from after the Civil War to about World War I (Higgs 1982; Margo 1984). Unless the wealth to income ratio increased quite significantly for blacks relative to whites over the same period, the narrowing black-white wealth gap would imply a narrowing black-white income gap. Race-specific estimates of homeownership recently compiled by Collins and Margo (2011) also show a narrowing gap between 1870 and 1910, consistent with the wealth data and also with racial income convergence.

What about the twentieth century? Here the pattern is mixed – periods of stability and, on occasion, retrogression interspersed with periods of significant convergence.

Smith (1984; see also Smith and Welch 1989) is a well-known article that provides estimates of black-white income ratios for adult males from 1890 to 1980. Over this period, the income ratio increased from 0.44 to 0.62. Little change occurred, however, between 1890 and 1940; all of the long-run increase happened after World War Two. According to Smith's estimates, the increase between 1940 and 1980 was split evenly between 1940 and 1960, and 1960 and 1980. Smith argues that the primary factors behind the convergence were racial narrowing in educational attainment and African-American migration from the South. Margo (1986, 1990), however, argues that the census data on educational attainment, properly interpreted, do not support Smith's argument and that racial divergence in incomes likely took place in the South before World War Two, impeding convergence at the national level.

Schooling and migration are supply-side factors in racial convergence. Further research suggests that racial convergence took place in two distinct episodes, both of which reflected significant increases in the demand for black labor relative to whites. The first episode was the 1940s. In the 1940s, blacks gained relative to whites

because of shifts in demand that favored less-educated workers, the only such period in the twentieth century, and also because large number of blacks left the rural south in response to wartime shifts in production (Goldin and Margo 1992; Margo 1995; Goldin and Katz 2008). In the second period, shifts in demand associated with the Civil Rights Movement were critical, particularly in the South (Donahue and Heckman 1991).

Since 1980 there has been limited racial convergence in incomes (Neal and Rick 2014). The absence of convergence reflects many factors. On the supply side, black-white differences in skills and education have not narrowed significantly in recent years, and this lack of narrowing is an important reason why labor market differences by race remain large (Neal 2006). The growth of incarceration, which has disproportionately affected African-Americans, may play a role; employers are reluctant to hire ex-convicts (Neal and Rick 2014). Since 1980 there has been a substantial increase in income inequality in the United States, a portion of which can be attributed to rising relative demand for better-educated workers. Because African-Americans continue to lag behind whites in educational attainment, these shifts in demand have impeded racial convergence (Juhn et al. 1991). African-American incomes have also been harmed by globalization trends that reduce the demand for manufacturing labor in the United States and also by the growing share of foreign-born workers, who are closer substitutes for African-American workers than for white workers (Borjas et al. 2010).

Directions for Future Research

This chapter has presented an overview of issues in the economic history of labor and labor markets, using the United States as a case study. The overview is both brief and highly selective in topics and method. I have concentrated on topics associated with the measurement of aggregate quantities and those involving the demand and supply of labor, rather than the institutions of the labor market (slavery is an exception). Aside from being selective in topic, my review is also selective in method – I have focused largely on research in the cliometric tradition.

Although cliometricians have made important contributions to our understanding of the long-term evolution of the American labor force, there is still much to be learned, even about the "bread-and-butter" topics surveyed in my chapter. In keeping with the supply-and-demand architecture of the chapter, I group my suggestions for further research into those pertaining to the quantities (e.g., unemployment or hours worked) versus those pertaining to wages and labor compensation.

Cliometricians such as Stanley Lebergott (1964) and Thomas Weiss (1992, 1999) have developed excellent estimates of the labor force and its components going back well into American history. Broadly speaking, these estimates are on a very solid footing for the census years beginning in 1850 but are less secure for earlier years. Further research on this topic, perhaps using archival records such as diaries documenting labor force activity for specific population groups (children, young women), would be helpful. Even more valuable would be improvements in the

reliability of annual estimates of employment and unemployment prior to World War Two, which would greatly enhance our understanding of economic behavior over the business cycle.

As in other advanced industrialized economies, the shift of labor out of agriculture was the defining feature of long-term economic development in the United States. New investments in human capital across generations figure prominently in this shift. Successive generations of children growing up on the farm realized – or rather, their parents did – that their future was not in agriculture, and to secure this future required learning new skills and, typically, going to school for more years. How this process played out across space and time in the nineteenth-century United States, when the frontier was still expanding westward, is very poorly understood. Census micro-data linked across generations (such samples are available from the IPUMS project at the University of Minnesota mentioned earlier in the chapter) might provide essential insights into this topic.

Although cliometricians have done much in recent years to map out the history of wages in the United States (see Margo 2000; Goldin and Katz 2008), there is still much to learn. In particular, more needs to be done to understand the relationship between wages and human capital, especially the "returns to schooling" – the change in wages associated with an additional year of formal schooling. For the twentieth century, estimates of the returns to schooling can be made at a national level for period after 1940 and for one state, Iowa, in 1915 (see Goldin and Katz 2008). However, for the nineteenth century, all that is known at present is how wages differed by occupation – for example, the difference in wages between carpenters and common laborers. While it may prove impossible to find suitable direct micro-data on schooling and wages for the nineteenth century, further documentation of the differences in schooling across occupations could still be useful in understanding shifts in the demand for labor relative to supply for different skill levels (see Katz and Margo 2013).

Abstract

Along with information and communication technology, infrastructure, and the innovation system, human capital is a key pillar of the knowledge economy with its scope for increasing returns. With this in mind, the purpose of this chapter is to investigate how industrialized economies managed to achieve the transition from low to high levels of human capital. The first phase of the human capital transition was the result of the interaction of supply and demand, triggered by technological change and boosted by the demands for (immaterial) services. The second phase of the human capital transition (i.e., mass education) resulted from enforced legislation and major public investment. The state's aim to influence children's beliefs appears to have been a key driver in public investment. Nevertheless, the roles governments played differed according to the developmental status and inherent socioeconomic and political characteristics of their countries. These features of the human capital transition highlight the importance of understanding governments' incentives and roles in transitions.

Keywords

Human capital · Education · Economic history · Economic policy

Introduction

The transition in human capital is arguably the most important economic and social transformation to have occurred. After all, human capital accounts for two-thirds of overall wealth (i.e., including natural capital) in most industrialized economies (Hamilton and Liu 2014) and, based on rough estimates, has over the last 200 years (McLaughlin et al. 2014). Reflecting its importance, the Council of the European Union states that "[e]ducation and training have a crucial role to play in meeting the many socio-economic, demographic, environmental and technological challenges facing Europe and its citizens today and in the years ahead" (Council of the European Union 2009, p. C 119/2). Given the fundamental role human capital plays in economic growth and development, and especially for the "knowledge economy," research related to growth needs to include human capital in its analysis (e.g., Hippe and Fouquet 2018).

The particular aim of this chapter is to better understand the following questions: What factors have driven the human capital transition since before the Industrial Revolution? Was there a market failure in the area of human capital such that governments had to step in to foster increased investment? What role did the state play in the provision of mass schooling? What drove the public's willingness to sacrifice scarce resources for this public good? What role did other stakeholders play?

The human capital transition over the last 500 years, triggered by the development and diffusion of the Gutenberg Press, and, particularly, in the 200 years, with expansion of public schooling, offers numerous lessons for growth. First, it tells us (part of the story of) how we got here – how one of the pillars of the "knowledge

economy" developed. Second, it offers an example of a major transition of a key factor of production (hence, crucial for understanding economic development and growth). Third, it provides a lesson about a major transition where market failures were prevalent and government stepped in and provided education. In all cases, understanding past transitions will offer insights into how to promote future transformations.

The history of the human capital transition highlights how the state can have a major role to play in future transitions related to investment in education. Even though demand for a knowledge economy in all its dimensions might be increasing in the most industrialized countries, an effective transition is likely to require further state action. Where demand is especially lacking, such as in less developed countries, the state's role in achieving a transition to a knowledge economy will be particularly acute. A crucial factor in determining whether the transition moves beyond a first phase may well be the extent to which government directly benefits from the transition.

The chapter is organized as follows: First, we highlight economic development in the long run and the contribution of human capital. Second, we review some of the basic principles of human capital theory. Then, we consider the characteristics and the evolution of the apprenticeship system and the production of books. Subsequently, we emphasize the role of different origins of demand for education. Government policy and its effectiveness are more closely analyzed in the following section. The last section considers different indicators that show the evolution of human capital during the last 200 years and the actions taken by governments in education. Finally, a conclusion sums up the lessons from the human capital transition.

Long-Run Economic Development and Human Capital

The idea that human capital may be considered as a determinant of economic development has a long history (Demeulemeester and Diebolt 2011). Smith and Marshall had already incorporated the notion of something akin to human capital in their thinking. However, the first exogenous growth models developed by Solow and Swan (Solow 1956; Swan 1956) only incorporated capital, labor, and technological progress in the aggregate production function. Subsequently, the importance of human capital was put forward in particular by Becker (1981), an important founder of human capital theory. Furthermore, Nelson and Phelps (1966) emphasized that human capital is important for implementing and adopting new technologies. Schultz (1975) argued that workers are better able to cope with changes in the economic structure and handle new technologies if they have more human capital. An extension of the original Solow-Swan model, the human capital augmented Solow model, was presented by Mankiw et al. (1992). It explicitly included human capital as a factor in the production function.

Nevertheless, the prominence of human capital's role emerged following the development of endogenous growth models. Romer's (1986) work can be seen as

the first important contribution in this field. These "new growth models" aim to endogenize the different sources that lead to growth. In this way, the growth rate is not exogenously determined (as in the Solow-Swan models) but is established within the endogenous growth model itself. The overall category of endogenous growth models can be divided into two main approaches (Aghion and Howitt 1998). The first line of thought focuses on human capital accumulation as the main driver of growth (Lucas 1988). The second approach underlines the importance of technological change for the creation of economic growth (Romer 1990). Since the original contributions by Lucas (1988) and Romer (1990), the literature has steadily been advancing (see Ang and Madsen 2011). In fact, these initial models (and models by, e.g., Segerstrom et al. 1990; Grossman and Helpman 1991; Aghion and Howitt 1992) are now considered as the first generation of endogenous growth theory models. A second generation of models takes semi-endogenous (e.g., Jones 2002) or Schumpeterian approaches (e.g., Aghion and Howitt 1998; Peretto 1998; Young 1998). The appropriateness of these new types of models is still being debated and empirically tested (e.g., Madsen 2010; Madsen et al. 2010; Ang and Madsen 2011).

While endogenous growth models have been central to human capital's prominence in economic growth theory, they are limited – in the sense that they are not able to explain the process of economic growth since the beginning of human existence (Galor 2005). A new ambitious theory has been developed aiming at understanding the growth patterns of human kind in the very long run. This unified growth theory (UGT) has particularly been advanced by Galor (e.g., Galor and Weil 2000; Galor and Moav 2002). UGT classifies economic growth in the very long run in the following way. First, a long phase of hunting and gathering was typical for human development between one million BC and 8000 BC. After the Neolithic Revolution, the Malthusian growth regime began. It was characterized by a per capita income which always fluctuated around low levels of subsistence. Accordingly, Fig. 1 shows that GDP per capita in several European countries and China was rather low and fluctuating between 1300 and the takeoff during the Industrial Revolution. Thus, the Industrial Revolution allowed the European countries to escape the Malthusian growth regime. This post-Malthusian growth regime lasted until the demographic transition in Europe around 1870. Economies and populations grew substantively during this epoch.

The final growth pattern is the modern growth regime, which has characterized the world's advanced countries from the nineteenth century onward. This regime shows an acceleration of technological progress. Moreover, human capital is increasingly demanded. Thus, UGT postulates that human capital played a crucial role in the transition from the post-Malthusian regime to modern growth. Human capital and technological progress brought about the demographic transition, which has led to lower population growth. The overall result has been high and sustainable growth in per capita output in the most advanced countries. However, not all countries have reached the modern growth regime, and some countries reached it earlier than others.

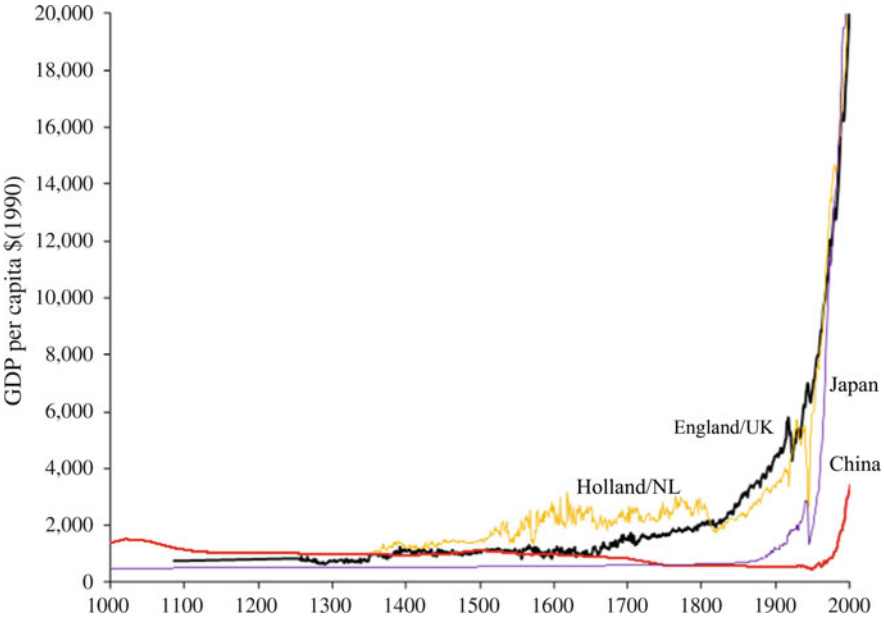

Fig. 1 GDP per capita in selected European and Asian countries, 1000–2000. (Source: Fouquet and Broadberry (2015), Bolt and van Zanden (2014))

Therefore, a Great Divergence has emerged between the most advanced countries and other countries.

These different theories show that human capital is an important driver for economic growth. Still, there has been some controversy about this issue over the last decades. In fact, Demeulemeester and Diebolt (2011) show that there have been several alternating waves of optimism and skepticism since the Second World War. The early contributions led to the consensus in the 1950s and 1960s that education makes an important contribution to economic growth. In contrast, the 1970s were characterized by skepticism in a time of economic downturn. The new important theoretical contributions of the 1990s once again reinvigorated the case for human capital. These optimistic ideas were supported by different empirical studies (e.g., Barro 1991; Mankiw et al. 1992; Barro and Lee 1993), but also more critical voices appeared, such as Benhabib and Spiegel (1994) and Pritchett (2001). However, measurement errors may account for some of these more pessimistic results (Krueger and Lindahl 2001). Thus, Sianesi and van Reenen conclude in their literature survey in 2003 that "as a whole we feel confident that there are important effects of education on growth" (Sianesi and van Reenen 2003, p. 197). Finally, more recent studies by, e.g., De La Fuente and Doménech (2006), Cohen and Soto (2007), Hanushek and Woessmann (2008), Ciccone and Papaioannou (2009), and Gennaioli et al. (2013) have further emphasized the crucial impact of human capital on growth and development.

Principles of Human Capital Theory

In the economics of education, the acquisition of human capital (through education or training) is assumed to give utility to an individual (see Brewer et al. 2010). It is an investment decision which enables an individual to obtain higher monetary returns in the future. The investment in human capital increases the knowledge and skills of an individual and thus his productivity (e.g., Schultz 1961; Becker 1964; Schultz 1971; Lucas 1988). This investment comes at an expense due to direct costs (e.g., schooling fees), foregone earnings, psychic costs related to the studies, and other related expenses. Still, the private returns of human capital acquisition can be numerous, e.g., higher earnings (Mincer 1958), a better job, and a lower probability of being unemployed. Further positive effects include a higher social status and social prestige, better health, higher social capital, higher cultural capital, and other benefits that are valued by an individual. The combined positive effects of human capital give incentives for individuals to invest in human capital to maximize their well-being during their life. Therefore, human capital theory suggests that a higher level of education is correlated with a higher level of earnings. This positive relationship has been found in many empirical studies, although the return to education can be influenced by many external factors. For example, 1 year of increased schooling gives a global average return of 10% (Psacharopoulos and Patrinos 2004).

Overall, an individual is part of a larger market which is characterized by demand for educational goods and its supply, leading to an equilibrium process whose outcomes can be observed. Thus, the consumption and investment characteristics of education make it similar to other durable goods. Thus, education cannot be described by the use of static models. In consequence, a longer-term view is inherent to the human capital concept. Therefore, the decision to invest in human capital has to be made in accordance with the expected discounted future returns and costs involved.

In addition, human capital may not only have important private returns but also significant social returns (see Lange and Topel 2006). These human capital externalities can be defined as "the sum of the private and external marginal benefits of a unit of human capital" (Lange and Topel 2006, p. 461). Human capital externalities have been analyzed from different perspectives. In particular, growth theorists such as Uzawa (1965) and Lucas (1988) have put forward the positive effects of interactions among individuals, leading to higher social than private returns of human capital. Individuals that have a higher endowment of human capital may increase the productivity of others, so that human capital accumulation leads to an increase in total factor productivity. On the other hand, it is also possible that positive externalities arise, which are not directly associated with productivity, such as lower criminality (Lochner and Moretti 2004), higher political participation (Friedman 1962), externalities connected to consumption, and higher economic growth (Sturm 1993; Hanushek and Kimko 2000; see Brewer et al. 2010).[1]

[1] In contrast, another strand of the literature suggests that there might also be negative externalities because human capital would not increase productivities but only waste valuable resources due to signaling effects (e.g. Spence 1973). However, Lange and Topel (2006) do not find important negative impacts; the positive effects largely dominate.

These social returns to human capital have been generally perceived by governments. Therefore, governments have spent an increased amount of public expenditures on education in the long run. One fundamental question that arises in this context is the allocation of these scarce resources to maximize human capital output. The state may not allocate these resources in an efficient manner because, in standard economic theory, markets provide an efficient method for allocating scarce resources. Still, it is possible that markets fail in their attributed task, so that a market failure occurs. Different reasons may lead to such a failure (Brewer et al. 2010). Firstly, it is possible that markets are not perfectly competitive. Thus, the market may become dominated by one or more agents who are able to set the prices. In the area of education, schooling markets are far from perfect. Secondly, information asymmetries may arise in a market. In particular, the quality of products or services may not always be perceivable by consumers due to a lack of information. In education, parents may not have sufficient information and may not perceive the true value of education. In addition, they may choose schools that may be socially suboptimal (e.g., preference for schools with a certain social or racial profile and not for the quality of a school). Although the market may satisfy the preferences of parents, the obtained solution may not be optimal for society as a whole. Thirdly, the existence of externalities suggests that consumption and production may have effects that are not included in prices. For example, the knowledge and learning of others can have a positive effect on an individual. Furthermore, the individual's decision to invest in education may have positive benefits but also costs for society. However, an individual does not take all of them into account when taking his investment decision. Even if the social benefits are higher than the costs, it is still possible that an individual may choose not to invest and consume a socially optimal amount of education. In this case, governments can intervene by making a certain minimum amount of education obligatory through compulsory schooling. Finally, public goods may not be sufficiently provided by markets because they are nonrival and nonexcludable. To some extent, the notion of public goods applies to education. For example, the consumption of services in the area of education does often not preclude others. A pupil obtains education together with other pupils by a teacher. Libraries give access to books to many individuals. Thus, education may not be sufficiently supplied in a perfectly competitive market, as is the case with other public goods.[2] For this reason, this has led to the "widespread belief that the market for educational services fails when left to its own devices" (Johnes 1993, p. 14).

Therefore, governments have intervened to avoid the consequences of market failures in this area. They have regulated the education sector, taken an important share of the financial burden, and operated education facilities. This involvement of the state may have led to suboptimal educational outcomes in some areas.[3] However,

[2]In addition, the assumption of perfect competitive markets implies that capital markets should be perfectly functioning. In this case, parents should always be able to find a way of financing the education of their children. This, however, is not the case either (Johnes 1993).

[3]For example, the existence of public schools may have led to a monopoly of these schools in certain geographical areas. Taking the point of view of the market, schools may thus not have been under market pressure to ensure quality standards and low operating costs. Some recent reforms have been aimed at improving the status quo and in part reorganizing the involvement of the state in this sector (Brewer et al. 2010).

the aim of the state may not always have been to maximize human capital levels. Schooling is never neutral but is a process of socialization that produces beliefs alongside human capital. Therefore, authors of the so-called class-conflict model suggest that there is a struggle between different classes of society in the area of education. The dominating elites of a country are assumed to use formal schooling to impose their social, cultural, and economic values and structures on other parts of society (Bowles and Gintis 1976; Carnoy and Levin 1985; Fuller and Rubinson 1992). Taking a more positive interpretation, one could also argue that "public schooling can promote social cohesion among disparate social groups and alleviate ethnic tensions by providing a core set of common norms that foster trust and promote interaction among individuals" (Gradstein et al. 2005, p. 5).

More generally, governments would not need to produce schooling but could sponsor the private sector to provide schooling. The simple production of skills could be contracted out, and private schools could be subsidized by the use of vouchers or mandates. Yet a government would not be able to control (cultural and ideological) beliefs, and private institutions (e.g., particular religious and social groups) could produce beliefs at school that could challenge the government and the political system.[4] Furthermore, egalitarian principles have given the state the moral responsibility to provide schooling to ensure that all children obtain a certain minimum level of education so that every child could have equal opportunities in later life. However, the external monitoring of schools is costly and difficult to implement effectively for the state. Therefore, it is argued that given the socializing and equalizing aspects inherent to education, a government needs to produce schooling in a direct way at arm's length (Pritchett 2003; Gradstein et al. 2005).

In addition, it should be mentioned that there are different types of schools and forms of training. More generally, according to Johnes (1993) one can distinguish between general and specific human capital. General human capital can be defined as skills and knowledge that can be used in any work context and increase the productivity of an individual. General human capital can take the form of skills such as numeracy and literacy. On the other hand, specific human capital can only be used in a specific work context to increase an individuals' productivity. For example, some of the specific skills of craftsmen could not be used in other professions. Similarly, if an individual works for a monopsonist, it cannot transfer its skills obtained through training to another employer either.

[4]For example, Milton Friedman also suggests that "a stable and democratic society is impossible without a minimum degree of literacy and knowledge on the part of most citizens and without widespread acceptance of some common set of values. Education can contribute to both" (Friedman 1962, p. 86; in Gradstein et al. 2005, p. 5). He further argues that "the major problem in the United States in the 19th and early twentieth century was not to promote diversity but to create the core of common values essential to a stable society… Immigrants were flooding the United States… speaking different languages and observing diverse customs … The public school had an important function in this task, not least by imposing English as a common language" (Friedman 1962, p. 96, in Gradstein et al. 2005, p. 9).

More generally, investments in human capital can occur (in the terminology of Becker 1993) in the form of on-the-job training in firms (distinguishing general and specific training analogously to the presentation above), schooling, information, and health.[5] Schools are considered to be specialized institutes that produce training, whereas firms additionally produce goods. Therefore, Becker argues that firms and schools are in many instances "substitute sources of particular skills. This substitution is evidenced by the shift over time, for instance, in law from apprenticeships in law firms to law schools and in engineering from on-the-job experience to engineering schools. [. . .] [T]here are complementary elements between learning and work and learning and time" (Becker 1993, p. 51). The level of complementarity depends partly on the quantity of formalized knowledge that is available. In some cases, schools can thus be treated as a special form of firms. Therefore, the effects of schooling (as mentioned above) are identical to those of general training.

In addition, there are still other possibilities than on-the-job training and schooling to accumulate human capital and increase one's productivity. These are particularly related to the investment in information. For example, more information about wages and employment possibilities may positively affect the future earnings of an employee. Thus, increased information and knowledge about the economic, social, and political system might increase productivity and incomes.

Finally, investments in health may also lead to improved productivity. Physical and emotional health has significant effects on earnings. While throughout most of history (and still today in some countries) physical strength has been an important factor for expected earnings (at least for an important share of the population), knowledge and skills have replaced physical strength in more developed countries. Similarly, emotional health has important effects on productivity and output (see e.g., Layard 2005).

Traditional Education and Skills Transmission

Apprenticeships

The transmission of technical skills from generation to generation has been central to maintaining productivity levels over centuries, and the transmission of new skills (often in conjunction with new technologies) spatially has been key to raising productivity levels from one decade to the next. Apprenticeships had been the most important source of training and technical knowledge acquisition for many centuries (Epstein 2004). In England, for instance, "domestic, agricultural or industrial apprentices and live-in servants made up 15–20% of the adult male population

[5]According to Sweetland (1996), the area of education can be further broken down: "[t]here is formalized education at primary, secondary, and higher levels (Cohn and Geske 1990), informal education at home and at work (Schultz 1981), on-the-job training and apprenticeships (Mincer 1974), and specialized vocational education at secondary and higher levels (Corazzini 1967)" (Sweetland 1996, p. 341).

in early modern England" (Humphries 2006, p. 79, referring to Stone 1966). "In the late sixteenth and seventeenth centuries roughly two-thirds of the English male labor force had at one time or another been apprenticed in one of the greater cities, primarily London" (Epstein 1998, p. 707; see Rappaport 1989). Even in the eighteenth century, apprentices in the nonagricultural sectors accounted for between 7.5% and 10% of the total labor force (Humphries 2006; Wallis 2008).

The apprenticeship was a contract (of between 3 and 7 years depending on the craft and the country (Epstein 1998; Wallis 2008)) between a master and his "student." Without a contract guaranteeing some return on the investment, few tradesmen would have been willing to share their skills with young men who were likely to leave once the training was complete and work for higher pay.

In addition, from the seventeenth century, masters required apprentices to pay an upfront premium. In eighteenth-century England, premiums were typically between 5 and 10 pounds (roughly £(2000)500 and £(2000)1,000) in the trades and about 50 pounds (£(2000)5,000) in the professional sector (Minns and Wallis 2013). In addition to the nature of the craft and prestige of the guild, premiums also varied according to family connections, experience, expected future income, and other factors that gave signals about the probability of attrition and the level of productivity of the apprentice.

The premium amounted to close to 1 year of a craftsman's salary, and the apprentice generally depended on financial help from parents and the wider family. For instance, it would take a youth 2 years of work in the agricultural sector to earn 5 pounds. Although a premium had to be paid in many instances, the apprentice received accommodation, boarding and subsistence wages (around 5 pounds per year in the eighteenth century), and a training. This training also offered important informal connections to colleagues and potential clients who might help recover the very expensive setup costs of one's own shop, which was often 10–20 times the initial cost of a premium (Campbell 1747, in Minns and Wallis 2013).

The Role of Guilds

Apprenticeships had their roots in the craft guilds, which began to exist from the eleventh century (Lauterbach 1994; Epstein 2004) – although the degree of control over apprenticeships by guilds varied and was greater in many German regions than in England. Apprenticeships were mostly left to the private decisions of masters and apprentices in some parts of Spain and France (Wallis 2008). The guilds were associations of craftsmen with tight regulations, creating conditions similar to cartels. They had many functions; in particular, they "supervised job performance, work conditions, and quality of instruction; enforced contracts through compulsory membership, statutory penalties, and blackballing; and protected apprentices against poor training in craft-specific skills within oligopsonistic labor markets" (Epstein 2004, p. 382). Most guilds sought to limit the poaching of trained apprentices among workshops, protect the apprentices from excessive abuse, and, therefore, promote proper training (Epstein 1998, pp. 691–692). By the sixteenth century, a national system of technical training was being introduced in England (Humphries 2006,

p. 75). Thus, along with their other roles, guilds were influential in the production of knowledge in the form of human capital.

Guilds provided an information pool and network for a particular supply of skills across regions. Although these networks were limited and far from efficient, the distribution of information helped signal changes in the demand for the skills and, therefore, provide a supply, if necessary (Epstein 1998, p. 694). Searchers wandered the country assessing practices and demands. Journeymen, either as part of a guild or as independents, travelled the country to provide their skills. In other words, the guilds acted as a means of disseminating knowledge (in the form of human capital) throughout the economy.

In fact, many of the European rulers tried to attract these skilled workers to their cities since the Middle Ages, and particularly during the times of the Renaissance and following the Reformation, especially if they were coming from the enemy. This development found a peak when mercantilist states and guilds tried to inhibit the emigration of skilled workers from the 1650s onward. However, these attempts were mostly unsuccessful due to the lack of administrative capacities and the incentives provided by other states (Harris 1998). Thus, Epstein believes that "technological leadership moved over time from southern to northwestern Europe [. . .] largely thanks to skilled migrants" (Epstein 2004, p. 385).

Apart from the opposition of governments and guilds, other factors contributed to the limitations of technical knowledge transfer: trade secrecy, information costs, transport costs, and the nonexistence of a sufficiently high skills base, which made it difficult to locally integrate the knowledge and inventions of migrants. However, where this knowledge base was sufficiently high, the accumulated knowledge of a country transferred by skilled migrants could be combined with the local knowledge, often giving a technological lead to this country. Information costs and transport costs were lowered due to urbanization and state competition over time, making it easier for technologies to diffuse (Epstein 2004).

Guilds have frequently been associated with stifling innovation. At times, they were probably a powerful force in encouraging knowledge to be embodied in human rather than physical capital. Yet, they were also responsible for the invention and diffusion of others. Evidence suggests that, in the face of growing competition and expanding markets, the guilds' barrier to technological innovation declined after the later Middle Ages (Epstein 1998 p. 694). Furthermore, craft guilds did "increase the supply of technology in three ways: by establishing a favourable environment for technical change; by promoting technical specialization through training and technical recombination through artisan mobility; and by providing inventors with monopoly rents" (Epstein 1998, p. 701).[6] Thus, Esptein (1998, p. 704) concludes, somewhat controversially (as more evidence is probably needed to conclude fully),

[6]An interesting question is whether there were also incentives for inventing technologies to sidestep the guilds. Epstein mentions that inventors had an incentive to keep their inventions secret from the guild. Yet, "although technical secrets were often kept within the craftsman's family, it is unlikely that significant breakthroughs could withstand a guild's scrutiny for long. On the other hand, an inventor had to weigh the guild's offer of a temporary quasi-monopoly rent against the possibility of obtaining a one-off royalty (net of migration costs) from a rival craft or government" (1998 p. 704).

the two opposing forces of a monopolistic support system for invention and of the demand for ever-wider competitive markets in skilled labor provided a healthy source of technological innovation and diffusion.

Yet the government increasingly saw the need to intervene in the transmission of these skills. A new structure was set up that defined the legal framework and regulated the apprenticeship training system. For instance, the guilds were formally abolished by decree in Prussia in 1869 – more generally, the state saw the guilds as a competing institution for power (Smits and Stromback 2001; Epstein 2004). Although the guilds may have formally been abolished, Smits and Stromback (2001) argue that they were only "transformed into the Chambers of Crafts and retained substantial control over the apprenticeship system" in Germany (Smits and Stromback 2001, p. 17). Therefore, the organization and ways of training were not determined by the state but were left to the self-administering chambers. In Germany, it may have been a "managed transformation of the highly restrictive guild system to a regulatory regime that allowed industrialisation to proceed" (Smits and Stromback 2001, p. 17).

The Decline of Apprenticeships

While the apprenticeship system and occupational skills played an important role before and during the Industrial Revolution (Mokyr 2009; Minns and Wallis 2013), the social changes it caused brought about a crisis in apprenticeship training during the late 18th and nineteenth century (Lauterbach 1994), arguing that, at least in Germany, the quality of apprenticeship training was being neglected. Meanwhile, the duration of apprenticeships in England fell to 4 years in the late eighteenth century (Wallis 2008).[7]

Structural shifts altered the demand for human capital during the Industrial Revolution (Weedon 2003, p. 62). Zeira (2009 p.63) argues that "industrialization changed the type of human capital required for production. While prior to the industrial revolution human capital was mainly specific to the profession, the industrial revolution created demand for more general human capital, which included the ability to read, to write, and to perform calculations. Hence, while the apprenticeship system could provide most of the required human capital prior to the industrial revolution, following it there was increasing demand for people who have a much broader and flexible human capital, which can be acquired only at schools." Similarly, Collins and Halverson (2010, p. 23) add that "[a]fter the Industrial Revolution, schools stressed the learning of basic skills that children would need to function as intelligent citizens and workers and on the knowledge in the different

[7]A comment from the early 1960s, after the decline in this form of training, summarizes what happened: "apprenticeship has all but disappeared, partly because it is now inefficient and partly because schools now perform many of its functions. Its disappearance has been hastened no doubt by the difficulty of enforcing apprenticeship agreements. Legally they have come to smack of indentured service" (Schultz 1961, p. 10).

disciplines." Thus, the apprenticeship partly lost its role because there was a changing demand for human capital.

Its decline was also partly due to changes in the supply of other forms of education. In principle, dissemination of this specialized technical knowledge could take different forms: through printed media, patents, or migrants. Epstein (2004) argues that, especially early on, texts were not a very successful method for the dissemination of specialized technical knowledge because the manuals were often incomplete and did not include some of the essential information to actually put a new technique into practice. Yet the costs of written education changed over time. In comparison with schooling, an apprenticeship was a much more expensive alternative. Minns and Wallis (2013) estimate that schooling costs were about 1 pound per year in the eighteenth century.[8] Eventually, in the eighteenth century, books on craft skills became the third most important category of books (the first being religion and the second being law), highlighting the increased importance of reading skills for tradesmen and craftsmen (Cook 2006).

Catalyzing the Human Capital Transition

The Gutenberg Revolution

Critical to the transformation of education in Europe was its ability to reduce the price of books and the written word. Before the invention of the printing press, book production involved the production of handwritten manuscripts. In addition to other costs, this was a very time-consuming exercise, as Clark (2007) illustrates (see also Clark and Levin 2001): Copyists were able to copy 3,000 words (of plaintext) per day, implying that one copy of the Bible took 126 man-days (Clark 2007). Because the copying of a text by hand needed more space than printing it, the area needed per word was also two times greater, further increasing the costs of the employed materials (Clark 2007). For this reason, books cost more than 1 year's salary for an average man and were, therefore, luxury goods (van Zanden 2009a).

Nevertheless, the supply and the demand of manuscripts were promoted by the growth of monastic institutions from the sixth century (see Fig. 2). Additional demand came from the growth of cities throughout Europe between the 12th and 15th centuries. Cities were characterized by an ever more elaborate division of labor, and they generated economic and military demands for individuals who were able to keep records, were trained in administration, and were able to communicate properly. Bureaucracy expanded continuously, and the oral tradition was slowly replaced

[8]They estimate this number in the following way: "Assuming that youths would earn a rising fraction of adult income with age (20% at age 14, 40% at age 15, 60% at age 16, 70% at age 17, 80% at age 18, 90% at age 19, and [100]% at age 20 – see Van Zanden (2009b), p. 160), a provincial adult unskilled wage of 1 s per day, that youths work 228 days per year (Voth 2001), and a discount rate of 7.5%, the present value of lost earnings during an apprenticeship, relative to a subsistence income of £5 per annum, was about 26 pounds" (Minns and Wallis 2013, p. 344).

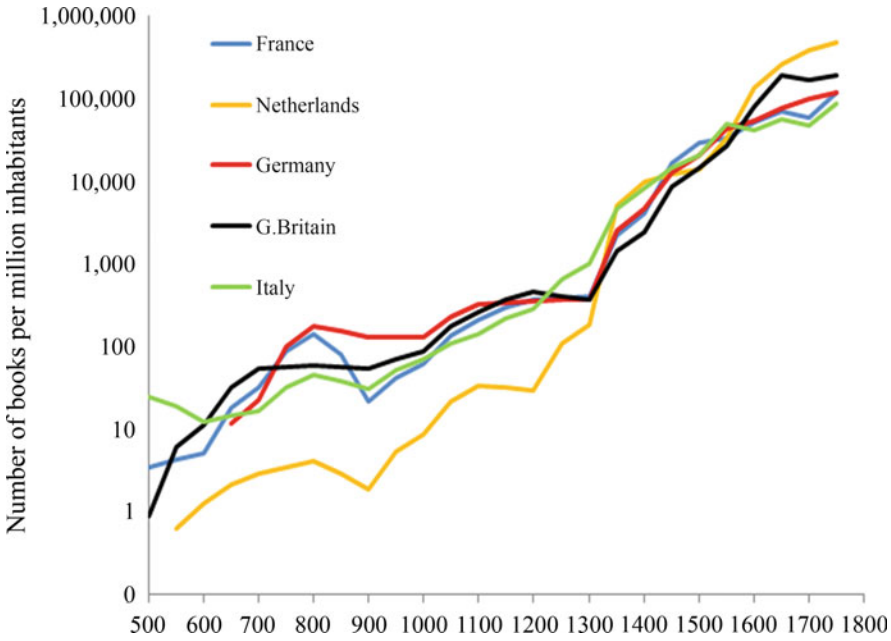

Fig. 2 Book production in Western Europe (per million inhabitants), 500–1750. (Source: Derived from Buringh and van Zanden (2009))

by the written word. For this reason more young people began to learn to read. In addition, universities were established for the purpose of advanced training and in turn created further demand for themselves (Venezky 1996, see also Hippe 2013a). In addition, the price of book materials was also lowered by economies of scale and learning effects associated with the increased use of paper (van Zanden 2009a). As a result of rising demand and declining costs, manuscript production increased until the eve of the invention of the printing press (see Fig. 2). It is estimated that more than 10,000 copyists worked in manuscript production in Paris and Orléans alone shortly before Gutenberg's printing press (Chassant 1846).

The invention of the printing press by Johannes Gutenberg in Mainz between 1446 and 1450 was, then, partly stimulated by this ongoing and increasing demand for written documents. In fact, Gutenberg was not the only one who tried to improve the existing manuscript production system. Different methods had been explored, including xylography and tabular printing. However, Gutenberg's printing press proved to be superior in quality and lower in cost for the production of books (Guellec 2004). Therefore, the printing press was not invented by accident but after many years of diligent pursuit carried out by Gutenberg.[9]

[9]In fact, the printing press was first invented in Korea. For more details, see Hippe (2015).

The fact that the printing press was invented in Mainz is itself not so much accidental, as the city was part of the Rhine valley, which was quite industrialized for its time and specialized particularly in metallurgy. In consequence, the broad timing of the printing press was the outcome of the several mentioned demand factors. These factors were again conditioned by the availability of paper in Europe in general, and in Germany in particular. Furthermore, the growing market made the development of the printing press increasingly competitive relative to manuscript production (Guellec 2004).

The printing press fundamentally changed the world of book production and knowledge diffusion. It enabled a much faster and less costly production of books. Cuijpers (1998) indicates that printed books were about 50–80% cheaper than their handwritten homologues in the 1460s. Furthermore, the printing press was a technology which was skill and capital intensive. Therefore, this high-tech innovation corresponded perfectly to the needs of the European economy, which was characterized by high labor costs (in contrast, e.g., to the Chinese economy) (van Zanden 2009a). Thus, the new technology spread quickly throughout Europe.

The spread of the printing press allowed a spectacular increase of book production, knowledge diffusion, and human capital accumulation. In the earliest centuries presented here (500–700), overall book production in Europe was restricted to only 12,000 manuscripts written every century, whereas in the eighteenth century, the number increased to more than 1,000,000,000 books (Buringh and van Zanden 2009). The decisive massive increase in book production clearly occurred during the period after the printing press was invented. The data show that more books (and manuscripts) were produced in Europe in the second half of the fifteenth century than in the entire 1000 years before the invention of the printing press. This radical change in the production of knowledge is also highlighted by the fundamental decrease in the price of books. The fall in book prices had the effect that a literate person was able to consume more books, which in turn increased the incentive (and reduced the cost) to learn to read. Furthermore, the increased output of books itself created economies of scale, lowering book production costs even further and leading to higher price reductions. Van Zanden (2009a) estimates the real price of books (i.e., deflating the book price by a cost of living index) for the Netherlands between 1460 and 1800 (see Fig. 3).

The dramatic fall in the real price of books is more than evident. Van Zanden (2009a, referring to Cuijpers 1998) illustrates this change by using the Gutenberg Bible as a point of reference. An original copy of the Gutenberg Bible was sold at a rate of about an annual wage gained by a laborer. A Bible of comparable quality could be obtained for a price of less than 12 days of a carpenter's wage before the end of the eighteenth century (and lower quality bibles were also available at prices equivalent to a daily wage).[10] Thus, van Zanden concludes that "within the span of one generation –

[10]This fall in prices also had a major impact on the spread of the ideas of Protestantism. For example, Luther's translation of the New Testament in 1522 was affordable even to laborers (Stöber 2004).

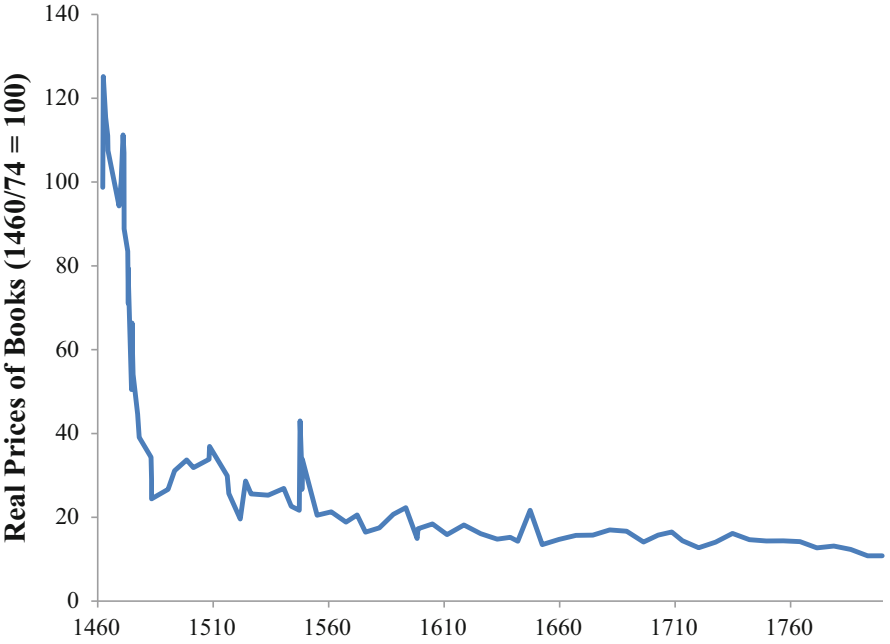

Fig. 3 Estimates of real prices of books in the Netherlands (1460/74 = 100), 1460–1800. (Source: Van Zanden (2009a))

from 1455 to 1485 – book prices may have declined (in real terms) by 85–90%, a revolution in the price of communication comparable to current developments in ICT [Information and Communication Technology]" (van Zanden 2009a, p. 182).[11]

Early Private Demand for Books and Literacy

Clearly, the dramatic decline in book prices following the diffusion of the Gutenberg Press was crucial to increasing the spread of the written word. At the beginning of the sixteenth century, literacy rates in most European countries were below 10%, possibly below 1% in German states (Engelsing 1973; Becker and Woessmann 2008). Then, over the next three centuries, particularly in North-Western Europe, such as the German states, Holland, Sweden, and England, greater access to books enabled literacy rates to increase (see Fig. 4 for England). However, literacy rates would not have reached 50% in the second half of the eighteenth century without a strong demand to read (Mitch 1992b).

[11]Similarly, Clark (2004, p. 8) calculates that "the estimated price of a standard page of text in the middle ages was 50 times the price in 1700–59."

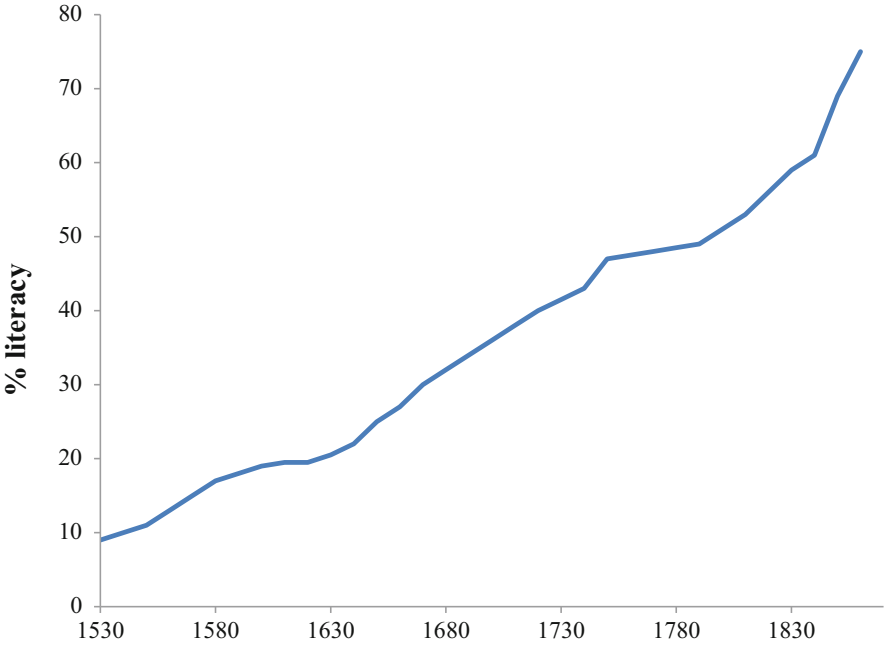

Fig. 4 Literacy in England, 1530–1870. (Source: Cressy (1980))

In fact, demand for literacy, numeracy, and a general education stemmed from many different private and social or public sources (e.g., Cipolla 1969; Fuller and Rubinson 1992; Mitch 1992a; Galor 2011). Commercial demand (i.e., coming from the trade sector), spiritual demand (from the Churches), military demand (to create a more efficient army), industrial demand (e.g., to increase labor productivity), parental demand (e.g., to improve the prospects of the future career of their children), status demand (to distinguish oneself as part of an elite), and "belief-formation" demand (to increase social control and advance nation building) were all private or social drivers to invest in education.

Mitch (1992b) has emphasized that early advances in literacy levels were brought about by private demand, rather than any direct actions by the state. "[T]he success of printing should probably be connected with more general changes in society. The end of the Middle Ages was marked by the rise of the bourgeoisie. Now that it controlled new economic and commercial sectors, the middle class intended to participate in political decisions that concerned them as well, and it signalled its social success by paying more attention to culture, which it adapted to its own interests" (Gilmont 1999, p. 215). Indeed, the percentage of households owning books increases from one in ten in 1560, one in four in 1580, and one in three in 1590 to nearly one in two by 1620 (Morgan 1997, p. 14). Similarly, the average size of personal libraries grew (Gilmont 1999). Increases in book collections offer an insight into the different income elasticities among different professions and social status.

"Between 1500 and 1525 the average physician's collection increased from 26 to 62 books; the average jurist's from 25 to 55; the average merchant's from four to ten and the average artisan's from one to four" (Morgan 1997, pp. 13–14).

Basic education in the form of literacy or numeracy had become increasingly important in economic affairs throughout history. Cook (2006, p. 71) suggests that "one of the earliest exceptions to the exclusion of literacy to all but social elites was its appearance among the trades," in particular due to the need of record keeping. For example, reading and writing ability became a prerequisite to obtaining an apprenticeship with English goldsmiths in 1478 (Anderson 1965; Venezky 1996). Increasing urbanization led to an economic environment that demanded more bookkeepers, administrators, and clerks, and more sophisticated forms of bureaucracy. More generally, "[l]iteracy continued [. . .] to be driven by practical utility, appearing first and to the highest degree in those trades most closely associated with the market economy (Thomas 1986), and in areas where new technologies were forcing change, such as navigation and warfare" (Venezky 1996, p. 59).

Meanwhile, demand for spiritual guidance, and the associated religious competition, was crucial ingredient for the explosion of printed works, particularly from the early sixteenth century. As already mentioned, the increasing number of monasteries throughout Europe during the Middle Ages reflected the growth in the supply of and demand for spiritual guidance.

With the cheaper costs of printing, Luther could dare to propose that everybody should be able to read the bible. Given that fewer than one German in one hundred was able to read at that time, his ambition must have seemed just a utopian vision (Engelsing 1973, Becker and Woessmann 2008). However, it is important to remember that for the first 70 years after the invention of the printing press, around 1450, the Bible had been printed in Latin. Most people did not read, but it made it harder to learn to read when the Bible was in Latin. Although translations had existed before (into Old French, Spanish, Catalan, and German in the thirteenth century and the Wycliffe Bible into English in 1383), these were usually banned and as a result were very hard to access and extremely expensive (Biller and Hudson 1996). The first printed non-Latin Bible was into Greek by Erasmus in 1516. However, it was Luther's translation into German of Erasmus' Greek Bible in 1521 that made the Bible accessible and at a low cost, electrifying the book market (see Fig. 5). In 1526, a Dutch Bible was printed; another German Bible was out of Zurich in 1530, in Italian in 1532, and in French in 1535 (Gilmont 1999). As a consequence, one of the most powerful drivers of European demand for books from the 1520s onward was the translation of the Bible into European languages.

Early Spiritual Demands for Mass Education

With the aim of ensuring that all should read the Bible, Luther argued for the establishment of compulsory schools and claimed that local rulers were responsible for their establishment. This would have effectively implied a shift of instruction from religious to secular authorities. In consequence, a range of ordinances

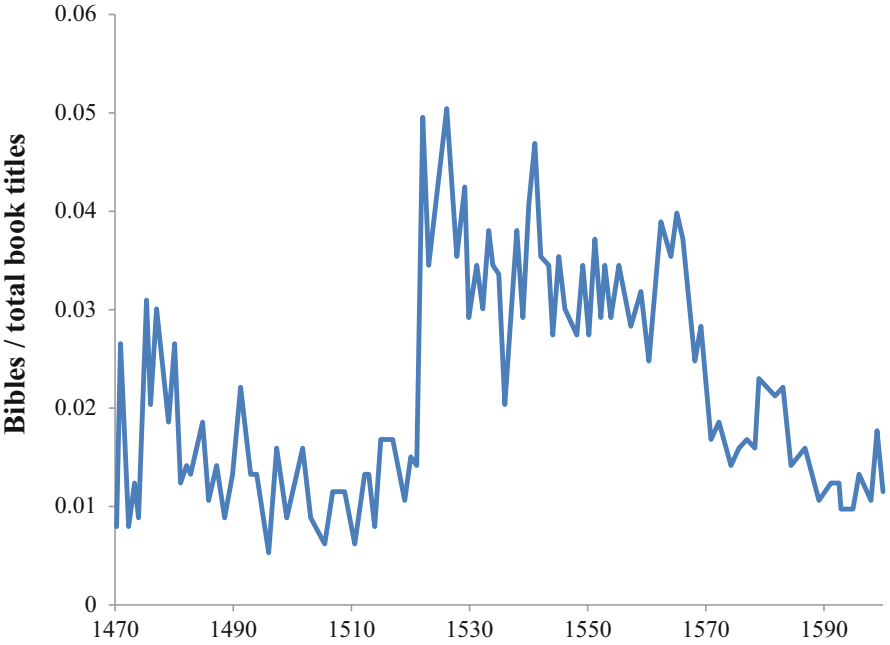

Fig. 5 Share of bibles in total book output in Europe, 1470–1600. (Source: Dittmar (2013))

that promoted schooling were passed in Protestant territories and their implementation was controlled (Becker and Woessmann 2009). For example, a first landmark church order was passed in Braunschweig in 1528, supporting the creation of new schools and defining the school curricula. It was soon followed by others (e.g., Saxony in 1557, Württemberg in 1559, Lüneburg 1564) (Green 1979). Yet Luther's preaching did not lead to universal mass schooling (Stone 1969; Ramirez and Ventraensca 1992).

Luther also urged parents to value the education of their children and send them to school. For example, he writes that "I see that the common people are dismissive to maintaining the schools and that they withdraw their children from instruction altogether and turn solely to the care for food and bellies, and besides they either will not or cannot consider what a horrible and un-Christian thing they are doing and what great and murderous harm they are doing everywhere in so serving the devil" (Luther 1909, p. 526, as cited in Becker and Woessmann 2009, p. 541). Thus, Luther's insistence over moral obligations might have altered the beliefs of parents and rulers about the benefits of educating children (Becker and Woessmann 2009).

At first, the Catholic Church attempted to ban Bible translations. Similarly, the state sought to censor publications. Henry VIII's experience highlights the difficulties of introducing policies to control information production and dissemination. In the early sixteenth century most publications read in England were printed on the continent. Following Henry VIII's break with the Catholic Church, Luther's

sympathizers were frustrated by Henry's lack of theological reforms and "bombarded England with highly aggressive pamphlets printed in Antwerp" (Gilmont 1999, p. 216). Unable to censor these publications, Henry VIII encouraged printers to be set up in England, which they did over the next two decades, and thus, he was better able to police their activities (Gilmont 1999).

Although the Catholic Church's Counter-Reformation[12] tried to undo many of Luther's teachings, it eventually embraced the ideal of improving literacy levels and the concept of schooling (Ramirez and Ventraensca 1992). Religious competition,[13] and the threat of losing an even greater share of the "market for spiritual and moral guidance," may have been an important factor. "In the face of Protestant competition, religious and secular authorities in Catholic areas also increased their efforts to provide popular schooling; it is notable that the parts of Europe where schooling lagged most seriously were those, like Spain and Italy, where the Counter-Reformation triumphed completely and eliminated religious competition" (Glenn 2012, p. 140).

Overall, the churches played a major role in the supply of schooling for the next 300 years. Their importance only declined with the rise of the national state. In the nineteenth century, religious authorities feared that state-provided education would be secular and educational content not in line with their own views (Boli 1992). This was the case of the Catholic Church in France. In France enrollment was relatively widespread before the central state developed a modern organized entity (Archer 1979) because the Catholic Church was interested in controlling the socialization of children. Later competition with the state further increased French schooling (Fuller and Rubinson 1992). Thus, enrollment rates of children were about one-third in the 1830s and reached 80% by the 1880s (see Galor 2011).

In other locations, particularly in Protestant regions, the state worked together with the Church. In particular, the early worldwide leader in reading, Sweden, passed a Church law in the seventeenth century with the intention of spreading literacy due to religious motivations. Thus, Venezky argues that "reading ability was pressed on the population by church and state [. . .] through regular parish examinations, fines for parents who failed to teach their children and denial of Communion and marriage rights to those adults who could not read and recite the catechism" leading to almost universal reading ability in the population until 1750

[12]See Ekelund et al. (2002) for an economic interpretation of the Protestant reformation and Ekelund et al. (2004) for an exploration of the economics of the Counter-Reformation.

[13]The question whether religious competition leads to more or less religious participation by individuals is still disputed. On the one hand, it is argued that the existence of various religions leads to a decrease in the plausibility of a given religion and thus less religious participation (Chaves and Gorski 2001). On the other hand, authors such as Adam Smith suggest that a non-state-sponsored religious group has to provide special care for its believers, raising the quality of and participation rate in religious activities (Iannaccone et al. 1997). For more information, see Höhener and Schaltegger (2012).

(Venezky 1996, p. 48). Similarly, the state cooperated with the Lutheran Church in Prussia (Soysal and Strang 1989).[14]

In general, where the state was weak, it had to rely more on the infrastructure of the Church, giving the Church more power and influence (Vincent 2000). The USA is another example where enrollment rates were high in the presence of a relatively weak central state. Meyer (1989) proposes that this fact can be explained by a particular faith in schooling and literacy (due to Protestantism) and its positive effects on nation building. These ideas originated in Britain and were spread to America. Once again, spiritual demand had been an important driver of education.

Demand for Education

The Pros and Cons of Mass Education

Although some early reformers had promoted mass education, formal schooling was not widespread before 1800. Instead, most education was provided in more informal settings. The diversity of opportunities to become literate is highlighted by Cipolla (1969), making reference to Rashin's (1958) study. Still, in 1883–1884, the study shows that in a province of Moscow, Russian Empire, the distribution of 7,123 factory workers with the capacity of reading according to the source of their education is that 38% became literate in their village, town, or district schools, 36% outside school, 10% in factory schools, 9% with clergy, and 7% during military service (Rashin 1958).

Mitch (1992b, referring to Briggs 1978; Mitch 1982) claims that fees for private schools at the elementary level were at levels that working-class families could afford in many European countries between the 16th and nineteenth century. He further argues that private instruction could then have achieved universal literacy without the state.

Yet different classes tended to have different demands for education. Whereas the middle class sought secondary or tertiary education for their children to move up the social ladder, workers might not seek education beyond the primary level because they failed to see the benefits of education. In this way educational differences among the classes, and perhaps also regions of countries, were exacerbated, and access to higher status jobs was often limited to particular groups of society, hindering mobility between social classes.

This point illustrates that the ruling elites in many countries were wary of the threat that more education posed to their political, economic, and social position. These elites feared that education would make the workers despise their lot in life, a

[14]More generally, the authors see the values in formal education close to those of Protestantism, as highlighted by Weber (1958): "formal education's emphasis on individual socialization and achievement parallels the Protestant emphasis on the individual's unmediated relation to God and individual salvation" (Soysal and Strang 1989, p. 279).

life that had been assigned to them "by nature." Therefore, education was perceived by some to lead them to seek more rights and make them more prone to resist domination (Graff 1991; Lindert 2004).

Despite these upper-class fears, there had been a growing demand for mass education for military and industrial reasons. Indeed, supporters of military conscription had particular interest in mass schooling. In fact, there had been an important demand for gunners in the sixteenth century (Cipolla 1969). Because gunners had to be literate to perform their profession, a number of European governments created specialized schools for their education. There they learned to read, write, and calculate, as well as some basics in ballistics. Sweden had promoted mass schooling for instilling national loyalty, teaching discipline, and lessening social tensions among the population, and their leaders found that literate soldiers were also considered much more effective in warfare (Malmström 1813). Similarly, Napoleon was aware of this fact and promoted the education of his recruits. Later on, his enemies used this insight to create an educated army (Vincent 2000). For instance, defeated Prussia successfully reformed its education system. This may have been one of the reasons Prussia (and the other German states) won the Franco-German War in 1870. "[I]n 1870 there were more than 20 per cent illiterates among the recruits of the French army while there were only about 3 per cent among those of the Prussian army [. . .]. As the French remarked at the time: Sedan est la victoire du maître d'école allemande" (Cipolla 1969, pp. 23–24, see also Fourrier 1965). Cipolla states that "[s]ocieties which produced an increasing number of literate soldiers had a decisive advantage over those that failed to do so" (Cipolla 1969, p. 23). Accordingly, Vincent notes that "[a]s Europe prepared for war, most of the potential combatants had ensured that their recruits would be able to read the instructions on their weapons and write back to their families" (Vincent 2000, p. 10). In other words, military objectives played a role in the provision of education by the state in the nineteenth century.

Books in the Industrial Revolution

The basic technology did not significantly change after Gutenberg until the nineteenth century (Chappell 1970). Afterward, the Industrial Revolution had a dramatic impact on the supply of printed materials. Steam power began to be used in the pressing process as early as 1810. At the same time, the first successful attempts were made with machine-produced (pulp fiber) paper, and machines for mass production entered the market in the 1840s. Further advances in paper production and in printing machines (in particular the linotype) immensely cut time and capital costs in printing in the second part of the century (Cook 2006). These changes had their effects on the number of published titles.

Weedon analyzes England over the period 1836–1916 in more detail. He concludes that the time between 1846 and 1916 "saw a fourfold increase in production and a halving of book prices" (Weedon 2003, p. 57, see also Fig. 4).

What were the determinants of these important changes in book and print production in the nineteenth century? Weedon suggests that technological transformations were essential in the process. She emphasizes that paper, an essential part of the production costs of a book, could now be produced by the use of machines. The cost of paper fell by about two-thirds between 1866 and 1896, making book production much cheaper.

Even more spectacular increases were recorded for the newspaper industry. Cipolla (1969) highlights that "in the United Kingdom in 1831, the average monthly issue of the newspaper press amounted to about 3,240,000 copies (equivalent to about 137 copies per 1,000 inhabitants). By 1882 it had gone up to 135 million (about 3,700 copies per 1,000 inhabitants) (Cipolla 1969, p. 107)."[15] To put UK newspaper circulation in perspective, Murch (1870) states that about 38,648,000 copies were in circulation in 1831, which increased to 546,059,000 copies in 1864 (i.e., an increase of 1,313%). Not only were more newspapers printed, but the cost of newspaper production decreased. For example, the price of newsprint fell by a factor of ten between the 1860s and 1890s (Cook 2006). In other words, steam power was revolutionizing all forms of print media.

Industrial Demands for Education

The industrial demand for literacy was slower to develop. In the first phase of the Industrial Revolution, industrial demand for skilled labor was rather limited (Galor 2011). Some factory workers needed to be literate and numerate, but most processes were still handled by illiterate workers (Landes 1969, in Galor 2011). Furthermore, the developing factory system increased the opportunity costs of education for young children because they could be employed in factories (Cipolla 1980; Venezky 1996), leading to stagnating educational levels. The evidence to date finds little importance for the role of formal education in the Industrial Revolution in Britain (Mitch 1999).

However, Becker et al. (2011) identify an important role for education in Prussia's industrialization catch-up during the second half of the twentieth century. Furthermore, industrial modernization led to the need for skilled labor and created demand in the second phase of the Industrial Revolution (Galor and Weil 2000; Galor 2011). Certainly by the second half of the nineteenth century, industrialists identified a growing need for workers to be educated in order to effectively use the machines.

Human capital became more important in the process of production because it was complementary to (physical) capital and technological progress. Labor productivity was also higher for skilled individuals (Galor et al. 2009; Galor 2011). In addition, educated individuals were considered to be more easily adaptable to

[15]Numbers from France emphasize the stark increase in newspaper production: "[i]n 1840 the monthly issue of all the Paris journals totalled less than three million copies. By 1882 it was up to 44 million copies (Cipolla 1969, p. 107)."

technological change and open to new arriving ideas (Cipolla 1969). Technological progress was advancing quickly during this period, and thus the corresponding demand for human capital took off. Therefore, Zeira argues that "[b]oth the mechanization of production and the increase in the scale of production changed dramatically the whole character of producing and marketing. It now required new skills, of reading, writing, and arithmetic. The need to handle and operate machines and to take care of them required some knowledge in science and engineering and at least some literacy skills, to read manuals, to correspond with producers on problems in machines, etc." (Zeira 2009, p. 602).

Mitch (1992a) estimates that a literate worker gained about 13% more than an illiterate one around 1870. The increasing opportunities for members of the lower classes to enter into competition for higher-ranked jobs and more frequent opportunities to use literacy skills in everyday life no doubt stimulated private efforts to become educated. More generally, the structural changes in the sectors of the working population had its own repercussions on the requirement of literacy with a long-run move out of agriculture, where literacy was less needed (Table 1). Finally, the demographic transition further increased the need to invest in each child due to the lower number of children.

According to Galor et al. (2009), capitalists had an interest in promoting public education because they needed skilled workers in their factories during the second part of the Industrial Revolution. In contrast, large landowners preferred to block educational expansion because industrialization threatened their social status. In addition, workers would be more prone to migrate to better-paying urban centers and would be less willing to accept existing working conditions in the fields. Finally, landowners were often those who had to pay the taxes for improving the educational system, and they did not want to take this financial burden (see also Baten and Hippe 2017).

Thus, against the interests of landowners, capitalists were active in lobbying for public education and tried to influence government actions toward intervention in the education field. In particular, technical education was seen to be an important way of providing skilled workers. The example of England may illustrate this. It was the industrial leader, but late in the provision of public education. According to Galor (2011), the government changed its prior laissez-faire politics when it became clear that other countries (such as Germany or France) were becoming more inventive and innovative in industry. According to a jury member of the Paris exhibition of 1867,

Table 1 Usefulness of literacy in English male population, 1841–1891

Category of occupational usefulness of literacy	1841	1851	1871	1891
Literacy required	4.9	5.6	7.9	11.1
Literacy likely to be useful	22.5	22.8	25.3	26.1
Literacy possibly useful	25.7	24.2	24.5	25.9
Literacy unlikely to be useful	46.9	47.0	42.3	37.0

Source: Mitch (1992a)
Note: "Usefulness" refers to the degree that literacy was useful in a work context

the exhibition showed that there was insufficient progress in the English industrial sector. The reason for this "upon which there was most unanimity conviction is that France, Prussia, Austria, Belgium and Switzerland possess good systems of industrial education and that England possesses none" (Green 1990, p. 296, in Galor 2011, p. 476). Later on, the vice president of the committee of the Council of Education believed that "[u]pon the speedy provision of elementary education depends our industrial prosperity . . . if we leave our work-folk any longer unskilled . . . they will become overmatched in the competition of the world" (Hurt 1971, pp. 223–224, in Galor 2011, p. 477). Thus, Galor (2011) argues that the English government finally gave in to the demand of capitalists and expanded public education.

Together with the process of industrialization, the public became increasingly aware that more modern skills and knowledge related to modern production processes had to be acquired. Therefore, in their analysis of the USA between 1890 and 1970, Rubinson and Ralph (1984) find a significant impact of technological change on the expansion of schooling (i.e., enrollment rates). However, they acknowledge the fact that schooling and literacy were already important in the USA before the Industrial Revolution. They were part of a process of status competition among different parts of the population (according to ethnic origins, occupational status, religious affiliation, etc.). Moreover, the importance of technological change weakened over time because the schooling system was expanded more by political considerations.

The Incentives for the Nation-State to Provide Mass Schooling

Alongside military and industrial reasons, illiteracy also started to be seen as a disgrace for a nation (Cipolla 1969), putting pressure on governments that did not want to fall behind the "civilized" leaders. Therefore, international reputation and competition can be seen as factors that influenced government policy in this context. In addition, there was a growing belief in the role of mass education in forming the beliefs of the population and in directing and possibly controlling their behavior.

Ramirez and Ventraensca (1992, p. 49) consider the later phases of the construction of mass schooling to be a project of the nation-state, emphasizing its overall transnational character. They argue that mass schooling evolved and standardized around similar ideological and organizational forms. It allowed the nation-state to connect with individuals. The rise of the nation-state was, therefore, intrinsically related to mass schooling. Public life became increasingly reordered around the nation-state, and former transnational populations were transformed into citizens of nation-states. Education as such became its own institution, with its own goals, interests, and stakeholders. "Almost all European governments took steps which homogenized their populations: the adoption of a state religion, expulsion of minorities, institution of a national language, eventually the organization of mass public instruction" (Tilly and Tilly 1973, p. 44, cited in Alesina and Spolaore 2005, p. 184). Later on, former colonies proceeded in a similar fashion to achieve the goal of nation building in the second part of the twentieth century.

In line with this idea, Alesina and Reich (2013) argue that the magnitude of homogenization aimed at by a government depended on its particular regime. In particular, they distinguish between democratic regimes, "safe" nondemocratic regimes, and "unsafe" nondemocratic regimes. For example, in France the Ancien Régime was powerful but not interested in pursuing homogenization. The French Revolution toppled the regime, but other elites soon came to power. Still, the threat of more democracy necessitated increased efforts of nation building and homogenization. One important way to homogenize the population was linguistic homogenization by enforcing French as the only language used at school. The cases of Italy and England similarly illustrate that mass schooling was perceived to be a requirement for nation building. Similarly, in many African states after decolonization, an important share of enrollments was only realized after the (re)organization of a more or less effective national state. Increasing enrollments had different advantages. It had a signaling effect, emphasizing that the nation-building process was underway. Moreover, it was aimed at showing that the ideals of progress were embraced by the elites, giving further legitimacy and credibility to their ruling. Thus, the erection of schools also had an important symbolic effect in several dimensions (Ramirez and Ventraensca 1992).

Government Intervention in Education

How can the European countries be classified according to the importance of government involvement in education? Mitch (1992b) distinguishes between two categories of European countries. First, the countries that were the leaders in industrialization (e.g., England, France, Germany) showed a gradual increase of literacy over several centuries prior to the eve of mass schooling (see Fig. 4 for England).[16] This gradual process may have involved local demand, which was met by local supply. Second, the late-industrializing nations (such as Russia, Italy, Spain) had much lower literacy levels, but then these countries increased them much more rapidly. In fact, the governments were aiming at closing the gap with the leading European countries. Thus, the role of the central state was much more important in these countries, and local elites had a less decisive influence in advancing educational levels.

Using a different approach, Soysal and Strang (1989) divide the European countries into three groups according to the conflict and competition within societies on the subject of education. The first category, the "statist construction of education," includes Prussia and Scandinavian countries (Denmark, Norway, Sweden). In these cases, the state was able to build upon the know-how and physical infrastructure of the national churches. In fact, instruction was mostly provided by churches before the nineteenth century (Vincent 2000). Thus, the alliance between the state and the church was crucial.

[16]The same can be said of the evolution in numeracy (A'Hearn et al. 2009).

Table 2 Introduction of compulsory education and primary enrollment ratios in 1870

Country	Introduction of compulsory education	Primary enrollment ratios in 1870
Prussia	1763	67
Denmark	1814	58
Greece	1834	20
Spain	1838	42
Sweden	1842	71
Portugal	1844	13
Norway	1848	61
Austria	1864	40
Switzerland	1874	74
Italy	1877	29
United Kingdom	1880	49
France	1882	75
Ireland	1892	38
Netherlands	1900	59
Luxembourg	1912	–
Belgium	1914	62
USA	–	72

Source: Soysal and Strang (1989)

Second, the "societal construction of education" took place in countries such as France, the Netherlands, Switzerland, Great Britain, and the USA. In these countries there were many conflicting interests articulated by important stakeholder groups. These were of a religious order (e.g., Great Britain and the Netherlands) or of local character (e.g., the USA). Therefore, a centralized, nationwide educational system was only constructed relatively late, although schooling had already been expanding quite significantly before the involvement of the state.

Finally, the "rhetorical construction of education" in countries such as Portugal, Italy, Greece, and Spain meant that compulsory education laws were passed relatively early, but actual action did not take place for many decades. The dates of the introduction of compulsory education and enrollment ratios in 1870 illustrate this discrepancy (Table 2). For example, although Greece introduced compulsory schooling quite early in 1834, its insufficient implementation led to primary enrollment ratios of only 20% in 1870. In this and the other countries that had a "rhetorical construction of education," there was no competition over education, and enrolment rates were also relatively low. In addition, the state was too weak and had too little power to enforce its own legislation in its territory.

Another question concerns the effectiveness of state policy in education. When was state action effective? Mitch (1992b) points out that a state's education policy might not have been very effective if demand was low. Even if a sufficient supply of education was guaranteed by the state, lacking interest or even resistance from parents meant that classrooms stayed half empty. Furthermore, state policy was

rather ineffective when there had already been a high level of literacy and a large supply of private schools. In this case, Mitch (1992b) argues that public policy initiatives were redundant, and in many cases already existing private schools were only turned into public ones. In contrast, a state's policy may have been quite effective when a clear shortage of supply did not meet popular demand. In addition, state policy could overcome local resistance where local elites blocked the provision of educational facilities against the will of the local population. Moreover, public policy could be effective when an initial level of instruction was present, but this level had to be advanced still further. Here, the state's policy (in particular in England, France, and Germany) was directed toward the construction of new schools, the standardization and improvement of teaching, the reduction or elimination of schooling fees, and the establishment of compulsory schooling laws. National literacy campaigns (e.g., in Scandinavia in the seventeenth century) may have also been an important tool to increase the effectiveness of education policy.

In consequence, Mitch emphasizes that an effective educational policy needed the concordance between the demand for instruction and the influence of policy measures. Both are dependent on the popular attitude toward literacy and the power relations within society.[17] Thus, education policy needed to count on popular and local elite support to be effective. Where one or both of those factors were lacking, national public policy was often without great effect. Therefore, local institutions and local elites played an important role. Accordingly, Lindert (2004) notes that many of the early high performers in mass education had decentralized education systems. For example, he argues that the Prussian education system was essentially based on bottom-up structures.[18] Other examples for decentralized education systems include the USA and Canada. In all of these countries, local governments were able to levy their own local taxes that financed the school system. Thus, local actors were able to choose whether they wanted to be committed to schooling or not and were freed of interests that may have been existing at the national level. Local leaders were thus influenced by local debates and local demand. Thus, local funding also meant that regional differences in education could become even more striking. In consequence, whereas in the first phase decentralization enabled educational levels to increase in the

[17]He distinguishes three cases: egalitarian, elite, and autocratic forms of power distribution. In the egalitarian case, the preferences of the majority were implemented by the elites. Thus, there was a high risk that policy measures were simply redundant or not meeting private demand. In these societies, the acquisition of education meant the prospect of moving up the social ladder, leading to popular demand. When the powers in society were more concentrated but upward mobility was still possible (e.g., in France and Germany), the effectiveness of public educational policy was probably higher. Finally, in the case of more autocratic forms of government, when power was extremely concentrated (such as in Spain and Portugal) and the masses lived at low standards of living, public action was ineffective. On the one hand, demand was low and actions by the state were perceived as intruding into family life. On the other hand, local elites blocked educational changes that may have been intended at the national level (Mitch 1992b).

[18]Overall, the Prussian kings were not fervent promoters of the spread of mass education. They "did as much, and said as much, to *block* schooling and free thought as to spread it" (Lindert 2004, p. 118).

most favorable regions, in the second phase, it tended to fail to increase educational standards in the laggard regions. In the latter phase, the government was needed to avoid such a market failure[19] and to centrally enforce higher educational spending.[20]

In what specific ways can the state act in order to avoid market failures in the education sector? First, the state can provide sufficient supply. In theory, the private sector could also be fully responsible for the supply side: according to Lindert (2014), investments in primary education have brought high private and social returns for at least the last 600 years. However, he points out that the private sector has never solved the "capital constraint" problem, i.e., that universal education investments are to be paid back by the increased future earnings of children. For this reason, the state has to step in to avoid underinvestment in education. Yet this supply of schools, teachers, and materials generates important costs for the government. This is one reason why the state was not able to finance public education throughout most of history. In fact, it did not have the necessary fiscal capacity due to inefficient state bureaucracies, etc. On the other hand, the willingness to invest in education, and thus to increase taxes, was dependent on the interests of the ruling classes. As long as these ruling classes, in particular landowners, were opposed to educational reforms, progress was limited or inexistent in this area (see also Baten and Hippe 2017). Therefore, Lindert (2014) argues that the provision of voting rights to larger segments of the population made a crucial change to the composition and attitude of governments toward educational investment. Thus, government spending on education has risen dramatically during the last two centuries. Higher spending does not necessarily translate into higher enrollments but is often well correlated (see Fuller 1983; Walters and O'Connell 1988).

Second, the state can create demand for education. Thus, investing in the quality and credibility of schools may have an important impact on demand and enrollment. The quality of schools depends on several factors, among other things on the quality of teachers. The supply of those teachers depends on their salaries and the social status of the teaching profession (Cipolla 1969).[21] Assuring the quality of teachers

[19]Here, it is assumed that all regions benefit socially from higher education levels.

[20]Some studies have suggested the existence of a human capital Kuznets curve, adapting the idea of Kuznets (1955) to education. In other words, increases in human capital inequality in earlier phases are followed by subsequent reductions in human capital inequality in later phases of economic development. For empirical contributions, see, e.g., De Gregorio and Lee (2002), Castello and Domenech (2002), Lim and Tang (2008), and Morrisson and Murtin (2013); for theoretical models see, e.g., Galor and Tsiddon (1996), Glomm and Ravikumar (1998), and Matsuo and Tomoda (2012).

[21]The level of salaries was quite diverse across Europe. However, for the most part, they seem to have been low. Thus, Cipolla (1969) suggests that the average salary of a teacher was comparable to that of a craftsman before the nineteenth century. In addition, the social status of teachers still varied importantly from one European country to the other in the nineteenth century. For example, teachers enjoyed high public respect in Germany (and Prussia in particular) (Cipolla 1969). Social prestige and income may thus be causes of high quality. Perhaps a long-standing tradition of the teaching profession was also an important factor. In contrast, schoolmasters and mistresses did not have a good reputation and did not have much prestige in England and southern Italy in the nineteenth century.

can thus be an important policy objective. In addition, the state can politically construct the organization of work. For example, it has the power to create minimum educational standards for the entry into jobs in the public and private sectors. If parents or their children want to enter this well-paid job market, they have to invest in education. In consequence, the state can create a public demand in a politically directed way. Likewise, the state can decrease the opportunity costs for sending children to school (e.g., by limiting child labor and giving schools a normative legitimization).

Finally, the ideological and symbolic compound associated with education (e.g., economic and social opportunity, but also Western ideals such as nation building, individual development, and progress) can be used by the state to advance mass schooling through corresponding signaling activities (such as literacy campaigns) (Fuller and Rubinson 1992).

However, it appears that the state's involvement to improve educational quality and quantity might have been too late in some countries. For example, Mitch (1986) indicates that this may have been the case in nineteenth-century England. In consequence, was the UK spending too little on education (and too late)? To have a better grasp of the amount of public spending in comparison with economic output, public investment in education can be directly measured as a share of GDP. Carpentier (2007) shows the relative position of the UK with other countries that were catching up. In particular, he considers the differences between the UK, France, and the USA (Fig. 6). The very low values of the UK until the end of the nineteenth century also appear to be quite low in comparison to these other industrializing countries. This illustrates the claim that the major deficiency of the UK in the second part of the Industrial Revolution was its lack of skilled workers due to a lack of education. The USA was by far the leading country among these three nations in 1870, spending almost 1% of its GDP on education. France follows with a large gap at about 0.5%, while the UK lags far behind. The UK became aware of this later on and the government increased its expenditures much more pronouncedly. France also increased its relative expenditure on education, for a decade becoming the leader of these three countries. Subsequently, the UK had the highest shares until First World War. However, the real takeoff in education spending shares occurred only between the 1950s and the 1970s. Since then, education spending has mostly been between 4% and 6% of GDP in all three countries.

These data illustrate the evolution of public expenditure on education. However, they do not include private investment in education. The overall investment in education might have been much higher than the public investment alone. Lindert (2004) provides some estimates on total (i.e., public and private) expenditure on all levels of education in a number of countries between 1850 and 1910 (see Fig. 7).

The data suggest that overall investment in education was highest in Germany throughout the second part of the nineteenth century, followed by the USA. France appears to have had much lower levels, and the gap to the leading countries

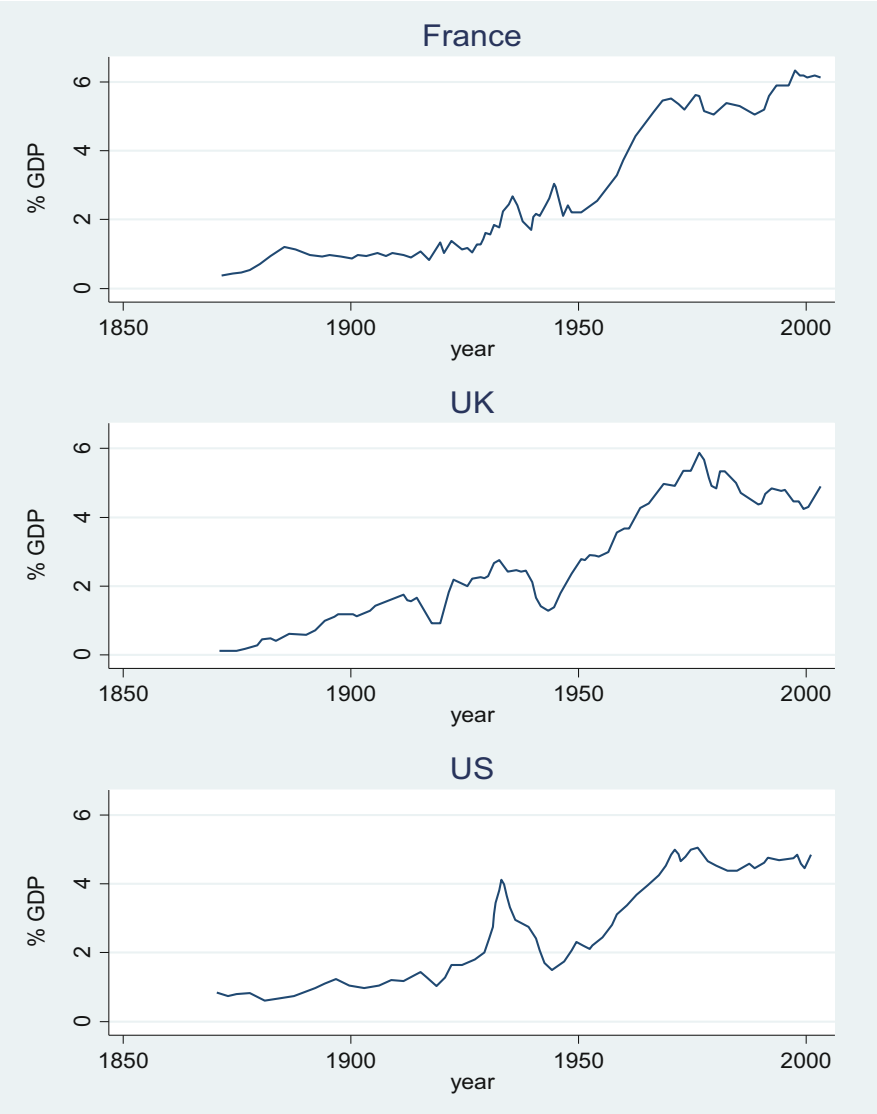

Fig. 6 Public expenditure on education as a share of GDP in the UK, France, and the USA, 1870–2003. (Source: Carpentier (2007); see also Diebolt (2000) and Diebolt and Fontvieille (2001))

widened at the end of the 19th and the beginning of the twentieth century. Data on Italy and the UK are even more tentative but could suggest a more intermediary position.

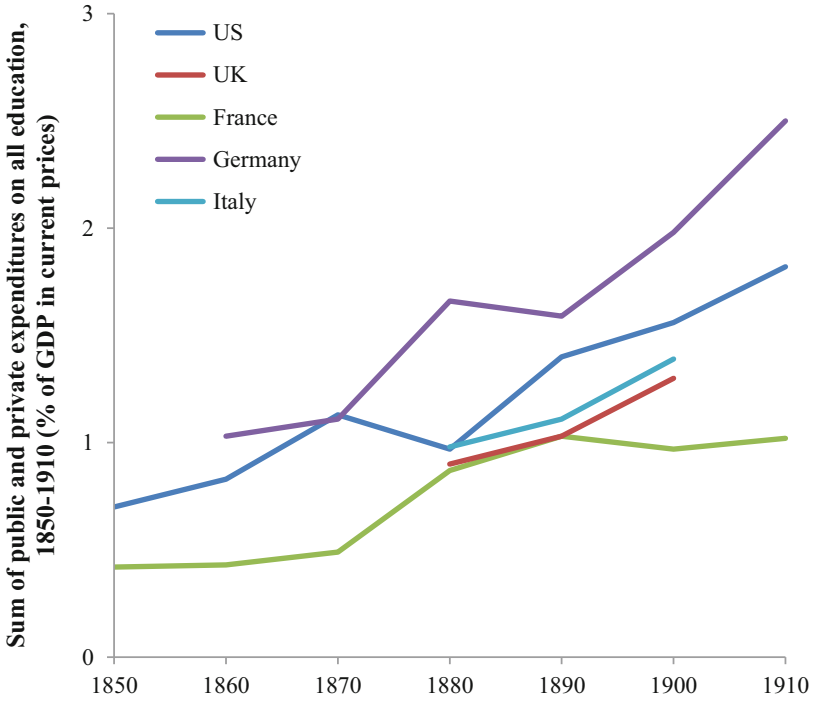

Fig. 7 Total of public and private expenditure as a share of GDP, 1850–1910. (Source: Derived from Lindert (2004))

The next logical step is to ask about the composition of this investment. Was private investment in education higher or lower than public expenditure? Thus, did public investment replace private investment over time? The next figure illustrates the relative importance of public and private investment (as a share of GDP) in these countries (see Lindert 2004 for details) (Fig. 8).

Three different patterns emerge. First, private and public expenditures were more or less at the same level in the USA in the 1850s. However, public expenditures as a share of GDP rise (almost) continuously, whereas private expenditures stagnate. The initially slightly higher levels for private expenditures might possibly suggest that public expenditures partly replace private ones. Second, public expenditures are much higher than private ones in both France and Germany throughout the period. The gap also widened, given the increased efforts of the government to provide schooling. Finally, private expenditures appear to have been higher in Italy and the UK at the end of the nineteenth century. Therefore, the tentative evidence would suggest that government spending became the major form of investment in education only in the twentieth century, much later than in other countries.

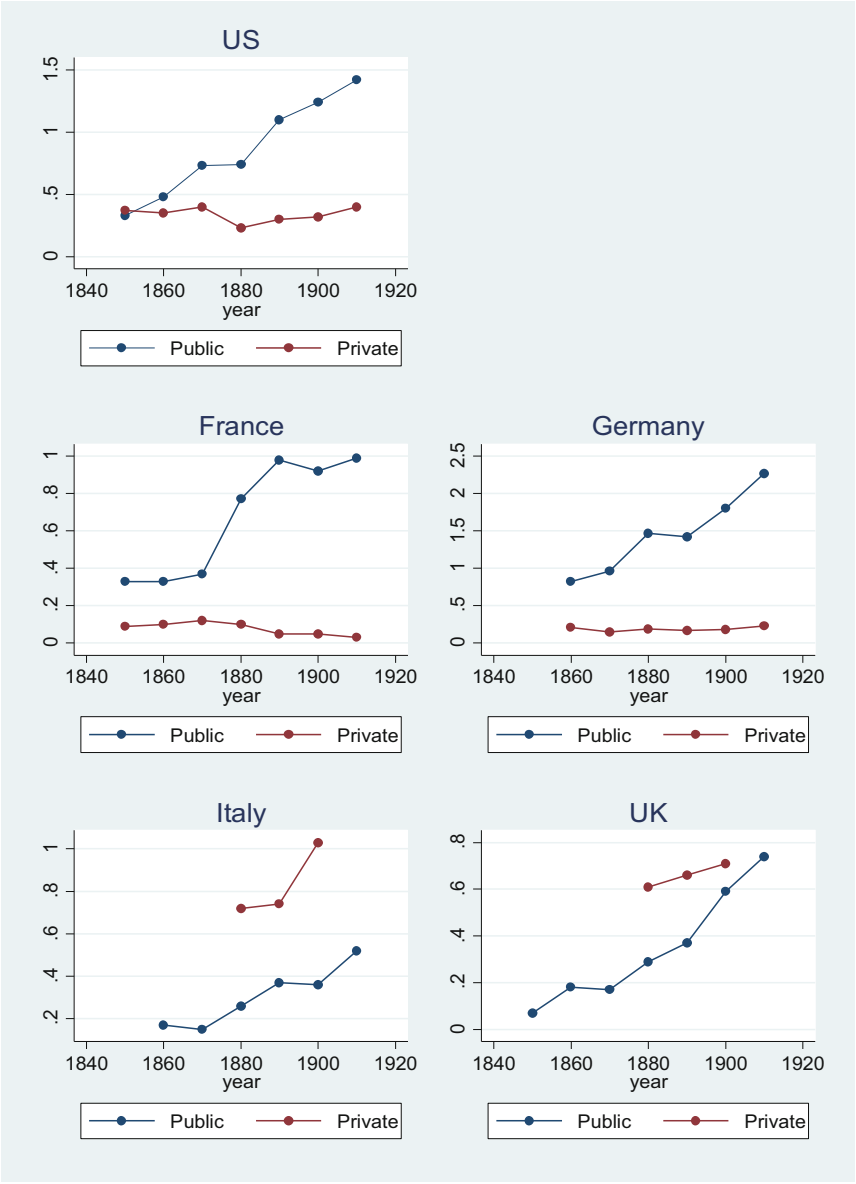

Fig. 8 Public and private expenditure as a share of GDP, 1850–1910. (Source: Derived from Lindert (2004). Note: Vertical axis refers to expenditures on all levels of education as a % share of GDP in current prices. The value for private expenditure for the UK in 1890 has been interpolated)

The Worldwide Human Capital Transition and the State

Trends in Worldwide Human Capital Levels During the Last Two Centuries

It appears important at this stage to provide a general overview of the long-run human capital transition in the world before moving on to the role of the state. We may begin with numeracy levels (Crayen and Baten 2010). Numeracy is measured here by the age heaping method, which measures the share of people who are able to count.[22] The industrial countries have the highest numeracy levels of all countries at the beginning of the nineteenth century. These countries are relatively closely followed by East Asia, which has similarly high numeracy levels as the industrial countries in the 1880s. Not far behind East Asia are the Eastern European/Central Asian countries, which achieve the maximum numeracy values by the 1900s. Thus, these three regions reach the upper limit of numeracy levels at the end of the nineteenth century. No other world regions were able to achieve such a level until the middle of the twentieth century. The most advanced area of these follower regions is Latin America/Caribbean, which has been inspired by the educational policies of the industrialized countries. The lagging world regions are Southeast Asia, Sub-Saharan Africa, and the Middle East/North Africa. South Asian countries had the lowest level of numeracy throughout the period.

Numeracy is just one indicator of human capital levels. Literacy is surely the most common variable for long-run education (see also Diebolt and Hippe 2017, 2018a, b; Hippe and Perrin 2017; Diebolt et al. 2018). The overall trends since 1870 (Fig. 9) are quite similar in many respects to the ones identified in numeracy. In particular, literacy levels are once again led by the West. The gap between the West and all other countries appears to be much more important than in numeracy. One important reason for this is that literacy levels are much lower than basic numeracy at the beginning of the period. This circumstance is related to the underlying concept of measurement: the numeracy indicator proxies very simple counting skills, which are even more basic than literacy skills. In any case, the West is again followed by East Asian countries (i.e., Korea-Japan and China) and Eastern Europe. Eastern European countries show a particular sharp increase in literacy between 1910 and 1950. In contrast to Korea-Japan, China does not substantially increase its literacy levels until the second half of the twentieth century and thus falls back. Latin America takes an overall similar evolution as China. Although its literacy levels speed up between 1910 and 1950, progress is more slowly achieved afterward. In China, the reverse is

[22]It uses a particular heaping phenomenon in the age distribution of censuses and other comparable data to calculate numeracy levels. More specifically, individuals over-reported ages ending in 0 and 5 to census takers, leading to significant spikes in the age distribution. The reason for this was that they were not able to count and to know their exact age, so that they rounded it. This is a well-known phenomenon that can be found in historical sources and in a range of developing countries today. For further information, see A'Hearn et al. (2009), Hippe and Baten (2012), Hippe (2012, 2013b, 2014).

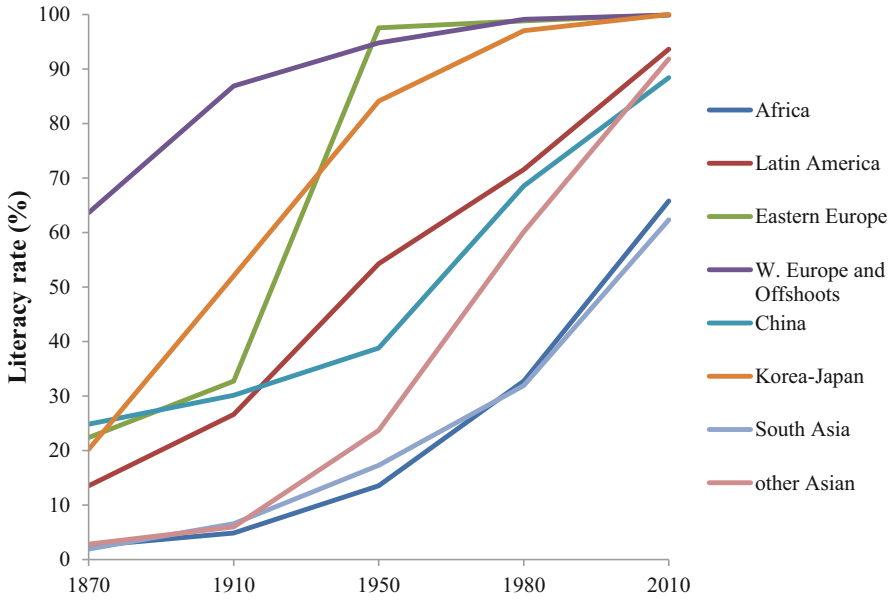

Fig. 9 Evolution of literacy in world regions, 1870–2010. (Source: Morrisson and Murtin (2013))

the case. Societies characterized by almost complete illiteracy in the 1870s come from South Asia, "other Asian" countries, and Africa. Whereas the "other Asian" countries are able to close the gap with the leading regions by 2010, South Asia and Africa show important, but not sufficient, progress. However, it seems that they may be able to join all other regions in the decades to come.

Taking another standard indicator, the years of primary education, the conclusions are quite similar (see Morrisson and Murtin 2013). Clearly, this variable is even more closely related to the state because most schooling has been provided by the state during the considered time span. The increases are not as impressive as in literacy in many cases, but this is partly due to the nature of the indicator. Still, the trends that were discernible in the literacy data can also be found here. Primary years of schooling amounted to about 3 years in the West in 1870, whereas it ranged from 0 to 1 years in all other regions. In 2010, three different regimes exist: about 6 years of primary education in the West, Korea-Japan, and Eastern Europe; about 5 years in Latin America, China, and other Asian countries; and, finally, about 3.5 years in South Asia and Africa. Except for the leading group, all other regions appear to be converging to the leaders in the longer run.

Primary education is a measure of basic human capital. Thus, it is similar to literacy and numeracy. If we want to enlarge the concept of human capital to include more advanced skills, we should also take into account the role of secondary education. Therefore, the total years of schooling indicator give a fuller comprehension of basic and more advanced human capital levels (Fig. 10). However, it is clear

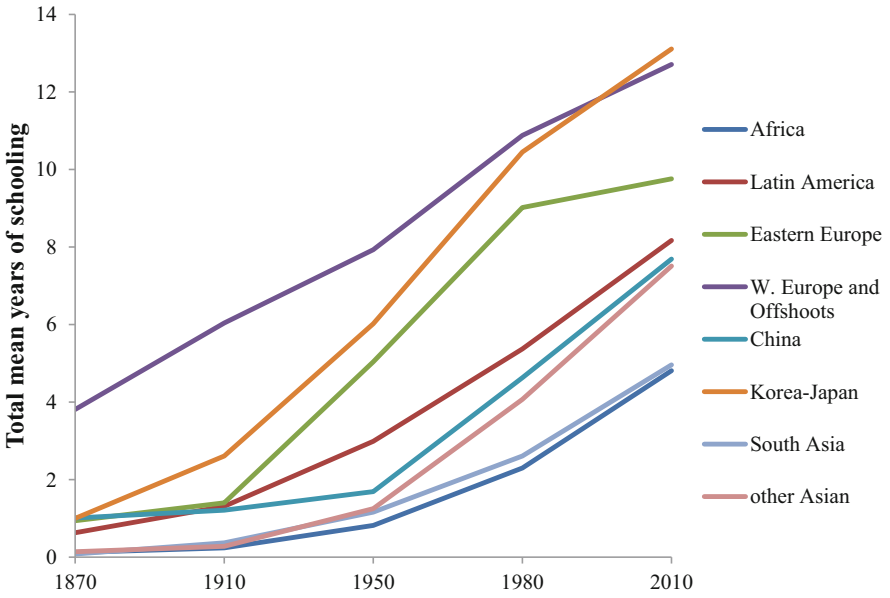

Fig. 10 Evolution of total years of schooling in world regions, 1870–2010. (Source: Morrisson and Murtin (2013))

that an important part of this variable is constituted by the levels of primary education, as shown in the previous figure. Most of the trends in the average total years of schooling are, therefore, in line with the results for primary education. The most evident change in the pattern is the evolution of Eastern Europe. In primary education, Eastern Europe was already at similar levels as the West and Korea-Japan by 1980. In primary and secondary education, there still remained an important gap of about 1.5–2 years. In addition, this gap was not closed, but actually widened until 2010. This change was probably motivated by the fall of Communism and the subsequent transition period in these countries.

One can also look at these data in another way. The notion of the technological frontier has been very important in the growth literature (e.g., Vandenbussche et al. 2006). The same idea can be applied to human capital. If we consider the leader of human capital (i.e., the West) as marking the frontier of human capital, we can calculate the simple distance of other regions to this frontier (using total years of schooling). Taking this perspective, it becomes clear that the gap between the West and "the rest" remained rather stagnant and very wide between 1870 and 1910. Only Korea and Japan exhibit significant progress. Afterward, all countries exhibit different rates of convergence to the human capital frontier, but (apart from Korea-Japan) all countries are still quite far away.

Thus, all the indicators employed in this analysis illustrate a move from relatively low human capital levels to much higher levels during the last 200 years. In schooling, this transition has taken place in all regions between

1870 and 2010. The West already had relatively high schooling levels in the second part of the nineteenth century (so that one needs to go back to the early nineteenth century to see the entire trend), but these levels are still very low compared to contemporary current levels. The human capital transition is a phenomenon of the last 200 years, and the state has been playing an important role in this transition.

Human Capital and the State

The involvement of the state in the transition from low mass levels of education to high levels becomes evident when considering different indicators. Passing compulsory schooling rules is one clear sign that a state intends – at least symbolically – to improve its educational levels. Figure 11 shows the evolution of the cumulative share of countries in a world region that have passed compulsory schooling rules. Western Europe appears to be the leader in state laws on education, achieving a rate

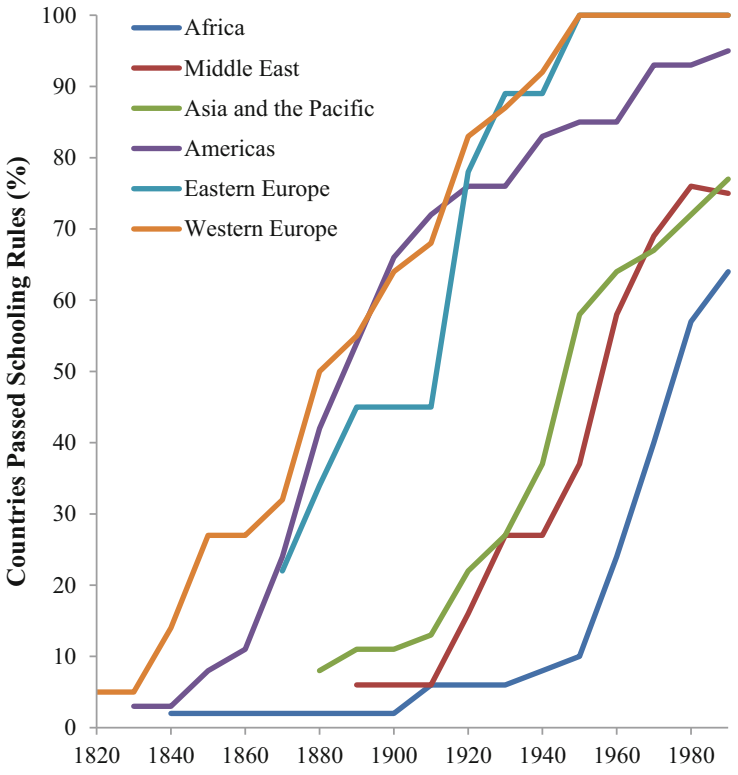

Fig. 11 Proportion of countries having passed a compulsory schooling rule, by region and decade, 1820–1990. (Source: Ramirez and Ventraensca (1992))

of around 50% by 1880. It is followed by the Americas and Eastern Europe, both culturally linked to the leaders. Asia and the Pacific were the next to follow slowly. The Middle East began its major involvement in state education even later, from the 1910s onward. Both regions show a parallel spectacular growth between the 1930s and the 1950s, with a lead of one decade for Asia and the Pacific region. Progress was less striking from then onward. In Africa, the turning point came in the 1950s and the period of decolonization. Afterward, similar levels as in the former two regions were almost reached. Accordingly, Ramirez and Boli-Bennett (1982) argue that there is an acceleration phenomenon, i.e., there is a correlation between the date of independence of a country and the time to pass compulsory schooling: the younger a country is, the faster it passes compulsory schooling laws (Adick 2003). Overall, the transition from almost non-existing official legal involvement in compulsory schooling to almost universal compulsory schooling in many parts of the world is very clear.

We can also consider another indicator related to state involvement. It is the cumulative share of countries within a world region that have created a central education authority (Ramirez and Ventraensca 1992). In some respects this indicator shows similar trends. Western Europe leads in this area until the 1870s. The share of countries with central education authorities then dramatically increases over the next century. Thus, all major world regions had almost universally central education authorities by the 1990s – except for the former leader Western Europe, where compulsory schooling laws and centralized state control have been contested for the last 200 years. For this reason, still in the 1990s, centralized state control was not implemented in a sizable share of Western European countries. In contrast, the idea of a central education authority has been deemed to be necessary in the other world regions that followed Western Europe. Less resistance and more conviction of the necessity of central state policy has characterized experiences in these continents. It highlights once again the connection between the (in part newly created) nation-states and mass schooling in these countries.

Conclusion

The expansion of the "knowledge economy" offers a potential way to place the global economy on a more sustainable trajectory. With this in mind, our aim in this chapter was to better understand the market and institutional forces that led to the human capital transition in present-day industrialized nations – that is, the development of a key pillar of the "knowledge economy."

To this end, we sought to answer the following questions: What factors have driven the demand for and supply of human capital over the last 1000 years in Europe? Has there been a market failure in the formation of human capital? What role has the state and other institutions played in the provision of schooling? Why

were government and the public willing to invest heavily in this public good? To better understand the forces that led to the human capital transition, we brought together a wealth of evidence on the history of education, and broader human capital formation, across Europe.

One of the central features of the history of the European human capital transition has been the decline in the price of written education, in the fifteenth century following the development of the Gutenberg Press and in the nineteenth century with its mechanization. This incentivized the development of written education and implied that traditional work skills were complemented by a broader education in literacy and numeracy and the ensuing improvements.

However, this narrative also seeks to emphasize, as Mitch (1992b) did, *the fundamental role demand played in driving the early human capital transition.* Early demands in transitions are often driven by "luxury" services, where some consumers have a relatively high willingness to pay, creating niche markets (Fouquet 2008). In the case of education, this was associated with the demand for spiritual guidance. The initial demand to read the Bible (either in Latin or, for most Europeans, in their mother tongue) was stimulated by Luther and other champions of the Reformation. In other words, capitalizing on a technological revolution, one persuasive voice (accompanied by a growing number of followers) can initiate a transformation in beliefs that stimulates an initial (immaterial) demand for one of the key sources of modern economic growth.

In time, the demand for written education stemmed from many additional sources, associated with commercial, military, industrial, parental, status, and "belief-formation" factors. So, the first phase of growth in human capital levels (particularly in literacy) in the leading countries can be explained by the interplay of supply and demand. This provided a basic level of education to upper and middle classes. Mirroring this experience, the declining costs of using ICT are enabling developing countries to accelerate investment in human capital and seek to catch up with the industrialized nations. However, if human capital transitions in developing economies unfold in a similar way to the transitions in Europe, then certain segments of the population will be left behind. That is, while probably upper and middle classes in developing economies become highly educated, a poorer segment will struggle to raise their levels of human capital. *Thus, without major efforts from government, educational and ultimately income inequality is likely to increase.*

Indeed, the second phase of the human capital transition (i.e., the spread of mass literacy and the construction of mass schooling beginning in the nineteenth century) was particularly driven by the state. In certain cases, *shocks (*e.g.*, wars, the loss of international competitiveness) played a key role in altering beliefs about the value of education and stimulating public investment in human capital.* For instance, Prussia's move to embrace education more forcefully was triggered by defeat in the Napoleonic wars. Similarly, industrialists in the UK at the end of the nineteenth century started to realize that their ability to keep up with foreign competitors, particularly Germany and the USA, depended on having a well-educated workforce from which to hire.

However, in general, the role of the state was more important in those countries that had to catch up with the leaders. Particularly in lagging economies in Europe, there was a market failure – in the sense that although the social and economic benefits of higher human capital levels would have been significant, education was not provided by the private sector. The construction of state fiscal capacities (including the building up of efficient bureaucracies) and falling resistance from social elites against public educational investments were often important prerequisites for state intervention. Once the state got involved in the education sector and created a mass public schooling system, this market failure was at least partly resolved over time. Naturally, recognition of the importance of the human capital investment needed to be followed up with effective implementation strategies and public financial support (often around 2–5% of GDP).

One reason the implementation and financial support for mass education often followed swiftly behind recognition was because the state, along with religious institutions and other nongovernmental organizations, placed a value on "belief-formation" and the control of the provision of education. The desire for nation building implied that instilling values and cultural attributes (e.g., language), which would encourage future generations to identify with the state, was an important driver of public investment in education (Pritchett 2003). In other words, this secondary benefit of education (to government) may well have been pivotal to the second phase of the human capital transition.

When considering potential future transitions, it is important to consider the benefits that government may gain from the transition. *Identifying the existence of a principal-agent problem and finding direct benefits for government might be a powerful means to incentivize government officials to develop effective implementation strategies and find public financial support.*

With this objective in mind, it is important to remember that major transitions are typically long-term processes. The human capital transition (here, defined as an increase from 10% to 90% literacy rate) in Europe took roughly 400 years, from Luther's printed translation of the Bible into a European vernacular language until the First World War. In Japan and Korea, it took a little over 100 years (from about 1850 to 1960). In South Asia and Africa, this is likely to take around 100 years. *Thus, even in countries implementing basic education programs today, there is a limit to how fast a transition can be achieved.* This is partly because new generations need to be educated, and this takes decades.

Yet even in the case of education, vested interests may inhibit a successful transition. *Therefore, these vested interests have to be identified and considered in any policy.* Indeed, the central state interacts with a range of stakeholders in educational policy. In particular, there are religious authorities (in Europe the churches), elites (landowners and capitalists), parents, ideological movements (including liberals and conservatives), and the local authorities. Any of these can alter the rate and nature of the transition. On the other hand, if government has direct benefits from a transition, then these vested interests are likely to be more swiftly overcome.

Abstract

This chapter discusses recent advances in our empirical knowledge of how education affected socioeconomic development during the industrialization. While early work attributed little role to formal education at the onset of the British Industrial Revolution, recent evidence is more positive. There is evidence, from Prussia and other European countries, that education played an important role in the first and second phases of industrialization in follower countries. While basic education seems to have been particularly relevant for the diffusion of the new industrial technologies, there is evidence that upper-tail human capital also played a role. In addition, the education of the population can account for major parts of the difference in Protestant and Catholic economic history. Beyond economic development, education also affected other societal developments during the industrialization. Educational expansion – in particular of advanced secondary schools – appears to have been an important force behind the decade-long process of secularization during the second phase of industrialization. In addition, the fertility decline during the demographic transition is closely related to increased education both in the generation of parents and of children, the latter indicating a significant trade-off between the quantity and quality of children.

Education · Industrialization · Economic development · Economic history · Nineteenth century · Human capital · Schooling · Protestantism · Secularization · Demographic transition · Fertility

Introduction

For most of the history of mankind, the vast majority of human beings received hardly any formal education. For example, estimates put the share of the German population in early sixteenth century that was literate at 1% at most (Engelsing 1973). The virtual nonexistence of education for the masses coincides with their meagre and rather stagnant economic fate, certainly compared to the dynamics of economic advancement over the past century. In modern times, the expansion of mass education clearly contributed to economic development (Goldin 2016). Beyond educational attainment, it is particularly the actual basic skills of the population that appears to play a crucial role in global economic growth since

World War II (Hanushek and Woessmann 2008, 2012, 2016). What is less clear is the role of education in the period of transition between stagnation and modern growth, in particular during the onset and spread of industrialization.

This chapter assembles evidence on how education affected human development during the phase of industrialization. Traditionally, economic historians have tended to be quite skeptical about the role that the education of the population played during the industrialization. For example, despite his emphasis on the role of technological creativity for economic progress, Joel Mokyr (1990, p. 240) quite vividly emphasized that "If England led the rest of the world in the Industrial Revolution, it was despite, not because of, her formal education system." Over the past decade, however, contributions to cliometric research have advanced – and, in our view, altered – our understanding of the role of education during industrialization, in particular in the countries that followed England in industrializing. These recent advancements will be the focus of the first part of this chapter. In covering the recent evidence, it will distinguish between the first and second phase of industrialization as well as between different levels of education.

While understanding the sources of improvements in economic prosperity is clearly of vital importance, the role of education for human development during the industrialization certainly reaches beyond the economic sphere. Therefore, this chapter also aims to cover selected additional aspects of the effects of education on the socioeconomic development of the population. Addressing the differential development of regions along denominational lines, the second part will focus on the particular role of education in Protestant economic history. Staying with the religious realm, the third part will address the effect of education on religiosity itself, investigating its role in the process of secularization. The final part will cover evidence that education contributed to the demographic transition, addressing the role that the educational advancement of both children and mothers played in the fertility decline.

Education and Economic Development

We start with the role of education for economic development during the industrialization. The Industrial Revolution presumably marks the most fundamental technological shift in modern history. The period of industrialization is characterized by profound technological change sparked by such inventions as the steam engine and mechanical spinning, their diffusion, adaptation, and improvement, the rise of the factory system, and accompanying social changes in households and markets (cf. Mokyr 1999). We follow recent economic theory that tends to distinguish between a first phase of industrialization during which educational requirements were purportedly low and technological change was skill saving and a second phase during which skills became increasingly relevant for production as technological change increased the demand for human capital (cf. Galor 2005).

The Relevance of Education for Industrialization

To provide some conceptual background, we begin by discussing several aspects of the possible role of education for industrialization from a theoretical perspective. A first dimension in which the education of the population may have facilitated industrialization is the direct productive use of skills. If the tasks of a factory require a certain minimum level of skills, such as the ability to read basic instructions and perform basic calculations, establishing and operating a factory requires workers with basic literacy. Formal education may also impart behavioral traits and non-cognitive skills that are relevant for factory production, such as conscientiousness, discipline, orderliness, and perseverance (e.g., Field 1989). In addition, industrial production creates service jobs that require literacy and numeracy skills, such as accountancy, commercial transactions, banking, and lawyers (e.g., Laqueur 1974; Anderson and Bowman 1976).

A second dimension of education that may be relevant, particularly in the context of industrial catch-up, is its role in the adoption of new technologies. In motivating their catch-up model of technological diffusion, Nelson and Phelps (1966, p. 69) argue that "probably education is especially important to those functions requiring adaptation to change. Here it is necessary to learn to follow and to understand new technological developments." In a dynamic setting of changing technology, education plays a particular role by fostering the "ability to deal with disequilibria" (Schultz 1975), i.e., to perceive a given disequilibrium, to evaluate its attributes properly in determining whether it is worthwhile to act, and to undertake action to appropriately reallocate resources (see also Welch 1970). Such abilities are particularly relevant when technical change is disruptive rather than incremental, as is the case for most industries emerging during the Industrial Revolution, with the possible exception of the textile sector.

A third dimension in which education may facilitate industrial development is its role for entrepreneurship and innovation (e.g., Kocka 1977). Education may impart higher-level scientific skills and the ability to innovate that are necessary to advance technical knowledge. While this may seem foremost the task of higher education, a system of basic education that covers the broad masses may be a prerequisite to screen the highest-capable entrepreneurs and researchers. Thus, Landes (1980, p. 118) argues that "elementary schooling as such has been important . . . as a device for the recruitment of talent. . . . the bigger the pool one draws from, the better the chances of finding gifted and original scientists and technicians." This genuinely innovative dimension of the role of education may have been particularly relevant in sectors with fundamental technological breakthroughs during the second phase of industrialization, such as certain electrical and chemical industries.

The specific skills required to facilitate the adoption of the new technical and organizational modes of the industrialization are multifaceted and general, rather than applied to one particular craft, and may be best described as a general understanding of the functioning of the world. They start with the basic "three R's" of reading, writing, and arithmetic, required for commercial communication, accessing practical handbooks, decoding instructions, debugging new processes, and reading

books about foreign places – all relevant actions in the given historical setting (Anderson and Bowman 1976). They may also encompass socialization and the creation of an aspiring human personality with attitudes favorable to adopting new technology (Easterlin 1981). Relatedly, literacy may create awareness of non-conventional possibilities (Anderson and Bowman 1976).

Even though the industrialization may initially have created demand for uneducated labor – and often child labor – to perform routine tasks in some industries, the role of education in creating the ability to adjust to changing conditions and to develop and use the new industrial technologies may ultimately have been of great relevance during both phases of the industrialization.

Evidence from the First Phase of Industrialization

While these arguments suggest a potential role for education in the industrialization, initial evidence on the role of formal education during the first phase of the British Industrial Revolution does not really support this view. Quite to the contrary, Mitch (1993, p. 307) concludes his seminal review of the role of human capital in the first Industrial Revolution by stating that "education was not a major contributing factor to England's economic growth during the Industrial Revolution." These early studies seem to support the interpretation that the first phase of industrialization did not require substantial educational inputs.

It has to be acknowledged, though, that the early British evidence suffers from severe data constraints. In particular, studies had to rely mostly on proxying education by signatures in marriage registers for limited parish samples, observed concurrent to, but not before, the Industrial Revolution. Furthermore, the bulk of British evidence on the role of education is for the textile sector, a focus that may be rather specific as innovations were much more incremental and less disruptive in textiles than in other emerging industries (cf. Komlos 2000).

In any case, more recent evidence calls for a re-assessment of the role of education in the British Industrial Revolution. Based on an extensive new database, Madsen and Murtin (2017) conclude that education has been a crucial driver of British economic growth since 1270, with its contribution equally important before and after the first Industrial Revolution. Trends in new data on years of schooling in England from extensive source material suggest education facilitated preindustrial development, although this was not sustained after the initial stage of industrialization (de Pleijt 2018). Evidence on book production also suggests that Britain became one of the most literate countries in Europe during the centuries before 1750 (Baten and van Zanden 2008). Taking a perspective of more broadly defined human capital, Kelly et al. (2014) show that on the eve of the Industrial Revolution, British workers had higher levels of physical quality and mechanical skills than their continental counterparts.

Additional evidence from the first phase of industrialization comes from the follower countries that aimed to catch up to Britain as the technological leader during early industrialization. As indicated above, models of technological diffusion

in the spirit of Nelson and Phelps (1966) suggest that education may be a key ingredient to absorb new technologies and adapt to change. A number of descriptive studies have looked at the role of education in the industrialization of the textile sector in specific regions outside Britain, such as Catalan cotton factories from 1830 to 1861 (Rosés 1998), textile firms in Lowell, Massachusetts, around 1842 (Bessen 2003), and Southern Italian textile factories from 1861 to 1914 (A'Hearn 1998).

Using data on school enrollment and factory employment that link 334 counties from preindustrial 1816 to the first industrial phase in 1849, Becker et al. (2011) study the role of education for catch-up in the technological follower country Prussia during the first phase of industrialization until the mid-nineteenth century. Their evidence indicates that initially better-educated regions within Prussia responded more successfully to the opportunities created by the outside technological changes from Britain. Interestingly, formal education played a minor role at best for industrialization in the textile industry, where innovation was less disruptive and child labor more prevalent. By contrast, already in the first phase of the Industrial Revolution, basic school education is significantly related to industrial employment in the metal industry and in the other industries outside metals and textiles, such as rubber, paper, and food.

By themselves, such cross-sectional associations do not necessarily reflect a causal effect of education on industrialization. In fact, the process of industrialization may itself cause changes in the demand for education. On the one hand, factory production may increase the demand for low-skilled labor, drawing children out of school into factory work (e.g., Sanderson 1972). On the other hand, to the extent that industrialization increased living standards, education may have become more affordable for broader parts of the population.

To circumvent bias from such endogeneities, Becker et al. (2011) use education in 1816, before industrialization in Prussia, as an instrumental variable for education in 1849. This instrument is not affected by changes in the demand for education that emerged during industrialization, and thus isolates a part of the variation in education that is not determined simultaneously with industrialization. The instrumental variable model that restricts the analysis to that part of the educational variation in industrial times that is related to educational variation that pre-existed industrial times confirms a significant effect of education on industrialization during the first phase in Prussia. The validity of the instrumental variable specification is corroborated by the fact that results prove robust to the inclusion of an unusually rich set of control variables for the state of economic development before the onset of industrialization, indicating that preindustrial schooling is unlikely to capture the effects of other measures that are themselves related to subsequent industrialization.

Evidence from the Second Phase of Industrialization

In their analysis of the role of education for industrialization in Prussia, Becker et al. (2011) also investigate the second phase of industrialization, from 1849 to 1882. During the second phase of industrialization, the new industrial technologies may have increased the demand for human capital (e.g., Galor and Moav 2006), which

creates an additional source of potential endogeneity bias in cross-sectional analysis. Again using preindustrial education as an instrument for education levels during the second phase of industrialization, and controlling extensively for preindustrial development, the evidence indicates that basic education is significantly associated with nontextile industrial employment shares also during the second phase of industrialization in 1882.

To further address concerns that any preexisting omitted variables might drive the cross-sectional findings, Becker et al. (2011) also estimate panel data models that pool all three periods of observation – 1816, 1849, and 1882. Results confirm the effect of education on industrialization, and county fixed effects rule out that the findings simply capture unobserved heterogeneity across the counties.

The results suggest that it may not be arbitrary that Prussia, which was the educational world leader at the time (Lindert 2004), was particularly successful in catching up to – and ultimately passing in many sectors – the industrial leader Britain. Indeed, Prussian educational leadership seems to have translated into technological catch-up throughout the nineteenth century.

The particular mechanisms of educational expansion are studied further by Schüler (2016), who uses data on schooling inputs provided by the first two Prussian censuses on primary schools in 1886 and 1891. Her results indicate that teacher quality, as proxied by teacher unit costs, and to a lesser extent expenditures on educational infrastructure, had a positive effect on the change in income, proxied by per-capita income tax, in the industrializing Western part of Prussia. By contrast, there were no effects of differences in class size, despite the fact that class sizes were very large by modern standards. An exploration of the sectoral composition of the economy suggests that the rise in income may have stemmed from a shift to higher-skilled and better-paid occupations.

Beyond Britain and Prussia, Sandberg (1979) presents evidence consistent with an interpretation that education was a leading factor in the catch-up process of Sweden in late nineteenth century. In a cross-country analysis, O'Rourke and Williamson (1996) conclude that schooling had a modest effect on catch-up for a cross-section of 16 countries in the period 1870–1913. Using panel data for seven countries over the same period, Taylor (1999) confirms this result.

Different Levels of Education

As discussed above, different levels of education may affect different aspects of the industrialization process. In particular, basic education may prove important for general production and for the diffusion and application of technologies, whereas higher levels of education may be particularly relevant for innovation.

The results for Prussian industrialization in Becker et al. (2011) refer to measures of basic education, namely years of elementary and middle schooling (derived from enrollment rates) in 1849 and adult literacy rates in 1882. By contrast, enrollment rates in upper-secondary schools and the existence of universities are not significantly related to industrialization in their analysis. These results may partly

reflect the fact that education beyond the basic level was not very widespread at the time, as upper-secondary enrollment rates did not surpass 5% throughout the nineteenth century, and no more than eight universities existed in Prussia. In any case, the results suggest that basic follower mechanisms that stress the role of basic education for technology diffusion, rather than higher-skill or entrepreneurial channels, were most relevant for relative regional industrialization in Prussia in the nineteenth century.

In their analysis of Prussian data, Cinnirella and Streb (2017) find that various dimensions of human capital played an important role in innovation and economic development during the second phase of industrialization. In particular, they show that both the literacy rate of the population and the density of master craftsmen are related to higher patent activities and thus to technical change and higher incomes. While enrollment rates in secondary schools are not significantly related to patenting, they are in fact positively associated with income as proxied by income tax revenues.

As a proxy for advanced literacy skills, Baten and van Zanden (2008) build a dataset on the number of books per capita in preindustrial Europe. Their results indicate that countries with higher levels of per capita book production in the eighteenth century (1750–1800) had faster economic growth during the nineteenth century (1820–1913). They also show that countries with higher initial book production experienced faster wage growth in the preindustrial era.

Two papers document an important role for upper-tail human capital during industrialization. Meisenzahl and Mokyr (2012) highlight the role of technical competence, reflecting the upper tail of the human capital distribution, as a key factor in Britain's economic leadership. Focusing on the industrialization in France, Squicciarini and Voigtländer (2015) use Encyclopédie subscriptions in the mid-eighteenth century as a proxy for the presence of knowledge elites. They find that subscriber density as a measure of upper-tail knowledge predicts city growth after the onset of the French industrialization. A main mechanism appears to be increased productivity in innovative industrial technology. By contrast, while associated with development in the cross-section, literacy levels do not predict city growth in their analysis.

Education and Protestant Economic History

The economic role that education played during industrialization has an interesting repercussion for the relative economic performance of different Christian denominations: it provides an explanation for Protestant economic history.

A Human Capital Theory of Protestant Economic History

In his *The Protestant Ethic and the Spirit of Capitalism*, Max Weber (1904/05) famously put forward the thesis that a specific Protestant ethic promoted economic success, among others by making Protestants work harder and save more. As an

alternative hypothesis for Protestants' relative economic prosperity, Becker and Woessmann (2009) propose a simple human capital theory: a higher level of education among Protestants made them more productive and therefore increased their economic prosperity. The core argument is that Martin Luther had urged his followers to advance education so that they could read God's Word, the Bible.

As indicated, during Luther's lifetime about 99% of the population was unable to read and write (Engelsing 1973). Against this background, it is noteworthy that in 1524, Luther published his pamphlet "To the Councilmen of All Cities in Germany That They Establish and Maintain Christian Schools" (Luther 1524), in which he pressured the Protestant rulers to build and maintain schools. He thus tried to foster the supply side of education. He also addressed the parents, in a sermon published in 1530 under the title "A Sermon on Keeping Children in School" (Luther 1530), trying to encourage the demand side of education.

For Luther, the Bible was the Word of God and thus the direct connection between God and humankind. For this reason, he wanted all Christians to be able to read God's Word by themselves. But since being able to read the Word of God, in the first place, required being able to read, the emerging Protestant church had to make sure that the population became literate. To that extent, led by the "Educator of Germany" (Praeceptor Germaniae) Philip Melanchthon, the Protestant reformers regularly inspected the Protestant cities and congregations during church visitations to make sure that they had introduced a proper education system. As Dittmar and Meisenzahl (2018) show, many Protestant cities introduced city-level ordinances that regulated many aspects of life, and these "constitutions" were of crucial relevance for public education.

This Protestant push for education, coincidentally, may have had the side effect in the economic sphere of serving as human capital that brought economic development. Instruction in reading the Bible may thus have generated an educated workforce that made Protestants more productive, leading to economic prosperity, so the argument goes.

Using county-level data from the first Prussian population census, Becker and Woessmann (2010) show that in 1816 the school enrollment rate in Protestant-majority counties was at about two thirds. In Catholic-majority counties, it was at less than 50%. Protestantism already led to more schooling before the industrialization. Its beginning in Prussia is typically dated to around 1830. In 1871, when the Prussian Statistical Office first collected data about the literacy of the population, Becker and Woessmann (2009) find literacy rates to be at 90% in Protestant-majority counties, 8 percentage points higher than in Catholic-majority counties.

As this finding could in principle be the result of reverse causality – if more education-prone counties had been the ones to adopt Protestantism – Becker and Woessmann (2009) use an instrumental variables strategy that exploits the initial concentric dispersion of the Reformation to disentangle cause and effect. As an instrument, they use a county's distance to Wittenberg, the birthplace of the Reformation, to predict its share of Protestants in 1871. Using only that part of the variation in the share of Protestants predicted by the instrument, they find that higher shares of Protestants indeed caused higher literacy rates.

The positive effect of Protestantism on education has also been shown in other contexts. Using Swiss data, Boppart et al. (2013) confirm a persistent positive effect of Protestantism on several education indicators, in particular in areas with conservative milieus. In the Swiss data, the effect of Protestantism was particularly large for reading skills, but also existed in other subjects (Boppart et al. 2014). Goldin and Katz (2009) show that in the United States in 1910–1938, areas that led in secondary education had higher shares of Protestant population. Similarly, Go and Lindert (2010) report that in some specifications, Protestantism had a positive effect relative to Catholicism on several schooling outcomes across US counties in 1850. In Ireland in 1871, illiteracy among different Protestant factions was between 7% and 14%, while it was 40% among Catholics (Cipolla 1969). In Finland in 1880, only 1.3% of Lutherans were not able to read or write, against 54.4% of Catholics (Markussen 1990). Also across countries, Protestantism and literacy were very strongly correlated in 1900 (cf. Becker and Woessmann 2009). Evidence from many countries thus supports the positive association between Protestantism and education.

Education and Protestant Economic Development Over the Nineteenth Century

Becker and Woessmann (2009) go on to show that the Protestant quest for education also had economic consequences: a more highly educated workforce did make Protestants more productive. Indeed, they find that Protestant counties had higher salaries, higher income tax receipts, and a higher share of the workforce in manufacturing and services. They assess how much of these differences in economic outcomes can be accounted for by the education differences that can be traced back to the exogenous part of the spread of the Protestant Reformation. Their point estimates suggest that once income differences are adjusted for literacy differences, the remaining difference is no longer systematically related to the religious denomination. Thus, if education had the same effect on economic outcomes here as it has been shown to have in other settings, the results suggest that the higher literacy of Protestant regions can account for at least some of their economic advantage over Catholic regions. In fact, they are consistent with the hypothesis that literacy can account for most, if not all, of the Protestants' economic lead. Similarly, in a simple "horse race" between literacy and Protestantism in explaining economic outcomes, literacy has a large and significant effect and Protestantism loses all its association with economic outcomes, suggesting that the whole economic effect of Protestantism may run through increased human capital. These economic consequences of the Protestant Reformation were probably not directly intended, but rather a side effect of the Reformation – one that had very long-lasting consequences indeed.

Education may thus be an alternative to Max Weber's specific Protestant work ethic in explaining Protestant economic success. Once differences in literacy rates between Protestant and Catholic counties are controlled for, little difference, if any, remains in economic outcomes. This implies that there is little room for

alternative explanations that are more in line with the Weber thesis, such as differences in work effort and in the propensity to save, at least in the Prussian heartland of the Protestant Reformation.

Further analysis suggests that the effect of Protestantism on economic outcomes appears to have been restricted to areas outside the major cities. Cantoni (2015) does not find an effect of the Reformation on the growth of city sizes in Germany, consistent with an interpretation that literacy was relatively high in cities independent of religious denomination.

Gender-Specific Developments

Interestingly, the available evidence suggests that girls benefited from the Protestant education push even more than boys did. As early as 1520, 3 years after the Protestant Reformation started, Luther published one of his main pamphlets: "To the Christian Nobility of the German Nation Concerning the Improvement of the Christian Estate" (Luther 1520). He writes: "And would to God that every town also had a girls' school, in which the girls were taught the Gospel for an hour each day."

This call was followed up with local church ordinances. In particular, Johannes Bugenhagen, one of the leading Protestant reformers, was to set the standard for subsequent systems in his church ordinance for the city of Braunschweig in 1528, which provided for girls to learn reading. In this ordinance, Bugenhagen requested that the city should have both four boys' schools and four girls' schools. In his church ordinance for Wittenberg, he extended the request for girls' schooling to writing and calculating.

The church ordinances in turn seem to have led to effective changes in the provision of schooling, as documented by Green (1979) for the example of the visitations by church officials to the local parishes in the Electorate of Brandenburg. In this core state of what later became Prussia, the number of schools for girls increased more than tenfold between 1539 (when the Reformation was introduced) and 1600. The request to also foster education for girls is quite in contrast to Catholic thinking even a century later: for instance, in Bavaria, the biggest Catholic state in Germany at the time, there were still strong objections to schools in the countryside in general as late as 1614 (cf. Gawthrop and Strauss 1984).

As a consequence of the Protestant Reformers' attempt to educate girls, Protestantism indeed led to a decrease in the gender gap in basic education in Prussia in 1816 as well as in the gender gap in adult literacy in 1871 (Becker and Woessmann 2008). Interestingly, while compulsory schooling laws closed the gender gap in primary education for both denominations over the course of the nineteenth century, the pattern of effects of religious denomination on the gender gap then continues to show up in secondary and tertiary education in the twentieth century. For instance, in the first year when women were admitted to university in Prussia in 1908, there were more than eight times as many female students of Protestant denomination than of Catholic denomination.

The gender pattern is also evident in cross-country data. Across European countries in 1970, a higher share of Protestants in the population is associated with a higher educational gender parity index, measured as the ratio of years of education in the female and male population (Becker and Woessmann 2008).

Education and Secularization

The period of industrialization not only brought change on the economic front, but it also led to broader societal developments that we want to highlight in the next two sections. One relates to modernization and the role of religion. The other is about the role of the family and the number of children families had.

The Expansion of Advanced Schools and Religious Participation

Industrialization went hand in hand with new demands on education. Different advanced school types offered education beyond compulsory schooling, and new teaching materials might have challenged old truths. This also affected the role of the church in society. Karl Marx (1844) described religion as "opium of the people" that is required to alleviate the ailments of poor economic conditions. If he was right, improved material conditions may have reduced demand for religious consolation and hence reduced church attendance. This particular point was analyzed by Becker and Woessmann (2013) using Prussian census data from the late nineteenth and early twentieth century. They find no effect of increased income on church attendance in a sample of Prussian counties.

A similarly prominent hypothesis links education and religion. The fact that education increasingly moved to center stage also posed a challenge to the role of the church. In his book *The Future of an Illusion*, Sigmund Freud (1927) – like David Hume and others before him – took the view that progress in education and science would lead to a decline in religion (cf. McCleary and Barro 2006).

However, cross-sectional evidence generally contradicts this view and finds a positive association between education and church attendance (Iannaccone 1998). Many studies using modern cross-country and individual panel data come to mixed results. However, it is unclear how these results transmit to the context of actual decade-long societal developments during important historical phases of secularization, in particular during the times of the industrialization.

Only a few studies take a truly long-run view, tracing developments over several decades. Franck and Iannaccone (2014) construct a cross-country panel data set for 10 countries over the period 1925–1990 to identify determinants of church attendance. They exploit their rich panel data using panel fixed effects estimates. In most of their specifications they do not find a statistically significant effect of educational attainment on church attendance. But they find a link between government spending on education and church attendance in their models, which may indicate a particular role for how governments shape the content of schooling.

Becker et al. (2017) go back further in time, to the period of Germany's second phase of industrialization, at the turn from the nineteenth to the twentieth century. It is a period where the influence of the church in society, as measured by Protestant church attendance (participations in Holy Communion), fell significantly, by about 2 percentage points per decade. At the same time, secondary schooling developed and might indeed be related to the decline in church attendance. Toward the end of the nineteenth century, enrollment in compulsory schooling (ages 6–14) was basically universal, leaving little, if any, variation in enrollment in elementary and middle schools. The focus of the analysis is on advanced schools (*Höhere Unterrichts-Anstalten*), which taught students to the age of 18. Variation in enrollment in advanced schools seems particularly relevant to test the effect of education on secularization because advanced schools were most likely to convey the kind of scientific thinking stressed by secularization hypotheses. Advanced schools were restricted to male students, whereas the separate advanced school type for female students (*Höhere Mädchenschulen*) had a different focus.

Did the expansion of upper schooling that went along with the industrialization in Germany affect the attachment of Germans to the Church, as one pillar of society? The data used by Becker et al. (2017) cover 61 cities in Germany over the period 1890–1930. Cities are of particular interest because advanced secondary schools were generally found in cities, whereas in rural areas only the most basic type of education was provided. Several editions of the statistical yearbook of German cities provide data on advanced-school enrollment rates and other city-level characteristics. The church attendance data were assembled by Hölscher (2001). These unique data about participations in Holy Communion were originally collected as part of the statistics of the Protestant regional churches of Germany and refer to church districts. Those typically extend beyond the boundaries of cities, but can be linked to the city-level data.

Taking a cross-sectional view at the data, cities with a larger enrollment rate in advanced schools have higher church attendance. However, this could well be driven by unobserved time-invariant city characteristics that may be correlated with both education and church attendance. It seems more convincing to use city-fixed effects and identify from variation within cities over time, in order to relate changes in church attendance to changes in advanced school enrollment. In fact, once city-fixed effects are being used, a negative relationship appears: cities with a stronger increase in advanced school enrollment see a stronger decline in church attendance. This also holds when controlling for measures of economic development, e.g., municipal tax receipts per capita that reflect income in a city, as well as for total population to capture (speed of) urbanization.

Alternatively to panel-fixed effects estimates, first difference estimates give the same finding of a negative link between advanced school enrollment and church attendance. Results are robust to a series of alternative specifications, such as controls for changes in industry structure, welfare spending, political vote shares, and different income measures.

Dynamic panel-data methods suggest that changes in church attendance follow changes in advanced school enrollment. The effect of advanced-school enrollment is strongest after a lag of about 10 years, speaking against bias from reverse causation

and suggesting that the effect of advanced education on religious participation materializes over time. By contrast, lagged church attendance does not predict advanced-school enrollment. Results are also robust in models with lagged dependent variables to account for persistence in church attendance over time.

Using the supply of advanced schools as an instrument for advanced-school enrollment yields similar results. This specification alleviates remaining concerns about endogeneity from the demand side by exploiting variation in advanced-school enrollment that originates from the opening and closing of advanced schools in a city.

Different Levels of Education

A fascinating question is whether the link between schooling and secularization is driven by advanced secondary schools only and whether different types of advanced schools make a difference. Starting with the first question, one might wonder whether universities played a similar role as advanced secondary schools for the decline in church attendance. To check this, Becker et al. (2017) use an indicator for openings of new universities as well as for the share of university students in the city population. Neither enters the model significantly, and the coefficient on the enrollment rate in advanced schools remains qualitatively unaffected.

Another issue that is of interest is the role of church-run schools and secular schools. During the period of observation, some advanced schools changed from being religiously affiliated into nonreligious schools. This might have been associated with a change toward a less religious curriculum. If that was the case, the main effect of advanced school enrollment might capture a change in curriculum and educational content rather than an increase in education per se (cf. Franck and Iannaccone 2014). To address this concern, Becker et al. (2017) include the share of Protestant advanced schools in a city as an additional control. This variable does not enter the model significantly and does not qualitatively change the main result. The same is true for the share of Catholic or secular advanced schools.

One issue of interest when looking at advanced secondary school types is the role of critical thinking versus scientific knowledge, which are two candidate mechanisms to explain the negative link between advanced school enrollment and church attendance. The school type most directly oriented toward scientific knowledge was the newly emerging *Oberrealschule.* Their curriculum focused on the natural sciences and students learned scientific facts that may have reduced their belief in religious explanations of natural phenomena. The traditional *Gymnasium* had a humanistic curriculum focused on classical languages and literature. It may have instilled only limited knowledge in modern sciences, but instead have sparked critical thinking toward the church as an institution in general. The same may be true, to a lesser extent, for the *Realgymnasium* with its curricular focus on modern languages.

Regressions where enrollment in these different types of secondary schools are introduced separately indicate that the relationship between educational expansion

and decline in church attendance is as strong for classical humanist grammar schools as it is for the newly emerging upper secondary schools whose curriculum focusses strongly on natural sciences. This pattern is more consistent with a leading role for the conveyance of critical thinking in general – which may undermine belief in the institutionalized church – than with a particular role for learning specific scientific knowledge of facts of natural sciences.

Overall, the results suggest that the Protestant push for education that can be traced back for centuries may ultimately and accidentally have led to a decrease in Protestants' attachment to their church.

Fascinating new research by Cantoni et al. (2018) gives somewhat related evidence on the link between Protestantism and secularization, even though not directly on the effect of education per se and secularization. Their evidence shows that in the immediate aftermath of the Reformation, in the sixteenth century, secular authorities acquired enormous amounts of wealth from monasteries closed during the Reformation. Graduates of Protestant universities increasingly took secular, especially administrative, occupations. Protestant university students increasingly studied secular subjects, especially degrees that prepared students for public sector jobs, rather than church sector-specific theology.

Education and the Demographic Transition

Another seismic change coinciding with industrialization is the demographic transition, the decline in fertility and mortality. The demographic transition was often studied in isolation, but unified growth theory models the transition from Malthusian stagnation to sustained growth in a unified framework (cf. Galor 2005). A key feature of many of these models is that the new technologies that emerged during the process of industrialization increased the demand for education, which in turn triggered the demographic transition at the end of the nineteenth century. The trade-off between the quantity and quality of children is a central ingredient of unified growth theory. While the child quantity–quality trade-off has been documented extensively in modern data, only recently have attempts been made to trace it down in historic data for periods before or during the demographic transition.

The Trade-Off Between Children's Education and Fertility

Becker et al. (2010) present the first evidence on the existence of the child quantity–quality trade-off before the demographic transition. Using Prussian data, they give support to a central tenet of unified growth theory, namely that it is a perennial trade-off. Using data for the year 1849, well before the demographic transition in Prussia in the later decades of the nineteenth century, they show that the child quantity–quality trade-off was already in operation then. The basis for the analysis is a unique micro-regional dataset of more than 330 Prussian counties stemming from full population and education censuses conducted in 1849 by the

Prussian Statistical Office. Using ordinary least squares estimations, they regress the county-level child–woman ratio (as the measure of fertility) on school enrollment (as the measure of education), and vice versa. Regressions controlling for many confounding factors all show a negative conditional correlation between fertility and education.

In order to get at causality, and in order to closely link with the theoretical logic of the child quantity–quality trade-off, which requires exogenous variation in the price of education, in parents' preferences for education, and/or in the cost of raising children, instrumental variables estimation is employed. Specifically, land ownership inequality and distance to Wittenberg are used as instruments for primary education to identify the effect of education on fertility. The idea of using land ownership inequality builds on Galor et al. (2009) who present a theoretical model where inequality in the distribution of land ownership negatively affects the implementation of human-capital-promoting institutions (see Cinnirella and Hornung 2016 for Prussian evidence). Since large landowners would not benefit from the accumulation of human capital, given the low complementarity between land and human capital, they will hold back provision of education. The second instrument, distance to Wittenberg, follows the work of Becker and Woessmann (2009) discussed above showing that the higher share of Protestants associated with distance to Wittenberg also predicts stronger educational attainment. Using any or both of these instruments together, the negative effect of education on fertility is confirmed.

For the opposite direction of causality, the adult sex ratio serves as an instrument for fertility. The adult sex ratio constitutes a measure of marriage market tightness affecting marriage rates and fertility. Using this instrument, the negative effect of fertility on education is confirmed.

Having established mutual causation between education and fertility, Becker et al. (2010) conclude that the child quantity–quality trade-off was already in operation before the demographic transition, in the 1849 cross-section. Building on this insight, they go one step further and ask whether school enrollment in 1849 predicts the fertility transition in 1880–1905. It turns out that it does. Counties with a higher primary school enrollment rate in 1849 see a faster decline in fertility during the period of the demographic transition in Prussia.

Becker et al. (2012) go back even further in time, using data from 1816 Prussia, to show the existence of a child quantity–quality trade-off even in that earlier cross-section.

Similar results of a child quantity–quality trade-off in historic data have recently been found in other countries. Diebolt et al. (2017) use French département-level data from 1851. Their results show that a decline in fertility during the French demographic transition caused an increase in educational investments. The inverse relationship is not borne out in their data though, a result they interpret as implying that the education effect on fertility may take time before being effective.

Very recently, Fernihough (2017) and Klemp and Weisdorf (2018) made further headway in uncovering evidence of the child quantity–quality trade-off in historic data. Fernihough (2017) uses individual data from the 1911 Irish census and

documents that children who attended school were from smaller families, as predicted by a standard quantity–quality model. These results are also in line with the US findings by Bleakley and Lange (2009) who use data from 1910, which, however, is after the main phase of the fertility transition in the US context. Klemp and Weisdorf (2018) go furthest back in time and exploit a genealogy of English individuals living in the sixteenth to nineteenth centuries. Using exogenous variation caused by fecundity differences, they find that increases in the number of siblings caused reductions in adult literacy.

It is fair to say that there is now ample evidence of a link between education and fertility before and during the period of industrialization, across a wide range of countries.

Going beyond the child quantity–quality trade-off, higher levels of education before the onset of the demographic transition predict the speed of the fertility decline during the demographic transition (Becker et al. 2010). Murtin (2013) uses cross-country data over more than 100 years, covering the period 1870–2000, to study the long-term economic determinants of the demographic transition. As predicted by unified growth theory, he finds that primary schooling is the most robust determinant of the fertility transition.

Women's Education and Their Fertility

The child quantity–quality trade-off is the most obvious incarnation of a link between education and fertility. It follows directly from theory and considers the trade-off faced by parents optimizing over the number of children and their education levels, linking quantity and quality within the same generation.

It is, however, conceivable that intergenerational factors matter as well. Becker et al. (2013) combine Prussian county data from three censuses – 1816, 1849, and 1867 – to estimate the relationship between women's education and their fertility before the demographic transition. Despite controlling for several demand and supply factors, they find a negative residual effect of women's education on fertility. Instrumental-variable estimates using educational variation deriving from land ownership concentration, as well as panel estimates controlling for fixed effects of counties, suggest that the effect of women's education on fertility is causal.

Similar evidence has been found for France. Murphy (2015) uses French département-level data for the last quarter of the nineteenth century. He exploits regional variation to study the correlates of fertility, estimating various fixed-effects models. His findings confirm the important role played by education in general, and female education in particular. He uses literacy rates of adult males as well as a measure of the literacy gap between adult females and males as predictors of marital fertility. In this sense, his work is more closely related to the intergenerational effect of (parental) education on their fertility than to the child quantity–quality trade-off. To conclude, education played an important role for the demographic transition via several avenues.

Conclusion

Recent advancements in cliometric research have furthered our understanding of the link between education and socioeconomic development during industrialization. We can summarize the findings of recent research as follows.

First, while the role of education during the British Industrial Revolution has long been the subject of scholarly debate, evidence from follower countries such as Prussia and France suggests that education helped these countries to catch up with the industrial leader Britain. The results on the important role of education during the first phase of industrialization in follower countries might call for a revision of the common interpretation in the literature that the first phase of industrialization had purportedly low educational requirements.

Second, recent research also points to regional differences in education and economic development that follow denominational differences. Protestant areas of Prussia had higher literacy than Catholic areas, a result that has also been found for Switzerland. These differences in education translated into further economic development in Prussian counties, pointing to an alternative interpretation of denominational differences in economic development than Weber's Protestant ethic. Instead of different attitudes to work or different saving behavior, differences in educational attainment may be a credible alternative explanation.

Third, the expansion of education also affected secularization. Cities in Germany saw church attendance decline as a consequence of higher enrollment in advanced secondary schools. These schools may have conveyed general critical thinking that may have undermined belief in the church as an institution.

Fourth, education interacted with fertility and was thus a factor in the demographic transition during the nineteenth century. In the context of the child quantity–quality trade-off, parents traded off the number of children against investments in education per child. The increasing payoff to education during the nineteenth century meant that parents increasingly opted for more education of fewer offspring. At the same time, more educated parents had fewer children, whereby education had a double effect on the fertility decline.

While taking a broad perspective, we have given substantial prominence to findings from the Prussian industrialization period, not least because Prussian census data start earlier (in 1816) than in most other countries (cf. Becker et al. 2014). Prussian county-level data had already been analyzed by demographers 25 years ago (cf. Galloway et al. 1994). More recently, these findings have been complemented with evidence from other countries where large-scale digitization efforts started somewhat later.

Certainly, education had additional consequences on human development during industrialization beyond those covered here. For example, Cinnirella and Schüler (2018) show that the share of central spending in education positively affected votes for pronationalist parties in Prussia in 1886–1911, suggesting that public primary education may have played a role of indoctrination that helped the process of nation building in the context of Imperial Germany. Without a doubt, the role of education during industrialization leaves abundant open questions for cliometric research to address in the future.

Gender in Economic History

Joyce Burnette

Contents

Abstract

This chapter explores how cliometrics has helped us answer five questions about the role of women in economic history: How much did women participate in the economy? Why did women earn less than men? Why did men and women do different work? What determines gender roles? What role did women play in economic growth? The answers reveal that understanding the role of women is essential to understanding economic history.

Keywords

Women's work · Women's wages · Labor force participation · Gender gap · Occupational segregation · Gender roles · Gender norms · Girl Power

Introduction

What can the study of cliometrics offer to the study of gender? While one answer might be that it can quantify gender differences in wages and employment, in fact cliometrics has much more to offer. Cliometric provides a method for understanding the causes of the gender differences we observe. Its method is to use economic theories to form hypotheses about the past and then test these hypotheses with data. The cliometric method has helped us answer interpretive questions that do not seem to need quantitative analysis, such as why the gender gap exists or why gender roles vary across societies. It has helped us to answer questions about why we observe gender differences in behavior or how norms change over time. Before cliometrics, the relationship between culture and women's work was usually seen as one-directional: gender ideology explains what women did and what they were paid. Cliometrics has given us a window into how gender ideology is determined and has turned this causation around, demonstrating how economic realities determine the gender roles of different societies. To demonstrate how cliometrics has shaped our understanding of gender in history, I will explore the answers to five questions about gender in economic history.

How Much Did Women Participate in the Economy?

In economics the history of women's work is often written as one of increasing participation. In the USA, female labor force participation grew from 18% in 1890, and less than 5% for married women, to approximately 60% in the early twenty-first century (Costa 2000). Similarly, in England, married women's labor force participation grew from 10% in 1900 to 74% in 1998. While this growth is striking, focusing on the twentieth century is misleading because it leaves the impression that women's participation before the twentieth century was low. Historians have corrected this error by pointing out that in fact women's participation in the past was quite high, and the low participation rates of the early twentieth century were not the historical norm but a brief deviation from the long-established pattern of women's economic activity. Goldin (1995) noted a U-shaped relationship between female labor force participation and GDP per capita across a wide range of countries, suggesting that women's participation declines during industrialization and then rises. The historical evidence for the USA and UK fits that hypothesis; in both countries married women's labor force participation declined during the nineteenth century before rising during the twentieth century.

Any attempt to determine women's participation in the past must confront the fact that our definition of labor force participation is both unfair and anachronistic. An individual is counted as part of the labor force if he or she worked for pay. The self-employed and those who work from home are included, but today these categories contain only a small percentage of workers. Home production of goods consumed by the household is not included, even though these activities are economically productive. While economists know that home production should be counted as part of a

country's economic output, they have failed to adjust measures of GDP, arguing that home production is too difficult to value. In acknowledgement of this failure, labor force participation is often described as "work outside the home." Such a definition, however, is problematic for the gender historian.

The modern definition of labor force participation is unfair to women because it defines work usually done by women as not economically productive. A child-care worker employed by a day care counts as participating in the economy, while a mother taking care of her own children does not. If counted, household production for family use would increase GDP between 25% and 40%. By failing to count housework, we ignore a substantial portion of productive activity that has historically been women's work. In 2003, women did nearly twice as much housework as men, down from 1965 when women did three and a half times as much housework as men. Labor force participation does a particularly bad job of describing women's work in the past. A seventeenth-century woman who spent her day milking the cow, spinning yarn, helping her husband in his craft, and preparing the family meals did not have a job, but she was working nonetheless.

Failing to count household production as work is also anachronistic. At the beginning of the nineteenth century, housewives were considered productive workers, but during that century, a combination of economists who did not value women's contributions and male unions who wanted to argue that men's wages should be high enough to support a family led to re-definition of housewives as dependents rather than productive workers (Folbre 1991). In Britain, the 1861 census included wives and widows without a stated occupation in the category "Persons Engaged in the Domestic Offices." By 1881, however, wives were included in the category "Persons without Specified Occupations." Our implicit assumption that household production is not work is itself the result of a historical process that defined housewives as unproductive.

The concept of labor force participation is also anachronistic because in the past most people, men as well as women, produced goods that they used themselves. Households grew their own food and manufactured their own clothing. Households also made their own soap, brooms, and furniture. Relatively few people worked for wages, and most of those did not live entirely on their wages. In the sixteenth century, two-thirds of English rural residents had access to enough land to produce their own food and did not have to work for wages. Among those who did work for wages, the vast majority kept animals and thus produced at least some of their own food. Over time, households specialized more and purchased a greater percentage of their consumption goods from the market, so that eventually self-provisioning became a marginal activity rather than the norm. By ignoring household production, labor force participation ignores the majority of what men as well as women did in the past.

In addition to being a flawed concept, female labor force participation before the twentieth century is poorly measured. Most measures are based on censuses or tax records, which systematically ignore women's work. Because women did many different kinds of part-time work, or simply because they were women, they were not recorded as having occupations. Sometimes the work of women was not

recorded because a husband legally represented his wife; medieval English court records often list men as paying brewing fines even though their wives did the brewing (Bennett 1996). Amsterdam's 1742 tax register lists various ship captains as the owners of shops; these shops must have been run by their wives when they were at sea, but the wife is not mentioned (de Vries and van der Woude 1997). Numerous historical studies have identified workers who were paid by an employer but were listed with no occupation in the census. If these errors are corrected, female market participation was not as low in 1900 as it first appeared, but there is still a U-shaped pattern, with participation declining in the nineteenth century and increasing in the twentieth.

While reported occupations are often more a statement of gender ideology than of actual work, we can often find information about what women did in records not intended to record occupation, such as statements of witnesses in court cases. In fact, these records probably recorded what women did more accurately than official occupational lists. Examples of studies that have used court records to examine women's work are Earle (1989) for London, Ogilvie (2003) for Germany, and Agren (2017) for Sweden. All of these studies reveal wide participation of women in productive work.

If we include all productive activity, women's participation in work was nearly universal in the pre-industrial world. Even noble women participated in textile production. If we limit ourselves to work for the market, female participation was still widespread. In the early eighteenth century, witnesses in London courts were asked how they made their living; 54% of female witnesses claimed to be wholly maintained by their own employment, 18% partly maintained by employment, and only 28% claimed to have no paid employment (Earle 1989). Paid employment was likely less common in the countryside, but still much higher than the 10% observed around 1900. Horrell and Humphries (1995) examine the budgets of poor English families from 1787 to 1865 and find that around half of the wives had cash earnings to contribute to the family income. In seventeenth-century Netherlands, women outnumbered men in the fish market and the eel market, and Montague noted that "more women are found in the shops and business in general than men" (van den Heuvel 2007, pp. 41, 98). Hufton (1975, p. 10) concludes that in eighteenth-century France, "No girl expected to renounce work on marriage." Women's occupations were less likely than men's occupations to appear in official records because the man was seen as the head of the household, because many wives worked as assistants to their husbands, and because women often combined many different part-time activities. Nevertheless, women certainly worked.

If female participation in the market economy was so high before 1800, why did it decline during the nineteenth century? A number of factors combined to produce this decline. One reason was simply that male earnings rose. While there has been a great deal of debate about whether real wages in Britain rose during the period 1760 to 1830, it is generally agreed that wages rose after 1850. In the Netherlands as well, male earnings rose and measured female labor force participation fell during the second half of the nineteenth century (Botar 2017). Labor supply usually falls in response to higher non-labor income (leisure is a normal good), so we would expect

female labor supply to fall in response to rising male earnings. Another reason for declining market participation was that it became less socially acceptable for women to work outside the home. Trade unionists argued for higher wages by claiming that men should earn a family wage that would allow them to support their dependents. In doing so they created a situation where a man lost status if his wife was seen to work outside the home, because it implied he could not provide for his family. Mokyr (2000) suggests that increased knowledge of diseases and the discovery of germs led to an increased demand for cleanliness. Households purchased cleanliness by shifting the wife's labor from the market to housework. A less optimistic interpretation of the decline in female participation is that the demand for female labor was declining, so that women were unable to find employment (Humphries and Sarasua 2012). If we ignore household production, the market participation of married women reached a historic low around 1900 when the labor force participation rates of married women were about 10% in Britain and 6% in the USA (Costa 2000, p. 106).

The rise in female market participation over the twentieth century has been more extensively studied, but most studies describe the changes rather than identifying their cause. It is difficult to determine the cause of rising participation because most of the important variables were both a cause and effect of the changes in participation. Lower fertility, increased education, and changing cultural expectations contributed to rising female market participation, but were also a result of that rise. Analysis is made more difficult by the fact that women make important lifetime decisions about education and fertility when they are young, based on what they expect their opportunities to be in the future, so that at a point in time women of different cohorts behave differently.

While increasing male incomes tended to discourage female participation, women's labor supply response to their own wages has been positive during the twentieth century. This means that the substitution effect, which implies that women work more because work is more rewarding, dominates the income effect, which implies that women with higher incomes would spend some of that income on leisure and work less. However, women's wages were also rising during the nineteenth century, when their labor force participation was falling (Goldin 1990). Either other factors were important or the relationship between wage and labor supply changed over time. Galor (2005) suggests that there was a threshold, after which the effect of women's wages on their labor supply turned positive.

Since female wages rose during the twentieth century at the same time as participation increased, there must have been an increased demand for female labor. The sectoral shift from farming and manufacturing to services and the feminization of clerical jobs increased the demand for female labor since women have a comparative advantage in services, and women preferred white-collar work to blue-collar work. Women responded to the increase in demand, and the higher wages they could earn in the market, by working more. Later in the century, women entered a wide range of professional occupations. Entry into these occupations was, of course, made possible by women's increased education, which may itself have been the result of women's expectations of increased participation. Improved

contraception, especially the legalization of the pill, made women more willing to make human capital investments in their twenties, and thus increased the number of women in professional schools (Goldin and Katz 2002). Cheaper child care also contributed to increasing female participation. In Europe, public policy in the form of paid maternity leave and subsidized child care has encouraged female participation.

While we might expect that household technologies such as plumbing, washing machines, refrigerators, and vacuum cleaners reduced the demand for household production, the evidence suggests otherwise. These innovations did not reduce the time spent by a wife in housework because households either shifted work from paid domestic servants to the housewife or increased standards of cleanliness. However, time-saving appliances may have had effects on the next generation of women. Lewis (2015) finds that electrification had no immediate effect on female employment, but that it was associated with increased school attendance by girls and subsequently higher participation and earnings for women in the next generation.

Attitudes towards women's work outside the home changed considerably over the twentieth century, a change that was to some extent a result of increasing participation. The fraction of Americans who say they approve of "a married woman earning money in business or industry if she has a husband capable of supporting her" increased from around 20% in the 1940s to around 80% in the 1980s (Fernandez 2013, p. 473). While in 1968 only about a third of teenage girls expected to be working outside the home at age 35, by the 1980s over 80% expected to be working at age 35 (Goldin et al. 2006). Given their changed expectations, young women invested more in education and delayed childbearing. Women whose mothers were in the labor force are more likely to be in the labor force themselves. Gay (2017) shows that regions of France that had higher World War I mortality also had higher female participation, and that daughters of these women also had higher participation rates. Men's preferences also mattered; men who had working mothers are more likely to have working wives, and World War II mobilization had a temporary impact on the generation who were mothers during the war, but a permanent effect on the next generation (Fernandez et al. 2004).

While rising female participation is the story of the twentieth century, it is not the story of earlier periods. The low levels of market participation around 1900 were a historical aberration. If we also include production of goods and services for the use of the household, then even the supposedly low participation rates of the late nineteenth and early twentieth centuries would be much higher. Women's work is not a new invention, but a long-established habit. For women as for men, work has been the normal state of existence throughout history.

Why Did Women Earn Less than Men?

With a few rare exceptions, women have consistently earned less than men. For some, this consistency is proof that wages were socially determined. Women's lower pay has been attributed to the patriarchal structures of society, custom, or institutions. An alternative hypothesis is that women's wages were lower than men's

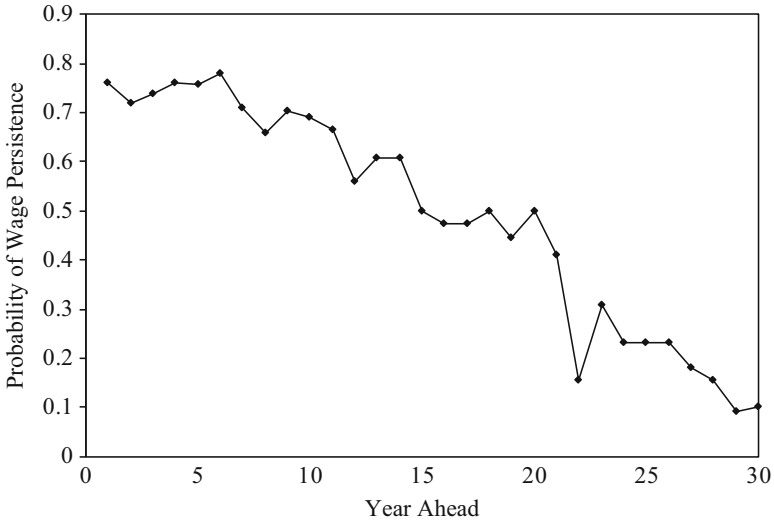

Fig. 1 The Persistence of Female Agricultural Wages over Time. (Source: Burnette 2008. Note: Based on a sample of 50 English farms. For each farm I record the modal summer wage for female day-laborers. The graph shows the probability that two wages at the same farm X years apart were the same.)

because their productivity was lower. Economic theory suggests that the wage is equal to the marginal product of labor, that is, the increase in the value of the firm's output that occurs when the worker is hired. If women had lower marginal productivity than men, a competitive market would pay them lower wages. Women could have had lower productivity than men even if they did the same work and put forth as much effort as men. Women might have had lower marginal productivity because they had fewer skills (which itself is socially determined) or because they are physically different from men. Women have less physical strength than men and, unlike for other gender differences, there is relatively little overlap in the male and female distributions; the average woman's maximum lift capacity is 2.5 standard deviations below the average man's (Burnette 2008). Throughout much of history, many production tasks depended on strength, and thus women's lesser strength would have given them lower productivity.

Since there are multiple hypotheses that predict that women will earn less than men, we need to examine other evidence to determine which hypothesis is correct. There is, of course, no reason to expect that the same hypothesis is correct for all times and all places. Future cliometricians will surely add refinements to the picture presented here. Currently the data suggest that, for most occupations before 1900, the gender gap was determined by market forces rather than custom.

If wages were set by custom, we would expect them to change relatively slowly, and they should not respond to changes in demand. The data allow us to reject these implications. Contrary to what has sometimes been suggested, women's wages were not fixed at the same level for decades, but did in fact change frequently. Figure 1

shows the probability that the female summer wage at a particular English farm remained the same a certain number of years in the future. The probability that a wage remained the same one year in the future was 76%, indicating that in 24% of the cases the wage changed from one year to the next. After 15 years, the probability of no change was only 50%. This flexibility suggests that women's wages were not determined by custom. There is also evidence that women's wages responded to changing economic circumstances. Women's as well as men's wages changed rapidly in response to the Black Death. For unskilled construction workers in Navarre, Spain, men's daily wages jumped from 9 pence in 1348 to 17.8 in 1349 and then fell a bit to 15 pence in 1353. Women's wages rose a bit more slowly but tripled over this period, rising from 4 pence in 1348 to 7 in 1349 and 12 in 1353 (Hamilton 1936). We also observe regional changes in English agricultural wages in response to the Industrial Revolution. Around 1750 women's wages were lower in the north of England than in the south. Over the next hundred years, however, women's wages rose in the north, where the factory production mushroomed, and stagnated in the south, where women lost traditional work such as hand spinning, so that by the early nineteenth century, women's farm wages were higher in northwestern England than in southern England (Burnette 2004).

It is also possible that wages did not match productivity because they were set by government regulation. There are numerous examples of governments setting wages, and some of these regulations were more effective than others. After the Black Death, the British government set maximum wages in an attempt to keep wages from rising. However, given that wages rose substantially in this period, the attempt seems to have been largely unsuccessful. Early modern Germany was more successful in enforcing maximum wages for spinners and seamstresses. The guilds and the state combined to enforce the maximum piece-rates, confiscating the wool and yarn of merchants promising to pay higher wages to spinners (Ogilvie 2003). The Germans had more success controlling wages because they generally had more control over activities in their community, including who was allowed to live in the community and who was allowed to marry. Thus market wages seem to have prevailed where markets were competitive, and non-market wages could be enforced only where there was a great deal of monopoly power.

Some have suggested that physical strength cannot explain the gender wage gap because this gap changed dramatically over time (Bardsley 1999; van Zanden 2011). In England, the female-male wage ratio for casual daily labor ranged from a high of 0.90 in the 1390s to a low of 0.32 in the 1840s (Humphries and Weisdorf 2015). However, the observed changes in the wage ratio are compatible with strength being an important determinant of the wage ratio. There is no reason to expect that the market price for strength would stay the same over centuries, any more than the market price of land or grain would remain fixed. The extent to which strength matters varies by task. It matters a lot for plowing, a little for weaving, and not at all for hand spinning. If we line up all the tasks in the economy by this ratio, an efficient economy would assign women tasks requiring less strength and men tasks requiring more strength. Employers will observe the market

wage ratio and hire women if the productivity ratio in their task is higher than the market wage ratio, and hire men if the opposite is true. The employer will hire both men and women only if the wage ratio is equal to the productivity ratio, so it is not surprising that men and women most often did different tasks, and only occasionally are found working together. The market wage ratio is then determined by the demand for different tasks and the number of male and female workers available. When a limited number of men were available relative to the demand for strength-intensive tasks, strength earned a premium. If a society had a high demand for strength-intensive tasks and the marginal task was plowing, the gender wage gap would be large, whereas if the society had a low demand for strength-intensive tasks and the marginal task was weaving, the gender wage gap would be smaller. Since labor markets were local, we would expect to find different wage ratios and different divisions of labor in each town. Even if strength did determine the female-male wage ratio, we would not expect the ratio to be constant over time or across locations.

While the female-male wage ratio in England fell from 80% in 1300 to around 40% in 1800, that fall was not continuous. The gender wage gap for day laborers increased between 1400 and 1600, fell until 1750, and then rose again (Humphries and Weisdorf 2015). During the fifteenth century, the expansion of the wool industry drove up wool prices and made sheep farming more profitable than arable agriculture. Evidence from later periods suggests that increased sheep-farming was associated with a decline in the demand for female labor in agriculture, reducing the relative female wage (Burnette 1999). If sheep-farming had the same effect on the demand for female labor in the fifteenth century, then we would expect to see an increase in the gender wage gap during this time. The fall in the English gender gap after 1600 corresponds to the increased demand for spinning due to the shift from woolen cloth to lighter worsted textiles, known as the "new draperies," which increased the relative demand for spinners. Muldrew (2012) estimates that for the older woolen cloths 59% of the workers were spinners, while for the "new draperies," 83% were spinners. This increase in the demand for spinning should have decreased the strength premium paid by the market. After the invention of the spinning jenny in 1764, machinery rapidly put hand spinners out of work, and the resulting decline in demand for female workers explains declining relative female wages over the period 1750–1850. Thus changes over time in the gender wage ratio are consistent with a strength-related gap, since the market price of strength can change.

When examining whether workers were paid for their productivity we must remember to compare outputs, not inputs. If a man and a woman did the same task for an hour, they provide the same input (one hour of labor) but do not necessarily produce the same output. If a woman reaped less grain in an hour than a man, and if she was paid the same rate per acre reaped, then she would earn less per hour. Evidence suggests that, when working at the same piece-rate, women did earn less per hour because they produced fewer units per hour. For nineteenth-century US manufacturing, Goldin (1990) finds that women produced 80% as much as men when working for identical piece-rates.

Table 1 Testing for wage discrimination

Date	County	Industry	Wage ratio	Productivity ratio	Source
1832	USA	Manufacturing	0.46	0.42	a
1839–1845	France	Cotton spinning	0.54	0.63	b
1839–1845	France	Wool spinning	0.49	0.43	b
1839–1845	France	Cotton and wool weaving	0.51	0.53	b
1850	USA	Manufacturing	0.49	0.41	a
1860	USA	Manufacturing	0.55	0.53	a
1870	Canada	Manufacturing	0.38	0.49*	c

One way to test the productivity hypothesis is to use firm-level data to estimate the productivity ratio and then directly test whether the wage ratio equaled the productivity ratio. A small number of studies have done this for historical and modern labor markets. Table 1 summarizes the results of these studies. Most studies find that female workers had a lower marginal product than male workers, a difference that reflects their relative age and work experience as well as strength, though two studies find that women were at least as productive as men. Generally the productivity ratio rises over time; twentieth-century ratios are higher than nineteenth-century ratios. There is evidence of wage discrimination in the twentieth-century USA and in Canada in 1870, in the sense that the female-male wage ratio was lower than the productivity ratio. In other countries, and in the USA during the nineteenth century, there is no evidence of wage discrimination. In 1900, US manufacturing exhibits wage discrimination among white-collar workers but not among blue-collar workers.

The evidence in Table 1 supports Goldin's (1990) claim that wage discrimination appeared in the USA during the early twentieth century among clerical workers. The gender wage gap was negligible when workers were first hired, but grew with

experience as males gained more from their years with the firm than females. Explanations of wage discrimination involve firms offering incentives to men but not women. Goldin (1986) suggests that firms chose different monitoring systems for men and women, paying women, who were expected to quit, piece-rates, and offering men, who were expected to stay at the firm longer, wages that increased with tenure to discourage quits and encourage hard work. Owen (2001) suggests that men's lower turnover rates were the result of internal labor market policies. She finds that men's quit rates were initially higher than women's, but fell more rapidly than women's in the 1920s, the time during which the firms she studied centralized employment decisions and began to reward tenure. Owen suggests that women did not benefit as much as men from incentives such as pensions and company housing, and thus when firms implemented internal labor markets, male turnover fell more than female turnover and became less sensitive to labor demand conditions. Thus, wage discrimination seems to result from the fact that men, but not women, benefited from internal labor market policies designed to reward persistence at the firm. Estimated productivity ratios from US manufacturing in 2002 suggest that among workers under 35, the wage ratio is close to the productivity ratio, but that as workers age these ratios diverge. While men and women have similar increases in productivity as they age, male wages increase substantially more than female wages, so that among older workers there is substantial wage discrimination (Burnette 2015).

Wage discrimination is not the only possible form of discrimination women could face. If women were confined to low-wage occupations due to discrimination, they would have earned less due to the fact that crowding lowered the marginal product in those occupations and we would not find evidence of wage discrimination. Since occupational segregation was a different type of discrimination, we need to ask why women typically worked in lower-paid occupations than men.

Why Did Men and Women Do Different Work?

Throughout history, women and men have usually done different work. In societies that used the plow, men dominated agricultural work. Where land was cultivated with a hoe, women did more of the field work. Women produced most textiles, but sometimes men did certain tasks in textile production. Hand spinning was women's work, while finishing tasks such as fulling and shearing were usually men's work, and handloom weaving could be either. Routine household tasks such as cooking, cleaning, fetching water, and child care were generally women's work. Women also prepared most food and drink, though men also participated, particularly where production was on a larger scale. For example, men took over brewing when the move from ale to beer introduced large-scale production in the brewing industry (Bennett 1996).

While there are clearly gendered patterns of work, we should not exaggerate the extent of the differences. Agren (2017) suggests that work done by men and women in Sweden was not as different as occupational titles would suggest. While men were labeled as doctors and women were not, both men and women provided care for the

sick. While the frequency of tasks differed across the genders, there were few tasks that were never done by one of the genders. Men occasionally provided childcare, while women sometimes drove horses, shoveled soil, or cut down trees.

Even when women produced for the market rather than for domestic consumption, they generally specialized in food, drink, and clothing. Earle (1989) uses the statements of witnesses in London courts c. 1700 to examine the work of men and women. Most of the women claimed they were at least partly maintained by their own employment, and most of the work they did involved cleaning or preparing food or clothing. Work relating to domestic service, textiles and clothing, food provision, and nursing accounted for four-fifths of all women's work in this sample. Such observations have led some historians to conclude that women were confined to occupations that were associated with household production. Perhaps women were allowed to participate in the market, but only in areas associated with the domestic sphere, and thus seen as appropriate for women. This claim, however, ignores the extent to which men were also involved in producing food and clothing. For English towns in the late fourteenth century, Goldberg (1992) finds that around three-fourths of female household heads were employed in victualing or in textile and clothing trades, but she also reports that 45% of all household heads (who were primarily male) were in these trades. As late as 1841 nearly half of British men were engaged in trades relating to food and drink (including agriculture), textiles and clothing, or domestic service (compared to 89% for women). There were differences of course. Women were more concentrated in domestic work than men, and women were much less likely to work in the most high-paid and high-status occupations, but the difference is one of degree.

The same is true of the claim that women worked in the home and men worked outside the home. Gender differences in the location of work were not as great as ideology would suggest. Ogilvie (2003) finds that 45% of the time that women are mentioned in German church-court minutes they were in the home, while men were in their homes 39% of the time. For medieval England, Hanawalt (1986) finds that 21% of women's accidental deaths, and 8% of men's accidental deaths, occurred at home. While it is true that women were more likely to be at home than men, we should not conclude that women were confined to the home.

One hypothesis for why women did different work than men is that entry into certain occupations was constrained, so that men monopolized the most lucrative occupations and women were confined to lower-pay and lower-status occupations. In the pre-industrial period, guilds were the most likely source of occupational constraints. When guilds were strong, they could decide who was allowed to enter their trade. With industrialization unions and professional organizations replaced guilds as sources of occupational constraints. Women may also have found it hard to enter capital-intensive occupations as a result of law and inheritance practices that left them with less control over their wealth and less access to credit than men. To the extent that such constraints kept women out of better-paying occupations, women earned less than they otherwise would have.

An alternative explanation for the sorting we observe is that women choose different work than men because they maximized their incomes by doing

so. Women would not choose occupations where output was most sensitive to strength, such as plowing, and would choose occupations were strength mattered little or not at all, such as spinning. According to this explanation, occupational sorting does not reduce women's incomes, because if a woman did choose to plow she would not be very productive and would earn less from doing so than from textile production or food preparation. According to this view, differences in men's and women's work are simply responses to the different comparative advantages of men and women.

There is evidence in favor of both of these hypotheses, depending on the location and type of work. In general, comparative advantage was more important in low-skilled work, and in more competitive societies such as England and the Low Countries, while constraints were more important for skilled work, and for more highly regulated societies such as Germany.

Men's comparative advantage in tasks requiring strength is able to explain some of the broader historical patterns of work. For example, women rarely plowed, mowed with a scythe, or hewed coal, because these jobs required a great deal of upper body strength. The broad association of men with plow-based agricultural and women with textiles, which is found in many different societies, is consistent with comparative advantage. In one of the earliest Western texts, Homer's *Odyssey*, we observe women engaged in textile production (spinning and weaving) and men engaged in agriculture and war. The association of women with textiles and men with agriculture is also observed in China. Within textile production, hand spinning was consistently women's work. Handloom weaving, which requires some strength, was sometimes women's work, and sometimes men's work, depending on the demand for strength in the economy. Around the year 1000 in Europe looms became heavier and men took over weaving. During the Industrial Revolution, women and children continued to spin with the spinning jenny and the throstle, but with the invention of the spinning mule, adult males took over spinning because the mule required a great deal of strength, at least in its early form. The mechanization of spinning greatly reduced the number of spinners needed, and many women entered handloom weaving.

In a few cases, certain domestic tasks were assigned to women in spite of the fact that they required strength. Before wind- and water-powered mills were built, early medieval women used hand mills to grind grain into flour. Laundry has also been women's work, in spite of the strength required. Laundry likely required more strength than weaving, suggesting room for improved efficiency in nineteenth-century Europe.

Constraints on women's employment were most effective when enforced by specific institutions and least effective when they were simply cultural expectations. While many people expressed gender role preferences, such expectations do not seem to have been strong enough to prevent employers from hiring women when it was profitable to do so. There are many examples of employers acting in ways that are inconsistent with their own ideologies. In 1833, a farmer from Cornwall noted that "Farmers in this neighborhood are obliged to employ men for what women and children should do" ("Rural Queries" Newlyn East, Cornwall). In 1876, the owner of

a lace warehouse told a parliamentary committee that "we have as a rule an objection to employing married women, because we think that every man ought to maintain his wife without the necessity of her going to work." But he also admitted to employing 49 married women and added that "we wish that the present state of things as regards married women should not be disturbed" (quoted in Rose 1992, p. 32). While both men clearly had ideas about proper gender roles, they were quite willing to act in ways that conflicted with their ideology. The empirical evidence also suggests that employers were willing to change the gender composition of their workforce in response to changes in wages. In the 1770s, farmers hired more men where female wages were high, and more women where male wages were high.

Institutional barriers were sometimes more effective in limiting female employment. When guilds or unions were powerful enough to enforce their rules, they were able to prevent women from entering an occupation. German guilds, with the support of the state, excluded all women except wives from their trades. British mule-spinners, using violence, were able to prevent women from working as mule-spinners. Requiring a university education, which was not open to women, was an effective method of excluding women from medicine and law. Women in business could also be limited by their legal status. Generally, such barriers were weakest in Britain and the Low Countries, and strongest in Germany.

In England, occupational constraints were relatively weak. Many guilds had female members, and some guild regulations were written in inclusionary language (Power 1975). Girls could be apprenticed, and women could take apprentices, though few actually did. In the eighteenth century, only 4% of apprentices (not including parish apprentices) were girls, and only about 3% of those taking apprentices were mistresses (Simonton 1991). Not all guilds were open to women, though, and some specifically forbade the employment of women not related to the master. Even when they did try to limit women's work, however, English guilds had little power. In the 1690s only 38% of London merchants were members of a guild. Large numbers of weavers practiced the trade without an apprenticeship. By the early nineteenth century, only 5–10% of weavers had served an apprenticeship. In Leeds, cloth makers who were not guild members had their own hall for selling cloth (Burnette 2008). As a result, women can be observed doing a wide range of work. Women made nails and screws, and some worked as auctioneers or merchants. In the 1841 census, only 23% of occupations were exclusively male (Burnette 2008).

Women in the Low Countries were also relatively free to engage in the market. With many Dutch men either at sea or dead due to the high mortality rates there, women outnumbered men in Dutch towns and women conducted much of the business of the towns. In some Dutch markets, more than half of the sellers were women (van den Heuvel 2007). Guilds were not particularly strong in the Low Countries, perhaps because there were so many cities competing for trade and industry. During the fourteenth and fifteenth centuries, trade shifted from Bruges, to Antwerp, and then to Amsterdam, each time moving to a town where guilds had less power. Later, in the sixteenth through eighteenth centuries, Dutch guilds increased in number. However, the power of these guilds was still limited. In the sixteenth century, cities attempted to prohibit new industry in the countryside, and

even obtained a prohibition on new rural industries from the central government in 1531, but this prohibition proved unenforceable (de Vries and van der Woude 1997). While some Dutch guilds were closed to women, many guilds had women as members, and a few guilds were exclusively female. The hacklers' guild in Gouda and the guild for pulling boards through the canals of Utrecht were all-female (Schmidt 2009; de Vries and van der Woude 1997). Attempts to exclude women often proved unsuccessful. While the tailors' guild attempted to exclude women in the late seventeenth century, they were not successful and eventually admitted women to the guild. In Gouda in 1788–1789, one-third of all guild members were female, mainly because the largest guild, the tailors' guild, included seamstresses and was 84% female (Schmidt 2009).

However, even in these relatively open economies, not all work was available to women, and it was the most skilled occupations that effectively excluded women. By the nineteenth century, unions and professional organizations were more important than guilds in limiting female employment. While many male unions attempted to prevent female employment, only the most effective were able to do so. Scottish coal miners attempted to ban women workers in 1836, but failed. Generally, unions of low-skilled workers, such as handloom weavers, were unsuccessful. In skilled occupations, unions were more successful in their demands that employers not hire women. Scottish calico printers and English woolcombers excluded women. The mule-spinner's union successfully excluded women even after the self-actor reduced the strength requirements of the machine. The English compositors' union was relatively strong, so England had fewer female compositors than Edinburgh or Sweden. Tailors excluded women until 1834, when the union lost a strike and women entered the trade in large numbers.

Professions also succeeded in excluding women, often by controlling licensing or requiring formal education which as not available to women. The medical profession had historically included women. Early modern women acted as healers and sometimes joined the barber-surgeons guild, and before the eighteenth century all midwives were women. In sixteenth-century Norwich, 10 of 73 medical practitioners were women (Burnette 2008). In the eighteenth and nineteenth centuries however, women were forced out of medicine. The Royal College of Physicians admitted only university-educated men and gradually eliminated their competition by convincing the public that others were not qualified. Beginning in the seventeenth century, and culminating in male dominance of the profession in the nineteenth century, physicians somehow convinced people that women were not qualified to act as midwives. In the clergy as well, professionalization edged out women. While the Church of England did not allow women to be priests until 1994, Quakers and Methodists both had women preachers during the early years of their movements. However, as those movements became established and began to keep official lists of clergy, women preachers were no longer welcome. Thus, even in a relatively open society such as Britain, women did not have access to the most skilled occupations.

In Germany, occupational constraints were more severe. While fourteenth-century guilds admitted women, and Cologne had some all-female guilds, over time guilds placed restrictions on women's work, arguing that women's proper

place was in the home. By the eighteenth century, German guilds were strong and kept tight control over employment. All occupations except farming, spinning, housework, and manual labor were guilded, and only males were admitted to guild apprenticeships (Ogilvie 2003). This meant that women's work options were narrow. As a result, women sometimes ended up doing strength-intensive tasks such as plowing, which were not their comparative advantage. The system benefited men, who had less competition for their guilded work and thus higher earnings. In addition to limiting the range of occupations in which women could work, guilds also used wage ordinances to keep the wages of spinners and seamstresses low. The piece-rates set for spinners in the seventeenth and eighteenth centuries were below market rates and thus required active enforcement.

French guilds were less successful than German guilds in excluding women, and French women were not confined to the lowest-paid occupations. Wives worked with their husbands when married and had the right to continue in the trade when widowed. Many of the women guild members were not widows of masters, but were wives or widows of men in other trades. Some guilds were exclusively female. In thirteenth-century Paris, at least 5 of 100 guilds had only female members (Power 1975). In eighteenth-century Paris, the linen draper and seamstress guilds were all-female. Other guilds included large numbers of women members. In Saint-Malo about a quarter of women were drapers in the early seventeenth century, and about half were women at the beginning of the eighteenth century (Collins 1989). In Rouen, 10% of guild masters were female (Schmidt 2009). Where men did exclude women from their guilds, they faced serious competition from women producing outside of the guild system. In Paris, the tailors' guild excluded women from membership (while using the labor of their own wives and daughters) but faced serious competition from the female seamstresses' guild, which claimed the right to produce clothing for women and children, and from unguilded workers. During the eighteenth century, the reluctance of local government to enforce guild rules contributed to the weakening of the guilds. Fourteenth-century Parisian doctors attempted to exclude women. In 1322, Jacqueline Felicie de Alminia was prosecuted for practicing medicine without a license. However, exclusion does not seem to have been very successful; this was not the first time Jacqueline was prosecuted for practicing medicine, and there were several other women practicing in Paris at the time (Power 1975).

The extent to which legal status constrained women also varied greatly by country. Married women were usually considered to be *feme couvert* who had no legal status apart from their husbands, so they owned no property and could not make contracts. Such laws would seem to limit their ability to engage in business, but in many cases they were not as binding as they would appear. Married women could escape these constraints by operating as a *feme sole*. The concept of *feme sole* was widespread throughout Western Europe, but in practice countries differed in how much freedom women had. At the one extreme was the Netherlands, where *feme sole* status applied to any married woman in business. In Britain *feme sole* status was available but declining over time, though women could still maintain control over their property within marriage using contracts enforced in equity courts.

Phillips (2006) argues that couverture was not a significant impediment, and was sometimes an advantage, for women in business. While in Britain and the Low Countries unmarried women and widows could conduct their own legal business, Germany limited the rights of even these women. German law required all women to be represented in court by a *Kriegsvogt*, a man who was supposed to be her legal representative. In practice, the *Kriegsvogt* often acted in the interests of the men of the community, and the system failed to protect wives from abuse or widows from having their land taken (Ogilvie 2003).

While some of the gender division of labor was due to sorting by comparative advantage, some was due to institutional constraints on what work women could do. The extent of such constraints varied over time and place.

What Determines Gender Roles?

Gender norms clearly exist. The relevant questions are where they come from and to what extent they influence behavior. Cliometrics, by demonstrating the economic origins of gender roles and examining their persistence, has contributed a great deal to our understanding of gender roles. Gender roles do affect behavior, but they are also affected by behavior and are not independent of economic incentives.

In spite of the rapid changes that have occurred over the past few decades, traditional gender roles still matter. Fisman et al. (2006) demonstrate that women care more about intelligence, and men care more about appearance when choosing a partner, and that men avoid women who are more ambitious than themselves. Violating the norm that husbands should earn more than their wives carries a price. Women who earn more than their husbands are less likely to report a happy marriage, are more likely to divorce, and spend relatively more time on housework. Women with potential earnings higher than their husbands are more likely than other women to drop out of the labor force or reduce their hours of work (Bertrand et al. 2015). Cultural determinants of behavior are probably deeper than we realize. Men generally enjoy competition more than women, but this difference is cultural; in a patriarchal society, men are more likely than women to choose competition, while in a matriarchal society, women are more likely to compete (Gneezy et al. 2009).

While gender norms clearly matter, we should not exaggerate their importance in determining behavior. People often say one thing and do another, and gender ideology was often ignored in practice (Vickery 1993). As noted above, we observe employers hiring women even when they express ideological objections to doing so. Sometimes women bridged the gap between ideology and reality by actively hiding their economic role to conform to social expectations. Sophie Henschel, who inherited her husband's locomotive company when she was widowed, was in fact the decision-maker in the company, but public statements presented her son as the head of the business and emphasized Sophie's charitable work (Beachy 2006). The popularity of work such as taking in washing or lodgers may have been partially due to the fact that, since the work was done in the home, women could earn money without publically violating norms.

Since gender roles appear in ideological statements, it has generally been assumed that their origin was ideological. Bennett and Karras (2013, p. 5) claim that medieval gender roles were "rooted in the three religions of the time, Christianity, Judaism, and Islam, in scientific teachings, and in political traditions." They do not mention economic incentives as a contributor. Recent developments in cliometrics, however, have demonstrated the extent to which gender roles are themselves the result of occupational sorting driven by economic incentives.

Some studies demonstrate that women are more highly valued in regions where they have greater economic value. Two papers have shown that areas where women have lower economic value also have more boys than girls. Sex ratios favoring boys, which may result from either selective abortions or differential care leading to more deaths among girls, are generally seen as a sign of a social preference for males. An advantage of this measure is that we don't have to wonder whether people are hiding their true opinions when we ask them what they think about gender roles. Qian (2008) exploits the fact that tea-growing uses more female labor and fruit-growing uses more male labor. She shows that when reforms increased the price of cash crops, the survival of girls increased relative to the survival of boys in tea-growing areas, but not in fruit-growing areas. Carranza (2014) shows that Indian areas with more loamy soil, and thus more time spent plowing and less time spent weeding, have lower female participation in agriculture and fewer girls per boy under age six.

Economic incentives affect current gender norms, and these norms have effects that persist over time. Cliometric studies have demonstrated that current outcomes are affected by economic circumstances in the distant past. Since plowing requires a great deal of strength, in regions using the plow, men specialized in agriculture and women in more domestic tasks. Regions using the hoe for cultivation, however, saw greater female participation in agriculture. Alesina et al. (2013) show that regions of the world that used the plough in the pre-industrial period have lower female labor force participation and express less equal gender attitudes today. Hansen et al. (2015) show that countries with a longer history of agriculture have lower female labor force participation today. They claim that use of the plough was less important than whether cereals or root crops were grown, as cereals required more processing by the women. In China weaving of cotton cloth has historically been women's work, and technological improvements in the fourteenth century increased women's earnings from weaving and thus their social status. These positive attitudes towards women have persisted over centuries. Xue (2016) shows that areas in China that are climatically better suited to cotton weaving have relatively more equal sex ratios today (relatively more girls) and their residents are less likely to express opinions of male superiority. Cultural norms must have some persistence if agricultural practices thousands of years ago can explain current attitudes and outcomes. Thus cultural norms do matter for behavior, though these norms are not exogenous but were themselves formed in response to the economic demand for female labor.

Other studies demonstrate persistence over shorter time horizons. Fernandez and Fogli (2009) demonstrate that in 1970, the labor force participation of a second-generation US woman was affected by her father's country of origin. The lower the female labor force participation in the father's country of origin, the lower the

US-born daughter's participation. Women are also affected by the ethnic origin of their husbands. The lower the female labor force participation in the country of origin of the husband's father, the less likely the wife was to work. Gay (2017) finds that French women who grew up in regions with higher World War I mortality were more likely to have had working mothers when young and were more likely to be in the labor force as adults. Grosjean and Khattar (2015) demonstrate that in Australian regions that had more men relative to women in the nineteenth century, due to the transportation of convicts, women were more likely to marry, less likely to work outside the home, and less likely to work in a high-earning occupation. These effects were persistent. In regions with higher sex ratios and lower female participation in the past, people today are more likely to agree that a woman's place is in the home, and women are less likely to work in high-ranking occupations. These studies suggest that gender roles, though persistent, are determined by economic incentives more often than we realize. Thus, they acknowledge that cultural norms have some power over our behavior, but suggest that these norms have economic origins.

Received gender norms can, of course, be changed. Xue (2016) shows that, even with inherited Confucian values, areas of China with cotton production and thus higher economic productivity for women came to value women more. Sometimes gender norms change quite quickly. The fraction of teenage girls expecting to work outside the home at age 35 doubled during the 1970s. Exposure to women leaders can reduce discrimination in a relatively short time. Beaman et al. (2009) show that only 10 years after West Bengal reserved one-third of local council seats for women, men in villages that were required to have a female leader evaluated female leaders more positively.

Thus, there is evidence both that gender norms are malleable and that they are persistent. Gender roles change in response to new technology or new ideas, and in some cases can change quite quickly. Yet in spite of this malleability, economic activities millennia ago have a measurable impact on behavior today. How are these findings compatible? One possible solution is to posit that gender roles are difficult to change but that when they do change they change quickly. This would happen if there are multiple equilibria and it takes a fairly large shock to move out of one equilibrium. Xue (2016) suggests that gender roles change only in response to relatively large changes in circumstances, not to small changes. Alternatively, it could be that gender roles didn't change for centuries because the underlying economics that caused them didn't change, but then changed rapidly when circumstances changed. However, it seems implausible that persistence could be explained by the absence of large shocks over periods of thousands of years.

Some economists have sought to explain why some societies experience more change than others. Giuliano and Nunn (2017) show that changes in ideology are faster for people from areas of the world that have historically experienced less stable weather. This makes sense because the tradition is less valuable in societies where circumstances vary more. Exposure to foreigners also reduces the persistence of prejudice. Voigtländer and Voth (2012) show that anti-Semitism is persistent over the period 1350–1930, but that such views were less persistent in cities that were

members of the Hanseatic League, suggesting that involvement in trade with foreigners decreased prejudice.

One way to reconcile evidence of persistence with evidence of rapid change is to note that studies of persistence are picking up small effects. Typically, the portion of the variance explained by the distant past is quite small. Historical use of the plough explains only 6% of variation in female labor force participation and 11% of variation in female business ownership (Alesina et al. 2013). Even with geographic control variables, Grosjean and Khattar (2015) are able to explain only 2% of variation in attitudes towards women's work and 3% of the variation in female labor force participation in 2011. Xue (2016) finds that premodern textile production explains 0.15% of the variation in the sex ratio in 2000, and only 3–5% of variation in stated gender values. While economic incentives in the past can be linked to small changes in the probability of behaviors today, these influences are clearly not the most important determinants of women's work today.

What Role Did Women Play in Economic Growth?

Perhaps the most surprising finding of the cliometrics literature is that women's economic empowerment, or "Girl Power," was an essential foundation of modern economic growth. It was not a nice byproduct, but part of the process. Women's high earnings in Northwestern Europe resulted in later marriage, lower fertility, and increased human capital, which led to rising incomes. In unified growth theory, technological change during the nineteenth century generated increased demand for human capital and for female labor (Galor 2005). In the Girl Power story, the demographic shock of the Black Death and the associated change in the relative prices of land and labor generated the higher female wages, which in turn increased human capital. The story has been told in different ways by different authors; what follows is an attempt to synthesize the literature into a coherent story.

The story starts in Northwestern Europe after the Black Death, as pastoral agriculture expanded. The plague, by making labor scarce and land relatively abundant, made animal husbandry more profitable. Various explanations have been given for why the shift towards pastoral agriculture was concentrated in Northwestern Europe. Voigtländer and Voth (2013) suggest that Southern Europe was geographically not well suited to cattle, and that Eastern Europe did not shift to animal husbandry because they had higher grain productivity and grain remained profitable. De Pleijt and Baten (2017) suggest that the shift to pastoral agriculture was concentrated in regions where the population was more lactose tolerant.

Given their physical endowments, men have a comparative advantage in grain production, where tasks such as plowing and mowing require upper body strength, and women have a comparative advantage in dairy production. Thus, areas that increased dairy production also saw an increase in the demand for female servants. The female-male wage ratio rose after the Black Death, and these higher wages gave women the option of living on their own wages. Also contributing to female independence were marriage rules established by the Catholic Church requiring

consent of both partners, giving women as well as men a say in who they married (de Moor and Van Zanden 2010). The resulting increase in female autonomy has been called Girl Power.

Increases in female agency led to increased economic growth for two reasons. First, female independence led to later marriages and thus lower fertility, which allowed for increases in income per capita. Second, Girl Power also led to higher levels of investment in human capital for women and for their children. These mechanisms were mutually reinforcing but could operate independently.

Higher female wages were associated with higher ages of marriage, a greater portion of women remaining single, and married couples living separately from their parents, all of which were features of the European Marriage Pattern. With opportunities for market work at good wages, women could afford to support themselves while waiting for a suitable spouse. Additionally, jobs for women as dairy maids typically took the form of year-round live-in service that was more suited for single workers, encouraging later marriage. Voigtländer and Voth (2013) estimate that the average English woman married 4 years later as a result of the shift to pastoral agriculture. Fertility then declined for two reasons. First, lower fertility was a mechanical result of higher age at marriage. Since fertility was low outside of marriage and relatively unconstrained within marriage, fewer years spent in marriage would reduce fertility. Second, female empowerment also created incentives to lower fertility. Women's higher opportunity costs of time increased the cost of having a child and encouraged a shift from child quantity to child quality. Lower fertility eased population pressures and increased human capital as parents with fewer children invested more in each child.

Female empowerment also increased human capital directly. Human capital in this context is not necessarily formal schooling, which was relatively unimportant for most work. Human capital in this context should be seen as the acquisition of "useful knowledge" (Mokyr 2009). Higher wages and labor force participation for women encouraged investments in human capital for girls. More skilled mothers, in turn, could transmit more human capital to their children. We would expect women's greater bargaining power to increase education for all children, and to increase relative expenditure on girls. Modern studies have shown that mothers are more likely than fathers to spend their income on children's education (Qian 2008) and that grandmothers are more likely to spend their money on granddaughters (Duflo 2003). Countries with lower fertility and higher education entered a virtuous circle: higher investments in child quality increased incomes, which in turn encouraged investment in child quality.

Cliometricians have demonstrated that Girl Power lead to higher human capital by using age-heaping to measure numeracy. Numerate individuals are more likely to report their actual age, rather than rounding to the nearest multiple of five, so countries where more individuals report age 40 than age 39 or 41 were less numerate than countries where reported ages are evenly spread over those years. Baten et al. (2017) demonstrate that, within Eastern Europe, numeracy was higher in areas where fewer women in their twenties were married and in regions where the soil was less suitable for grain production. Comparing eighteen countries in Europe, de Pleijt and

Baten (2017) show that regions with more lactose tolerant populations had higher ages at marriage and, as a result, higher numeracy. (The connection between female power and human capital has been shown in other contexts as well; Qian (2008) shows that increases in female income increased educational attainment for both boys and girls in twentieth century China.)

High human capital, in turn, was important for economic growth. While Mokyr (2009) does not emphasize the importance of formal schooling in the British Industrial Revolution, he does emphasize the mechanical skills developed in trades such as clockmaking, skills obtained through apprenticeship, and scientific knowledge. Statistical evidence of the link between human capital and growth comes from de Pleijt and van Zanden (2016), who demonstrate that book consumption, their measure of human capital, was the most important determinant of GDP in Europe between 1300 and 1800.

This process is said to explain the "Little Divergence" in which England and the Low Countries pulled ahead of the rest of Europe in the seventeenth century. Many of the changes described above were reversed during the "Malthusian intermezzo" of the eighteenth century (van Zanden 2011). Women's relative wages fell, their age of marriage fell, and fertility rose. Somehow, in spite of the reversals, England was the first country to experience the "Great Divergence" of the Industrial Revolution, many centuries removed from the rise of Girl Power. Any connection between the two requires long lags. Fortunately for our story, the origins of the Industrial Revolution have been traced to processes that began much earlier. Mokyr (2009) has argued that it was the scientific revolution, beginning with Francis Bacon, that set the stage for the dramatic gains of the Industrial Revolution. Van Zanden (2009) emphasizes the increase in book production in Europe, beginning even before the printing press, both as evidence of and contributor to increasing human capital. In northwest Europe, literacy rose continuously between 1500 and 1800. Numeracy, as measured by age heaping, rose throughout Europe between 1350 and 1800, though data is scarce in the earlier centuries (A'Hearn et al. 2009). Though there were several centuries between the Black Death and the onset of modern economic growth, the story still makes sense if you believe that the Industrial Revolution was made possible by the gradual accumulation of human capital over many centuries.

Dennison and Ogilvie (2014) challenge the Girl Power story, noting that countries with the highest age at marriage were not necessarily those that developed first. Denmark and Iceland had higher age at marriage than England, but England reached modern economic growth first. However, while age at marriage is commonly used as a measure of Girl Power, it is not the same thing. The crucial change was female independence: women gained the ability to support themselves by wage labor and the ability to decide for themselves whether and whom to marry. This power led to a higher age at marriage, but a high age at marriage that appeared for other reasons would not have the same effects. Dennison and Ogilvie note that women's economic power was limited in some countries that exhibited characteristics of the European Marriage Pattern, leading them to doubt its causal power. In Germany, the age of marriage was high, but women were prevented from entering high-paid work and

were not allowed free choice in where they lived or whether they married. The solution to this dilemma is to see women's economic power as the underlying cause and the European Marriage Pattern as a byproduct. While a higher age at marriage was important for a reduction in fertility, the human capital mechanism does not require it. Increased female wages and participation in the labor market could increase human capital formation even if the age at marriage did not increase. It is also true that high earnings and a high age at marriage were not sufficient, if not accompanied by independence. Chinese women had high earnings in textile production, but did not get the control over their earnings, marriages, or education that European women got (Xue 2016). The Girl Power story then is truly one of the benefits of female empowerment.

Conclusion

In economic history, women have gone from an after-thought to a central character in the stories that we tell. We cannot understand economic growth without examining what happened to women. In general, we cannot understand the past unless we take women's contributions seriously. The statistical methods of cliometrics have been central to uncovering and proving the importance of women to history. Statistical methods have not only measured the extent of women's work and wages but have also identified the sources of gender norms and have demonstrated the importance and persistence of those norms.

International Migration in the Atlantic Economy 1850–1940

Timothy J. Hatton and Zachary Ward

Contents

Abstract

This chapter focuses on the economic analysis of what has been called the age of mass migration, 1850–1913, and its aftermath up to 1940. This has captured the interest of generations of economic historians and is still a highly active area of research. Here we concentrate on migration from Europe to the New World as this is where the bulk of the literature lies. We provide an overview of this literature focusing on key topics: the determinants of migration, the development of immigration policy, immigrant selection and assimilation, and the economic effects of mass migration as well as its legacy through to the present day. We explain how what were once orthodoxies have been revisited and revised and how changes in our understanding have been influenced by advances in methodology,

Mass migration · The Atlantic economy · Immigrants and emigrants

Introduction

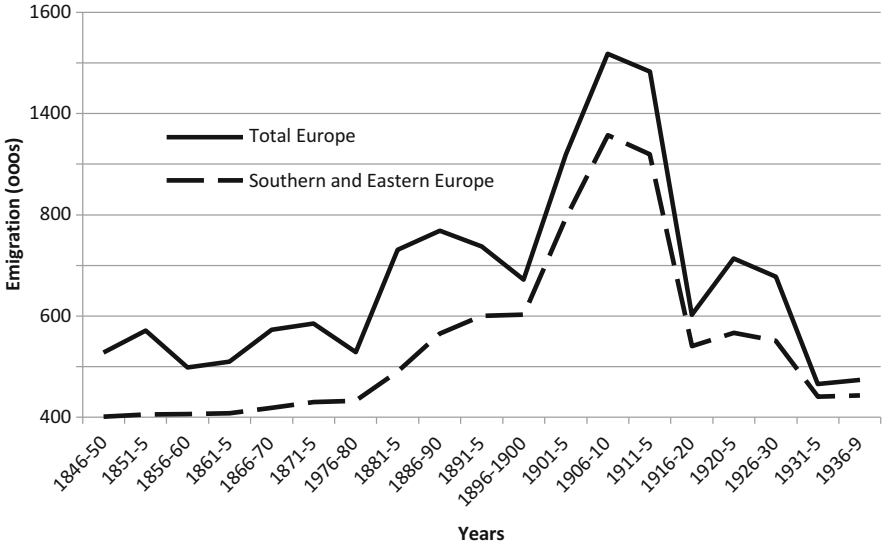
This chapter provides a survey of cliometric research on international migration. We focus on studies of migration from Europe during the age of mass migration from the middle of the nineteenth century up to 1913 and during the interwar de-globalization that followed. While there were other important migrations within Europe and Asia during this period, we focus on what might be called the "greater Atlantic economy" and especially on migration to the United States. This transformed the world economy, and it is where the vast bulk of the cliometric literature has focused attention. The literature has evolved over recent years with old interpretations being challenged as new insights have emerged, although some issues are still contested. The application of new approaches has strong parallels with the research of economists on more recent periods, and this has been underpinned by the emergence of new and more comprehensive data.

We start with an overview of the determinants of aggregate migration streams, a well- established literature that has been less active in recent years. This includes time series analysis of the push-pull variety as well as studies that focus on cross-sectional differences in emigration intensity between origin countries and regions. Migration flows were shaped by immigration policies that became increasingly restrictive in the early twentieth century. We review the literature on the formation of immigration policy, focusing on the political economy determinants. We then turn to the question of whether international migrants were positively or negatively selected from source-country populations. This micro-level analysis, based on unit record data, has been the focus of much of the recent literature and has challenged the conventional wisdom that migrants were positively selected. The self-selection of migrants has implications for the old debate about immigrant assimilation, and we review recent research that marks a return to the more pessimistic view of the older literature. We then turn to the economic effects of immigration in New World destinations as well as the effects of emigration on the Old World. The traditional concerns about the effects on wages and living standards have been examined using a variety of methods that yield a range of different results. Finally we briefly review a recent literature that seeks to explain economic outcomes in the present as the very long-run consequences of the age of mass migration.

Determinants of International Migration

From 1850 to 1940, an estimated 50 million migrants traveled from Europe to the New World (Fig. 1), with about three fifths going to the United States and smaller streams heading for South America and the British Dominions. There is a long-standing interest in what determined the year-to-year movements in migration, a literature that goes back to work by Jerome (1926) and Thomas (1941). This literature sought to explain cycles in transatlantic migration using time series models that focused on variations in economic conditions in source and destination countries. The "push" versus "pull" literature that flourished in the 1960s and 1970s was critically reviewed by Gould (1979). As he pointed out, when cyclical indicators such as industrial production are included for both source and destination countries, the latter typically dominate in terms of the size and significance of the coefficients. On the whole, these studies suggested that short-term ups and downs in aggregate migration were dominated by pull rather than by push factors. And in their presence, other variables representing the incentive to migrate, such as income or wages at home and abroad, often failed to achieve significance. Gould (1979, p. 668) concluded that "By and large, reaction to this literature is one of some disappointment, for not only has it failed to generate important new insights . . . it has had only limited success in confirming or denying old interpretations."

It is difficult to believe that emigration decisions were determined exclusively by conditions in the destination or that they did not depend on the prospects of higher



Source: Kirk (1946), p. 297.

Fig. 1 Emigration from Europe 1846–1939 (five-year averages). (Source: Kirk (1946), p. 297)

wages or incomes. Emigration must have been determined by some assessment of the expected gain and hence by some comparison, however approximate, between conditions at home and abroad. But the first generation of studies lacked a coherent underlying model of the emigration decision, which made the coefficients difficult to interpret. Using a basic economic framework, Hatton (1995) developed a model in which representative potential migrants base their decisions on the comparison of future expected incomes at home and abroad. In the manner of Todaro (1969), expected income in a location depends on both the wage rate and the probability of employment. The latter accounts for the effects of the business cycle and, if migrants are risk-averse and there is greater uncertainty about conditions abroad than at home, that would help to explain the dominance of cyclical conditions, especially at the destination. In addition, the time series dynamics that were often included to soak up serial correlation can be accounted for by adaptive expectation formation.

A number of studies have used this framework or can be interpreted within it. Estimates for emigration from the United Kingdom from 1870 to 1913 show that the wage gap and employment rates at home and abroad all matter in a manner consistent with the model (Hatton 1995). While short-run fluctuations are largely accounted for by the business cycle, longer-term trends can be accounted for by the slowly changing income gaps between origin and destination countries. For example, the 17% fall in the ratio of US to Irish wage rates between 1876–1880 and 1909–1913 accounted for a long-run decline in emigration from Ireland of 4 per thousand of the population (Hatton and Williamson 1998, p. 83). Another important variable that features in these models is the stock of previous migrants at the destination. This strong pull effect of emigrant networks or diasporas is often interpreted as reducing the costs and risks for new migrants. In the Irish case, the declining ratio of emigrant stock to home population reduced emigration by another 4 per thousand. New migrants were often assisted through remittances or prepaid tickets sent by previous emigrants. Consistent with this, Magee and Thompson (2006) find that the flow of money orders to the United Kingdom from 1880 to 1913 depended on both the migrant stock and the average income of the English-speaking destination countries.

The direct costs of passage should also matter, but these have been absent from most econometric studies for lack of suitable data. The cost of sea voyage fell after 1850 with the shift from sail to steam and the effective price fell even more steeply with shorter passage times (Keeling 1999; Cohn 2005; Sánchez-Alonso 2007), not to mention improvements in overland travel to and from seaports. On the North Atlantic routes, sharp swings in ticket prices were associated with changes in the effectiveness of shipping cartels. Using quarterly data for 1899–1913, Deltas et al. (2008) find that passenger numbers on routes to the United States and Canada were 22% lower at times when cartels were keeping prices up. Other elements of costs also mattered. Assisted passages to Australia substantially reduced the costs for UK emigrants in 1911–1913, leading to a surge of emigration (Pope 1981). For Spanish emigrants, the depreciation of the peseta between 1882 and 1905 increased the travel costs of emigration from Spain, which had the opposite effect. Sánchez-Alonso (2000a) finds that this reduced emigration during those years by as much as 30%.

Time series models account fairly well for the ups and downs of well-established migration streams, and perhaps this is one reason that they have not been the focus of much of the recent literature. A greater challenge is to account for the initial rise of emigration that got these streams started and the differences in emigration intensity between origin countries and localities. Among Western European countries, annual average gross emigration rates varied widely from 12 per thousand for Ireland to less than 1 per thousand for France. The trends also differed. The Irish emigration rate declined from the 1860s, and those of Germany, Norway, and Sweden fell from the 1880s. From that time, emigration from Italy and Spain and from some countries in Eastern Europe increased steeply up to the outbreak of war in 1914. One stylized fact is that, during the onset of modern economic growth, emigration rates often increased from low levels, reaching a peak after some decades and then gently declining. This long swing in migration, though often not complete, has been identified for at least some European countries (Akerman 1976; Hatton and Williamson 1998, Chap. 3).

Several studies suggest that demographic trends were important. The present value of migration would be greatest for those with the longest time horizons and the lowest costs: the young and single. Ellis Island records show that the average age of immigrant arrivals to the United States in 1900–1910 was 26, two thirds were male, and the majority were single (Bandiera et al. 2013). Using decade-average emigration rates for 12 European countries, Hatton and Williamson (1998, Chap. 3) found that the birth rate lagged two decades had a large positive effect. Annual time series for Scandinavian countries also supports this view (Quigley 1972; Larsen 1982; Hatton and Williamson 1998, Chap. 4). Interestingly, Greenwood (2007) finds that a higher current birth rate tended to reduce the emigration rate for those of parenting age, probably reflecting the higher costs of family migration. However, demographic effects were weaker for countries such as Italy and Spain (Sánchez-Alonso 2000b; Hatton and Williamson 1998, p. 113) because other constraints mattered more.

Emigration often gathered momentum just when the pace of development was quickening at home. In the early stages, most migrants were too poor to migrate, even though the incentive was large, but economic development served to ease the "poverty constraint." Thus on the upside of the long swing, emigration grew as wages at home increased, while on the downside, further increases in the home wage reduced the incentive to emigrate. Using annual time series from the 1870s to 1913, Faini and Venturini (1994) find for Italy, and Sánchez-Alonso (2000b) finds for Spain, that rising income per capita at home positively influenced emigration. The evidence also suggests that poverty constraints became less binding as the stock of previous emigrants, who could provide assistance, increased (Hatton and Williamson 2005, p. 65). This interaction helps to explain why emigration from Ireland (with its large post-famine emigrant stock) declined while emigration from equally poor Italy (with a low initial stock) increased as development gathered pace. Bohlin and Eurenius (2010) find a positive effect of the interaction between poverty and the emigrant stock in a panel of emigration from Swedish counties 1881–1910. Poverty constraints are also observable at the micro-level. In the Hesse-Cassel region of Germany from 1832 to 1857, Wegge (1998) found that networked emigrants

carried less cash with them. By the 1920s, these effects were weaker, but Armstrong and Lewis (2017) provide evidence that the need to save served to delay emigration to Canada.

There were many political and economic events that led immigrants to seek refuge during the age of mass migration, including the Great Irish Famine in the late 1840s, failed political revolutions in 1848, the Swedish and Finnish famine of 1866 to 1868, the Mexican Revolution of the 1910s, and the religious persecution of Jews in the 1880s, the early 1900s, and the interwar period. Mokyr and Ó Gráda (1982) and Cohn (1995) examine immigrant flows during the Great Famine, and Boustan (2007) and Spitzer (2014) study Jewish emigration. While short-term shocks boosted emigration in the short-term and then subsided, their effects often persisted through the powerful effect of the stock of previous migrants on subsequent flows.

Less attention has been paid to how potential migrants chose among alternative destinations in the New World. Differences between destinations in the pre-existing migrant stock, colonial ties, common language, and cultural affinity meant that they were often poor substitutes (Taylor 1994). But there was greater scope for choice among English-speaking countries, as between the United States and Canada (Green et al. 2002) and also within South America. Balderas and Greenwood (2010) examine the effect of emigration to one destination on emigration to other destinations using annual time series for emigration from 12 source countries to 3 destinations. Using instrumental variables, they find evidence of substitution between Argentina and Brazil, but not between either of these and the United States. The political climate in host countries could also matter. Bertocchi and Strozzi (2008) examine the effects of political institutions on migration between 11 European countries and 3 New World countries (Argentina, Canada, and the United States) on decade-average data for 1870–1910. In addition to economic and demographic variables, they find that immigration was positively related to political participation (democracy and suffrage) as well as to rights for immigrants (access to citizenship, land, and education).

Many migrants retuned, often after just a few years. The conventional estimates indicate that the ratio of out-migrants to in-migrants was about 40% (Gould 1980; Kuznets and Rubin 1954). However, recent estimates by Bandiera et al. (2013) put the figure much higher. Using the Ellis Island records, they calculate that gross immigration from 1900 to 1910 was about 20% higher than the official figures report. Comparing this inflow with the change in the stock of immigrants from the census implies that outflows were 60% of inflows, as compared with the previously accepted figure of 40%. The same calculation for the following decade, when the immigrant stock hardly changed, yields an outflow-inflow ratio of 75–80%. Some of these migrants may have been short-term visitors, but, even so, high return rates call into question the treatment of migration as a once-and-for-all decision, suggesting instead a significant share of circular migration. Indeed, Ward (2016) shows that between 1897 and 1914 repeat entrants (foreign-born who had previously been in the United States) accounted for 10–20% of all foreign-born arrivals. These were not mainly the *golondrinas* or seasonal workers from Southern Europe so often referred

to in the literature: repeat entrants were instead often from Northern and Western Europe and were higher skilled, suggesting that the circular flow was not dominated by low-skilled laborers.

Immigration Policy

The era before the World War I is seen as one of free migration in the greater Atlantic economy – but only for some migrants. The United States severely restricted immigration from China in 1882 and from Japan in 1907. Immigration from the poorest parts of the world was unrestricted only because there was no pressing "threat" of immigration. In 1885 Canada introduced an entry tax on Chinese immigrants, which was raised in subsequent steps. Similar policies were adopted in the Australian colonies and in 1901 newly federated Australia followed the 1897 policy of Cape Colony and Natal by introducing a dictation test designed to keep out non-Europeans. This was adopted by New Zealand in 1907 and by Canada in 1910. Other more incremental changes included entry taxes and restrictions on criminals, lunatics, and those "liable to become a public charge."[1] And the positive inducements to immigration offered by some countries such as Argentina, Australia, and Brazil were eventually reduced or withdrawn.

In the face of continuing anti-immigration pressure, more radical restrictions were introduced from World War I onward. In 1917, the United States introduced a literacy test for all immigrants and a ban on immigration from the "Asiatic Barred Zone." This was shortly followed by the first numerical quota in 1921, which became tighter in the Act of 1924 and its amendment in 1929. As illustrated in Fig. 1, international migration was dramatically lower in the 1920s as compared with the decades before 1914, and much of this was due to policy. The decline in immigration was most dramatic in the United States; for the source countries covered by the 1921 quota, immigration fell by two thirds in the following year. By linking them to the source composition of the foreign-born in the past, the quotas bore heavily on the so-called "new immigrant" countries, as illustrated in Table 1. Although the sharp shift toward restriction in the United States has received most of the attention, other countries followed. In 1923, Canada introduced a formal distinction between immigrants from preferred and non-preferred countries. Escalating restrictions were adopted in South Africa and Brazil, culminating in quota systems in 1930 and 1934, respectively. Even the British Dominions adopted severe restrictions limiting immigration from Britain: Australia in 1930, New Zealand in 1931, and Canada in 1932.

The retreat from free migration is sometimes seen as a backlash against mounting numbers (Williamson 1998). But what were the political economy mechanisms? As Foreman-Peck (1992, p. 360) put it: "The two key questions of any political

[1]For example, the US Immigration Act of 1882 introduced a head tax (extended in 1891); the Act of 1903 imposed restrictions on anarchists, beggars, those with epilepsy, and importers of prostitutes.

Table 1 Prewar immigration and postwar quotas

	Annual immigration	Quota allocation		
	1908–1914	1921	1924	1929
Belgium	5186	1563	512	517
Denmark	6117	5694	2789	1181
France	8209	5729	3954	3086
Germany	31,292	68,059	51,227	25,957

Source: Greenwood and Ward (2015), p. 79

economy of international migration are: (1) who gains and who loses from migration? And (2) who is in a position to do something about it?" The answer to the first question depends on who was most likely to face direct competition from immigrants in the labor market. As immigration from Southern and Eastern Europe expanded, the immigrants were increasingly low-skilled workers. In the 1860s, the average immigrant to the United States came from a country with GDP per capita 95% of the United States. By the 1900s, the ratio had fallen to 50%, and similar declines occurred for immigration to Canada and Argentina (Hatton and Williamson 2007, p. 223). On the other hand, the owners of capital and land, and perhaps the more skilled and educated workers, were less likely to favor restriction.

In order to test for these effects, Timmer and Williamson (1998) developed an annual index of immigration policies for five New World countries for 1870–1930. They found that for Argentina, Brazil, Canada, and the United States, more restrictive policies were associated with declining relative unskilled wages. In Canada and the United States, where immigrant origins were more diverse, it was the rise of immigration from low-wage countries, differing in ethnicity and religion from earlier waves, which helped to close the door. For the United States, this is consistent with the imposition of quotas that radically reduced immigration from Southern and Eastern Europe. In Argentina and Brazil, where immigrant origins were less diverse, the rising share of all foreign-born also led to restriction.

While immigration policies typically get tighter in recessions (Shughart et al. 1986), recessions seem to have more decisive effects when they are preceded by a gradual accumulation of forces that shift opinion against immigration. This may help to explain the imposition of the emergency quota in the United States, as the postwar resurgence of immigration coincided with an increase in the unemployment rate from 5.2% in 1920 to 11.7 in 1921. While the United States led in the early 1920s, the door was closed in other New World countries as unemployment increased

during the Great Depression. But another factor may also have been important. The interwar period saw a dramatic decline in international capital mobility. So the effect of capital inflows in muting the wage effects of immigration would have been smaller than before 1914 (see further below). For this reason, workers could have been more opposed to immigration than in the era when capital chased labor (Hatton and Williamson 2007).

At first sight, the answer to Foreman-Peck's second question depends on who had the right to vote. As suffrage widened, it typically percolated down the hierarchy of class and income, diluting the political weight of landowners and capitalists and giving a stronger voice to urban blue-collar workers. At the turn of the century, voting rates were about one third of the adult population in North America (much higher for males) but less than 10% in Latin America (Engerman and Sokoloff 2005). Severe immigration restrictions came earlier in the United States than in the (comparably democratic) British Dominions, which chose to remain open, at least to immigrants from the United Kingdom. On the other hand, in independent Latin America, where the franchise was much narrower and excluded immigrants, and where the Latifundia retained their grip on power, restriction came earlier than might have been expected. Sánchez-Alonso (2013) analyzed a newly created index of immigration policy for Argentina from 1870 to 1930. She found that some of the shift toward restriction was accounted for by rising immigration, declining migrant education relative to natives, and growing inequality. But restrictive immigration policies were instigated not through the ballot box but as a result of strikes and protracted labor unrest.

The underlying political economy mechanisms have been explored in the greatest detail for the United States. Turning to the attitudes of workers, Richardson (2005) analyzed the opinions of 2,000 blue-collar workers surveyed by the Kansas State Labor Bureau in 1895–1897. He found that the vast majority wanted immigration to be restricted or to be completely suppressed. Opposition to immigration was stronger among union members than among non-unionists; interestingly those with incomes in the middle of the range were more opposed than those with the lowest wages. Not surprisingly, the first- or second-generation foreign-born were the least likely to favor restriction. There was also some evidence that opposition to immigration was greater in counties with strong growth in the immigrant population.

How did this anti-immigrant sentiment get translated into restrictive immigration policy? In an influential paper, Goldin (1994) examined voting patterns in the US Congress. Beginning in 1897, a series of bills incorporating a literacy test failed to pass into law until 1917 when the House of Representatives and the Senate both overrode President Wilson's veto. By 1906, representatives from the South had joined those from other rural areas in supporting restrictions, and the key battleground was the cities of the East and the Midwest. Goldin found that a representative was more likely to vote for an override in 1915 the more rapid the growth in the foreign-born population and the slower the growth of wage rates in their city in the preceding decade. But the higher the immigrant share in the district (the level, not the change), the less likely was a vote for restriction and especially when the share reached 30%. Looking across cities from 1910 to 1930, Tabellini (2017) finds that

greater immigrant inflows, especially from "new" source countries, reduced electoral support for the Democrats, led to the election of more conservative congressmen and increased the likelihood that they would vote for the quota act of 1924.

Biavaschi and Facchini (2017) analyze the House votes on all 14 immigration bills from 1897 to 1924, estimating with fixed effects by session and by congressional district. They find that a representative was less likely to vote for restriction the greater the share of employment in manufacturing and the lower the share urban in the district. The characteristics of the Representative mattered too, with northern democrats and those with non-Ivy League backgrounds more likely to vote for restriction. Interestingly they also find that, while higher shares of foreign-born made a vote for restriction less likely, this was tempered where state residency laws made it more difficult for immigrants to naturalize and to gain the vote. This is consistent with the findings of Shertzer (2016) that the rate of naturalization was greater where immigrant interests aligned with other sizeable minorities to form a winning coalition.

Contemporary controversies over immigration policy have stimulated renewed interest in the shaping of immigration policies in the past. Recent cliometric studies have uncovered a range of influences that are broadly consistent with the political economy of immigration policy mapped out in more qualitative accounts. Working through interest group politics, immigration itself has mixed effects. While a sizeable and well-established stock of past immigrants tends to favor more liberal immigration policy, the recent inflow has the opposite effect. It also seems likely that under certain conditions, shocks such as wars and recessions trigger an immigration backlash. As most of the evidence is for the United States, it is less clear how these influences played out in countries with different political and institutional settings.

Immigrant Selection

Who migrates and how they compare with those left behind is a long-standing question in the literature. The selection of immigrants is related to the fortunes of immigrants in the host-country labor market, immigration's impact on the wages and incomes of the native-born, and to the longer-run effects of immigration – topics explored further in later sections. The selection of immigrants can be measured in a variety of ways: one dimension is the origin-country composition, which, as we have seen, shifted toward the poorer parts of Europe, raising the concerns of policy makers. Another is the demographic profile; immigration to the United States increasingly comprised young unattached males – those with low dependency burdens and high labor force participation rates. But the focus of much of the recent cliometric literature is on selection by skill or ability.

The basic framework is the Roy model as adapted to migration by Borjas (1987). In this model, the incentive to migrate depends on the individual's skill level and the returns to skills in the home country compared with the destination country. If the return to skills is greater at the destination, then the skilled will be more likely to

emigrate; if the return to skills is higher at the source, then the unskilled will be more likely to emigrate. But the costs of migration must also be considered; higher costs of migration will reduce the net present value of migrating more for poorer, less skilled workers than for those with higher skills and incomes. This framework is particularly applicable to the age of mass migration, an era before the advent of restrictive immigration policies, and a time when most migrants were moving for economic reasons rather than fleeing famines, wars, or political persecution. If the postbellum United States became more unequal than European sources, then that would favor more positive selection from any given source country. On the other hand, declining transport costs and, above all, assistance from the growing stock of previous emigrants would work in the opposite direction.

Testing different theories on the selection of immigrants first requires measuring selection, which can be difficult for numerous reasons. First, measures of immigrant quality in historical data are often crude and rarely include key metrics of interest such as ability, entrepreneurial spirit, or attitude toward risk. One way to get a summary measure of a migrant's productivity is by using his wage, but since the researcher does not observe the immigrant's wages in the source country if he had stayed, we need to either measure selection on a premigration variable or estimate the counterfactual wage. Despite these methodological problems, there have been significant advances in the literature due to the recent digitization of census and immigrant arrival records. Arrival records document immigrants prior to any assimilation forces causing a change in occupation or other observables, which allows for a (mostly) straightforward comparison of immigrants relative to stayers as observed in source-country census data. However, the quality of information in ship records may be low if ship captains were careless filling them out, and variables in the arrival records may not always match with variables in census data. Instead, some researchers have linked censuses across countries, allowing us to observe the immigrant's characteristics before and after migration.

The predominant finding of studies using arrival records or census data is that European immigrants to the United States during the age of mass migration were intermediately or negatively selected. Using individual census data on Norwegian immigrants to the United States in the late nineteenth century, Abramitzky et al. (2013) find that they were negatively selected as the fathers of movers had less wealth than the fathers of stayers. Negative selection has also been found for Irish emigrants prior to 1850, based on the age-heaping reported in arrival records and in the Irish Census (Mokyr and Ó Gráda 1982); Irish immigrants to the United States were also negatively selected in the early twentieth century based on linked census records (Connor 2016). Italian emigrants in the early twentieth century were shorter than the average Italian left behind, suggesting that they had a worse health environment than stayers (Spitzer and Zimran 2017).

Most studies measure migrant selection on observable characteristics, but the selection of immigrants on unobservable characteristics is more difficult to gauge. Furthermore, it is unclear whether selection on observable and unobservable characteristics is correlated; it could be that a low-skilled immigrant from an observably poor family was also highly ambitious and entrepreneurial. Abramitzky et al. (2012)

use an innovative approach to measure selection on unobservables: they compare the return to immigration measured with and without brothers' fixed effects. The idea is that a naïve estimate of the return to immigration by comparing migrants' occupations to stayers' occupations is biased if immigration is correlated with a positive or negative omitted variable; however, one can gauge the direction of this bias by estimating the return to immigration within brothers to control for unobservables across households. Abramitzky et al. (2012) find that the naïve return to immigration is more negative than the estimate within brothers and interpret the negative bias on the naïve estimate as reflective of negative selection into immigration. The negative selection on unobservable characteristics is consistent with other findings of negative selection on observable characteristics such as father's wealth, perhaps suggesting that the observable measures of selection are a good proxy for unobservable selection.

Can these findings of mostly intermediate or negative selection be rationalized in the context of the Roy model? Stolz and Baten (2012) test the Roy model on data from the age of mass migration by comparing measures of inequality with measures of selection. They use measures of inequality and selection that are well known within the cliometric literature: for inequality, the amount of variation in height data and, for selection, the amount of age-heaping on zeroes or fives for immigrants relative to those remaining in the source (Steckel 1995, 2008; Tollnek and Baten 2016). The coefficient on relative inequality across sources offers strong support for the Roy model: migrants to a destination from more equal origins were more negatively selected on numeracy. They also find that sharing a common language is associated with positive selection while wars and upheavals at the origin lead to negative selectivity. This latter effect may also apply to famines, which would help explain the negative selection of emigrants from mid-century Ireland. However, neither the predicted positive effect of origin-country poverty nor the negative friends and relatives effect could be consistently identified.

The effect of liquidity or wealth constraints on migrant selectivity is something of a puzzle, but it seems likely to have become less important over the nineteenth century, if for no other reason than assistance from the growing stock of previous migrants. For example, in 1908, 92% of immigrant arrivals to the United States were joining a relative or friend at arrival and about one third had their tickets paid for by someone else. Therefore, while on the margin poverty constraints did limit some migrants, they were not binding for many. However, wealth constraints were likely stronger during the earlier stages of the mass migration, when networks were less developed and prior to cost reductions due to the diffusion of steam technology following the Civil War (Cohn 2009). As noted earlier, Wegge (1998) shows that networked migrants from the Hesse-Cassel region in mid-century Germany required less cash to move, implying that they depended on help from previous migrants. And even though Irish emigrants were negatively selected overall, during the Great Famine the very poorest were less able to emigrate and were more likely to have starved (Mokyr and Ó Gráda 1982; Cohn 1995). There is other evidence that poverty constraints limited migration from the lower end of the skill distribution. While Italian immigrants were negatively selected overall, they were positively selected

from the poorest provinces, suggesting that costs restricted migration of the poorest (Spitzer and Zimran 2017).

Focusing on the drivers of immigrant skill levels, Covarrubias et al. (2015) use US inflow data from 1899 to 1932 to determine the relative importance of source-country income and costs of immigration on the skill composition of inflows. They find that higher origin-country income levels increased the total number of migrants but slightly decreased their quality, suggesting that a poverty constraint was alleviated. On the other hand, transport costs had little effect on the skill level of the inflow, perhaps because costs are represented by freight rates rather than by passenger fares. The severe restriction on immigration imposed from the early 1920s caused the selection of immigrants to be more positive, at least in terms of occupation, as the implied policy costs fell more heavily on the lower skilled. Therefore, not only did the immigration quotas have a between-country effect as the quotas imposed different degrees of restriction across origin countries, but there was also a within-country effect as lower-skilled individuals were more likely to be restricted (Covarrubias et al. 2015; Massey 2016).

Perhaps what policy makers and economists are more interested in is the quality of the net flow rather than just the inflow. As we have seen, since millions of migrants returned to Europe, the quality of the net flow depends on the selectivity of return migration. The evidence suggests that the average return migrant was lower-skilled than the average permanent immigrant, a pattern that holds both within and between source countries (Abramitzky et al. 2014; Ward 2017a).[2] The negative selection of return migrants presents something of a puzzle as the Roy model predicts that the selectivity of the return flow should be opposite to the selectivity of the inflow (Borjas and Bratsberg 1996), which was also negatively selected. This may be because those who returned home were more likely to receive a negative shock in the US labor market, perhaps due to occupational downgrading after arrival.

The recent literature has challenged the view often presented in qualitative accounts that immigrants into the United States were, on the whole, positively selected. Instead the evidence suggests that immigrants overall were somewhat negatively selected but with variations by country and region of origin. So far, there is little comparable evidence for other New World destinations during the age of mass migration, but there is reason to think that the results could be different. For example, Italian migrants to migrants to Argentina had relatively high literacy rates, especially those from Spain and Portugal (Sánchez-Alonso 2007). And the occupational composition of emigrants to Australia 1877–1913 was more skilled than that of Canada and the United States (Pope and Withers 1994).

[2]Abramitzky et al. (2016b) provide new microdata on returners to Norway and show that despite return migrants being negatively selected relative to both movers and non-movers, they achieved higher outcomes upon return to Norway, reflecting a positive return to temporary migration.

Immigrant Assimilation

These new findings on immigrant selectivity raise questions about other widely debated issues. Following (Borjas 1987), the selectivity of immigrants has been intimately connected with their assimilation into the US labor market. The assimilation of immigrants tackles a similar question to the selection literature but from a different reference point. Instead of comparing immigrants to nonmigrants in the source country, the assimilation literature compares immigrants to the native-born in the destination country. This comparison is most often for wages or occupational status but has also been made along different dimensions such as geographical location, fertility, or marriage rates. In this section, we will primarily focus on standard economic outcomes such as occupation, wages, and employment.

The classic finding in the literature is that for the post-1950 decades, immigrants initially received lower wages than natives and then converged to native wages in the decades after arrival (Chiswick 1978). This finding is often interpreted in a human capital framework: at arrival, immigrants lose some value of their human capital acquired at home since it does not transfer across borders perfectly, but then they gain host-country-specific human capital, such as language fluency, after arrival. Another reason for convergence between immigrants and natives (which links to the selection issue) is that immigrants are thought to have different abilities or ambition and drive than the native-born, which implies that they would upgrade income throughout the life cycle faster than the native-born. However this optimistic view of immigrant assimilation has been downgraded in the subsequent literature that takes account of cohort effects and selective return migration (Borjas 1985; Lubotsky 2007).

Immigrant assimilation in the late-nineteenth-century US labor market has been explored using data on the earnings of immigrants and native-born from a range of reports from state labor bureaus. The initial results seemed to support the revisionist view that the age-earning profiles of immigrants were no steeper than those of the native-born and that, over the life cycle, immigrants may even have fallen further behind their native-born peers (see for example Hanes 1996). By contrast, Hatton (1997) showed that the results turn partly on the shape of the age-earning profile combined with the fact that the immigrants in these samples are typically older than the native-born. Taking this into account, immigrants that arrived before the age of sixteen had age-earning profiles very similar to the native-born. Those that arrived as adults had earnings that were initially lower and that increased with age, but did not overtake the native-born. However these results stem from cross-sectional analysis of subsets of blue-collar workers, and they do not account for cohort effects or for selective return migration.[3]

[3]However, analysis of grouped data by origin country from the reports of the US Immigration Commission and of cohort occupational progression in the 1900 and 1910 censuses reaches similar conclusions (Hatton 2000; Minns 2000). For a more detailed review of this generation of studies, see Hatton (2011).

This view has now been subjected to further revision. Abramitzky et al. (2014) find that the average immigrant arrived similarly skilled and upgraded at the same rate as natives. The difference in results is due to data structure: both cross sections and repeated cross sections, as were used in the earlier literature, overstate immigrants' assimilation rate because of declining cohort quality and negative selection of return migrants. Abramitzky et al. (2014) improve on repeated cross sections with new panel data by linking immigrants across the 1900–1920 US Censuses. Since the immigrants in the panel data are the same ones throughout time – as opposed to pseudo-cohorts used in the repeated cross-sectional methodology – selective return migration does not bias the estimates. Abramitzky et al. (2014) recreate the finding of positive assimilation using repeated cross sections but then demonstrate that this pattern disappears once using the panel data, which implies that the positive rate of assimilation in earlier studies was primarily driven by negatively selected return migrants.[4]

One limitation of these results is that the 1900–1920 censuses do not record wages, but only occupational status; it is possible that immigrant assimilation profiles were steeper for earnings. But a lack of relative occupational upgrading after arrival is still surprising given the human capital model of assimilation, suggesting either that post-migration human capital was not valuable or that immigrants were negatively selected on ambition or drive relative to native-born Americans. Ward (2018) explores the importance of one piece of post-migration human capital that is highly valuable today – English fluency – and finds that acquisition of English skills was associated with only a small upgrade in occupation. While the reason for a low occupational return to English skill is unclear, it may be related to the structure of the early twentieth century economy: the skill premium was relatively low, and jobs which required communication skills were not as prevalent.

Despite a low occupational return to English fluency, people at the time were convinced of its importance (Jenks and Lauck 1926). This was a contributing factor to the "Americanization" movement of the 1910s and 1920s, which aimed to assimilate immigrants into American society typically through education programs (United States Immigration Commission 1911; Bandiera et al. 2018). However, it is unclear how effective the Americanization movement was: Lleras-Muney and Shertzer (2015) argue that compulsory schooling and English-only laws were ineffective for raising immigrants' income in 1940. Moreover, these laws also led to a backlash from the targeted population. For example, German Americans in states that banned German instruction were more likely to give their children German names and less likely to volunteer in World War II (Fouka 2015).[5] While

[4]Abramitzky et al. (2014) focus on European arrivals given their importance in the flow. For non-European sources, Kosack and Ward (2018) estimate the assimilation rates of Mexican immigrants, and Hilger (2016) estimates outcomes for descendants of Asian immigrants.

[5]This behavior of resisting assimilation is also explored for French Americans in New England by MacKinnon and Parent (2012).

programs aiming to assimilate immigrants may not have been effective, there is evidence that the appearance of being American was economically important: Biavaschi et al. (2017) show that adopting a more American-sounding name yielded a large occupational-based return, and Abramitzky et al. (2016a) show that the second generation with less foreign-sounding names had higher incomes relative to their brothers with more foreign-sounding names (see also Goldstein and Stecklov (2016) and Carneiro et al. (2015)); moreover, becoming a citizen was associated with improved occupational status (Catron 2017). This is consistent with Alexander and Ward (2018) showing that younger-arriving brothers were both more socially assimilated and had a smaller wage gap with natives compared with their older-arriving brothers.

The assimilation literature for the United States is limited in that the US Census does not record incomes until 1940; therefore, while immigrants had similarly paid occupations as white natives, they may not have had similar incomes. Fortunately, the 1911–1931 Canadian Censuses did measure income, which Inwood et al. (2016) use to show that immigrants upgraded at faster rates than natives through the life cycle – a result that differs from the lack of occupational-based assimilation in the United States. The Canadian result is consistent with a positive return to Canadian-specific human capital and a positive return to English skills. Yet this result must be interpreted with caution because the Canadian random samples form a repeated cross section, making it unclear whether their assimilation result is due to true upgrading or selective return migration.

In contrast to the lack of upward occupational mobility for immigrants relative to natives in the United States, there was more success for Europeans who headed to South America. Using data that links immigrants and natives across censuses, Pérez (2017) shows that immigrants to Argentina upgraded their occupations at faster rates than natives, ending up higher skilled than natives after decades of stay. Importantly, this pattern exists when tracking the same individual over time, which avoids the problem that selective return migration may bias rates of upward mobility. This relative advantage for the first generation also persisted to the second generation of Europeans, who were more likely to be literate and own property than the sons of natives.

This persistence of occupational outcomes across generations of immigrants has been shown not only in Argentina but also in the United States (Abramitzky et al. 2014); moreover, it contrasts with the "melting pot" analogy which suggests that parents' or grandparents' country of birth does not strongly predict outcomes. Ward (2017b) extends the intergenerational literature beyond the second generation to the third generation and shows that immigrants' grandchildren in 1940 tended to be in the same occupational categories as the first generation in 1880. Mean skill level by country of origin persisted more strongly than would be predicted from a standard multigenerational model, suggesting that it took more than three generations for occupational differences across source countries to disappear. Therefore, while the melting pot may have been hot in terms of social assimilation, strong persistence in occupational outcomes meant that it was cooler for economic assimilation (Abramitzky et al. 2016a).

The Effects of Migration

One of the most contentious issues in the immigration debate has been the effect of immigration on the economy in general and on the wages and incomes of non-immigrants in particular. A variety of methods have been used to estimate the impact of migration on average wages in origin and destination countries during the age of mass migration. Taylor and Williamson (1997) estimate the effects of international migration from 1870 to 2010 for 5 New World countries and 12 Old World countries. They first calculate the cumulative effects of immigration or emigration on the country's labor force and then use labor demand elasticities to estimate the long-term effects on real wages. For the New World, they find that, in the absence of immigration after 1870, real wages would have been higher in 1910 by 9% in the United States, 17% in Australia, and 27% in Argentina. Emigration from European countries increased real wages relative to the counterfactual but by smaller amounts, corresponding to the more modest effect of emigration on labor force growth. According to these estimates, the real wage gap between the New and Old Worlds fell by 11%, whereas under the no-migration counterfactual, it would have increased by 10%.

Some studies have allowed for a richer set of adjustments by using multi-sector computable general equilibrium models that include three factors of production (land, labor, and capital) and also account for international trade. To give one example, O'Rourke et al. (1994) estimated that, in the absence of international migration after 1851, urban wages would have been higher in 1910 by as much as 34.0% in the United States and lower by 12.2% in Britain.[6] To the extent that factor intensities become more similar, migration tends to be a substitute for trade and so trade grows less rapidly than it would have in the absence of migration. But more important is the assumption that is made about international capital mobility. With perfect capital mobility rather than totally inelastic capital (as assumed above), the effects of immigration on wages are much smaller as capital chases labor to exploit the incipient increase in its returns. Thus with full capital mobility, the no-migration counterfactual US wage in 1910 would have been just 9.2% higher (as less capital flowed in) and the UK wage would have been 6.6% lower than the actual (as capital stayed at home).

Exercises such as these hinge on assumptions about the structure of the economy, in particular the assumption of diminishing returns to labor and therefore downward sloping labor demand curves. In the economic literature, attempts to test these effects have met with mixed results and have led to substantial disagreement about how to model and estimate the labor market impacts of inflows within an economy. Various approaches have been taken, including exploiting the variation in skill mix of inflows at a national level (Borjas 2003), the variation in the number of immigrants across geographical regions (Altonji and Card 1991), or a combination of skill mix and region (Card 2001). More recently, Ottaviano and Peri (2012) assume that immigrants and natives are imperfect substitutes even within skill groups, which

[6]Other studies in this vein are reviewed in more detail by Hatton (2011).

tends to reduce the direct negative effect of immigrants on the wages of comparable natives as estimated by Borjas (2003).[7]

Rather than directly estimating the effect of immigration on native outcomes, several studies explore the effect of immigration on average earnings overall (including both natives and immigrants). Goldin (1994) uses average wages by occupation and city to demonstrate that a 1% point increase in the foreign-born share led to a 1–1.5% decrease in wages for unskilled workers – an effect that is larger than one would expect purely from a compositional shift to more immigrants. Examining state-level time series from 1929 to 1957, Biavaschi (2013) finds that immigrant inflows had a negative effect on earnings, while outflows had a positive effect. Exploiting the reduction of inflows from the 1920s immigration quotas, Xie (2017) finds that a one percentage point decline in the foreign-born share at the county level increases manufacturing wages by 2% – once again, an effect that cannot be explained by compositional changes. Studies of national time series have estimated that the effect of mass migration was to widen skill premiums in the United States and narrow them in Europe (Anderson 2001; Betrán and Pons 2004), results that are consistent with the effects on inequality found in general equilibrium models (Betrán et al. 2010).

Some studies have followed the modern-day literature in seeking to identify the effect of immigration on the earnings of natives (rather than on average earnings) using microdata. Green and Green (2016) use microdata on earnings by occupation from the Canadian Censuses of 1911–1931 to estimate the impact of immigration on natives, following the methodology of Ottaviano and Peri (2012). Their estimates show that immigration did not have a large impact on native earnings and thus did not cause the increase in Canadian inequality during the early twentieth century. This contrasts with the negative effects of immigration found for the United States (using different approaches). But given the similarity in the immigration inflow between Canada and the United States, it seems likely that the same method applied to US data would yield the same null effect. Unfortunately there are no data on earnings in the US Census until 1940, so any analysis of immigration's effect on wages must use wage data at a level higher than the individual.

Studies that can separate native and immigrant outcomes with microdata in the United States must resort to occupational status, and these tend to find a small negative effect or even a positive effect of immigration on native outcomes. For example, Ferrie (1999) uses 1850 and 1860 US linked data and estimates that immigration caused unskilled natives to move faster up the occupational ladder, while immigration had a negative effect on skilled natives. Ager and Hansen (2017) show that a reduction of inflows due to the 1920s quotas caused natives to enter lower-skilled jobs, suggesting

[7]Ottaviano and Peri's (2012) method is to specify a structural model of the economy where newly arrived immigrants, long-established immigrants, and natives are different types of labor. Further, labor is differentiated by skill in terms of education and labor market experience. The elasticity of substitution between labor types is measured with the data, and then the structural model is estimated. Dustmann et al. (2016) critique this methodology because, due to occupational downgrading at arrival, immigrants' effective skill level is lower than their observed skill level, which implies a misspecification when allocating immigrants to education-experience cells.

that more immigration would have positively affected native jobs (as defined by occupational score), a finding which Tabellini confirms (2017). In addition to the measurement issue of lacking microdata on native wages, these studies all use different empirical methodologies, leaving the effect of immigration on natives unclear, similar to the modern-day literature (Dustmann et al. 2016).

There are several other margins besides wages and occupation on which immigration affects the economy, such as outflows from high-immigration areas, changes in the output mix, and technological adoption or invention. Hatton and Williamson (1998, Chap. 8) estimate that immigration to the northeastern states displaced around 40 natives to other states for every 100 of the migrant inflow. And Collins (1997) demonstrates that the fall of inflows due to World War I and the immigration quotas contributed to the Great Migration of African-Americans from the South to the North. While immigration is often associated with urban areas in the early twentieth century, immigration also had important effects in rural areas. For example, a reduction of inflows to a county between 1910 and 1940 shifted the crop mix toward less labor-intensive and more capital-intensive crops, although it had no effect on the adoption of labor-saving technologies (Lafortune et al. 2015). Besides agriculture, there were important effects on innovation: Moser et al. (2014) show that the inflow of Jewish scientists escaping from Germany to America during the 1930s led to a large increase in chemical patents, with no evidence of negative or positive spillovers on incumbent scientists.

The large volume of inflows into the New World implies that there were also significant impacts on the sending countries. For Ireland, Hatton and Williamson (1998, Chap. 9) find that from the 1860s onward, the population loss induced by emigration led to more rapid wage growth. Rising labor costs also led to a shift within agriculture away from tillage and fostered mechanization (O'Rourke 1991). And in Sweden, higher out-migration rates were associated with more inventions per capita (Andersson et al. 2016). The effect of outflows from the source country may not simply be due to a loss of labor; those who left could still have important effects in the source due to remittances or eventually returning home with savings acquired abroad. As noted earlier, remittances were often used to finance further emigration, but the flow of remittances also enhanced financial development in countries of the European periphery (Esteves and Khoudour-Castéras 2011). Qualitative evidence also suggests that return migration to Italy increased farm prices due to savings brought back home (Wyman 1993; Cinel 1991), and linked census data from Norway shows that return migrants improved their occupational standing due to their temporary trip abroad, likely because of bringing back savings (Abramitzky et al. 2016b). Thus while the effects of immigration on the working population in the New World seem to have been rather mixed, for those that remained in the Old World, the economic effects were largely positive.[8]

[8]On the other hand the contemporary social effects are less clear. For the extreme case of Sweden, which lost nearly a quarter of its population to the New World, Karadja and Prawitz (2016) show that areas with higher outflows had higher strike participation, welfare expenditures, and support for left-wing parties, which they argue is due to greater political power for citizens.

The Legacy of Historical Immigration

The immigration literature is primarily concerned with estimating the immediate consequences of inflows, but it is possible that historical migrations have important long-run effects, over 100 years later. It is often asserted that immigrants leave a distinctly positive legacy to subsequent generations. One recent book carried the title: "Exceptional people. How migration shaped our world and will define our future" (Goldin 2011). While such descriptive accounts tend to accentuate the positive, the economic literature has offered a more nuanced interpretation of the long-term effects of immigration on productivity and economic growth, as well as on inequality and on social cohesiveness.

The literature stresses two enduring effects. On one hand ethnic and birthplace diversity brings skills and knowledge that are complementary in production and may lead to higher incomes. For instance, in cross-country analysis, Alesina et al. (2016) find that, in the presence of a range of controls, greater birthplace diversity, particularly within the immigrant population, leads to higher income per capita and more patenting activity. On the other hand, diversity could reduce intergroup communication and overall levels of trust, and it may also imply divergence in attitudes toward inequality and in preferences over welfare policy and public goods. Alesina et al. (1999) find that, across US cities and counties in 1990, ethnic fractionalization is associated with higher public expenditure but a lower share of expenditure on public goods. Similarly, for the age of mass migration, Ager and Brückner (2013) estimate a positive effect of fractionalization on income at the county level, consistent with gains from specialization, but on the other hand polarization tended to reduce income. And Tabellini (2017) finds that cities in 1910 to 1930 with more immigration had higher employment and manufacturing output but lower tax rates and public spending; the more so the greater the cultural distance between immigrants and natives.[9]

To the extent that culture, human capital, or other traits are correlated across generations, there may be long-run effects stemming from the ancestries of today's population and ultimately from the countries that their immigrant forebears came from. Although disentangling the effects of past immigration from other mechanisms is difficult, a recent literature investigates the effects inherited from immigration over the very long run. This reflects the wider trend in economics toward estimating the causal effects of events and characteristics from deep in the past that shape culture and institutions and influence economic outcomes up to the present. As Spolaore and Wacziarg (2013) note, this literature has increasingly focused on the qualities that

[9]Output is measured as the sum of manufacturing value added plus agricultural value added. Fractionalization measures the likelihood that two randomly selected individuals are from different backgrounds, while polarization measures the difference between the distributions of ethnicity from a bimodal distribution. See Ager and Brückner (2013) for a further discussion. Rodríguez-Pose and von Berlepsch (2017) extend the analysis to 2000 and argue that fractionalization in the late nineteenth century is positively correlated with county income in 2000, while polarization is negatively correlated.

migrants brought with them; thus, what matters for economic development is not a country's geographic location or resources but the characteristics of its population.

For a cross section of countries, Putterman and Weil (2010) examine the effect of origin-country political organization and economic development since 1500 using as weights the ancestral origins of the current population. They find that GDP per capita is higher in countries where the ancestral composition is associated with more advanced state organization but that the greater the degree of fractionalization in ancestry the higher the inequality. Interestingly, they find that the effects of ancestry are stronger than those stemming from the current foreign-born mix. This is consistent with a range of studies finding that past levels of human capital positively influence institutional quality and predict living standards in the present (Glaeser et al. 2004; Easterly and Levine 2016; Chanda et al. 2014; Spolaore and Wacziarg 2013). Human capital persistence is one mechanism through which immigration shocks have long-lasting effects but cultural traits also matter. Algan and Cahuc (2010) show that trust levels persist across generations; for example, Swedish immigrants had high levels of trust in the past, which they transmitted to their descendants today.

Much of the mixing of ancestries occurred during the age of mass migration and, even within countries, this could have differential effects in the present that reflect the settlement patterns of the past. Fulford et al. (2015) explore these effects by estimating the ancestries of the population of the United States for each county in each census between 1850 and 2010. Analyzing the data as a panel, they find that incomes are higher in counties which received immigrants from origins with high levels of income, education, and trust. And the effects of ancestry persist beyond the age of mass migration up to the present, with little change in intensity. Consistent with other studies, they find that while the degree of ancestral fractionalization alone has a positive effect on GDP per capita, ancestry, when weighted by attitudes toward trust, thrift, and cooperation, has a negative effect. This is consistent with the notion that while diversity itself has a positive effect, diversity in attitudes does not.

One channel for a long-run impact of immigration is stronger economic connections abroad. Burchardi et al. (2017) explore the correlation between a county's population ancestry and foreign direct investment to or from the ancestor's origin country. Using an instrumental variables strategy to predict ancestries across counties, they show that doubling the number of descendants from a foreign country increases the likelihood of present-day foreign direct investment with that country by 4%.[10] Provocatively, they argue that FDI with China would be much larger if not for the Chinese Exclusion Act of 1882 and the Asiatic Barred Zone in 1917. This finding parallels the shorter-run work on international trade of Dunlevy and Hutchinson (1999), who show that between 1870 and 1910 more immigration from a country

[10]Burchardi et al. (2017) instrument for the number of foreign-born in a county using a mix of push factors, as proxied by the total outflow from the country to the United States, and pull factors to the specific county, which is proxied by the number of foreign-born entering the county from other continents.

was associated with more international trade. One reason why FDI is correlated with the number of descendants from a country is the reduction of information frictions between countries (Burchardi et al. 2017).

Rather than connecting historical migrations with modern outcomes through the ancestral channel, Sequeira et al. (2017) gauge the relationship between a county's foreign-born share (no matter the source) between 1860 and 1920 with county-level outcomes in 2010.[11] Using an instrumental variables strategy to predict the foreign-born share across counties, the authors find that counties with a higher foreign-born share between 1860 and 1920 had higher levels of income and education in 2010, an outcome that is not simply due to reallocation across counties.[12] This effect did not appear without precedent in 2010 but can be traced through intervening decades. Counties with more immigrants had higher manufacturing output per capita, greater farm value per acre, and more patents also in 1930. Akcigit et al. (2017) confirm this positive effect of immigration on inventions by showing that areas with more foreign-born expertise between 1880 and 1940 had more patenting and citations between 1940 and 2000.

Some of the persistence in the effects of immigration during the age of mass migration may be due to the persistence of immigration itself. Long-established traditions of migration from a particular origin, by eroding the communication gap with the host population, allow subsequent immigrants from the same source to assimilate more easily (Hatton and Leigh 2011). But perhaps more significant is the effect of immigration on education and human capital. As noted earlier, Bandiera et al. (2018) find that the introduction of compulsory state schooling took place earlier in states with higher proportions of immigrants and especially those from origins with no experience of compulsory schooling. To the extent that immigration stimulated such nation building projects, these could have persistent effects.

It is possible that long-term effects might be different for countries where immigrants met rather different host-country conditions than in the United States. However, there is evidence that immigration from Europe to Brazil and Argentina led to higher incomes in the long run. Rocha et al. (2017) examine long-term outcomes of European immigration across municipalities in Brazil, focusing on the establishment from the 1870s of state sponsored settlements, designed to attract immigrants. These municipalities experienced faster transitions to manufacturing

[11]See Rodríguez-Pose and von Berlepsch (2014) on a similar long-run relationship, where instead of instrumenting immigrants with an interaction with the railroad and decade of arrival, they test the relationship with a variety of different instruments, such as distance from New York and the standard shift-share instrument. They also find that immigration had a long-run positive effect on modern-day outcomes, which they explore further by examining the effect by immigrant country of origin in a separate paper (Rodríguez-Pose and von Berlepsch 2015).

[12]To separate the effect of immigration from other factors on long-run growth, they interact the volatile time series of immigration with variation in when a county was connected to the railroad network; they argue that some counties received more or less immigrants not due to county-specific factors but because counties happened to be connected to the railroad during a boom decade of immigration.

and subsequently to services due to human capital accumulation. By 2000, they had income per capita 15% higher than municipalities without settlements. For Argentina, the economic effects seem to have been even larger. Looking across counties, and using frontier military campaigns as an instrument for immigration to localities, Droller (2017) finds that immigration from 1895 to 1914 was associated with more than double the level of income per capita in the present. Again, persistence in human capital was the mechanism, as reflected in the present by more years of education and a higher proportion of skilled workers.

Immigration may have effects on a range of social outcomes, transmitted down the generations by the persistence of cultural norms (Nunn 2012). One example is the effects of immigration on sex composition. For the United States from 1920 to 1940, Angrist (2002) finds that where inflows were heavily skewed toward men, second-generation females had lower labor participation rates and were more likely to be married and to have a more-skilled spouse (Angrist 2002). And Lafortune (2013) shows that males responded to a scarcity of potential marriage partners with more investment in education in order to improve their attractiveness in the marriage market. These imbalances tended to dissipate over time but their effects lingered. Grosjean and Khattar (2015) study the legacy of the high male to female ratio in mid-nineteenth-century Australia, owing originally to convict transportation. They find that across counties, high historic sex ratios are associated in the present with lower female participation rates, fewer women in professional occupations, and more conservative attitudes toward women.

Overall the literature is almost unanimous in finding that immigration during the age of mass migration generated positive economic outcomes both within and between countries. This is all the more remarkable as immigrant arrivals during the age of mass migration do not appear to be exceptional in terms of their selection and assimilation. The main transmission mechanism was by stimulating human capital formation not only among immigrants and their descendants but also as an externality to the wider population. We may speculate that human capital diffusion also helps to explain why the negative effects of fractionalization, which are sometimes observed as contemporary effects, become muted in the longer term.

Conclusion

In this chapter, we have examined a wide range of studies focusing on the age of mass migration and its later demise. The literature on the time series determinants of migrant streams is relatively settled and has not been the focus of the bulk of recent research. On the other hand, the cliometric literature on the political economy of restriction is still comparatively small and deserves further attention. The most recent wave of research on immigrant selection and assimilation has revised pre-existing views, downgrading the view of immigrants as somehow exceptional. And while their effects on host-country labor markets are still contested, there is at least some evidence that they had characteristics broadly comparable with the native-born and competed on relatively equal terms. In that light, it is all the more remarkable that the

long-term legacy of the age of mass migration should have been so positive, especially for the United States.

The literature has produced many advances, not only in methodology and data but also in the questions asked and the subtlety of the answers given. Clearly, there is room for further research to deepen these insights. But the focus has been heavily skewed toward migrants to, their experience in, and their effects on, the United States, something that is strongly reflected in the studies cited here. The largest dividends for future research probably lie in other New World countries on which less attention has been lavished. And our account completely omits migrations in Asia, which were quantitatively significant and have left enduring legacies but have not received comparable attention. Perhaps a future Cliometric Handbook chapter could be devoted to that, but if it were written now, it would be very short.

Cliometrics and the Concept of Human Capital

Charlotte Le Chapelain

Contents

Abstract

The role played by human capital in the historical process of economic development is an important issue in cliometrics. This chapter traces the history of the human capital concept and underlines that it has undergone criticism since its origins. Among these criticisms, we stress that the human capital research program was plagued with measurement difficulties. This issue has recently fostered a sense of strong reluctance toward the concept. Portraying a growing debate in cliometrics – the role of human capital in the first stage of the industrialization process in the late eighteenth and early nineteenth centuries in Western Europe – we emphasize that recent cliometric contributions on the issue open up stimulating lines of thought about what human capital is and how it can adequately be measured.

Introduction

Analysis of the economic role of individuals' skills and abilities long preceded that intellectual moment which is today referred to as the "human capital revolution." But the formalization of these ideas and their introduction into the core of economic theory emerged only in the 1960s, under the impulse of Theodore Schultz, Gary Becker, and Jacob Mincer. Prior to the 1960s, human beings or their skills were indeed considered in certain analyses as a particular form of capital, but they appeared therein only in a metaphorical way. The human capital theorists of the 1960s provided solid and precise theoretical foundations for that metaphor by using the analytical framework of standard capital. By considering human skills and abilities in analogy with physical capital, they laid the foundations of human capital theory.

Several moments are habitually recognized as fundamental steps in the building of the human capital research program. Schultz's articles published in 1959, 1960, and 1961a, the issue of *the Journal of Political Economy*, "Investments in Human Beings" in October 1962, Gary Becker's book *Human Capital* (1964), and the work of Mincer (1957, 1958), are identified as crucial contributions (see, for instance, Blaug 1976, Teixeira 2000, Ehrlich and Murphy 2007). Schultz, Becker, and Mincer, through different approaches, are generally seen as the fathers of the "human capital revolution." Since that time, a huge literature has developed.

Although this revolution was a success in the sense that the concept came into wide use both in economics and in various social sciences, human capital theory has come in for a great deal of criticism. These critiques are diverse, but the thrust of a large number of them concerns the major empirical challenges faced by the theory: at root, they address the difficulty of measuring human capital, especially at the macro level.

This chapter traces the history of the human capital concept by providing an overview of the way the idea of human capital was conceptualized, the historical background in the late 1950s against which the human capital revolution took place, and the critiques that have been levelled at it since. In particular, we point out that the concept has recently come under severe pressure through a resurgence of criticisms based on the problem of measuring human capital.

The cliometric approach quickly embraced the theoretical insights provided by human capital theorists. The role of human capital in the process of industrialization is a prominent issue for today's economic historians. Early analysis on the issue had come to the paradoxical conclusion that human capital was not important as regards the first stage of the industrialization process, but this thesis is currently under re-evaluation. By reviewing the cliometric contributions on the role of human capital in the first phase of industrialization, we highlight that this re-evaluation opens new and innovative avenues to tackling the issue of human capital measurement.

The chapter is organized as follows. Section "The Development of the Human Capital Research Program" provides an account of the human capital revolution of the late 1950s. We highlight the context in which the revolution took place, stress the importance of the figure of Schultz in promulgating the research program, and finally describe the theoretical synthesis it achieved. Yet while Schultz, Becker, and Mincer succeeded in imposing human capital theory in the mainstream economics, it nevertheless met criticisms from competing methodological perspectives also to be found within the mainstream. Section "Reservations, Old and New, About the Concept of Human Capital" retraces these criticisms and underscores that the empirical difficulty in measuring human capital is an issue that has been and is still currently a source of misgivings about the concept. In section "Human Capital and the Industrialization Process," we describe a growing debate within the field of cliometrics, namely, the (re-)evaluation of the role of human capital in the first stage of the industrialization process. The view that human capital played only a minor role in the first stage of industrialization is currently under reconsideration. The revisionist literature builds upon the idea that early literature was plagued by shortcomings concerning the way the human capital endowments were evaluated. This view has spawned new and innovative reflections within cliometrics about which type of knowledge was truly productive in eighteenth- and nineteenth-century Western Europe, which types of skills can be assimilated to a form of (human) capital, and thus how to accurately measure human capital.

Section I. The Development of the Human Capital Research Program

Forerunners

Analysis of the economic role of individuals' skills and abilities long preceded the human capital revolution of the 1950s and 1960s. Many authors have considered human beings, and their skills, as capital. Kiker's survey (1966) refers in particular to Petty, Smith, Say, Senior, List, von Thünen, Roscher, Bagehot, Ernst Engel, Sidgwick, Walras, and Fisher.[1] For his part, Sweetland (1996) considers that "the most prominent economists to address issues of human capital were Adam Smith, John Stuart Mill, and Alfred Marshall. Irving Fisher, prominent in his own right, expressed the pivotal arguments connecting early economic thought to contemporary human capital methodologies" (Sweetland 1996, p. 343). As pointed out by Kiker (1966), some authors attempted to provide a monetary evaluation of human beings or their skills via cost-of-production (costs of "producing a human being") or capitalized-earnings procedures, which refer to the estimation of the present value of future income streams. Different motives led them to the following monetary evaluation of what is recognized today as human capital: demonstrating the power

[1]For an exhaustive analysis of the authors who treated human beings as capital, see Kiker (1966).

of a nation, estimating the cost of the war, and assessing the economic effects of education, health, or migration. Other authors never attempted to provide monetary evaluations yet still considered human beings and their skills as a form of capital, whether explicitly or implicitly. This is notably the case for Adam Smith, Jean-Baptiste Say, John Stuart Mill, William Roscher, Walter Bagehot, and Henry Sidgwick.

Smith's thought on the issue deserves special attention. The treatment of human skills within the analytical framework of capital is in fact very explicit in Smith's thought. Recalling that Smith was "concerned with education for the betterment of men, not for the creation of human resources," Bowman (1966, p. 113) rightly notes that Smith's analysis of human skills is by far the closest to the concept developed in the 1960s.

For this reason, Smith is generally recognized as having laid out the premises on which the modern concept of human capital has drawn. Spengler (1977) and Schultz (1992) explicitly attributed it to him, while Rosen (2008) refers to Petty and Marshall but acknowledges Smith as the forerunner of the concept. Becker (1962) himself,[2] in his formulation of the analytical framework explaining investment choices in human capital, invokes the Smithian analysis.

In *the Wealth of Nations* (1776, p. 282), Smith wrote:

> The acquisition of such talents, by the maintenance of the acquirer during his education, study, or apprenticeship, always costs a real expense, which is a capital fixed and realized, as it were, in his person. Those talents, as they make a part of his fortune, so do they likewise that of the society to which he belongs. The improved dexterity of a workman may be considered in the same light as a machine or instrument of trade which facilitates and abridges labor, and which, though it costs a certain expense, repays that expense with a profit.
>
> When any expensive machine is erected, the extraordinary work to be performed by it before it is worn out, it must be expected, will replace the capital laid out upon it, with at least the ordinary profits. A man educated at the expense of much labor and time to any of those employments which require extraordinary dexterity and skill, may be compared to one of those expensive machines. The work which he learns to perform, it must be expected, over and above the usual wages of common labor, will replace to him the whole expense of his education, with at least the ordinary profits of an equally valuable capital. It must do this, too, in a reasonable time, regard being had to the very uncertain duration of human life, in the same manner as to the more certain duration of the machine. (Smith 1776, pp. 118–119)

The idea that acquiring skills is costly but that it contributes to the accumulation of a particular form of capital that yields future returns is clear in Smith's analysis. Yet that "investment" orientation is precisely what, in Blaug's words (1976, p. 829), forms "the 'hard core' of the human-capital research program" developed at the end of the 1950s. More particularly, Smith's analysis comes very close to the analytical framework Becker developed in his landmark 1964 book. Despite these early developments, the acceptation and generalization of this theoretical perspective made no progress until the end of the 1950s.

[2]Becker also mentions Mill and Marshall's legacy.

Schultz's Early Developments and the Opportunity of Solow's Residual

As we have emphasized, the human capital revolution does not mark the emergence of a new analytical perspective but rather the acceptation and the concrete deployment of this perspective at the core of economic analysis. The 1950s saw a renewed interest in the issue of economic growth and growth accounting exercises, which are commonly recognized as the decisive factors in the success of the human capital revolution: "Much of the original work that led to the 'human capital revolution' of the late 1950s and early 1960s followed an earlier revolution in economic thought spawned by the neoclassical growth model (Solow 1956)" (Ehrlich and Murphy 2007, p. 1).

Teixeira (2000) cites some other features of the intellectual context of the 1960s which created favorable conditions for the human capital revolution. Besides the flourishing of analysis concerned with the sources of economic growth – growth accounting research after World War II and the rise of development studies – he points outs the methodological and institutional dimensions that underpinned the human capital research program and ensured its rapid development. He underlines the role of the Chicago Department of Economics and the rise of Milton Friedman's positive economics, which promoted an empirical trend in economics more widely. The political context was also favorable: the "spread of the Keynesian gospel" had shaped the idea that public education expenditures are economically meaningful and, according to him, created an environment conducive to the emergence of human capital theory. Finally, he underlines the influence of some international institutions, which rapidly endorsed human capital ideas (especially the World Bank and the OECD).

Growth theories, in fact, played a critical role in the development of human capital theory, notably through the puzzle of the residual which was brought to light by the growth accounting exercises of the 1950s and 1960s. Showing that much of the US economic growth was not explained by the rate of growth of inputs but by the residual contribution of total factor productivity (TFP), Tinbergen (1942), Fabricant (1954), Abramovitz (1956), and in particular Solow's contribution of 1957[3] sets the stage for new challenging research opportunities. Considerations about the quality of the factors of production, especially the labor input, were raised in order to resolve the puzzle, and these made a crucial contribution to the rise of human capital thinking. The problem of the residual highlighted the inconsistency between the theoretical insights and the empirical evidence in growth approaches, which in fact provided Theodore Schultz, who is recognized as "the father of the human investment revolution in economic thought" (Bowman 1980, see also Blaug 1966), a favorable context in which to promote the reflections he had developed since the 1940s in his works on agriculture. While Schultz's articles published in 1958, 1959, 1960, and 1961a are often regarded as a starting point for the human

[3]Solow's contribution of 1957 was a landmark in the development of growth accounting.

capital research program (see Bowman 1966, 1980, Sobel 1978), his thought on human capital traces its origin back to his analysis of agricultural poverty. The great influence these works on agricultural economics exerted on the later development of human capital theory has been outlined by Nerlove (1999) and has been examined in further detail by Le Chapelain and Matéos (2018).

As early as 1943, in his book *Redirecting Farm Policy*, Schultz identifies differences in educational expenditures as lying at the origin of labor productivity inequalities in agriculture and, consequently, of income inequalities. From this analysis, he sketched out the idea that educational expenditures can be regarded as a form of investment. These first forays into the idea of human capital, developed in a rather piecemeal fashion in the 1940s and 1950s, evolve into a full-blown research program from the end of the 1950s onward.

In his signal contributions of 1959, 1960, 1961a, and 1962 to the "human capital revolution," Schultz in fact explicitly introduced the idea of considering education as a form of capital in the light of the puzzle of the residual[4]:

> The principal hypothesis underlying this treatment of education is that some important increases in national income are a consequence of additions to the stock of this form of capital. Although it will be far from easy to put this hypothesis to the test, there are many indications that some, and perhaps a substantial part, of the unexplained increases in national income in the United States are attributable to the formation of this kind of capital. (Schultz 1960, p. 571)

Denison's work of 1962 provided empirical support for the hypothesis formulated by Schultz (Schultz never properly proceeded to growth accounting research). His approach relies on an estimation of the quality of labor measured through education, and it shows that taking this "educational capital" into account sharply reduced the value of the residual. But Schultz is recognized as one of the founding fathers of human capital theory because he explicitly linked the empirical analysis of aggregate input-output series with the theme of investment in human beings.

The Synthesis Provided by Schultz, Becker, and Mincer

> I propose to treat education as an investment in man and to treat its consequences as a form of capital. Since education becomes a part of the person receiving it, I shall refer to it as human capital. (Schultz 1960, p. 571)

The human capital revolution marks a shift in the way economic analysis examines individual skills and capacities (accumulated through education, experience, health, etc.). These skills would henceforth be considered a form of capital and therefore be seen as arising as the result of an investment, whereas education-related spending

[4]The residual was not the only puzzle that led Schultz to build the foundations of human capital theory. We must also cite the Leontief paradox (see Schultz 1972a). But the residual appears to be by far the most decisive element in the development of human capital theory.

had hitherto only been addressed through the prism of consumption. For Bowman (1966), this investment orientation is the prime characteristic of the human capital revolution ("investment in human beings").

Besides Schultz's prominent role in the early conceptualization of the human capital idea, Becker (1964) and Mincer (1958) are recognized as two other great leaders of the human capital revolution. Their respective works exerted great influence on the diffusion of the concept of human capital within economic analysis at the end of the 1950s.

Becker's 1964 monograph *Human Capital* is well known for providing a framework for analysis of individual investment decisions in human capital, based on a cost-benefit assessment. Relying on rational choice theory as a framework of analysis (Teixeira 2014), Becker gave solid micro foundations to Schultz's proposals,[5] and his text is now recognized as one of the most decisive contributions to the emerging research program: indeed, his 1964 monograph is considered the *locus classicus* of human capital theory (Blaug 1976). In Becker's canonical model, education yields future income flows under the form of wage increases coming from the enhanced productivity due to higher individual human capital. Education also involves direct and indirect costs, which correspond, respectively, to expenditures directly related to education – such as education fees, transportation costs, or books – and to earnings forgone due to continuing schooling. Through this cost-benefit approach, and by an analogy with physical capital, the rate of return to human capital investment is defined as the rate of discount that equalizes the stream of discounted benefits with the stream of costs. This analytical framework explaining the individual's choices of investment in education has progressively become the most representative piece of a theory of human capital grounded on methodological individualism,[6] that is on "the view that all social phenomena should be traced back to their foundation in individual behavior" (Blaug 1976, p. 830).

Mincer's works were also motivated by an initial interest in an issue that was distinct from Schultz's macroeconomic concerns with economic development and growth.[7] His 1957 and 1958 contributions to human capital theory analysis dealt with the question of wage inequalities and are, as with Becker's approach, grounded on the application of rational choice theory to provide a theory of personal income distribution:

> The starting point of an economic analysis of personal income distribution must be an exploration of the implication of the theory of rational choice. (Mincer 1958, p. 283)

[5]Schultz pays explicit tribute to Becker's theoretical model of investment in human capital, developed in the 1960s. See, for instance, Schultz, 1961b, p. 1037; at about the same time he also wrote: "I have placed the paper by Gary S. Becker first because it gives the reader an overview of the pervasiveness of human capital and because it reveals many vistas awaiting to be explored" (Schultz, 1962, p. 2).

[6]For a critical review of the meanings associated with methodological individualism, as well as its contradictions, see Hodgson (2007).

[7]"Becker and Mincer were not engaged in making aggregative estimates of the contribution of education to income growth" (Bowman, 1964, 453).

Mincer's theoretical proposal treated education as a determinant for wages. In this way it contributes – albeit unintentionally, since Mincer's first developments were isolated[8] – to the development of human capital theory. His work was deployed mainly in the field of labor economics (Teixeira 2007, 2011).

While Schultz, Becker, and Mincer developed a body of work research arising from distinct questions and motives and took different routes of analysis, their respective works constituted the human capital research program, which rapidly spread to the various fields of economic analysis.

Section II. Reservations, Old and New, About the Concept of Human Capital

Although the success of human capital theory is undeniable – as attested by the broad usage of the concept in economics and beyond – the human capital program has faced criticism ever since its inception. This section reviews the history of these concerns.

Section "Theoretical and Methodological Objections" offers an overview of major criticisms stemming from a reluctance to apply standard capital theory to the question of individual skills and capabilities or based on a rejection of the methodological foundation of human capital theory, i.e., the rejection of methodological individualism.

We then turn to questions that arise from the mixed results of the empirical literature on economic growth. We show in the section "Skepticism About the Measurement of Human Capital" that the ambiguous findings of analyses exploring the contribution of education to economic growth have led to the resurgence of doubts about the concept of human capital. The criticism here is distinct from those stemming from theoretical objections or methodological disputes. It arises out of the issue of the measurement of human capital that has bedeviled the human capital research program since its origins. This issue has more recently led to a radical revision of the concept, prompted by the so-called "quality of education" approach.

Theoretical and Methodological Objections

Marshall's critique of the idea of human capital was the most influential in the period preceding the human capital revolution itself. The status of the concept of human capital in Marshall's thought was controversial. The debate between Kiker (1966,

[8]As underlined by Teixeira (2005, p. 137): "A peculiar aspect was that the initial development was isolated and only after Schultz saw Mincer's dissertation and decided to invite him to Chicago for a post-doctoral fellowship (1957–1958), they interacted more closely. Then, they became aware of the closeness of their research and its *unplanned* complementarity." See also Biddle and Holden (2016).

1968) and Blandy (1967) is enlightening in this respect. The thrust of this debate lies in the question of whether Marshall analyzed human skills within the analytical schema of capital – which is precisely what was done by the proponents of the "human capital revolution." According to Kiker (1966, p. 481), "Marshall discarded the notion as 'unrealistic'." Yet Marshall did not neglect the importance of human investments and their economic consequences, quite the contrary. As quoted by Becker in the introduction to his landmark book (1964), Marshall wrote: "The most valuable of all capital is that invested in human beings" (Marshall 1890, p. 469).

Marshall built upon Smith's legacy to assert:

> The motives which induce a man and his father to invest capital and labour in preparing him for his work . . . are similar to those which lead to the investment of capital and labour in building up the material plant and the organization of a business. In each case the investment (so far as man's action is governed by deliberate motive at all) is carried up to that margin at which any further investment appears to offer a balance of gain, no excess or surplus of utility over 'disutility'. (Marshall 1890, p. 514)

But, according to Kiker, Marshall was reluctant to place human skills within the definitional scheme of capital; a view which Blandy (1967) opposed, even though he recognized that Marshall "felt that its [the idea of human capital] inclusion in the notions of wealth and capital in all circumstances was not in harmony with the usage of ordinary life and would lead to confusion if it were included in his general definition" (Blandy 1967, p. 875). Sweetland (1996) also supports Kiker's view, claiming that Marshall discarded the notion as unrealistic. Without a market for human capital, determining its value was a gamble. He was therefore not convinced that there was any possibility of providing a reliable estimation of the monetary value of human beings or their skills.

According to Schultz, Marshall's reluctance about the application of capital theory to individual skills and capabilities played a major role in the belated acceptance of the concept of human capital.

> But Fisher's approach to capital was not accepted by the mainstream of economists, mainly because of Marshall's adverse reactions to it, backed by his great prestige. Although Marshall at many points in his own work refers to the abilities man acquires by schooling and by working as an apprentice and to the economic role of knowledge, his view was that, whereas human beings are incontestably capital from an abstract and mathematical point of view, it would be impractical to extend the traditional market place concept of capital to include human capital. (Schultz 1972a, pp. 6–7)

Shaffer's commentary (1961) on Schultz's presidential address delivered at the annual meeting of the American Economic Association in 1960[9] offers a snapshot of the criticisms addressed to the idea of human capital at the time. These criticisms did not question the proposal that educational expenditures enhance productivity nor

[9]Schultz's presidential address to the American Economic Association in 1960 is seen as one of the fundamental moments in the emerging theory of human capital (see, for instance, Teixeira 2000).

did they deal with the fact that considering men or their abilities as a form of capital raised moral issues. The core of Shaffer's criticism is that disentangling the consumption and the investment part of total expenditures on man (education, health, etc.) is unfeasible.

As with Marshall's qualms developed 50 years earlier, Shaffer doesn't ignore the importance of human skills, and he accepts that it can be considered as a form of human capital but only in a metaphorical sense. He claims, in fact, that considering men and their abilities as a form of capital should be regarded as a metaphor but can be analyzed within the framework of and with the tools of capital theory.

> Any attempt to show that rational individuals tend to undertake expenditure on education up to the point where the marginal productivity of the human capital produced by the process of education equals the rate of interest – a point at which the marginal expenditure on education yields a return equal to the return on marginal expenditure for any other factor of production – would be a mockery of economic theory. (Shaffer 1961, p. 1028)

On this occasion, Schultz, Becker, and Mincer definitively won the battle against human capital's skeptics. But new offensives arose at the turn of the 1970s.

The new criticisms came, on one side, from competing methodological approaches. The radical school articulated its criticism around the rejection of the individual choice framework and took a firm stance against the methodological individualism that characterized human capital theory (see Bailly 2016). The objection it raised concerned the fact that the human capital research program traces the dynamics of the education system back to individual choices alone and neglects the role of class conflicts in determining inequalities in education: "Human capital theory is the most recent, and perhaps ultimate, step in the elimination of class as a central economic concept" (Bowles and Gintis 1975, p. 74).

The institutionalist approach – which had dominated labor economics before the rise of human capital theory (see White 2017) – also rejects the methodological orientation of the human capital research program. Institutionalist-oriented analyses of the dynamics of the education system reject the individual choice model as a basis for a theory of the supply of education (see Chirat and Le Chapelain 2017) and, in opposition to human capital theory, confer a leading role to corporations and the requirements of technology. "Nothing is more alien to the human capital research program than the manpower forecasters' notion of technically- determined educational requirements for jobs" (Blaug 1976, p. 846).

On the other side, within this set of challenges to human capital theory that flourished in the 1970s, criticisms also emerged from within mainstream economics. The filter theory of education (Arrow 1973) and the theory of "screening" (Stiglitz 1975) didn't attack the neoclassical methodological basis of the research program, but both put forward a criticism targeting a pivotal argument of the human capital theorists: namely, the positive link between education and productivity. These theories consider that education reflects an individual's productivity potential, but they oppose the view that educational investment contributes to the accumulation of skills that enhance agents' productivity.

Henceforth, as emphasized by Sobel at the beginning of the 1980s, "Human capital, with its individualistic approach, while still the dominant theory, is not the only game in town" (Sobel 1982, p. 268).

Skepticism About the Measurement of Human Capital

The first questions about the positive relationship between human capital and growth arose at the turn of the 1970s (see Demeulemeester and Diebolt 2011). In the economic context of the 1970s, marked by falling economic growth rates, doubts began to be expressed about the virtues of mass higher education (see notably Freeman 1976).

Endogenous theories of growth (Romer 1986, 1990, Lucas 1988) revived the idea of great importance for human capital on the growth process. This strand of literature expects there to be a positive relationship between growth and human capital *accumulation* (mainly, in these models, through education) (Lucas 1988) or – emphasizing the role of human capital on technological imitation and innovation – predicts that *stocks* of human capital are decisive as regards growth inequalities. In the 1990s, this literature, as well as the exogenous growth models incorporating human capital (Mankiw et al. 1992, for instance), led to a series of empirical exercises aimed at improving the understanding of the relationship between human capital (education) and growth. This empirical literature has given rise to puzzling results. Benhabib and Spiegel (1994) and Pritchett's (2001) studies, notably, have called into question the contribution of education to economic growth and hence have questioned the relevance of the human capital theoretic approach itself.

Several contributions have outlined the paucity of the educational proxies used in the empirical macro literature and their weakness in correctly reflecting different amounts of stocks and flows of knowledge and skills (see Woessmann 2003, Cohen and Soto 2007, Folloni and Vittadini 2010, and Prados de la Escosura and Roses 2010). According to these approaches, the ambiguous empirical findings about the contribution of human capital to economic growth can directly be explained by the poor quality of the data (as advanced by Cohen and Soto (2007)) or by the human capital proxies inappropriately reflecting the nature of the theoretical concept.

Woessmann (2003) has stressed the weaknesses of the three most commonly used human capital proxies in the empirical literature: the literacy rate, the enrollment rate, and the average years of schooling of the active population. According to the author, an appeal to literacy rates leads to an underestimation of the stock of human capital in an economy, as this proxy ignores all human capital investments that go beyond reading and writing itself. Nor do enrollment rates provide a more suitable appraisal of the endowments in human capital: as the students do not belong to the active population, assessing the effective stock of human capital of this population by using this indicator is likely to induce significant gaps. Appeal to the average number of years of schooling of the workforce does overcome the previously mentioned limitation. Different methods, based either on the enrollment rate (when sufficiently long-term data allow for it) or on censuses, are used to assess the average years of schooling of the active population (see, for instance, Lau et al. (1991) and

Nehru et al. (1995)), and this seems to constitute the least imperfect indicator of human capital among the indicators previously mentioned. This measure, however, has its own weakness: it considers that a year of education leads to an equivalent accumulation of human capital, independent of the grade which the year of education covers, i.e., its rank in the schooling hierarchy,[10] and independent of the quality of the education system itself.

This last channel, i.e., the effect of the unequal quality of teaching on the effective accumulation of human capital, has a vast literature devoted to it. The seminal work of Hanushek[11] contributed significantly to promoting the idea that purely quantitative educational variables were only poorly able to illuminate the role of human capital on wages at the individual level or on economic growth at the macroeconomic level.

This field of research firstly considered different educative outputs (education-related spending, size of classrooms, level of training of the teachers, etc.) to reflect the differences in the quality of education systems and their impact on the accumulation of human capital (see, for instance, Behrman and Birdsall (1983)). Progressively, the ability of these indicators to accurately reflect differences in the quality of schooling has been called into question. The use of scores in international tests (e.g., PISA, TIMSS) now permits a more direct evaluation of these differences by measuring the skills accumulated through education.

The research program on the quality of education has made salient the difficulty of measuring human capital. First, due to inequalities in the quality of education, the same amount of education can lead to different levels of human capital accumulated. Second, research has shown that education quality matters for growth and, accordingly, that the human capital proxies commonly used have failed to properly estimate human capital endowments at the macro level.

On this basis, the research program on education quality has taken a somewhat radical turn. In their latest book, Hanushek and Woessmann (2015) come down hard on the state of the human capital research program. Their criticism now centers on the view that human capital endowments at the macro level are very badly calculated due to the use of inappropriate measures. As a result, the message sent by the literature on the role of education on economic growth is fundamentally distorted. They claim that the concept of human capital should be abandoned in favor of a new concept of "knowledge capital."

> The conclusion of the analysis we develop in this book is that Adam Smith was right: human capital, as we now call it, is extraordinarily important for a nation's economic development. The significance of education, however, has been obscured by measurement issues. (Hanushek and Woessmann 2015, p. 2)

[10]Microeconometric approaches have highlighted the existence of decreasing private returns of education (see notably Card (1999) and Psacharopoulos and Patrinos (2004)).

[11]Eric Hanushek significantly contributed to the development of the so-called approaches of the "quality of education." His early work on the subject began in 1970. Regarding the role of the quality of education in the contribution of human capital to growth, see, for instance, Hanushek and Kimko (2000), Jamison et al. (2007), or Hanushek and Woessmann (2008, 2011, 2012).

Hanushek and Woessmann's critique of the concept of human capital does not turn on doubts about the relevant theoretical framework – i.e., the theoretical logic driving the human capital program – but rather on the inability of this framework to accurately contribute to economic policy recommendations due to the overwhelming empirical difficulties it faces. They emphasize that the measurement problem thus seriously threatens the credibility of the human capital research program.

The measurement of human capital is a major issue for cliometric approaches to the question of the industrialization process. These approaches have recently opened up new avenues of thought on the measurement problem, which though not so radical as to propose the abandonment of the concept tout court, nevertheless raise knotty and fascinating issues.

Section III. Human Capital and the Industrialization Process

The human capital revolution at the end of the 1950s coincided with another revolution, albeit a distinct one, namely, the development of the *New Economic History,* or cliometrics, also initiated in the United States (Diebolt and Haupert 2017). In its analysis of the determinants of growth, the cliometric approach quickly came to appropriate the theoretical synthesis fostered by Schultz, Becker, and Mincer.

The issue of the growth process, which motivated the development of human capital theory at the end of the 1950s, is a prime question for cliometric studies (see Goldin 2016). The understanding of the determinants of economic growth has in fact been a main challenge for cliometrics ever since its origin. In tackling this field of inquiry, cliometricians have naturally built on the contributions provided by human capital theorists, and the concept of human capital is widely used in the examination of national or regional growth trajectories. The concept has also been appealed to in support of cliometrics's new interest in unified growth theories, which builds on the idea of the inverse relationship between fertility and human capital to provide a unified explanatory model of the transition from Malthusian stagnation to modern growth (Galor and Weil 2000, Galor and Moav 2002, Galor 2011).

In the investigation of the causal relationships linking human capital and growth, namely, in its attempt to illuminate the contribution of the endowments in human capital to the growth processes, the cliometric synthesis was primarily applied in a specific field of investigation: the industrialization process experienced by Western European countries in the eighteenth and nineteenth centuries. It is in fact out of the industrial revolution, and the associated massive accumulation of human capital, that the complex question of the underlying relationships linking these two phenomena arises.

The role of human capital at the time of the second industrial revolution is close to the predictions of contemporary theory, which considers human capital as a driver of growth and defends the idea of "skill-biased technological change." In contrast, and paradoxically, the role of human capital in the first stage of the industrialization

process has long been regarded as minor (Human Capital and Early Industrialization: A Paradox in Economic History). This dominant view is currently under review (The Paradox Under Review: Re-evaluating What Human Capital Is).

Human Capital and Early Industrialization: A Paradox in Economic History?

As regards human capital and early industrialization, cliometricians have addressed two main issues. On one side, a large strand of literature has examined the importance of human capital as an explanatory factor in the industrial takeoff and of the subsequent transition to the modern regime of economic growth. On the other, the effect of the industrialization process on the formation of human capital has prompted attention. By showing that human capital was not a key factor in the industrial takeoff and that the industrialization process did not trigger human capital accumulation, these two interrelated strands of research have emphasized the inconsistency between neoclassical growth models – and of human capital theory – and the features that had characterized the first stage of the industrialization process.

Indeed, the early literature in this field didn't see human capital as a key factor in the industrial takeoff. On the basis that Britain experienced a low and stagnant level of education at the time of its industrial takeoff, Mitch (1999) was one of the first to assert that human capital endowments didn't play a major role in the British industrial revolution. Allen (2003) and Clark (2005) also support the view that human capital theory cannot provide a convincing explanation of the British transition from the Malthusian era to modern growth. Sandberg (1979) helped diffuse the same idea by highlighting that despite a large stock of human capital, in the mid- nineteenth century, Sweden experienced low and stagnant income levels ("the theory of the impoverished sophisticate"). Emphasizing the role of culture and values, Mokyr (2016) and McCloskey (2006, 2010, 2016) – though on different grounds – provide a more nuanced account of the role of human capital in the transition to modern growth. For McCloskey, the great enrichment experienced by Western European countries since the eighteenth century is rooted in the evolution of culture and ideas, and more precisely in changes to expressed attitudes to capitalism and in changes in thought about the bourgeois ("The bourgeois 'Revaluation'"), but not in capital accumulation nor human capital accumulation (nor in institutions, coal, etc.). Mokyr's argument, while distinct from McCloskey's, also stresses the importance of culture – the culture of the intellectual elites, not the role of bourgeois culture – as a key root of the great enrichment. Mokyr points out that the transition to modern economic growth in eighteenth-century Europe must be regarded as the result of the development in Europe between 1500 and 1700 of new values and new ideas that diffused notably through the influence of the *Republic of letters*. This new culture – and not the narrow differences in literacy rates – is regarded as decisive for having set the stage for the industrial revolution.

Besides the thesis that human capital was unimportant to the industrial takeoff, early cliometric contributions dealing with the effect of the industrialization process of the eighteenth and nineteenth centuries on human capital accumulation came to

the conclusion that industrialization was, first, a deskilling process. Early views on the issue have argued that industrialization and technological change were not skill-demanding but, on the contrary, at least in the first stage increased the relative demand for unskilled labor (see, for instance, Nicholas and Nicholas 1992, Mokyr 1993, Mitch 1999). Expansion of production and the mechanization of industry notably increased the demand for female and child unskilled labor (Sanderson 1972), thus impairing school participation and human capital accumulation. Early contributions on the issue have all suggested that the tasks required by booming production during the first stage of the industrialization process didn't require a workforce with a high level of skills. According to Goldin and Katz (1998), the complementarity between innovation and skills took place in the early twentieth century with the technological shift from steam power to electricity.

Overall, whether the issue is the determinants of the takeoff or the complementarity between industrialization and skills, cliometric analyses have spread the message that human capital mattered little in the first phase of industrialization. But this conclusion is currently under reconsideration.

The Paradox Under Review: Re-evaluating What Human Capital Is

A new wave of analysis is currently challenging the idea that human capital is not a relevant dimension in the analysis of the industrialization process. Interestingly, this recent literature has developed on the basis that early accounts of the human capital-industrialization relationship are subject to limitations because of their unsatisfactory evaluation of human capital endowments. This has opened up new paths of reflection about what human capital is and hence how to measure it.

On the one hand, efforts have been made to improve the quality of the human capital estimates. Jacob (2014) stresses the weaknesses of British educational records prior to 1850. According to her, the weak role attributed to education in the first industrial revolution partly derives from the poor state of the relevant historical sources. Work by De Pleijt (2018) provides a reassessment of the evolution of formal education in Britain between 1307 and 1900 by estimating – on the basis of information on literacy rates, primary, secondary, and tertiary schooling – average years of education over the period. These estimations bring to light that literacy rates alone are misleading, since they underestimate human capital accumulation in the period of the industrial revolution. Trends in the evolution of educational attainment are rather poorly reflected in literacy rates on the eve of the industrial revolution.

Madsen and Murtin (2017) also provide a reassessment of British human capital over the long run, based on educational attainment at primary, secondary, and tertiary levels. Analyzing the determinants of GDP growth over the period 1270–2010, they come to the conclusion that education was the prime driver of British economic growth over the period, a result which contrasts starkly with early contributions. They also put forward the fact that primary education was of prime importance in explaining growth in the pre-1750 period and that the role of secondary and tertiary education became predominant from 1750 onward.

More generally, faced with the difficulties raised by the nonavailability of historical data, the cliometric approach has developed new and innovative strategies to measure human capital. Within the spirit of the procedure based on marriage registers, the *age heaping method* has recently been developed (see, for instance, A'Hearn et al. 2009, Crayen and Baten 2010, Baten et al. 2014, Baten and Fourie 2015, Tollnek and Baten 2016, Cappelli and Baten 2017). This method relies on "the tendency of poorly educated people to round their age erroneously. For example, they answer more often '40', if they are in fact 39 or 41, compared with better educated people" (Crayen and Baten 2010, p. 452). Age heaping uses accuracy of age reporting as a proxy for numeracy.

On the other hand, another path of research builds on the idea that human capital endowments are badly evaluated, not because of the quality of the data or of the estimates used in empirical exercises but because assessing human capital through literacy rates or crude enrolment rates only (the common practice in empirical exercises at the macro level) shows just one side of a larger picture.

In the context of measuring human capital endowments, the effort required for an extensive understanding of the historical context necessarily highlights the need to keep the institutional and organizational features of the education systems under close review. From this knowledge, highly aggregated educational attainment measures of human capital, which are commonly used in early literature, quickly become unsatisfactory as they cannot reveal the differences in national experiences – i.e., the orientation of knowledge taught (general vs. vocational), the importance of apprenticeships, the presence of knowledge elites, the degree of centralization of the education, the way it was financed, etc. All of these dimensions may have an impact on the level of human capital effectively accumulated at the aggregate level but are ignored as soon as empirical approaches come to rely on aggregate enrolment rates or literacy rates only.

The need for a proper assessment of human capital has thus triggered reflections on the education systems per se and more specifically about their specificities at the institutional and organizational levels. The specific understanding of these specificities and their manner of inclusion in the establishment of relevant indicators of human capital are derived from the methodological nature of cliometrics itself. Because its methodology necessitates developing linkages between theory and measurement within the analysis of a specific historical context, the cliometric approach has opened new perspectives on the human capital empirical problem.

> Clearly human capital as a concept is indispensable, but we need to be far more specific as to what kind of human capital was produced, for and by whom, what was the source of the demand for it, and how it was distributed over the population. (Mokyr 2005, p. 1155)

At stake in this revisionist literature, which builds on the idea that there are different types of human capital, is the determination of what type was important for industrialization. Yet the early literature, by the way it measured human capital, has only considered differences in basic knowledge, namely, differences in literacy, without considering the other forms of accumulated skills.

Some approaches underline the idea that the human capital of the elite was decisive in the industrialization process, not the basic or average level of human capital (of the country), i.e., the human capital of the mass of workers. Mokyr (1990, 2005) has emphasized the need to "focus not on the mean level of human capital [. . .], but just on the *density in the upper tail* of the distribution, that is, the level of education and sophistication of a small and pivotal elite of engineers, mechanics, and chemists" (Mokyr 2005, p. 1157). Emphasizing that science and technique were concretely connected in the industrialization process, Jacob (1997, 2014) places at the forefront the role of scientists' and innovators' human capital. In that vein, Meisenzahl and Mokyr (2012) outline the key influence of the human capital of the elite in the British industrialization process. Because innovation and technological change were at the core of the industrial revolution, they argue that prime importance must be attributed to "the top 3 to 5 percent of the labor force in terms of skills: engineers, mechanics, millwrights, clock and instrument makers, skilled carpenters and metal workers, and wheelwrights."

Recently, Squicciarini and Voigtländer (2015) have developed a similar thesis about French industrialization. Relying on subscription density to the *Encyclopédie* (Diderot, d'Alembert) to measure the repartition and the density of French scientific elites (*knowledge elite)*, they show that the human capital of the elites in the eighteenth century, unlike the average human capital, played a significant role on the subsequent French industrial takeoff, starting in the first half of the nineteenth century.

Besides approaches that focus on the elites, analysis concentrating on the role of the apprenticeship system has also played a role in reviving the idea that human capital was of importance in the first stage of the industrialization process. A key argument behind the idea of a key role for apprenticeships is that the skills accumulated through it – the skills of the technical or mechanical workers – were decisive in fostering technological change, not because they promote technological innovation but because they were crucial in promoting the capacity to implement devices and maintain them while also promoting incremental innovation on the shop floor. "These characteristics did not require much science or even originality, but they needed people who were good with their hands and had been taught how to use them. It is that resource that the apprenticeship institution in Britain supplied better than anywhere else" (Zeev et al. 2017, p. 245). Zeev et al. (2017) suggest that the flexibility and effectiveness of Britain's system of apprenticeship is an important factor in explaining why England entered first into industrialization. Kelly et al. (2014, p. 364) assert explicitly that if the early literature has rejected human capital as a key driver of industrialization, it is because it "focuses on the wrong variables." For them too, Britain had a decisive advantage in terms of the quality of labor. The high level of technical competence of artisans and workers was linked, according to them, to the effective British apprenticeship system, and this explains the rapid industrialization. Humphries (2003) also sees in apprenticeship a decisive explanatory dimension behind early industrialization in Britain, pointing out that, in connection with the Elizabethan Poor Law, it played a role in reallocating labor to industry in eighteenth-century England. Focusing on pre-industrial

growth, De La Croix et al. (2018) emphasize the role of apprenticeship as a driver for *tacit* knowledge diffusion and stress its importance in the technological and economic advance of Western Europe in the century before the industrial revolution.

The importance of the British apprenticeship system in the second stage of the British industrialization process has been emphasized by Broadberry (2005, 2006), who opposes the widely held view that low levels of education in the British labor force, as compared to Germany or the United States, explained the British productivity decline at the end of the nineteenth century. In order to provide a convincing analysis of the relationship between human capital and productivity performance, he sought to disaggregate productivity indicators (according to the different sectors of the British economy) from education variables. By considering formal education and vocational training, he shows that "the key institutions of human capital accumulation in Britain were the system of apprenticeships and the body of professional associations" (Broadberry 2006, p. 128). Through the examination of the whole education system, he rejects the view that human capital endowment in Britain was low or that it explains the British productivity decline from the end of the nineteenth century until the eve of World War I. He therefore puts emphasis on the necessity of considering "human capital accumulation strategies" in order to provide proper measures of human capital. In fact, commonly used proxies of human capital, such as literacy rates or average years of education of the workforce, would have completely concealed what historical analysis has here brought to light: the key importance of specific vocational paths of education in Britain at the end of the nineteenth century.

Turning to the still open debate on the role that industrialization played on the accumulation of human capital, investigations into other forms of human capital (i.e., other than literacy standards and enrolment rates in primary education) have called into question the early consensus that industrialization was a deskilling process. Franck and Galor's (2017) seminal analysis was the first to question the idea that the path of economic development during the first industrial revolution was characterized by unskilled-based technological change. Examining early French industrialization (1839–1847), they show that technological change did indeed foster human capital accumulation. Showing that the number of apprentices and their share in the cohort of 15-year-olds increased in response to inventions, Feldman and Van der Beek (2016) also claim that technological progress was conducive to skills acquisition in eighteenth-century England. De Pleijt and Weisdorf (2017) show that there was a large decrease in average skills in agriculture and industry from the end of the sixteenth century to the beginning of the nineteenth century in England. They claim that deskilling generally occurred along with technological progress, despite a modest increase in the share of "high-quality" workers. This finding gives support to the view, already defended by Mokyr (1990, 2005) and more recently for the French case by Squicciarini and Voigtländer (2015), that upper-tail knowledge played a prominent role in early industrialization. For De Pleijt et al. (2016), the effect of industrialization on human capital is mixed. They show that

in the first phase of British industrialization, more steam engines were associated with a higher skilled labor force, and thus they claim that technological adoption was skill-demanding. But they also highlight that adopting new technologies was not conducive to elementary education (where this is approximated by literacy rates and enrolment rates). Diebolt et al. (2017) distinguish the accumulation of basic human capital (basic literacy skills) from intermediate human capital (basic scientific and technical knowledge and basic knowledge in law and trade) in nineteenth-century France. They show that French industrialization was not deskilling but that a shift in the kind of skills required occurred in the second half of the nineteenth century. Focusing on lifelong training, Diebolt et al. (2018) provide evidence that technological change contributed significantly to the development of adult education during the period 1850–1881 in France. They show that steam technology adoption was skill-demanding, highlighting that it triggered the development of evening classes for workers and apprentices.

Finally, the education systems at the time of the first industrial revolution evolved following different patterns, which privileged different types of institutional organizations. The focus on general vs. vocational education, the nature of the skills taught, the degree of centralization, types of funding – private or public – but also their attitudes toward social and gender inequalities (girls' access to education) are important dimensions that single out the education systems of the countries that entered industrialization in the eighteenth and nineteenth centuries. These dimensions also inflect the respective paths of human capital accumulation.

Goldin (1998, 2001, 2016) and Goldin and Katz (1999, 2008) have shown that the US educational model differed profoundly from European elitism, having been based since the nineteenth century on the principle of egalitarianism. Several characteristics reflect this principle of egalitarianism: public financing, the separation of church and state, the decentralized functioning, and the access of girls to education (gender neutrality). Goldin and Katz (2008) point out that this orientation of the education system constitutes an incremental ingredient of the accumulation of human capital in the United States and of the economic success of the country in the twentieth century.

Contrary to Mitch's (1999) findings, which call into question the contribution of formal education to the British takeoff, Becker et al. (2011) show that the Prussian education system, characterized by the large and early diffusion of elementary education, created favorable conditions for the adoption of existing technologies in Prussia and therefore contributed to its industrial takeoff. Consequently, they assess the importance of the education system in the process of industrial catch-up in Prussia in the nineteenth century. Analyzing primary, secondary, and higher education separately, they argue that secondary and higher education were not of significant importance in this process.

Cinnirella and Streb (2017) consider different types of human capital and their influence on innovation at the time of the second industrial revolution in Prussia. They outline how highly skilled craftsmen were still important – as recent literature has maintained in the case of the first stage of industrialization – for the innovation

process in the second stage of Prussian industrialization. Contrary to the first phase, they claim that the quality of basic education became important at the end of the nineteenth century, since it fostered both labor productivity and firm innovation. In addition, Cappelli (2016) has recently shown that the centralization that characterized the organization of the Italian education system in the nineteenth century negatively influenced human capital accumulation. His analysis shows that the move to decentralized primary schooling in the late nineteenth century was an important driver for the increase in Italy's human capital endowment.

Conclusion

This chapter has sketched the development of the study of human capital. We have noted some of the challenges to the human capital revolution. There were theoretical objections to the idea of analyzing human skills within the framework of capital theory and opposition to the methodological orientation of the program. The radical school and the institutionalist approaches both criticized the failure of human capital theory to adequately describe the mechanisms and driving forces behind the dynamics of human capital accumulation.

Somewhat surprisingly, however, the most severe criticism directed against the human capital program comes from what we might describe as an operational problem of measurement. Currently, the deadlock faced by human capital as regards the issue of empirically measuring stocks of skills (at the macro level) severely threatens the achievements of the late 1950s. We have emphasized in this chapter that, in its analysis of the role played by human capital in the first phase of the industrialization process, the cliometric revisionist literature paves the way toward renewed insights into the measurement of human capital. Due to its particular methodological character, lying at the crossroads between theory, measurement, and history, the cliometric synthesis promotes a reformulation of the question of the measurement of human capital in a unique and, we believe, successful way, as regards the empirical challenges faced by the concept. The question of measurement is raised through the question of national and/or regional strategies of human capital accumulation and of their efficacy regarding economic growth. This distinction is not trivial. It indicates that the difficulties of measuring human capital should not be reduced to a purely operational problem but are linked with a more fundamental challenge: the accurate and precise understanding of education spending, at the aggregate level, that effectively contributes to the accumulation of human capital, i.e., by relying precisely on investments, and not on a form of consumption. This perspective brings us back to an original challenge of the human capital revolution, which was to disentangle the investment and the consumption part of education expenditure. This challenge has never been fully taken up; which led Schultz to assert that "a satisfactory theory of economic growth should explain the mechanism that determines the formation of human and nonhuman capital, including the accumulation of knowledge" (Schultz 1972b, p. S6). Cliometric approaches have recently embarked on this route.

Abstract

In this chapter, we provide comprehensive insights into the implementation and the use of the age-heaping method. Age heaping can be applied to approximate basic numerical skills and hence basic education. We discuss the advantages and potential issues of different indicators, and we show the relationship of those indicators with literacy and schooling. The application of age-heaping-based indicators enables us to explore various topics on basic education such as the gender gap and the divergence of countries in the very long run. This well-established technique has been used by a great variety of authors who also show that numeracy has a large impact on growth.

Keywords

Age-Awareness · Development · Education · Numeracy

Introduction

Education is one of the driving factors for the development and long-term economic growth of countries. Many projects in development aid are set up to increase school enrollment rates or years of schooling to improve education and thus the prospects of future generations. Nowadays, there are plenty of measures and indexes at hand to quantify different levels of education among children, adolescents, and adults. Through various tests and methods, the levels of education or human capital are comparable on an international basis. In the famous Programme for International Student Assessment (PISA), scholars compare cognitive skills of students from various countries around the world. On the one hand, the impact of such a program is enormous: The countries with lower scores invest financial means or restructure their schedules to push forward in the range. On the other hand, the results build one of the largest databases on students' education worldwide with which scholars are able to conduct analyses and draw conclusions for the future.

However, if we go some decades further back in time, we have to rely on other measures of human capital such as years of schooling, enrollment rates, or literacy because we simply lack other indicators. The differentiation between different years of schooling, for example, is slightly less exact than that of the cognitive skills tests of the PISA study. Moreover, there are other issues that might occur with these indicators. If a child is enrolled in school, it does not necessarily mean that he or she acquires a certain level of reading or mathematical skills before potentially dropping out. Literacy rates are often self-reported or even have to be constructed from people's ability to append their signatures to documents, such as marriage registers or wills, which does not necessarily imply that the person is able to read and write. Reis (2005) reports such estimated literacy rates for a number of European countries around 1800. The English database implemented by Schofield (1973) reaches back to the middle of the eighteenth century. By analyzing wills, Gregory Clark (2007) constructed another large database on English literacy that even dates back to 1585.

The construction of databases on literacy reaching back to the sixteenth century is, of course, an exceptional case and only possible for a country such as England where the availability of sources is much better than in most of the other countries in the world. In most countries, data sources are scarce and do not provide literacy or enrollment rates until after the Industrial Revolution. For some less developed countries or world regions, we do not even find comprehensive enrollment rates for the past 50 years because schooling was not obligatory or there were no schools nearby for children to attend. But how can we measure human capital in times in which education was only available for the rich or in regions where data sources are very scarce?

In numerous surveys, church registers, or census lists, people reported information from which scholars are able to derive a basic indicator of human capital: their age. The underlying concept for calculating such an indicator is the so-called age heaping: In earlier times, when people did not have birth certificates or passports, they were often not aware of their true age or they simply did not know it because no one kept record of their exact date of birth. As a consequence, when people were asked for their age and they did not know it, they tended to state a "popular" number. For instance, they claimed to be 35 when they were in reality 34 or 36. Hence, the age distribution shows "heaps" or "spikes" at these popular digits that are mainly multiples of 5. Why does this clearly not reflect the true distribution of ages? We can explore that with a small example: If in the year 1935, for example, 100 people stated to be 35 years old but only 50 people reported being 34 or 36 years of age, this would mean that twice as many children were born in 1900 compared to the years 1901 and 1899. This is a very unlikely scenario and most probably due to age non-awareness. This phenomenon causes problems for demographers because they have difficulties estimating the true distribution of males and females in certain age groups or the life expectancy of a population (see, e.g., A'Hearn et al. 2009). But, while being a disadvantage to the accuracy of demographic research, this pattern is actually a benefit for the research on basic education: By implementing an indicator such as the Whipple, we can calculate the ratio of the individuals who were able to report their own ages exactly in contrast to those who stated rounded numbers. Consequently, an indicator based on age heaping enables us to conduct studies on basic numeracy or human capital for a great variety of countries and in the very long run.

Many authors used the by now well-established age-heaping method on various topics related to basic education: Myers (1954); Mokyr (1983); Zelnik (1961); Duncan-Jones (1990); Budd and Guinnane (1991); Ó Gráda (2006); Manzel et al. (2012); as well as Crayen and Baten (2010a, b), among others, studied differences in numeracy of various countries, world regions, and time periods. A'Hearn et al. (2009) demonstrated the strong relationship between age-heaping-based indicators and literacy. De Moor and Van Zanden (2010), Manzel and Baten (2009), and Friesen et al. (2013) assessed gender inequalities in numeracy in different world regions, whereas Juif and Baten (2013) compared the numeracy levels of Inca Indios before and after the Spanish conquest. Stolz and Baten (2012) analyzed the effects of migration on human capital selectivity – hence, they measured the extent

of "brain drain" or "brain gain" of countries through migration.[1] Charette and Meng (1998), for instance, assessed the impact of literacy and numeracy on labor market outcomes.

In the following section we will explain in greater detail the advantages and potential caveats of the age-heaping method. We also discuss the indicators that are commonly used to approximate basic numeracy, and we describe in which way they are calculated. Furthermore, we explore the relationship between age-heaping-based indicators and other measures such as literacy and schooling. In section "Applied Age-Heaping Indicators in Various Research Topics," we describe different research topics that have been assessed by implementing the age-heaping method, while in section "The Development of Numerical Skills in Different World Regions and Time Periods," we discuss studies that explore differences in numeracy levels across various world regions. In section "Numeracy Trends of Women and the Gender Gap in Different World Regions," we present the development of women's numeracy and the gender gap. Section "Conclusion: The Impact of Numerical Abilities on Growth" provides concluding remarks concerning the impact of basic numeracy.

Age-Heaping-Based Indicators: Advantages, Potential Biases, and Indexes

Advantages, Potential Biases, and Heaping Patterns

The requirement for employing numeracy as an indicator for human capital is that a certain share of people in earlier times – especially before the Industrial Revolution – was not aware of their actual age because they did not know their date of birth or they were not able to calculate the number of years from their date of birth to the actual year.[2] Consequently, when individuals were asked for their age and could not state it exactly, they did not choose any number randomly, but they typically tended to report a number divisible by 5 such as 35, 40, 45, and so on (Duncan-Jones 1990; A'Hearn et al. 2009).

[1]Brain drain means that highly educated people emigrate from their country of origin to another. Brain gain means the opposite effect.

[2]However, we have to keep in mind that there are individuals still living today, predominantly in the least developed countries, which are not aware of their true age when they are asked for it (Juif and Baten 2013).

While the aforementioned is the most commonly detected heaping pattern, there is also some heaping on multiples of 2 – hence even numbers.[3] In the Chinese culture, one might also think of a different heaping pattern, for example, the avoidance of the number 4, which when pronounced sounds similar to the word for "death," or the preference of the number 8, which can be associated with fortune (Crayen and Baten 2010a). However, Baten et al. (2010) found that Chinese migrants to the United States (US) heaped considerably more on multiples of 5 than on the birth year of the dragon, for instance, which is a very popular animal sign in China.

One great advantage of an age-heaping-based indicator is that it enables us to assess basic numeracy for a large number of countries over a very long period of time because this phenomenon presumably appeared in most societies until a certain point in time (Duncan-Jones 1990). The second advantage is that there exist a large number of sources that can be employed to calculate numeracy indexes. In principle, we can use any list for which people had to report their age including census lists, ecclesiastical surveys, tax lists, marriage registers, death registers, and shipping lists, just to name a few. Of course, selection biases need to be studied. One very early census in the history of mankind that we are aware of is the population census decreed by Emperor Augustus – around the birth of Christ – for which Maria and Joseph were heading to their place of birth to be enumerated. Duncan-Jones (1990, p. 79), however, reveals another way to measure age awareness in ancient times: the inscriptions on tombstones in the Roman world. Age heaping on multiples of 5 was very common in the first centuries after Christ, with levels of age misreporting of up to 60%.

[3] De Moor and Van Zanden (2010) even report a preference for multiples of 12 in different medieval and early modern sources, among them a census from Tuscany in 1427 and another from Reims in 1422. This phenomenon could be the result of religious orientations and the underlying usage of the number 12 as a holy number. Interestingly, this heaping pattern was more often adopted by women than by men, especially during early modern times in the South Netherlands. This could be due to a stricter adherence of religious practices or beliefs by women than by men, though this is not scientifically proven so far.

Another pattern might also occur if a certain share of the population was surveyed and the results were written down in year t, whereas the rest of the data collection was performed in the following year t + 1. After the census was finished, the census official compiled the results in a clean and comprehensive list in year t + 1. Because he or she was aware of the age statements that had been reported in year t, he added 1 year to those ages. As a result, we find heaping on the terminal digits one and six in these lists. If this pattern can be identified without reasonable doubt, the additional year should be subtracted from all of the affected age statements.

In a similar way, the authors of some studies have found that numeracy estimates based on age statements of marriage lists tend to be upwardly biased (which is partly due to the fact that marriage was restricted to those who earned a living and could nourish a family in many historical societies). Death registers on the other hand tend to yield downwardly biased estimates. This type of bias could happen if the deceased person did not have any relatives or close friends whom the recorder could ask for an age statement. Consequently, he or she estimated the age by himself. Adjustment factors for these types of sources are available from the authors.

The most important factor when calculating age-heaping levels derived from the aforementioned lists is that the ages of the individuals are self-reported and not counterchecked.[4] In some cases, particularly church survey data, such as marriage registers, it is possible that an ambitious priest counterchecked the ages of the bride and groom by their respective birth dates in a birth or baptism register. In the case that ages are counterchecked, we usually cannot detect any age heaping at all. Hence, if numeracy levels are extremely high, particularly in the case of very early samples of rural parishes, we should either eliminate the sample from the dataset or check the possibility of high numeracy levels. We could, for example, compare the numeracy levels to the corresponding literacy rates of the parish or to the numeracy levels of regions or villages with a similar infrastructure, education system, and so on (A'Hearn et al 2009). Generally, we can say that the further back in time the period of interest lies and the higher the age heaping is, the more likely it is that ages are not counterchecked. In censuses executed by governmental authorities and in times in which obligatory identification did not exist, we can assume that ages are not counterchecked.

Another possible objection could be the question: Whose age heaping do we measure after all? Do the statements truly reflect the pattern of the respondents or is the observed age heaping actually caused by the census taker? Critics could argue that the census taker might have estimated the ages of the people by himself or herself or corrected those that seemed implausible to him or her. This potential issue has to be examined carefully for each data source. However, there are various hints that this is not the case in the studies under discussion. According to Manzel and Baten (2009), some of the executive authorities explicitly required the census takers to interrogate the people individually.[5] Moreover, if the age-heaping results were influenced by the individual numeracy level of the census taker, the results of different censuses should vary within one region or country for the same birth cohorts. The authors, however, find that the results of different censuses display very similar levels of age heaping for the respective birth decades.

Another strong argument in favor of the self-reporting of surveyed individuals is the difference in numeracy levels that we find between occupational and social groups. Baten and Mumme (2010) as well as Tollnek and Baten (2013) reveal that better educated groups of professionals, such as merchants, show significantly higher levels of basic numeracy than unskilled or partly skilled individuals. Furthermore, A'Hearn et al. (2009) show that the correlation between literacy and numeracy rates is very strong on a regional or countrywide basis. Clearly, we are only able to

[4]Self-reporting is, of course, not an option if we consider tombstones or death registers. The ages provided in these sources reflect the heaping pattern of the individual who reported the age in place of the respective person. But even in such cases, there are gender- or social group-specific differences observable (Duncan-Jones 1990, p. 83). It is most likely that the persons providing the ages for the tombstones were related to the deceased person or at least of similar social or educational status.

[5]They found information on censuses from which it becomes clear that the authorities required the census takers of surveying each person individually.

detect such considerable region- or occupation-specific differences if people stated their ages by themselves.

Related to information about households or married couples, there is a further possible question to discuss: Did women report their ages themselves or did their husband help them – or even answer for them? How reliable are comparisons between male and female numeracy originating from the same source? In various studies, scholars suggest that we can rely on the age statements made by or assigned to women: According to De Moor and Van Zanden (2010), the indexes of women and men in a Belgian census, for example, were actually not that different. Hence, it seems plausible that the individuals responded by themselves. Furthermore, they find that women sometimes displayed preferences for different numbers than men – such as multiples of the number 12 – which can only occur if the women stated their ages by themselves.

Manzel et al. (2012) also find evidence in favor of the self-reporting of household members, which is based on results from the 1744 census of Buenos Aires: If it was the case that the head of household stated the ages in place of the other family members, there should be substantial differences in the numeracy levels, because one might assume that the heads were better educated than the other members, given that he or she provided the family income and in most of the cases had an occupation. However, the difference is almost negligible. Moreover, the authors report sources in which the interviewer made complementary remarks. Related to a certain person who reported to be 30 years old, he noted, "[. . .] but looked considerably older" (Manzel et al. 2012, p. 940). Such statements strengthen the assumption that census takers asked the people individually for their ages and did not accept someone else answering in their place. With all the results of the aforementioned studies and the information provided on the procedure of various censuses, we can assume that the studies discussed in this paper deliver reliable information on the basic education of the respective population.

Whipple, ABCC, and Other Indexes

There are various indexes we can adopt for measuring age heaping. In some cases the employed scheme varies from one study to another, depending on the author. What many of the indexes have in common, though, is the assumption that ages, stated as integers, follow a discrete uniform distribution. For example, 10% of the people in the 10-year age group from 30 to 39 are expected to report their age as 31, i.e., with "1" as the terminal digit since it is the only number ending with this digit in this 10-number interval. Applied to heaping on multiples of 5, this implies that 1/5 (two out of ten) or 20% of the ages in this age group end in the digit "0" or "5." Ó Gráda (2006), for example, implements a simple index by observing the frequency of the numbers divisible by 10 in the age groups 30–34, 40–44, etc. Observing five ages in each group should, in the simplest case, deliver the same frequency for each digit. A value greater than 0.2 (which equals 1/5) indicates a rounding pattern of the respondents. As a consequence, we expect each age to be

reported by about the same number of individuals. However, we have to be careful concerning the assumptions of age distributions in general. Especially in older age groups, it is most likely that a higher share of people is alive at age 60 in contrast to those aged 69 (Crayen and Baten 2010a, p. 84).

When it comes to measuring the actual degree of age heaping, there are some desired properties that can improve the results of the indicator, as described by A'Hearn et al. (2009). First, the index should be scale independent, which means that it delivers comparable results for two samples with the same heaping patterns but different sample sizes. The second valuable feature is the linear response to the degree of heaping, which implies that the indicator increases linearly when heaping rises. Finally, the coefficient of variation should be as small as possible across different random samples.[6]

There are several established measures with at least some of the desired properties such as the indexes suggested by Mokyr (1983); Bachi (1951); Myers (1954).[7] A'Hearn et al. (2006) state that the indicators proposed by Mokyr and Bachi are not calculated on the basis of specific expected frequencies. Hence, they do not rely on a particular assumption about which terminal digit appears with a certain frequency. However, there is a common procedure also discussed by Myers (1954) that implies the expected proportion of each terminal digit to be 10%. For this procedure it is necessary to sum up all of the ages ending in zero, then those ending in one, and so on, starting at age 20, for example. In the next step, the share of the population stating the respective terminal digit (zero to nine) relative to the whole population is calculated.[8] Consequently, each percentage share greater than 10% means an overrepresentation of the ages with the respective digit. The "blended" index proposed by Myers (1954) works in a similar way as this procedure but with some adjustments: Instead of starting the aggregation at age 20, he uses the terminal digits at each age between 23 and 32, for example, as the starting point. He then proceeds with the aggregation of the ages with each terminal digit (zero to nine), but instead of counting each unit digit once, it is counted several times, according to the "leading" digit.[9] The result of this procedure represents the relative share of the people that reported ages with the respective last digit. If there is no age heaping in the data, the percentage share of each figure should not differ largely from 10% (Myers 1954, p. 827).[10]

While the Bachi and Myers indexes are scale independent at least in the mathematical sense, none of the indexes turns out to be scale independent in the statistical

[6]Please see A'Hearn et al. (2006, pp. 11–21) for a more detailed discussion on the properties.

[7]The Mokyr index we refer to in this section is also called the Lambda index (A'Hearn et al. 2006).

[8]The digit "0" includes all ages ending in zero, hence 30, 40, 50, etc. The digit "1" includes all ages ending in one, hence 31, 41, 51, and so on.

[9]Myers criticizes that starting the aggregation at a certain age, for example, 20, increases the share of people with a digit ending in zero because ". . . the 'leading' digits naturally occur more frequently among the persons counted than the 'following' ones." (Myers 1954, p. 826).

[10]For a more detailed description of the "blended" method, see Myers (1954).

sense, meaning that the mathematical scale independency does not hold in random sample settings, as A'Hearn et al. (2006) show.[11] Each of the three indexes discussed in this section can be adopted to reveal any kind of heaping, be it rounding on multiples of 5 or the preference for any other of the 10 digits. This might be a small advantage in contrast to indicators that can only detect a preference for multiples of 5. However, there is an indicator that exceeds all of the others in terms of its properties: the Whipple index. The Whipple is statistically scale independent, its expected value rises linearly with the degree of heaping, and its coefficient of variation is lower than that for the other indicators discussed (A'Hearn et al. 2009). The Whipple index is calculated as presented in the following formula (1):

$$Wh = \frac{\sum (n_{25} + n_{30} \ldots + n_{65} + n_{70})}{\frac{1}{5}\sum_{i=23}^{72} n_i} \times 100 \tag{1}$$

In the enumerator, the number of people reporting ages ending in zero or five is aggregated. This is divided by all of the reported ages in the age range 23–72. Subsequently, we multiply the sum of the reported ages by 1/5 in the denominator. This is based on the assumption that 20% of all the people correctly report an age ending with zero or five. The whole term is then multiplied by 100 for convenience. Hence, the Whipple can take on values usually ranging between 100 and 500. If exactly 1/5 of all the individuals state an age ending in a multiple of 5, the Whipple takes on the value 100. In the case that all of the people report a multiple of 5, the Whipple increases to 500. However, we have to be careful when interpreting this figure: A value of 500 would still mean that 1/5 of the individuals who state a rounded age were doing so correctly. Admittedly, with an age-heaping effect of this size, we might as well assume that these individuals did not report their correct age because of age awareness. In theory, the Whipple can also take on the value zero, if no person reports a multiple of 5 – this would be the case of perfect "anti-heaping" (A'Hearn et al. 2009). The Whipple increases linearly, which means that it rises by 50% whenever the proportion of people reporting a multiple of 5 increases by 50% (Crayen and Baten 2010a, p. 84)

Because of its design, the Whipple index obviously does not account for the fact that fewer people are alive at higher ages. Thus, there is naturally a higher number of people reporting the age of 60 than the age of 69, even if there was no age heaping in the population otherwise. We are able to reduce this potential bias by calculating the Whipple for age groups of 10-year steps. Additionally, we arrange the age groups such that the multiples of 5, and especially the numbers ending with zero, are more evenly distributed within the age groups: The first age group starts at age 23 and ends with age 32. The other age groups are arranged accordingly: 33–42, 53–62, and so

[11] Statistical scale dependency means that the assumed mathematical scale independency can change when applying an indicator to random samples of different sizes. For more information on this topic, see A'Hearn et al. (2006, pp. 11–21).

on. It is more reliable to exclude individuals older than 72 years because they tend to exaggerate their age. In principle, the survivor bias effect could also play a role because people with a higher basic education might have a higher life expectancy due to a higher expected income, for example. However, Crayen and Baten (2010a) showed that it did not have an empirical impact.

It is also common to exclude the individuals younger than 23 years of age from the analysis for two reasons: First, young people often married around the age of 20 or entered military service at that time. As they often had to report their ages at such occasions, their age awareness is expected to be better than that of older individuals. Second, younger people tended to round their ages to a much greater degree on multiples of 2 than of 5. Additionally, for children still living with their parents, we do not know if they reported their ages themselves or if their parents answered for them (Manzel and Baten 2009). To account for a higher degree of heaping on multiples of 2 among this group, which is not captured directly by the Whipple, Crayen and Baten (2010a, Appendix A) propose an upward adjustment of the Whipple index. With this adjustment, the value of the youngest age group increases, and hence, the estimated numeracy decreases.[12]

The Whipple index combines a number of desired properties and is – after making some adjustments – a reliable measure for the degree of age heaping. However, the adopted scale and the interpretation of its outcomes are not particularly intuitive. A'Hearn et al. (2009) solved this issue by introducing another indicator which they called the "ABCC."[13] The calculation works as shown in the following formula (2):

$$ABCC = \left(1 - \frac{(Wh - 100)}{400}\right) \times 100 \text{ if } Wh \geq 100; \text{ else } ABCC = 100 \qquad (2)$$

The ABCC is a simple linear transformation of the Whipple and ranges between 0 and 100. For the case of "perfect" heaping and thus a Whipple of 500, the ABCC takes on the value 0. If every person states their age correctly, the ABCC value increases to 100. Hence, the ABCC can intuitively be interpreted as the share of people reporting their age correctly. This measure has been successfully used in a variety of studies so far (Manzel and Baten 2009; Baten and Mumme 2010; Manzel et al. 2012; Stolz and Baten 2012; Juif and Baten 2013 as well as Baten and Juif 2013).

[12]If the Whipple indicator is larger than 100, they suggest adding 0.2 units to the value of the age group 33–42 for every Whipple unit above 100. The resulting value is aggregated to the value of the age group 23–32, which delivers the new estimate for this group. For example, if the value of the age group 23–32 is 150 and that of the age group 33–42 is 160, then the digit above 100 has to be multiplied by 0.2 (60 * 0.2 = 12). The result is added to the original value of those aged 23–32 (150 + 12). Consequently, the new estimate for the youngest age group is 162 (Crayen and Baten 2010a, Appendix A, pp. 95–96).

[13]The name of the index is constructed by the initials of the last names of the three authors plus Gregory Clark's.

Because age-heaping indicators such as the Whipple and the ABCC index are employed to approximate basic education if other indicators are not available, it is very important that these indexes correlate with other measures. It turns out that there is a strong correlation between the share of people reporting their correct age and indicators such as literacy or schooling. Myers (1954) finds a correlation of high literacy rates and low levels of age misreporting for Australia, Canada, and Great Britain. Duncan-Jones (1990) also reports a significant correlation between age heaping and illiteracy in a number of developing countries in the twentieth century, among them Egypt (1947), Morocco (1960), and Mexico (1970). Furthermore, A'Hearn et al. (2006, p. 21) perform analyses on the relationship between age heaping and illiteracy in various countries. They detect a very strong, significant, and robust correlation between the two indicators for almost all of the 52 countries in their dataset. In the very detailed analysis for the United States, the correlation is particularly strong, even when controlling for birthplace, ethnic group, and gender balance; and it is evident for both pooled and regional fixed effects regressions (A'Hearn et al. 2009).

Moreover, Crayen and Baten (2010a) tested the impact of several factors such as primary schooling, height, and state antiquity on age heaping.[14] For a global dataset, they found that school enrollment is one of the driving factors for the development of numerical abilities among societies. In all of the modifications and independent of the factors controlled for, it is always highly and significantly correlated with age heaping. Consequently, we assume that age-heaping-based indicators are valid estimators for basic education.

Applied Age-Heaping Indicators in Various Research Topics

Reconstructing Very Early Numeracy Differences: The Example of Inca Indios

Acemoglu et al. (2001, 2002) studied the differences between former European colonies. They compare the former colonies that are rich today to those that are poor. Acemoglu et al. argue that the Europeans created exploitative institutions in the colonies that had an adverse disease environment for Europeans. In contrast, they implemented growth-promoting types of institutions in those colonies in which Europeans settled. Examples for the latter would be the United States, Australia, Argentina, and South Africa in part, whereas a classical example for the former would be West Africa. The more or less growth-promoting nature of colonial institutions translated into better or worse institutions during the late twentieth century. This had an impact on today's difference in real income per capita because

[14]Height is employed as a proxy indicator for infant malnutrition because the smaller a person is, the more likely it is that he or she did not have access to protein-rich nutrition which also hinders the development of numerical skills. State antiquity approximates the quality of institutions.

institutions tend to remain similar for a longer period. Applying the age-heaping technique to this topic is particularly useful because alternative views suggest a strong role of human capital channels (Glaeser et al. 2004). A related question is, for example, whether there were "precolonial legacies": How much did the ancient economies and societies invest before the colonialists arrived?

A paper by Juif and Baten (2013) employs an early Spanish census that was taken directly after the invasion of the Incan Empire. It makes use of the fact that basic numeracy is usually attained during the first decade of life. Clearly, the question needs to be considered whether such a birth cohort-specific analysis could be distorted by later learning processes. However, the numeracy values of the cohort born before the invasion are close to zero and thus cannot be upwardly biased. The numeracy levels of the cohorts born after the invasion, in contrast, were slowly rising. Consequently, the most important result of this study was that in fact some precolonial legacy – or burden – existed in Andean America. This legacy has not been reduced during colonial times, as colonial institutions such as the Peruvian "Mita" reinforced educational inequality (Dell 2010). During the early period, it is interesting that some Indio groups that were allied with the Spanish during the invasion (and received tax exemptions and a slightly less terrible standard of living after the invasion in return) also displayed a better numeracy. A likely interpretation is that their slightly higher net income allowed more investments in the basic numeracy of their children. This observation also stands in contrast to the suspicion that cultural attitudes could have implied a different number rounding behavior. Another problem considered by the authors is whether colonial officials did not ask the Indios for their age, but tended to estimate it without asking (if they estimated after asking, this would not be a problem for the age-heaping procedure because in this case the respondent did most likely not know his or her age either). Juif and Baten rejected these doubts in their study with arguments based on the effect that the social difference of numeracy within the Indio groups was substantial. In addition, the colonial officials sometimes explicitly noted thoughts about the appearance of a person if the self-reported age and the official's impression differed. This clearly indicates that the Indios were in fact asked for their age. As a result, this earliest numeracy study for a non-European country revealed that a negative precolonial legacy was in fact very likely.

Religion and Numeracy

A number of scholars have recently studied potential religious determinants of human capital formation (see Becker and Woessmann 2009 for a widely cited study and a good overview). The relative exogenous character of religious rules has been stressed by this literature because beliefs about the necessity to read religious texts are considered to be less influenced by economic factors and profit-maximizing educational investment decisions. Botticini and Eckstein (2007) explained how religious rules for the provision of education of one's (male) offspring appeared in the Jewish faith. In the first century BCE, a conflict between two

influential religious factions of Judaism took place. One of these factions, the Pharisees, stressed the religious duty to educate, and they gained stronger influence on Judaism than the other group. Botticini and Eckstein emphasize that the education rule was not economically motivated because the large majority of the Jewish were farmers and rural day laborers, for whom a substantial educational investment would not yield sufficient returns during this period. Only with the substantial urban growth in Mesopotamia during the eighth and ninth centuries CE could the Jewish population living there use their religiously determined education to achieve profitable positions as merchants and, later on, as bankers. Medieval Western Europe actually first tried to attract this religious and occupational group because the kings of England and France assumed correctly that government revenues might increase. The famous restriction of Jewish population groups to being exclusively merchants, bankers, and other traders - occupations that were forbidden to the Christian population - was only created later, during the High Middle Ages. Botticini and Eckstein (2007) therefore reject the hypothesis that this restriction caused high Jewish educational levels.

The debate over religious differences of education and numeracy in particular has important implications for history and for our understanding of human capital formation. For that reason, Juif and Baten (2014) studied the differences between the average population and the persons who were accused by the inquisition of practicing Jewish beliefs in Iberia and Latin America. The period under study runs from the fifteenth to the eighteenth centuries. The sources that are available for this early period were primarily created by the inquisition. A question about the age of the accused was included for identification purposes. Besides the evidence from the inquisition lists, we also included census-based numeracy evidence to compare the average population in the same regional units. We studied potential selectivities and biases intensively and dismissed them ultimately. The most important result of this study of religion and numeracy is that persons who were accused of being Jewish had a substantially higher numeracy than the average population. If we accept the working hypothesis that most of the persons accused of Judaism came from families of a different educational behavior (and a different educational self-selection), the religious factor appears to be of important influence. However, the authors also find that the catholic elites (such as priests) had a substantially higher numeracy compared to the average Iberian and Latin American population.

Path Dependency of Early Numeracy and Land Inequality as Determinants of Modern Math and Science Skills?

Within the framework of Unified Growth Theory, Galor et al. (2009) have focused on land inequality as one of the crucial obstacles to human capital formation. They describe the political economy of regions and countries with higher and lower land inequality, assuming an influential role of two different elite groups: large landowners and industrial capitalists. In regions with lower land inequality, industrialists wielded larger relative power in the decision-making process concerning educational

investments. In contrast, in regions with high land inequality, large landowners remained in power and were not particularly interested in spending their taxed income for primary schooling: First of all, their agricultural day laborers did not have to be educated to fulfill their manual tasks (at least that is the traditional view). Secondly, additional primary schooling would have increased their burden of taxation. Thirdly, educated workers might have moved to cities or may even have initiated land reforms. In a study of this land inequality effect on modern math and science skills, Baten and Juif (2013) also include early numeracy (around 1820) as the second main determinant. They find that early numeracy has a large explanatory share, even after controlling for land inequality and a number of other factors. It seems that this path dependency worked via economic specialization: If an economy specialized early on the production of human capital-intensive products, the relatively high income allowed investing in education for the next generation. In addition, such human capital-intensive production methods probably resulted in substantial switching costs – hence, the countries specialized in this type of production and developed a branding and reputation for their products. As a consequence, they were most likely entering a high degree of path dependency.

Numeracy Differences Between Occupational Groups in Preindustrial Times

When it comes to the question of who stated the ages written down on a census list – the enumerator or the respondent – the analysis of numeracy between occupational groups is crucial. If the age-heaping levels between occupational groups vary significantly, this might indicate that the respondents stated their age themselves. De Moor and Van Zanden (2010, p. 204) were able to verify differences in numeracy between three occupational groups for the seventeenth century in Amsterdam: professionals, craftsmen, and unskilled laborers. While the highly skilled professionals had relatively low age-heaping levels (with an ABCC index of 100), the opposite was the case for the non-skilled individuals, who displayed a high degree of age heaping.[15] The craftsmen had slightly better values than the unskilled group.

Tollnek and Baten (2013) assess the numeracy of occupational groups for four countries in early modern Europe (Austria, Spain, Southern Italy, and Germany) as well as for Uruguay. Additional information is provided by literacy data from Switzerland. In total, the comprehensive dataset includes nearly 30,000 observations with information on age, sex, and occupation of individuals. The authors distinguish between six occupational groups, adapting the Armstrong scheme (Armstrong 1972): the professionals (doctors, lawyers, etc.), the intermediate (administrators and higher clerks), the skilled group (craftsmen and shopkeepers), the partly skilled (herdsmen and carriage drivers), the unskilled group (day laborers), and the farmers

[15]De Moor and Van Zanden (2010) use the Whipple index for their calculations. We translated the numbers into ABCC values for convenience.

(smallholders and farmers with medium-sized or larger farms).[16] The descriptive analysis already reveals large differences between the groups. In all of the European countries, the professionals have the highest numeracy values (ABCC index between 86 and 96), followed by the intermediate and skilled groups that reflect lower numerical abilities (Tollnek and Baten 2013, p. 33). The two lowest groups of society, the partly skilled and the unskilled groups, have the lowest values of numeracy in all of the countries.[17] Interestingly, the farmers have low age-heaping levels, with numeracy values similar to the skilled group. In Germany and Uruguay, the farmers' values are even close to the groups with the highest levels, which are the professionals in Germany and the skilled in Uruguay.

The authors also assess these differences in a logistic regression with "numerate" as the dependent variable that assumes the value of one if the individual stated an exact age and zero otherwise.[18] They control for the birth half century, the country, the age (because younger people might know their age more exactly), and, most importantly, the occupational groups. The regression results strongly confirm the descriptive results for all of the countries in the sample. The three upper groups and the farmers have a significantly higher probability of being numerate than the partly skilled and unskilled groups (Tollnek and Baten 2013, p. 28). The values of the coefficients range between roughly 18 for the professional groups and 8 for the skilled. The farmers have the third highest chance for success (hence, "numerate" takes on the value one) with a coefficient of nearly 9, which can be translated into a higher probability of being numerate of about 9% in contrast to the two lowest groups. These results are also confirmed by regression results using literacy evidence from Switzerland.

The Development of Numerical Skills in Different World Regions and Time Periods

A Human Capital Revolution in Europe

A'Hearn et al. (2009) discuss the development of numeracy all over Europe from the late middle ages to the early modern period. The European countries experienced a striking increase in numeracy during this time period, which can be identified as a "human capital revolution." While the numeracy values rose in all of the European countries, there was variation between the different parts of Europe. The Western European countries showed an exceptional development. As early as around 1450,

[16]The occupations in brackets are only examples. In total, there are hundreds of occupations in the dataset that were arranged according to the Armstrong scheme.

[17]Germany is an exceptional case because the values of the intermediate, skilled, partly skilled, and unskilled groups differ only slightly.

[18]The coefficients are subsequently multiplied by 125 to correct for the 20% of the people who state a multiple of 5 correctly. For further information, please see Appendix B in Tollnek and Baten (2013).

the Netherlands represented numeracy values (approximated by the ABCC index) of roughly 70% (A'Hearn et al. 2009, pp. 801/804).[19] Britain and France surpassed this value at around 1600 and 1650, respectively. Britain and Denmark, on the other hand, already experienced numeracy rates of 90% or more in the period of 1700. While Denmark's rates grew continuously until the end of the period at around 1800, Britain's values remained at the same level.

The picture looks similar if we look at Central Europe (A'Hearn et al. 2009, pp. 801/804). Austria and Protestant Germany already had high numeracy levels of between 78% and 87% around the period of 1600. Catholic Germany had lower values (68% in circa 1700), but it converged strongly thereafter. The Eastern European countries, in contrast to the rest of Europe, lagged slightly behind: Around 1600, Bohemia represented numeracy values of only 44%. One period later, around 1650, Russia and Hungary showed levels of 43% and 32%, respectively. However, toward the end of the early modern era at approximately 1800, the overwhelming majority of the European countries managed to increase their human capital values significantly. Even the regions that lagged behind, such as Bohemia and Russia, reached numeracy levels well above 80% or close to 90%.

Numeracy Levels in Latin America

Manzel et al. (2012) analyze long-term trends in numeracy for a number of Latin American countries from the seventeenth to the beginning of the twentieth century. Some of the countries, such as Argentina and Uruguay, experienced strong increases of human capital throughout the whole time period that are comparable to those of some European countries. While Argentina started with an ABCC value of less than 20% in the birth decade 1680, it reached values of almost 70% around 1800 (Manzel et al. 2012, p. 954).[20] With an exceptional increase during the nineteenth century, Argentina reached almost full numeracy at the beginning of the twentieth century. The development of Uruguay is similar, showing even higher numeracy levels than Argentina in parts of the nineteenth century. Despite such great examples of convergence, some of the Latin American countries underwent a process of divergence during the nineteenth century: In Colombia, Mexico, and Ecuador, the ABCC levels stagnated. While Mexico started off well with continuously growing numeracy levels from 1680 to 1790, there was almost no improvement throughout the

[19]The data are arranged in age groups and then transferred into birth half centuries. Hence, the value of the respective age group is subtracted from the census year. The resulting values are rounded to 50-year-intervals. For example, if the census year was 1740, then the age group 23–32 was born in the half century 1700.

[20]The values for Argentina and Mexico are estimates based on regression results. They are controlled for capital effects and male share. For further information, please see Manzel et al. (2012). The data of all of the countries are arranged in birth decades. Hence, the value of the age group is subtracted from the census year, and the resulting values are rounded to 10-year intervals. For example, if the census year was 1940, then the age group 23–32 was born in the decade 1910.

nineteenth century. Ecuador's levels even worsened slightly during the nineteenth century. Brazil was a particular case because it began with increasing levels of numeracy during the eighteenth century, then experienced a short period of stagnation at the first half of the nineteenth century and managed to increase human capital again in the following decades. Toward the beginning of the twentieth century, numeracy levels rose considerably in all of the observed countries.

Industrialized Countries Versus the Rest of the World?

Crayen and Baten (2010a) assess long-term trends of numeracy in 165 countries all over the world. The development of some industrialized countries not discussed so far is of interest: The United States started with ABCC values below 87% at the beginning of the nineteenth century, which are among the lowest numbers compared to the other industrialized countries in the same period (Crayen and Baten 2010a, p. 85).[21] Toward the middle of the nineteenth century, the values of the country increased significantly to around 94%. The United States converged continuously in the following decades and reached values of circa 98% at the end of the nineteenth century. Spain had values of about 88% around 1830. The increase of Spain's numeracy developed more slowly than that of the United States, but it also reached levels close to 100% at the beginning of the twentieth century. Exceptional cases are also Greece and Cyprus, which had values below 75% and 78%, respectively, at the end of the nineteenth century. However, their rates increased dramatically throughout the twentieth century. Ireland is one of the few industrialized countries in which the ABCC index decreased slightly in the 1870s, which is likely due to the behavior after the Great Famine that took place two decades earlier.

The comparison of world regional numeracy trends reveals some crucial differences. South Asian countries had the highest age-heaping levels with ABCC values of less than 13% around 1840 (Crayen and Baten 2010a, p. 87). The numbers increased steadily throughout the following decades, reaching an ABCC index of above 55% toward the 1940s. The Middle East and North Africa had the second lowest levels of numeracy with values lower than 25% in the 1820s. Egypt most likely had the highest age-heaping level in this region with an ABCC of almost 0 (the case of "perfect" heaping) (Crayen and Baten 2010a, p. 86). But similar to South Asia, the Middle Eastern and North African countries managed to increase their numeracy levels continuously (Crayen and Baten 2010a, p. 87). The industrialized countries were on the upper range of the strata with the highest numeracy levels. East Asia still had ABCC levels of below 88% at the beginning and toward the middle of the nineteenth century.[22] In only a few decades, though, age heaping in China

[21]Crayen and Baten (2010a) use the Whipple index for all of their calculations. We translated all of the numbers into ABCC values for convenience.

[22]East Asia is dominated by Chinese data, since Japan is considered part of the industrialized countries.

decreased strongly and vanished around 1880. Southeast Asia and Latin America ranged between the regions with fairly high and relatively low levels of age heaping.

Numeracy Trends of Women and the Gender Gap in Different World Regions

Numeracy Trends of Women in Some Industrialized Countries

Gender equality in education and wages is a controversial topic. Even in countries with relatively high levels of income and education, such as the European countries or the United States, there is an ongoing debate about wage differentials between men and women. Women with the same degree of education and experience often receive considerably lower wages than their male counterparts working in the same field or position.

But what about educational differences between men and women before formal schooling became accessible for most people? When did the gender gap open and did it worsen or improve over time? Duncan-Jones's (1990, p. 86) analysis of inscriptions on tombstones reveals a numeracy difference between men and women in Roman times that is most likely the earliest measurable gender gap. Although the age reported on the tombstone supposedly reflects the numerical abilities of a relative, the ages of women show a higher heaping pattern than those of men. The indicator implemented by Duncan-Jones represents the percentage share of people who report a rounded age, relative to those who state their age correctly.[23] While in some regions, such as Moesia or Pannonia, the women had considerably higher heaping levels than the men (28.1% and 17.1%), the differences were relatively small in most of the other regions: In Mauretania, for instance, the women's index was only 4.8% higher than the men's index. In Rome, the difference was 6.8%. However, there were also regions in which women had lower heaping values, such as Italy outside Rome (−1.9%).

De Moor and Van Zanden (2010) assess human capital levels in the medieval and early modern Low Countries. The results of the numeracy levels of Bruges in Belgium (1474–1524) suggest that the differences between women and men were relatively small in total: The men have an ABCC index of about 85% and the women 83% (De Moor and Van Zanden 2010, p. 194).[24] In the city of Bruges, the women even surpassed the men slightly.[25] The authors also found similar results for Holland

[23]He subtracts the 20% of the people who report a multiple of 5 correctly from the total number of people who state a rounded age. Hence, the reported percentage share contains those who incorrectly state a rounded age.

[24]De Moor and Van Zanden (2010) use the Whipple index. We translate the results from the Whipple index into ABCC levels for convenience.

[25]The women, however, represent higher values at the "dozen index" that detects rounding behavior on multiples of 12. This is likely due to religious practices among Catholics (De Moor and Van Zanden 2010).

during the sixteenth to eighteenth centuries. The gender gaps were small then and women sometimes had higher numeracy levels than men.

For the United States, Myers (1954 p. 830) reports that women showed significantly higher levels of age heaping than men in the 1950s. For the other countries included in his study – Australia, Canada, and Great Britain – he detects only very slight differences in age misreporting between women and men in the late 1940s or early 1950s. In Great Britain, women reported their ages even more precisely than men in that time period.

The Gender Gap in Latin America

The previous examples suggest that in particular regions and time periods, women's access to basic education was not as limited as one might have expected. However, we have to keep in mind that the Low Countries, for example, are different from many other countries with respect to the position of women in the society. Men and women already seemed to have had a relatively equal standing in the household in early modern times (De Moor and Van Zanden 2010). But what about the basic education of women in the rest of the world?

Manzel and Baten (2009) assess the development of women's basic education for a large number of countries in Latin America via age-heaping-based indicators. They perform their analyses following a fundamental theory about labor force participation developed by Goldin (1995). Goldin argues that female labor force participation follows a U-shaped pattern over time. In societies with low income and low levels of education, women engaged to a large extent in home production of agricultural goods and work on family farms. At this stage of the process, labor force participation shares are high for both men and women. With increasing levels of income and market integration, more women are tied to household activities and childcare, while men work in factories, for example, where new production techniques overcome the traditional home production. Hence, women's level of labor market participation decreases. One possible reason for that development could be that women's work in factories is socially stigmatized. The third stage of the process is observable in countries that have reached a high level of income and education. Women are able to achieve higher degrees of education and enter white-collar occupations that are less stigmatized than manufacturing work. In this last phase of the U-shape, women participate actively in the labor force again.

Manzel and Baten (2009) were able to confirm this pattern based on numeracy estimates for 28 countries in Latin America and the Caribbean from 1880 to 1949.[26] Instead of testing the relative labor force participation of women, they implement "the relationship between average education and the ratio between female and male education" as an indicator to demonstrate the U-shaped development. As a general

[26]The data are arranged in birth decades.

measure of educational equality between men and women, they subtract the Whipple index of men from that of women and divide the result by the Whipple of men. This is subsequently multiplied by −100 for convenience. If the outcome is positive, the women have a numeracy advantage over the men (and the other way round, if the index is negative). The positive index is defined as "gender equality" in basic education. It turns out that the equality index is negative for most of the countries. However, for some of the countries with high levels of basic numeracy throughout the time period, the equality is relatively high as well, indicating the last stage of the U-shaped hypothesis. This is the case for Argentina, Uruguay, Guyana, and Suriname, meaning that gender equality increases if basic education is well established in the society in general (Manzel and Baten 2009, p. 50/51). The ABCC values for Argentina, to state an example, reach from about 95% to 100% and the equality index is slightly above zero (Manzel and Baten 2009, p. 51 and Appendix p. 69). In Guatemala and the Dominican Republic, for example, the authors find the opposite effect, namely, low levels of basic numeracy and low equality indexes. Colombia, however, has ABCC levels between roughly 80% and 90%, while the equality index ranges between approximately −26 and −10, meaning that women have large educational disadvantages in Colombia at the beginning of the period, which decrease over time (Manzel and Baten 2009, p. 50/51 and Appendix pp. 69–71). But there are also cases such as Haiti where numeracy is low, whereas gender inequality is not observable, indicating the first stage of the U-shaped hypothesis. In general, the non-Hispanic parts of the Caribbean represent considerably higher equality indexes as well as higher ABCC levels than the Latin American countries during the whole time period.[27] Toward the end of the period, equality rises with increasing levels of basic numeracy in all of the countries. In Latin America, the ABCC values increase from roughly 78% in 1880 to about 93% in the 1940s and in the non-Hispanic Caribbean from about 90% to 99% (Manzel and Baten 2009, p. 52). The equality values increase from less than −12 to about −5 in Latin America and from roughly −3 to slightly above zero in the non-Hispanic Caribbean (Manzel and Baten 2009, p. 55). The ABCC and equality values of the Hispanic Caribbean are mainly lower compared to the values of Latin America.

To test the U-shaped hypothesis, Manzel and Baten perform a regression analysis with the equality index as the dependent variable, controlling for a number of other factors such as female voting rights and a democracy index. The most important factors for the U-shape are the ABCC values to approximate basic education: They are included as a linear parameter to control for initial levels of education, and they are added as squared values to test for higher levels of education. As a result, the linear (and hence lower) ABCC values have a significant and negative impact on equality, while higher levels of education (squared ABCCs) have a significant and

[27]The low inequality of non-Hispanic countries might be due to the institutional framework created by slavery. As both men and women were torn away from their home countries and had to work equally, the "traditional" gender roles did not evolve as they did in other countries. Besides, Caribbean women tended to work outside the household more often than Latin American women (Manzel and Baten 2009).

positive impact on gender equality. The authors also plot the estimated values to illustrate the U-shape: The downward slope tends to be smooth, whereas the upward sloping part is strongly observable in the data. Hence, they demonstrated that Goldin's hypothesis also applies to basic education in Latin America and the Caribbean.

The Gender Gap in Asia

Friesen et al. (2013) test the U-shaped hypothesis for 14 countries in Asia from 1900 to the 1960s.[28] They use the ABCC index to approximate basic numeracy. Furthermore, they employ the educational gender equality index based on the Whipple index in the same way as Manzel and Baten (2009) did. Besides the age-heaping-based indicators, Friesen et al. (2013, p. 7) discuss literacy and school enrollment rates in the Asian countries in the dataset that clearly indicate high levels of inequality between men and women.

The analysis of the ABCC values provides further information on basic education between the sexes, especially when enrollment rates are not available for some of the regions. The authors find different results for the women's ABCC indexes among the observed regions: The vast majority of Southeast Asian women were already numerate around 1900, especially in Hong Kong and Thailand, while Indonesia lagged slightly behind (Friesen et al. 2013, p. 18). However, the picture looks different for women in South and West Asia: While Sri Lanka began with ABCC values of around 59% in 1900 and reached almost full numeracy in the 1950s, all of the other countries in this region reflected values far below. Women from Pakistan and Bangladesh had the lowest levels, not even reaching values of 50% toward the end of the period (Friesen et al. 2013, p. 16).

The equality index primarily reflects the different stages of the U-hypothesis. In the countries with very low human capital values for both women and men, such as Pakistan, Bangladesh, and India, equality values are only slightly below zero, indicating relative equality between women and men (Friesen et al. 2013, p. 23). This is also the case for the countries with high numeracy values, for example, Hong Kong and Thailand, for which the equality values range slightly below or above the zero line (Friesen et al. 2013, p. 25). The equality indexes of most of the other countries lie considerably below zero (e.g., in Indonesia or Sri Lanka). Most of the countries with negative values experienced an increase toward the end of the period, which in some cases even turned the negative into a positive index, such as in the Philippines. The opposite effect takes place in Afghanistan, for instance. While the inequality is not as high around 1910 (about −12), it decreases continuously until reaching a value below −60 in the 1950s (Friesen et al. 2013, p. 23).

[28]Included countries are Afghanistan, Bangladesh, India, Iran, Sri Lanka, Nepal, Pakistan, Hong Kong, Indonesia, Cambodia, Federation of Malaya, Sarawak, the Philippines, and Thailand.

In the next step, the authors test the U-hypothesis in different regression models in which the equality index is the dependent variable. They control for factors such as female voting rights and religion. The most important determinant, the ABCC index, is included as a linear and a squared parameter (as in Manzel and Baten 2009). The results for the ABCCs are always highly significant, and the correlation is negative for the linear ABCCs and positive for the squared ones. Furthermore, Friesen et al. (2013, p. 35) plot the regression results to illustrate the fitted values. The scatterplot shows an exact U-shaped pattern. Hence, the assumption of low gender inequality at low levels of human capital, rising inequality at increasing levels of education and, in the last phase, high levels of education and equality is fulfilled in the analysis of the 14 Asian countries under study.

Conclusion: The Impact of Numerical Abilities on Growth

In this chapter we showed that the age-heaping technique provides a unique opportunity to approximate basic education, especially in preindustrial times. One might argue, though, that the mere knowledge of numeracy levels between different countries, for example, does not contribute to achieve a higher goal. However, although numeracy correlates strongly with literacy, number discipline might even have a larger impact on the development of market exchange (see, e.g., De Moor and Van Zanden 2010). In many cases, we do not even know what literacy measures exactly: A broad range reaching from "is able to read and write" to "is only able to sign with his or her name" is possible. On the other hand, numeracy, or the ability to count, is the basis for participating actively in market mechanisms and for the emergence of capitalism. Crayen and Baten (2010a) show that numerical skills, in fact, have a strong impact on growth patterns across different world regions. In their analysis, the authors regress GDP growth rates on various factors, "growth capabilities," such as initial GDP levels and numeracy, approximated by the Whipple index, as well as a number of other control variables. It turns out that numeracy has not only a significant but also an economically meaningful impact on the growth rates of the included countries. Hence, the economy of those countries displaying higher levels of numeracy also grows at a faster pace than the economy of the countries with lower numeracy. All in all, we showed that age-heaping-based human capital estimates provide the opportunity to track potential reasons for the divergence of countries or world regions in the very long run.

Church Book Registry: A Cliometric View

Jacob Weisdorf

Contents

Abstract

This chapter links economic history to demography, looking into the use of church book data to investigate topics in economic history. Using the Malthusian population model to cast light on scholarly debates about the Great Divergence and the wealth of nations, the chapter illustrates some of the main advantages (and drawbacks) to using church book registry in this context.

Keywords

Cliometrics · Demography · Development · Great Divergence · Malthusian model · Church book registers

Introduction

Church book registers provide data regarding three main life events: births, deaths, and marriages. Two claims central to the use of such statistics in economic history are that economics influences all of them and that all of them in turn influence economics. For example, the timing of a marriage or childbirth in the past depended on people's earning possibilities, and a death or a miscarriage often followed from

harvest failure and hunger. Conversely, births and deaths determine the size of the population, which impact on prices and wages through people's demand for goods and supply of labor.

These relationships can be formulated in a widely applicable, but visually simple framework: the Malthusian population model. Scholars commonly believed that historical societies were characterized by *Malthusian population dynamics*. These dynamics are easily illustrated in terms of Fig. 1, which captures the links between economics and demography outlined above. Malthus hypothesized that changes in wages exercised a dual effect on the growth of a population (Malthus 1798). On the one hand, lower wages causes fewer and later marriages, leading therefore to fewer births. This *preventive check* mechanism is captured by the upward-sloping birth schedule in Fig. 1. Lower wages simultaneously raise death rates, capturing the *positive check* mechanism illustrated by the downward-sloping death schedule in Fig. 1. The intersection point between the birth schedule and the death schedule determines the equilibrium wage rate, defined as the wage rate that keeps the population constant over time (a *steady state*).

The dynamics of the Malthusian population framework are completed by the addition of Ricardo's notion that population growth historically drove down the marginal product of labor (Ricardo 1817). This feature, in the Malthusian model, often builds on two key assumptions: a constant returns-to-scale production technology and a fixed factor of production (normally land). Hence, when wages are above the equilibrium wage rate, and births thus exceed deaths in Fig. 1, the population size grows. Diminishing returns to labor in production then puts downward pressure on the wage rate, leading to fewer births and more deaths, until the wage rate eventually returns to its equilibrium level and births equal deaths.

The Malthusian framework provides a powerful tool to help understand why some historical societies were rich and others poor. That is, a permanent deviation in the equilibrium wage rates between two societies must be grounded in different structural arrangement causing the positions of birth and death schedules to differ. Within this context, the underlying question often asked by scholars concerned with these topics are the following: what are the short- and long-term effects of shocks to the Malthusian system, and how might these shocks consolidate themselves in permanent shifts in the positions of the birth and death schedules? The answers

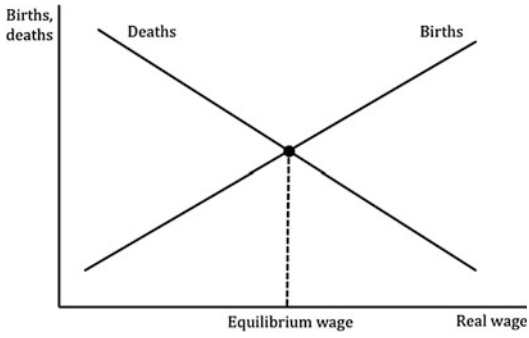

Fig. 1 The Malthusian model

can cast light on several unresolved debates in economic history, and church book registry is an excellent tool to achieve such hindsight.

One such debate concerns the Great Divergence in real wages within Europe. Why did England and the Low Countries pull away from the rest of Europe between 1500 and 1800? Bob Allen's European *welfare ratios*, which measure the number of (prefixed) consumption baskets that a family can afford (Allen 2001), are a great illustration of this (Fig. 2).

A temporary divergence in real wages can, of course, be viewed as a disequilibrium episode. Any shock that pushes the Malthusian system out of its steady state will ignite the dynamics described above and ensure a return to the system's steady state. That is, wages will fall back to their original level. The Black Death, a huge and sudden decline in Europe's population in the mid fourteenth century, is the perfect example of that. This disequilibrium approach, however, does not complete the picture. As the population level gradually restabilized in the centuries following the plague, most European wages fell back to their pre-Black-Death level. But in England and the Low Countries they did not. This leaves the question: did the Black Death do more than just push the system out of its equilibrium temporarily? Did it entail a structural transformation that shifting the birth schedule or the death schedule, escalating the English and Dutch equilibrium wage level?

There are multiple candidates for a structural change to the system. These have been extensively discussed by theorists. One example concerns the influence of the Black Death briefly mentioned above. It is well documented that the Black Death, by reducing the English population by almost 50%, entailed a "golden age of the English peasantry." That is, a dramatic increase in workers' remuneration as landowners struggled to recruit and retain laborers. De Moor and van Zanden (2010) and

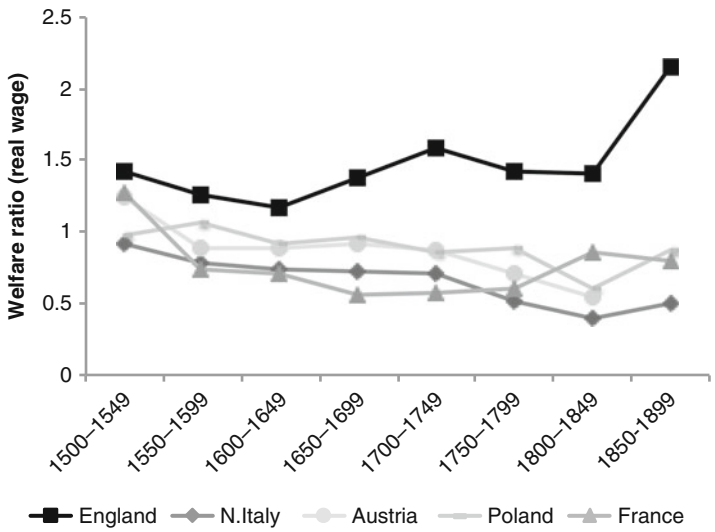

Fig. 2 The Great Divergence within Europe (Source: Allen (2001))

Voigtländer and Voth (2013) have linked the economic superiority of Northwestern European economies after 1500 to the demographic and economic legacy of the Black Death. The argument, which runs from the influence of women's remuneration on the timing of their marriage, is inspired by John Hajnal's hypothesis about the *European Marriage Pattern*. Hajnal (1965) noticed that for much of the medieval and early modern period, a line drawn from St. Petersburg to Trieste demarcated distinctive demographic regimes: in the east, women married young and almost everybody are married; in the west, brides were older and celibacy was higher. De Moor and van Zanden and Voigtländer and Voth have interpreted these distinct scenarios in terms of differences in the economic opportunities of women. Women's improved position in the post-plague labor market and especially the growth of opportunities as servants in husbandry linked to the relative expansion of "horn" (in which women had a comparative advantage) versus "grain" (in which they did not) allegedly pushed up female wages and labor force participation. Since women, unlike men, split their time between raising children and working, improved wages and labor opportunities for women place a premium on child birth, causing delayed marriage and increased celibacy, both resulting in reduced fertility. In terms of Fig. 1, the rising premium on childbirth would shift the Malthusian birth schedule downward inaugurating Hajnal's European Marriage Pattern. As an indirect consequence of the Black Death, Northwest Europeans therefore found themselves in a new steady state with greater female employment, later marriage, lower fertility, and higher per capita incomes (Voigtländer and Voth 2013).

Other hypotheses have been forwarded to try to motive Northwest Europe's economic superiority through shifts in the birth or death schedules in Fig. 1. De Vries's (2008) idea that a "consumer revolution" preceded the Industrial Revolution provides an alternative approach to understanding the rise of a premium on children and hence a downward shift in the position of the birth schedule in Fig. 1. The consumer revolution refers to the introduction of novel commodities (such as tea, coffee, sugar, books, and, clocks) between 1600 and 1750. The argument made, then, is that households have *love-of-variety* preferences and hence accommodate the novel commodities in their consumption basket by allocating *less* resources to the goods they already consume. Since children, or the goods that children consume, are among the goods already consumed, the demand for these goods, and hence for children, declines. Thus, the consumer revolution shifts the birth schedule downward, causing a new equilibrium with fewer births and deaths and a higher level of wages (Guzman and Weisdorf 2010).

Technical progress offers a third explanation for why the cost of children went up and pushed the birth schedule down. Galor (2011) hypothesizes that the complexity of new and more advanced jobs that industrialization entailed placed a premium on education. This incited parents to increase the investment in the human capital of their offspring, powered by a decline in their number of births. The increased cost per child would mean the birth schedule shifted downward, generating a new equilibrium of fewer births and fewer deaths but higher real wages.

Still others, such as Clark (2007), have used the Malthusian framework to highlight the "benign" effect of fatality on wages. Indeed, anything that pushes the

death schedule of Fig. 1 upward will cause the equilibrium wage rate to permanently rise. Voigtländer and Voth (2014) have use this point to draw a link between European wars and high rates of urbanization to explain Europe's economic prosperity vis-à-vis that of other world continents (i.e., the Great Divergence between Europe and the rest).

Common to all these theoretical accounts of what explains the Great Divergence – both within Europe and between Europe and other continents – is a lack empirical depth. This is where church book records can bring news to the table. The next section gives an illustration of the nature of the vital information concealed in church books, followed in the subsequent section by a series of examples of how previous studies have used the church recordings to cast light on some of the main research questions surrounding the debates about the Great Divergence and the wealth of nations. The chapter concludes by pointing toward some future research roads building on source material derived from church book registers.

The Nature of Church Book Registers

Early civil registration in Europe was usually done by the church on request from the crown. From the mid-nineteenth century on, civil registration was gradually taken over by secular institutions. Systematic census registrations, often first done every 5 or 10 years but later annually, were slowly replaced by a central authority gathering vital information as it appeared. The information recorded in the population censuses and later the central registers is obviously superior to that of church book records, partially because they include the entire population regardless of religious affiliation and partially because census data provides a spot image of the entire population and not just those reporting a vital event to the church in a given year.

The main advantage of the church book registry (also known as parish registry) is that these provide large-scale vital information before 1800, i.e., the period during which the Great Divergence began to take hold. Although the church book registry only captures people during three life events – birth, death, and marriage – it is nevertheless able to inform us about some key links between economics and demography, and vice versa, as we shall see below.

In the Old World, church registers become widespread in the late middle ages or early modern period. In the New World, notably in many of today's developing countries, vital registration began with the arrival of European missionaries after the mid-nineteenth century, a practice that has continued up until the present day. Although church book registers appeared much later in the New World than in the Old World, the fact that central registers emerged relatively late in many developing countries, often not until the 1960s or even later, makes church book registry of the New World a particularly interesting source of vital information during the late eighteenth and early nineteenth centuries.

Perhaps the most prominent dataset building on church book registration, and certainly the one most frequently subjected to scholarly scrutiny by economists and economic historians in the past several decades, is the so-called CAMPOP data

(Wrigley and Schofield 1981), collected by the *Cambridge Group for the History of Population and Social Structure*, which was founded in the 1960s by Peter Laslett and Tony Wrigley. The Group's work on collecting, transcribing, and analyzing English church book information, an effort spanning nearly five decades, has been used for three main purposes. The first is population *back projection*. By starting with the population level of the English census of 1831, and then counting the annual number of births and deaths recorded in 404 well-documented English parish registers, the Group was able to come up with an estimate of the size of the English population back to c. 1541 when church registration first began. The second purpose is *family reconstitution*. This is based on the idea, developed by French demographer Louis Henry, that vital events can be used to track the marriage date of a married couple, as well as the birth and death dates of their parents and their offspring, hence reconstructing the entire family based on church book statistics. The third and last purpose of the Group's work, which is still ongoing, is a reconstruction of the occupational structure of Britain based on the male occupations recorded in the church books.

One of the key advantages of church book registers is the information it provides *in addition* to the dates of the vital events. The details of the recorded statistics depend, of course, on the recording policies of the church in question. True of both the Protestant and Catholic churches, the recording of a birth (or baptism) would usually include the names of the parents as well as the time and place of the child's baptism. A marriage record would hold the names of the spouses, their civil status before the marriage, and the time and the place of marriage. This is occasionally supplemented by the names of fathers of the spouses, as well as those of (usually two) witnesses. Lastly, a death (or burial) would contain the name of the deceased person and the date and place of the burial.

An important notice concerning the dates is that church books normally record the dates of baptisms and burials rather than the dates of births and deaths. However, the time intervals between the ecclesiastical and the vital events were usually rather short. For obvious reasons, people were buried immediately after their death, typically in England within 3 days of death (Schofield 1970). Furthermore, English children were usually baptized within 1 month of birth (Midi Berry and Schofield 1971), although this could vary somewhat depending on local traditions and the distance from the family home to the church.

Also true of most Christian churches is that they would ask the parents or spouses (as well as fathers and witnesses) to certify and endorse the event in question by placing their signature in the church book. This practice has served as an important measure of literacy rates in past societies. When someone was unable to sign their name, the vicar would write their name instead, and the illiterate person was simply asked to leave a mark in its place to prove his or her consent. While it is obvious that people who are able to write down their name are not necessary literate, a signature has proven to be a reasonable proxy for this (Schofield 1973).

Sometimes the church registers hold even more profound information about human capital attainments than an indication of their literacy status. Some churches, during some time periods, also recorded the occupational title of the individuals

involved in the registration of the vital event. This is often (but not always) the case in Protestant church registers, a practice that, for Anglican Protestants especially, was made compulsory by the passing of Rose's Law in 1812, specifically asking the ministers to record the occupation title of parents, spouses, and fathers-in-law (and sometimes even the witnesses).

The recording of someone's profession provides a critical insight into the socio-economic conditions of that person, including his or her social status, working skills, and income potential. Occupational information would sometimes even include individual land holdings, providing further knowledge about social status and wealth of the person in question.

There are several ways in which occupational information can be coded and thus made subject to systematic studies of the links between demographic variables and socioeconomic conditions at the individual level. Starting with one of the broader systems for categorizing professions, the *Primary-Secondary-Tertiary* (PST) system, developed by Tony Wrigley of the Cambridge Group (Wrigley 2010), has been used to code the entire occupational dataset collected from British church books in order to study the occupational structure of Britain since medieval times. The great advantage of the system is its classification of all occupations depending on whether the work related to primary, secondary, or tertiary sector activities. A main downside to this system, however, which the Group is still struggling to solve (ibid.), is the problem of categorizing the occupation title "laborer," which was not only a very common occupational title but also one that does not reveal the nature (and sector) of the work conducted.

Another classification system, which is comparable as well as compatible to the PST system, is the *Historical International Standard Classification of Occupations* (HISCO), developed by Marco van Leeuwen, Ineke Mass, and Andrew Miles and documented in Van Leeuwen et al. (2002). This HISCO is an extension of ISCO (International Standard Classification of Occupations) for which the International Labour Organization (ILO) is responsible. The HISCO contains 1,675 historical job categories. The world coverage of the HISCO, along with its time range (spanning the sixteenth to twentieth centuries), allows a categorization of occupational titles from almost any historical population worldwide in which historical occupational records exist.

In a subsequent book, titled *HISCLASS*: *A historical international social class scheme*, labor historians have ranked all the occupations coded in HISCO based on an assessment of the working skills required for an average performance on the job (van Leeuwen and Maas 2011). The ranking of occupational titles builds on the principles of the *Dictionary of Occupational Titles* (DOT). The DOT was developed in the 1930s by the US Employment Service in response to a rising demand for standardized occupational information to assist job-placement activities (US Department of Labor 1939). In order to efficiently match jobs and workers, the public employment service system required that a uniform occupational language be used in all of its local job service offices. Through an extensive occupational research program, occupational analysts collected and provided data to job-market interviewers to help them match the specifications given in job openings to the

qualifications of job applicants. Based on the data collected by occupational analysts, the first edition of the DOT was published in 1939, containing some 17,500 job definitions, presented alphabetically, by title, with a coding arrangement for occupational classification.

The transformation in HISCLASS of occupational titles into working skills builds on two main scores used in the DOT: the *general educational development* score and the *specific vocational training* score. The score concerning the general educational development captures three key features regarding intellectual competencies necessary to fulfill the tasks and duties of an occupation: the incumbent's reasoning development, his or her ability to follow instructions, and the acquisition of language and mathematical skills needed to conduct the work. The score concerning specific vocational training captures the time investments needed in three main areas: that required by the worker to learn the techniques used on the job, that needed to acquire the relevant information to conduct the work, and that necessary to develop the competencies required for an average performance in a job-specific working situation.

Building on the expertise provided by Bouchard (1996) and a team of labor historians, van Leeuwen and Maas used the two DOT scores to code the occupational titles categorized in HISCO according to the skill content of the working titles contained in the HISCO, as part of a procedure to create a historical international social class scheme. In HISCLASS, occupational titles are grouped in four categories as either *unskilled*, *lower skilled*, *medium skilled*, or *higher skilled*. Ongoing work by van Leeuwen et al. (2014) is taking the skill categorization one step further, estimating the actual time investment needed to conduct the work that described the entire set of occupational titles contained in the HISCO system (van Leeuwen and Maas 2011). A further advantage of the HISCLASS scheme is its division of workers into blue-collar (manual) and white-collar (nonmanual) work.

Alan Armstrong's occupational classification scheme offers an alternative to using HISCLASS, splitting jobs into five class categories (Armstrong 1974): Professional, Intermediate Occupations, Skilled Occupations, Partly Skilled Occupations, and Unskilled Occupations. Both systems (HISCLASS and Armstrong's) are useful in their own rights depending on the question at hand. A further advantage of the HISCO scheme, however, is its extension system called HISCAM, a scheme for coding occupations according to the social status of the work linked to the job title offering a finer categorization of social status than the HISCLASS (Lambert et al. 2013). The SOCPO, a competing scheme to the HISCAM, provides a similar coding of occupational titles into social class (Van De Putte and Miles 2005).

Social status and working skills are, of course, both imperfect approximations of individual income or wealth. Greg Clark and Neil Cummins' work, which uses will records to link wealth to professional titles, provides a mapping of occupations into seven social groups based on the wealth recorded in the wills, as described in Clark and Cummins (2010). From the poorest to the richest, these social groups are laborers, husbandmen, craftsmen, traders, farmers, merchants, and gentry. This classification is particularly helpful for looking at links between income potential and fertility decisions (discussed below).

Last but not least, the church book data truly comes to life when combined with other database information. So far, very little work has been done in this regard. Klemp et al. (2013) offer a demonstration of this, linking the CAMPOP data to statistics regarding apprenticeship (see further below). Other possibilities include combinations with census data, will records, probate inventories, poor law information, and tax records. Much work needs to be done in this regard.

Church book records become especially helpful when they come in the form of reconstructed families. The huge advantage of family reconstitution data is the linkage of family members across family generations. This enables studies of intergenerational social mobility, marriage patterns, birth and death patterns, and much more. Although the work needed to reconstruct families based on the raw vital events can be quite laborious, the procedure is surprisingly simple. Start with a marriage. Then track the records back in time to find the birth date of the spouses (linking them to their parents) and possibly any previous marriage (indicated by the civil status at their current marriage). Go forward in time to find the death date of the spouses and, if the couple went to baptize (or bury) any children, to find the birth, marriage, and death dates of their offspring. It took several decades for the Cambridge Group to reconstitute the families within 26 English parishes (Wrigley et al. 1997). But this was before modern computer programming appeared that can aid this process significantly.

The work of reconstituting families based on church book data is further complicated by the fact that people do not always remain in their parish of origin or indeed in a parish where they were once observed. The flipside to that problem is that the lack of someone's birth or death indicates they moved into or out of the parish in question, conveying important information about patterns of migration in the past (Souden 1984). A head-on way of dealing with the issue of lifecycle migration is by tracking down individuals as they move from place to place (arguably an even more laborious task than sticking to the same location). The French TRA data provide such statistics, tracking individuals whose names begin with "Tra" (as in "Travers," a common French family name) across time and space. Comparable datasets exist for other European countries as well.

Some scholars have raised criticism against the transformation of church book data into family reconstitutions. Perhaps the most prominent critiques of the work done by the Cambridge Group come from Peter Razzell (2007) and Steven Ruggles (1999). Much of their criticism is focused against underregistration, linkage failure, selection bias, and the consequences thereof. These potential shortcomings are good to keep in mind when working with family reconstitutions.

How the Registers Have Been Used

There are numerous examples of how church registers have been used to analyze topics in economic history. This section focus on some recent studies connected to the debates regarding the Great Divergence and the wealth of nations, notably how and why the development path of rich countries parted from that of poor countries.

The Malthusian population framework described above has often served as a starting point for analyzing these questions. This scholarly work is split into two categories. One sets out to assess the relevance of the Malthusian model and its two main components, the *positive check* and the *preventive check*, for different countries and regions. The other uses the implications of the Malthusian model to understand various aspects of the Great Divergence and the wealth of nations. Church book data provide a key empirical foundation for analyzing both types of work.

Probably the most prominent statistics used for these purposes (the CAMPOP data discussed in the previous section) are based on British parish registers. These data are made available by the Cambridge Group (Wrigley and Schofield 1981; Wrigley et al. 1997). There are two main reasons for the large popularity of these data. One reason is that the British parish registers are of very high quality and cover three centuries of British population history, from the origins of parish registration in 1541 until the main census registrations started to appear in the early nineteenth century ending in 1871. The other reason for their high esteem is that England was the world's economic leader between 1500 and 1800 and that she was the first nation worldwide to experience an industrial revolution.

Tests of the relevance of the Malthusian population framework span from relatively uncomplicated empirical investigations, exploring the existence of short-term *preventive* or *positive check* mechanisms, to highly advanced econometric examinations of the short- and long-term dynamics and stability of the entire Malthusian framework.

Despite a strong belief in the relevance of the Malthusian framework and its widespread use to understand the process of economic development in preindustrial societies, there is surprisingly little evidence in support of the preventive check hypothesis (Kelly and O Grada 2012). This has faced scholars with a large challenge, because the idea that falling living standards entail a short-term reduction in birth or marriage rates seems particularly appealing to the English case.[1] There is general agreement among scholars, though, that the Malthusian population model is correct and thus that the failure to obtain supporting evidence is due to issues of data and mismeasurement.

A key suspect for the lack of empirical support for the preventive check in England is data aggregation. Ideally, one would explore the direct link between the living standard of a particular couple and the demographic decisions (marriage or birth) made by this couple. But the scholarly reality is that living standards (captured by wages and prices) as well as vital rates (captured by marriage and birth rates) are often measured at the national level. This inaccuracy can be eliminated by moving from the macro to the micro level.

Morgan Kelly and Cormac O Grada have taken a first step in this direction, looking for preventive checks at the *parish* level (Kelly and O Grada 2012). Instead

[1]Some scholars have even found evidence of the opposite, documenting a positive relationship between nuptiality and the price of wheat, a phenomenon they coined *permissive checks* (Sharp and Weisdorf 2009).

of using the aggregated data of the 404 parish registers included in the CAMPOP file, they look at the parish level response to changes in real wages. Even though the real wages are still at the national level, Kelly and O Grada are able to document the existence of preventive checks in many of the parishes included (but not all).

An even closer inspection of the preventive check mechanism requires access to even more detailed vital accounts than aggregations at the parish level. This is where the CAMPOP's family reconstitution data prove useful. While other works have relied entirely on the use of *crude* vital rates, meaning the number of birth, death, and marriages per 1,000 population, it is clear that these rates are only a rough approximation for family-level decision variables, such as the timing of a marriage and a birth.

Cinnirella et al. (2013) have used the CAMPOP's family reconstitution data to try to measure the effect of real wages and food prices on the timing of the marriage, the timing of the first birth, the timing of subsequent births, and the timing of the last birth. They find strong evidence of a *preventive check* mechanism operating in England in the three centuries leading up to England's fertility decline of the nineteenth century. Figure 3 illustrates how birth-spacing intervals expand when real wages are low, and vice versa. Although the wages and prices used to measure standards of living are still at the national level (and certainly never at the family level), the church book recordings of the occupational titles of the husbands help control for the exposure (or lack thereof) to economic pressure during economic downturns. The work similar to that of Cinnirella et al. has been done for Sweden (Bengtsson and Dribe 2006) and Germany (Dribe and Scalone 2010), also showing evidence of deliberate within-marriage birth-spacing behavior.

Among examples of more advanced (and holistic) approaches to testing the relevance of the Malthusian framework, Esteban Nicolini's original work, as well

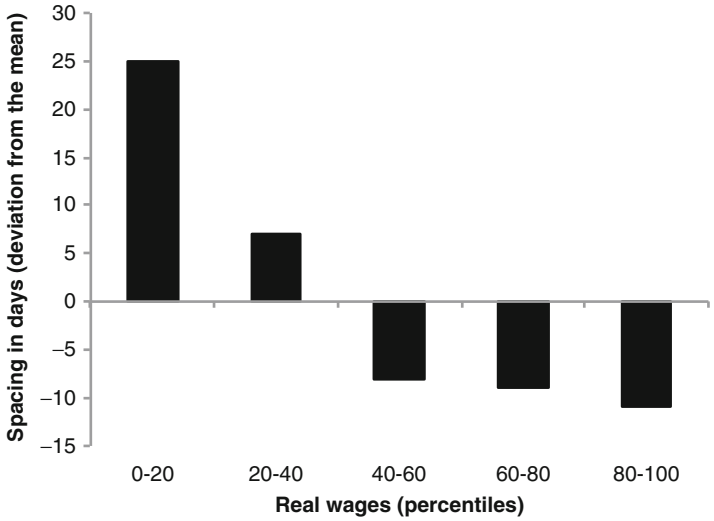

Fig. 3 Birth-spacing intervals by real wage percentiles (Source: Cinnirella et al. (2013))

as follow-up work by Marc Klemp, Niels Frameroze Moeller, and Paul Sharp (cited below), deserves a mention. Common to these studies is the use of crude vital rates for birth, deaths, and marriages (notably of the CAMPOP data), which they then attempt to link up with historical living standards measured by (national) real wages, usually provided by Clark (2005).

Nicolini's (2007) work does not fit some crucial assumptions of the Malthusian model. Using a vector autoregression for data on fertility, mortality, and real wages over the period 1541–1841 and applying a well-known identification strategy broadly used in macroeconomics, Nicolini's results show that endogenous adjustment of population to real wages functioned as Malthus assumed only until the seventeenth century: evidence of positive checks disappeared during the seventeenth century and evidence of preventive checks disappeared before 1740. This implies that the endogenous adjustment of population levels to changes in real wages – one of the cornerstones of the Malthusian model – did not apply during the period of the Industrial Revolution.

Moeller and Sharp (2014) reexamine the question using data identical to those of Nicolini but with a somewhat different economic specification. They formulate a post-Malthusian hypothesis that on the one hand involves co-integration between real wages and the birth and death rates. But on the other hand, it allows a negative Malthusian feedback effect from population on income (as implied by diminishing returns to labor) to be offset by a positive so-called *Boserupian-Smithian* scale effect of population on technology. This setup means they reach a different set of conclusions from Nicolini, namely, that, as early as two centuries preceding the Industrial Revolution, England had already escaped the pattern described by the standardized Malthusian model and instead had entered a post-Malthusian regime, where income per capita continued to spur population growth, but that the real wage was no longer stagnant. Tests of the relevance of the Malthusian (or post-Malthusian) framework are not confined to Britain. Klemp and Moeller (2013) have also experimented with church book data from Denmark, Norway, and Sweden, looking for evidence for the existence of a post-Malthusian phase in the transition from stagnation to growth in Scandinavia, and studies of other regions are currently in the making.

Gregory Clark and Gillian Hamilton (2006) provide an example of a crossroad study between assessing the validity of the Malthusian model and using its predictions. One of the key features of the Malthusian model is that there is a unique wage rate at which births equal deaths. But since the reality is that some earn more than others, the Malthusian model implies that the rich have more surviving offspring than the poor. Clark and Hamilton used information derived from will records to test this implication, investigating the relationship between the total value of the wealth left by male testators and the total number of offspring who inherited their wealth. Their results are replicated in Fig. 4.

The same exercise can be conducted using church book family reconstituted data. What the church book registry lacks in terms of wealth information, it compensates for by its vital statistics. Not only does it provide the total number of births by family, but it also permits a count of how many of these children actually made it through into their reproduction period (i.e., lived beyond the age of 15). By exploring the

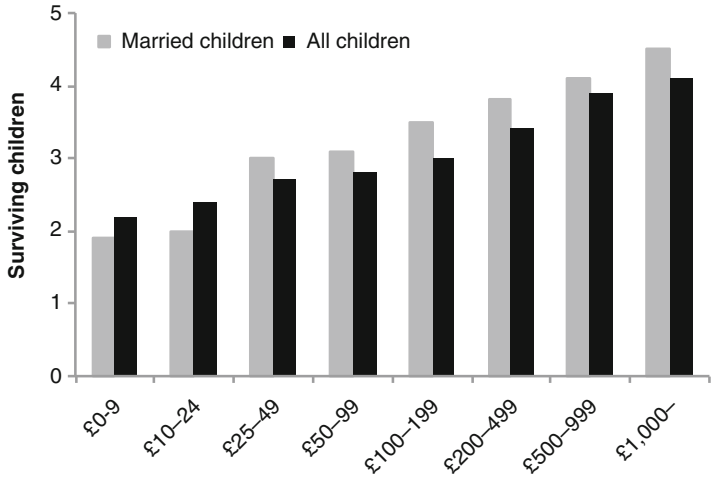

Fig. 4 Reproductive success by wealth (Source: Clark and Hamilton (2006))

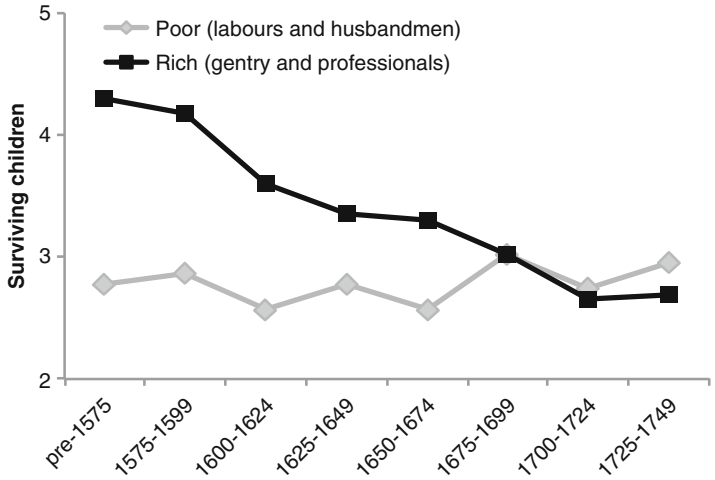

Fig. 5 Reproductive success of rich and poor (Source: Boberg-Fazlic et al. (2011))

CAMPOP statistics, Boberg-Fazlic et al. (2011) divided the male occupational titles found in the church registers across the seven income groups (see above) defined by Clark and Cummins (2010). Figure 5 illustrates how the preindustrial period confirms the inferences of the Malthusian model and also how this pattern dissolves around the time of the Industrial Revolution.

The CAMPOP family reconstitution was also used to look at Malthusian positive checks. While the magnitude of the *short-term* effects of hardship on mortality has received ample support (Galloway 1994), very little attention has been paid to the *long-term* effects: the influence of hardship on mortality later in life. Klemp and

Weisdorf (2012a) raised this question looking at the so-called "fetal origins" hypothesis. This is the idea that undernutrition in early life leads to a disproportionate growth in utero and in infancy, which in turn enhances the susceptibility to illness and hence increases the death risk later in life. Using survival analysis, they find that birth during the great English famine of the late 1720s entailed a largely increased death risk *throughout* life among those who survived the famine. The death risk at age 10 among the most exposed group – children born to English Midlands families of a lower socioeconomic rank – was up to 66% higher than that of the control group (children of similar background born in the 5 years following the famine). This corresponds to a loss of life expectancy of more than 12 years.

The Malthusian framework has been used repeatedly to understand the long-term economic development and the wealth (or lack hereof) of nations. One of the key arguments for why England enjoyed comparatively high living standards in the past is linked to the response of demography to economics. A central hypothesis concerns the parental trade-off between the quantity and quality of their offspring. The existence of a child quantity-quality trade-off is particularly relevant for the assessment of theories that explain the transition from millennia of economic stagnation to an era of sustained economic growth as well as the accompanying demographic transition (e.g., Galor and Moav 2002). Indeed, the leading theories explaining the origins of modern economic growth depend crucially on the presence of a trade-off between the number of children in a family and the attainment of human capital of the offspring. For instance, Galor and Weil (2000) have argued that the enhancement of technological progress during England's Industrial Revolution motivated parents to invest in the human capital of their offspring, leading to lower fertility and hence slower population growth, ultimately facilitating an increase in income per capita.

Census data has been a generous sponsor of the vital information needed to test the existence of a trade-off effect during early stages of industrialization. Basso (2012) has demonstrated the existence of a trade-off in Spain, Becker et al. (2010) in Prussia, Fernihough (2011) in Ireland, and Perrin (2013) in France.

Church book statistics, notably in the form of family reconstitutions, provide an alternative to using census data to test the relationship between the total number of family births and the human capital achievement of the offspring. The work by Marc Klemp and coauthors provide some examples. Using the CAMPOP data, Klemp and Weisdorf (2012b) show a negative link from parental reproductive capacity to the socioeconomic achievements of their offspring later in life. Using the time interval between the date of marriage and the first birth as a proxy for the couples' reproductive potential (i.e., their fecundity) and hence unplanned variation in family size, the authors establish that children of parents of low fecundity were more likely literate and employed in skilled and high-waged work than those of highly fecund parents. Along similar lines, Galor and Klemp (2013) have used Canadian church book data to show that a parental disposition toward having many children was not as conducive for long-run reproductive success as more moderate reproductive dispositions: subsequent generations of couples prone to restrained fertility turned out to be more successful in terms of reproduction than those of more fertile couples.

Finally, the church book data can be linked up with other databases. Klemp et al. (2013) provide an example of how the CAMPOP family reconstitution data can be linked with records of substantial educational achievements. Although the church books may provide someone's occupational title, and hence give a hint about the educational attainments of the person in question, they do not record any specific information about the schooling or actual occupational training. By use of a matching procedure, Klemp and coauthors were able to link up the vital statistics from the church books with information from nationwide Stamp Tax registers providing the names of apprentices and fees paid by apprentices to masters. The linkage of family data to individual apprenticeship training opens the possibility to explore a long line of questions regarding parental education decisions, such as whether parents followed customary tradition (such as birth order) or decided to educate children was based on their aptitude.

The availability of church book records is, of course, not limited to Britain and continental Europe. Wherever the European missionaries went, they left a trace revealing the local demography elsewhere. More than that, because the missionaries brought with them the recording methodologies used in Europe, church book registry elsewhere is often fully identical to the registry in Europe. This means church book data of the Americas, Asia, and Africa can help understand the economic development, or lack hereof, in the third world, particularly those areas that were previously colonized by Europeans.

One of the main topics in the context of understanding the Great Divergence between Europe and the third world is the influence of European colonial powers on the economic development of third-world regions. Figure 6 captures well the Great Divergence between England on the one hand and sub-Saharan Africa on the other (Frankema and van Waijenburg 2012).

Much of the data used to analyze the Great Divergence between Europe and the third world come from the colonizers themselves. For example, empirical

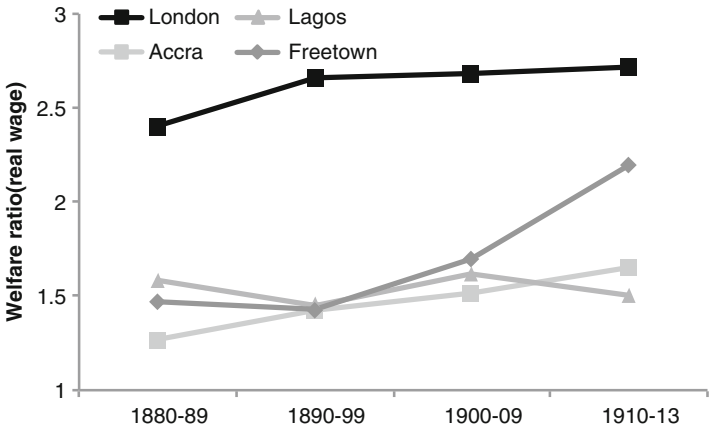

Fig. 6 The Great Divergence between Europe and Africa (Source: Allen (2001), Frankema and van Waijenburg (2012))

investigations into Africa's economic past are often limited to the study of national-level variables (production, export, taxes, etc.) recorded long ago by colonial agents who gave primacy to numbers concerning the colonizers' own activities. Church book records provide a source of information *independent* of those recorded by the colonizers. Christianity caught on rapidly in Africa, especially in sub-Saharan Africa, which today is predominantly Christian. Some Christian churches, such as the Anglican Church, recorded the occupational information of their affiliates. This means church book data represents a broader section of the population than those working for the colonial administration. Moreover, Christian missionaries often arrived ahead of the colonial agents, making it possible to explore the statistics of the church books to investigate not only the impact of colonial influences on Africans but also the results of African independence.

The work of Felix Meier zu Selhausen and coauthors demonstrates well the potential of Sub-Sahara African church book registers (Meier zu Selhausen 2014; Meier zu Selhausen and Weisdorf 2014; Meier zu Selhausen et al. 2014). Meier zu Selhausen and his collaborators have used marriage registers from one of the earliest and largest Protestant churches in sub-Saharan Africa, St. Paul's Cathedral in Kampala, Uganda, to study the long-term evolution in human capital formation and labor market participation among Protestants affiliates. British missionaries arrived in Uganda in the 1870s, shortly prior to the British colonizers who ruled Uganda until the 1960s. The chronology in the line of events makes it possible to study the demographic influence of the missionaries, followed by the colonizers, followed by the exit of the colonizers and subsequent independence of Uganda and up until the present day.

The consistent recordings of (especially) women's occupations since the arrival and spread of Protestant missionaries in Africa in the latter half of the nineteenth century made it possible to explore several aspects of gender (in)equalities and the influence hereon of both missionaries and colonial powers. One of the key indicators of female agency is the spousal age gap (Carmichael 2011): the older the husband is and the younger the wife, the more power the husband is assumed to hold and the less agency the wife has. This is also captured by the so-called *girl-power* index, measured as the female age at marriage minus the spousal age gap. By dividing women into two groups, depending on whether or not they engage in salaried work, Meier zu Selhausen (2014) finds that those women who worked for wages married significantly later than others and that the spousal age gap among these women was smaller, and the girl-power index higher, than among other women. Women rarely worked for the colonial administration, however. Their sole employer was the missionaries, who trained and used their expertise in mission schools and hospital work (as teachers, nurses, and midwives).

Other variables used to measure gender inequality include the literacy rates, the numeracy rate (ability to deal with numbers), the labor force participation rates, the wage rates, and the rates of skilled and nonmanual (high-status) workers. Meier zu Selhausen and Weisdorf (2014) found that males quickly acquired literacy, which helped provide access to formal-sector (salaried) jobs. Women took somewhat longer to obtain literacy and considerably longer to enter into salaried work. The authors observe a *gender Kuznets curve*: although inequality in literacy and access to

Fig. 7 The shares of Kampala men and women in salaried work (Source: Meier zu Selhausen and Weisdorf (2014))

salaried jobs grew substantially during the early colonial period, it gradually vanished during the postcolonial period. Today it is largely gone. Figure 7 shows the evolution in the share of men and women employed in salaried work in historic Kampala, indicating the gender gap therein.

The passing of Rose's Law in the early nineteenth century (mentioned above) meant that Anglican Protestant records are particularly useful for the purpose of studying social mobility. The reason is the recording of not only the spouses' occupations but also those of their fathers, setting the scene for a study of intergenerational social mobility at the family level. Meier zu Selhausen et al. (2014) found that social mobility in Uganda was very large during the colonial period, primarily because of the salaried labor market that arose following the creation of a colonial economy. After Uganda's independence from the British colonizers, economic development slowed down; fewer new jobs were created; and the prospects for social mobility declined.

Uganda is just one example of how church book records from third-world countries can be explored to shed light on the Great Divergence between Europe and the third world. The missionaries' recordings of vital events can be found practically everywhere the missionaries went, including most of today's developing regions covering the continents of Africa, Asia, and South America.

What Is Next?

There are two scholarly roads forward that can make even better use of church book data in future research. The first is to improve the use of existing data. Many independent datasets exist, but these are currently not directly comparable, making

it difficult to conduct cross-country or cross-regional comparison. Comparable work is important to reach an understanding of the influence of demography on the different economic performances of past economies. Much of the church book data, which are already transcribed, can be used for the purpose of family reconstitution. That will provide a much more profound understanding of family patterns and household decisions in past societies.

The second road forward concerns the collection of more data. We know practically nothing about the demographic history of Africa, Asia, and the Americas. By collecting this information, it can be used to shed light on developments and fertility, mortality, life expectancy, literacy rates, occupational structures, gender inequality, social mobility, and their connection to economic development, notably in third-world countries.

Growth

Cliometrics of Growth

Claude Diebolt and Faustine Perrin

Contents

Abstract

This chapter lays the theoretical foundations of long-run economic growth. After providing an overview of the three fundamental regimes that have characterized the process of development over the course of human history on the basis of the seminal work of Galor and Weil (2000), we review existing theories offering explanations of the different stages of development. In particular, we examine the predictions and underlying mechanisms of the traditional theories of economic growth and the theories of demographic transitions. We then show the relevance of the Unified Growth Theory to explain and capture the underlying mechanisms of the development process. Finally, we highlight the importance of integrating a gendered perspective in the study of long-run economic growth.

Introduction

The movement of the production potential of the industrialized nations over long periods of time is at the center of the very latest economic debates. This preoccupation is far from new. The classical economists were already concerned about how to increase welfare by increasing growth. The subject remained controversial after World War II with the theoretical debate on the long-term stability of market economies. However, through Solow's (1956) economic-growth model, neoclassical thinking gradually exerted its power. Its reasoning is clear, and it also explains numerous aspects related to economic growth, which are summarized perfectly in Kaldor's (1963) six "stylized facts." At the same time – perhaps paradoxically – scientific interest in work on growth and economic fluctuations disappeared. There were two main reasons for this: First, the short sightedness of economists whose attention was centered almost exclusively on the study of short-term movements and second, the comparative weakness of theoretical models unable to solve the aspects that remain unexplained by the different theories of growth. This partially explains why the postwar neoclassical models are unsatisfactory. Indeed, in the long run, they only account for economic growth by involving exogenous factors (except for Ramsey's (1928) model that was rediscovered very recently). In addition, Solow's reference model does not provide any way of explaining the divergence in growth rates at the international level. The theory of long-run equilibrium suggests that all countries should progress at identical, exogenous rates of technical progress. Similarly, it should be noted that the hypothesis of the systematic existence of a negative correlation between income level and economic growth rate is not based on any satisfactory empirical verification. Finally, nothing really corroborates the convergence hypothesis, that is to say, the transfer of capital from the richest to the poorest countries.

However, the work of Lucas (1988) and Romer (1986, 1990) attracted attention, and the 1980s marked a renaissance of the neoclassical theory of growth. The prime objective was to go beyond the weakness of the old theoretical models. The aim was also to answer new questions: What are the determinants of sustainable economic growth? Can technical progress alone increase social welfare or can capital accumulation also lead to a permanent increase in per capita income? What are the factors of production that engender sustainable economic growth: physical capital, environmental capital, human capital, or technological knowledge? What are the mechanisms that guarantee growth over a long period for a market economy? And finally, what is/are the market structure/s within which economic growth can be achieved? Strengthened by its focus on these questions, the debate on the determinants of the economic growth

process has recently attracted renewed attention, both in the importance of its implications in terms of economic policy and in the number of theoretical and empirical analyses that it engendered.

In fact, during the past two centuries, the Western world witnessed dramatic economic, demographic, and cultural upheavals. This period marked a turning point in historical economic and demographic trends. Despite some variations in terms of timing and speed of changes (Galor 2012), Western countries exhibited similar patterns of economic and demographic transition. Before the Industrial Revolution, all societies were characterized by a very long period of stagnation in per capita income with high fertility rates and the dominance of physical capital over human capital (Clark 2005). Since this fateful period Western countries experienced a complete reversal with high and sustained income per capita and low fertility rates (Becker et al. 2012; Klemp 2012). Human capital became an important source of income.

The main objective of this chapter is to present the theoretical approaches attached to the understanding of the process of development and growth. Empirical regularities raise numerous questions about the potential interactions linking demographic developments and the economic transition and about the role they have played in the transition from the stagnation to sustained growth. What are the underlying behavioral forces behind this demographic transition? What are the endogenous interactions between population and production? What accounts for the unprecedented rise in income per capita? Why has the transition to a state of sustained economic growth occurred together with the demographic transition?

This chapter that lays the theoretical foundations of cliometric analyses that aim at providing a better understanding of the long-run economic growth is organized as follows. First, we provide an overview of the stylized facts of three fundamental regimes that have characterized the process of development over the course of human history on the basis of the seminal work of Galor and Weil (2000).[1] Second, we explore existing theories offering explanations of the different stages of the process of development. We briefly examine the predictions and underlying mechanisms of the traditional theories of economic growth and development and the theories of demographic transitions. Third, we highlight the relevance of the unified growth theory to explain and capture the underlying mechanisms of the development process, and we provide an example of the unified growth model, introducing a key concept of development: the level of gender equality.

[1]The seminal work of Galor and Weil was quickly followed by new contributions, including Jones (2001), Lucas (2002), Hansen and Prescott (2002), Galor and Moav (2002), Doepke (2004), Galor (2005), Cervellati and Sunde (2005), Strulik and Weisdorf (2008), among others.

The Stylized Facts of the Development Process

Evolution of Output and Population Growth in Western Europe

Demographic behaviors are a key underlying aspect of the process of development that occurred in Western countries over the past 200 years. In order to have a better comprehension of the evolution of economic growth, demographic trends must be studied coincidentally with economic developments.

Figure 1 presents a broad picture of the joint evolution of output growth and population growth in Western Europe over six periods between 1000 and 2008. The first two periods, 1000–1500 and 1500–1700, are highly similar with a population growth rate slightly larger than the output growth rate (respectively, around 0.16% and 0.12%). Both average annual growth rates start to increase slowly over the period 1700–1820 (respectively, 0.41% and 0.15%). The wealth generated was absorbed by the rise in population growth. This positive relationship between income and population continues over the period 1820–1870 but becomes progressively narrower.

The period 1820–1870 experiences a sharp rise in economic growth. The takeoff in growth rates of GDP per capita was associated with a rise in population growth as observed in all regions of the world (Galor 2011). However, the population growth remains relatively restrained in comparison to the output increase. More precisely, the average growth rate in GDP per capita in Western Europe between 1820 and

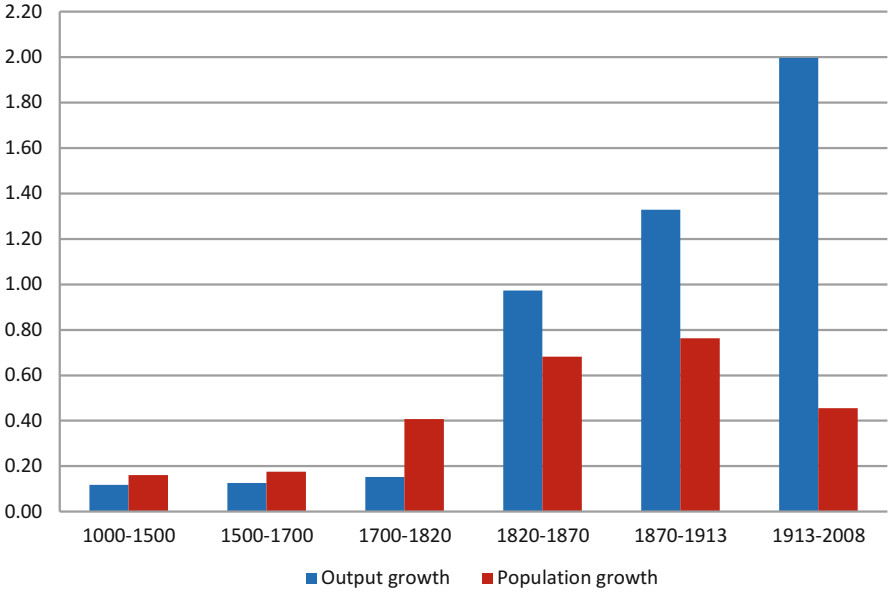

Fig. 1 GDP per capita and population growth rates in Western Europe (30 countries) (Source: Data from Maddison (2008))

1870 rose to an annual growth rate of 0.97% (from 0.15% during the period 1700–1820) while the average population growth rate increased to 0.68% (from 0.41% during the period 1700–1820). If we compare Western Europe with France, we note that population growth was significantly lower in France than in Western Europe, with an average annual growth rate of 0.42% over the same period. From 1870 to 1913 the pace of the population growth rate slowed down (0.42%) while that of the GDP per capita increased further to 1.11%. The last period, 1913–2008, is marked by an unprecedented reversal in the relationship between population and output growth. For the first time, the rate of population growth decreased while the growth rate of per capita GDP continued to rise. The rate of GDP per capita then grew by 2% per year while population growth rate declined to a yearly average of 0.45%. Ultimately, Western Europe experienced a demographic transition in parallel to the continuous increase in GDP per capita.

The Three Phases of the Development Process

Several important features stand out from Maddison's (2008) data. Human history can be divided into three fundamental regimes: the Malthusian Epoch, the Post-Malthusian Regime, and the Modern Growth Regime.

Stagnation: Malthusian Era

Maddison indicates that the average level of world per capita income fluctuated around $450 per year over the period 1–1000 and around $670 per year from then until the end of the eighteenth century. The monotonic increase in income per capita during the Malthusian era was associated with a uniform evolution of the average population growth rate (0.01% per year in the first millennium; 0.1% per year in the years 1000–1500; 0.27% per year over the period 1500–1820), keeping living standards fairly stable. The stagnation has characterized human history for thousands of years. At that stage, population growth was positively affected by the level of income per capita. The monotonic increase in income per capita during the Malthusian era was associated with uniform growth rate of the population, which did not result in variations in the standard of living (Galor 2011). The absence of significant changes in the level of technology trapped the income per capita around a subsistence level, and population size remained relatively stable.

Takeoff: Post-Malthusian Phase

At the beginning of the nineteenth century, Western countries experienced a takeoff from Malthusian stagnation. This shift took place with the increase in the pace of technological progress in association with the process of industrialization, presumably stimulated by the accumulation of human capital.[2] Based on Maddison (2008), we note that the world average growth rate of output per capita increased from 0.05%

[2]The demand for education increased from the end of the period.

per year for the period 1500–1820 to 0.54% per year during the period 1820–1870 and reached 1.3% per year in the years 1870–1913. Similarly, the average rate of population growth in the world increased from 0.27% per year in the period 1500–1820 to 0.4% per year in the years 1820–1870 and to 0.8% per year in the interval 1870–1913. Hence, we note that this period is still marked by a positive relation between income and population growth. The acceleration of technological progress resulted in a significant increase in the growth rate of output per capita, generating an unprecedented increase in population growth. The timing of the takeoff differs across regions. In less developed countries[3], the takeoff occurred progressively with a one-century delay, from the beginning of the twentieth century. The decline in population growth marked the end of the so-called Post-Malthusian Regime by the end of the nineteenth century in Western countries and by the second half of the century in less developed regions.

Sustained Growth: Modern Growth Regime

The acceleration of technological progress during the second phase of industrialization, its interaction with the human capital accumulation, and the reversal in the relation between income per capita and population growth marked the transition toward a state of sustained economic growth. The entrance in the Modern Growth Regime, associated with the phenomenon of demographic transition, has led to a great divergence in income per capita in Western countries over the past two centuries (Galor 2011).

Using Maddison's data, the reversal in the rate of population growth occurred by the end of the nineteenth century and the beginning of the twentieth century for particular regions of the world (Western Europe, Western Offshoots, and Eastern Europe). From an average of 0.77% per year in the period 1870–1913 in Western Europe, the population growth rate decreased to an average of 0.42% per year in the years 1913–1950, while it continued to grow in other parts of the world. At the same time, the world average growth rate of GDP per capita kept on increasing, reaching a peak of 2.82% per year between 1951 and 1973.

Although industrialization initiated the demographic transition in most Western countries by the late nineteenth century, the process started nearly a century earlier in France. Figure 2 makes a comparison of the ratios of output and population growth in France, the United Kingdom, and Western Europe over the period 1000–2008. After centuries of stability in the output-to-population growth rates,[4] there was a sudden and dramatic rise. France, UK, and Western Europe witnessed this unprecedented increase at the same time, namely, by the first decade of the nineteenth century.

[3]By less developed countries, we mean Latin America, Asia, and Africa.

[4]About 0.6 in France, 0.8 in UK, and 0.7 in Western Europe.

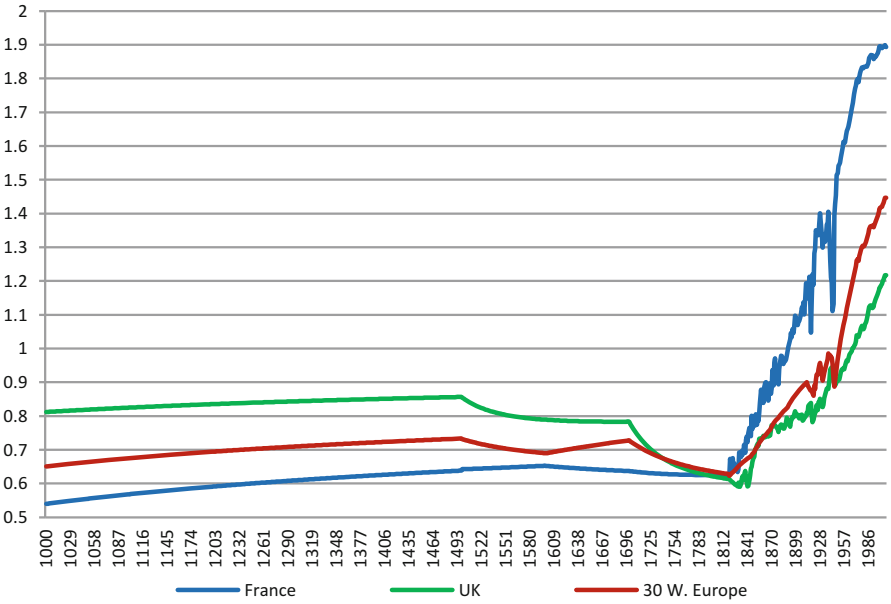

Fig. 2 Ratio of output-to-population growth rates in France, UK and Western Europe, 1000–2008 (Source: Using data from Maddison (2008))

However, while the ratio of population and output growth rates reached one in France in 1891, Western Europe reached this ratio in 1953 and the United Kingdom in 1968 only. The growth rate of GDP per capita relative to population growth has been much faster and intense in France than in the rest of Western Europe. Two main issues emerge from these findings. Why did population and output growth reverse at the same time in France and in other Western European countries? Why was the rise in the ratio between output and population growth so much faster in France than in the rest of Western Europe?

Main Challenges

As previously mentioned, the development process raises a number of questions and puzzles. This has piqued the interest of cliometricians specializing in the field of growth and development. Unprecedented upheavals occurred during this process. The demographic transition, the transition from stagnation to growth and the phenomenon of great divergence in income per capita, took place at different times across regions of the world. Many mysteries persist. Contemporary growth theorists, as well as cliometricians, need to improve their understanding of the development process and of the driving forces and underlying determinants that led to the escape from the Malthusian trap and allowed for the transition to sustained growth.

The main questions addressed (Galor 2005, 2011) are the following:

- What can explain the centuries of stagnation that characterized most of human history?
- What are the driving forces that account for the sudden increase in growth rates of GDP per capita and the persistent stagnation in others?
- What led to the Industrial Revolution? Why did this phenomenon occur first in Great Britain?
- What factors can account for the relationship between population and output growth? Why has the positive link between income and population growth reversed its course in some economies but not in others?
- What are the main forces that initiated the process of demographic transition? Why did this phenomenon occur first in France?
- What has caused the Great Divergence in income per capita across regions of the world over the last two centuries? Would this transition have been possible without the demographic transition?

In other words, what are the underlying behavioral and technological structures that could simultaneously account for these distinct phases of development? Additionally, what are their implications for the contemporary growth process of developed and underdeveloped countries?

Toward a Unified Theory of Growth: Theoretical Background

The fundamental challenge faced by cliometricians specializing in economic growth is to provide reliable answers to the previous set of questions using the contributions of economists, historians, and sociologists. The issue for growth theorists is to develop a unified theory of growth that can account for the main features of the three distinct phases that have characterized the process of development. This was first undertaken by Galor and Weil (1999, 2000), with the development of the unified growth theory.[5] This theory aims at giving a better understanding of the driving forces that triggered the escape from the Malthusian trap and the subsequent transition to a state of sustained growth.

Traditional Theories of Economic Growth

The theories and models of economic growth have evolved considerably over time. The theories of endogenous growth have emerged in response to the inability of

[5]The term was coined first by Galor (2005).

exogenous growth models to explain the origin of technological progress. These two types of modeling have themselves borrowed some basic elements from the classical theories of growth and stagnation.

The Malthusian Theory

The world of economic history has been dominated by the Malthusian stagnation. For a long time, theories aimed at explaining economic growth and development found their inspiration in Malthusian and neoclassical conceptions. In his *Essay on the Principle of Population*, Malthus (1798) defends a "pessimistic" vision of the impact of population growth on long-run economic development, coherent with the world economic history prior to the Industrial Revolution. Malthus's thinking can be summarized by the two following postulates: (i) Population growth is bounded by the means of subsistence and (ii) population increases with livelihoods in a geometric progression while production of food grows in arithmetic progression. The theory developed by Malthus matches the empirical evidence of the relation between income and population dynamics prior to the Industrial Revolution fairly well. According to this theory, the effect of population growth is counterbalanced by the expansion of resources, reflecting the fluctuations of the income per capita around a subsistence level. Malthus argued that two types of barriers contributed to reduce the size of the population at the subsistence level: the "positive checks" and the "preventive checks." The "positive checks" raise the death rate through hunger, disease, or war. The "preventive checks" affect birth rates through birth control, abortion, late age of marriage, or celibacy.

Without changes in the level of technology and resources, both the population size and the income per capita would remain stable. However, periods of technological progress and expansion of resources would lead to an increase in population growth, which ultimately triggered a decline in income per capita. Despite the capacity of the Malthusian theory to capture the characteristics of the epoch of stagnation, its predictions appear inconsistent with the features of the post-demographic transition era and the Modern Growth Regime. At the end of the nineteenth century, liberal economists such as Leroy-Beaulieu (1913) found that the theory was contradicted by the facts. He found that the movement of population was slowing down and output growth was accelerating. As a consequence, doctrines evolved toward the idea that population growth followed different rules than output growth. Boserup (1965, 1981) notably argued that the demographic pressure would lead to a reorganization of agricultural production. According to Boserup, the size of the population drives changes in the operating modes and not the subsistence level. Technological progress may then allow the subsistence level of production to consistently exceed population growth.

Classical economists such as Malthus (1798), Smith (1776), Ricardo (1817), and later Schumpeter (1934) have provided basic ingredients that appear in modern growth theories, such as the interplay between income per capita and the rate of population growth, the role of technological progress, and the accumulation of physical and human capital.

The Neoclassical Theory

Exogenous Growth Model

Contrary to the Malthusian theory that has investigated the relation between population and production prior to the demographic transition, neoclassical growth models focused largely on the growth process during the Modern Growth phase. Far from being limited to agricultural productivity, population growth is affected by complex socioeconomic-cultural phenomena related to the enrichment of society, culture, and choices of social organization that triggered families to limit their number of children. Growth models only gradually started to integrate these aspects.

In opposition to Malthus' approach, exogenous growth models, such as Solow (1956) and Swan (1956), deal with demographic growth as an exogenous variable and assume demographic behaviors to be independent of wages, incomes, and prices. Without technological progress, the income per capita converges toward a stable steady state independently of the size of the population. The Solow model is based on the assumption that the factors of production separately have diminishing returns. However, returns to scale are assumed to be constant, and factors of production are assumed to be used effectively by all countries. In an economy with more capital, the productivity of labor increases. As a consequence of diminishing returns to factors of production, economies will reach a point where any increase in production factors does not generate an increase in output per capita. In neoclassical growth models, the rate of long-run growth is determined by factors that remain unexplained (exogenous), such as the rate of technological progress in the Solow model.

New Home Economics

Parallel to the evolution of exogenous growth models, a branch of theoretical economic literature started to methodically analyze household decisions, such as consumption, savings, and labor supply. The lack of consideration of family behavior and its impact on economic models indeed led to the creation of a new stream of research, the so-called "New Home Economics."[6] The New Home Economics extended the domain of microeconomic analysis to a wide range of behaviors and human interaction, such as demographic behavior, investments in human capital, and intergenerational transfers. The (static) modeling of household production and time allocation was notably used to explain the sexual division of labor and the market behavior of household members. Among the first publications were Becker (1960) on fertility, Mincer (1962) on women's labor supply, and Becker (1965) on the allocation of time. Key assumptions of this literature are that institutions and cultures influence decisions in the home (Folbre 1994) and that these decisions are made by families as a unit. Manser and Brown (1980) have introduced household (two-sex) bargaining models, taking into account the separate interests of individual household

[6]Ironically, the etymology of "economics" is derived from the Greek *oîkos* (house, dwelling) and *nómos* (law, custom) and refers to the art of properly administrating one's home.

members. Their framework was then extended by authors such as Chiappori (1992) and Lundberg and Pollak (1993). A decade after the creation of the New Home Economics, Nerlove (1974), Razin and Ben-Zion (1975), and Srinivasan (1988) developed models linking demographic behaviors to macroeconomic evolutions in order to analyze their implications on the general equilibrium.[7]

The Endogenous Growth Theory

Endogenous growth models were developed in the 1980s as an extension to exogenous growth models in order to address the issue of the origin of technological progress – holding that economic growth results from endogenous (and not external) forces. The first endogenous growth model was published by Romer (1986) and was then extended by Lucas (1988), Romer (1990), and Barro (1990). These theories are constructed around the central idea that factor returns no longer decrease when it is accepted that components other than physical capital (such as human capital) exist and can display endogenous accumulation. Endogenous theorists identified four key factors of growth: returns to scale, research and innovation (Romer 1990; Grossman and Helpman 1991; Aghion and Howitt 1992), knowledge and human capital (Lucas 1988), and state intervention (Barro 1990). The structure of these models is identical. Endogenous growth becomes possible after the introduction of a new accumulation factor that compensates the decreasing returns of capital accumulation. According to Lucas, the source of economic growth lies in the unlimited accumulation of human capital. This boundless increase in human capital is based on major hypotheses of nondecreasing returns of technology and training and the existence of externalities. In the models in line with Romer (1990), economic growth is a function of research and development that depends on the share of human capital allocated to the research sector. The accumulation of knowledge (innovations) is the engine of growth. Other models achieve self-maintained growth through similar mechanisms by means of hypotheses concerning the nondecreasing returns of the new factors of accumulation.

The AK Model. The simplest version of endogenous growth models is the AK model. This formalization eliminates all the fixed factors that are not reproducible and therefore cannot be accumulated, thus making it possible to achieve endogenous growth in spite of the absence of increasing returns to scale or externalities. The essence of endogenous growth resides in the use of reproducible factors that can be accumulated. This central hypothesis makes it possible to affirm that capital returns are constant. The production function is then summarized by the following expression: $Y = AK$, where A is an exogenous scale parameter indicating the level of technology and K describes capital, including human capital, the stock of knowledge, and financial capital. Human capital is subject to accumulation and substitutes for the labor factor – which is by nature not reproducible. Capital is therefore a

[7]Within the framework of the neoclassical growth model with endogenous fertility, the authors attempt to determine the optimal population growth rate.

composite component incorporating all the accumulation factors. The nondecreasing returns allow self-maintained growth.

Family-Based Endogenous Growth Models. Inspired by the New Home Economics literature and by endogenous growth models, growth models with explicit microeconomic foundations of family have developed progressively (Barro and Becker 1989; Becker et al. 1990; Ehrlich and Lui 1991; Galor and Weil 1996; Dahan and Tsiddon 1998; Iyigun 2000). Growth theorists, exploring mechanisms by which fertility and growth are related, focused primarily on the modern era (Barro and Becker 1989; Barro and Sala-i-Martin 1997; Becker et al. 1990; Moav 2005; Tamura 1994, 1996). The so-called endogenous growth theory, taking into account family behavior (as a single decision-maker), is able to explain the empirical regularities that characterized the growth process of developed countries over the last 100 years. The pursued objective of these models is to provide a theoretical growth model with microeconomic foundations consistent with the stylized facts of the demographic transition.

The Theories of Demographic Transition

The demographic transition is identified as having played a key role in the process of development. From a theoretical point of view, different factors have been put forward to explain the process of demographic transition. Becker (1960) argued notably that the rise in per capita income had an effect on both households' income and opportunity cost of raising children. However, this explanation does not seem sufficient to fully explain the empirical regularities described previously. Why did demographic transitions occur simultaneously across countries that significantly differ in income per capita? Why did France experience its demographic transition prior to other countries?

The gradual rise in the demand for human capital along the process of industrialization has been seen by some researchers as a prime force leading to the onset of the demographic transition, specifically during the second phase of the Industrial Revolution. Taking family as a single decision-maker, Becker's models manage to generate the demographic transition but do not differentiate between the behaviors of males and females. Becker et al. (1990) model the relationship between human capital, fertility, and economic growth. In this "one-sex" model with altruistic parents, higher productivity leads to higher wages and favors human capital accumulation, which in turn raises the opportunity cost of children. This feature highlights the existence of two locally stable steady states: a Malthusian steady state with many children and little human capital and a steady state with few children and high human capital.[8] In the interpretation of the model, they consider changes in female labor force as implicit. Galor and Weil (1999, 2000) developed the idea that the acceleration in the rate of technological progress would gradually increase the

[8]Tamura (1994) finds the same result.

demand for human capital, inducing parents to invest in the quality of their offspring rather than in the quantity. The existence of a negative correlation between education and fertility has been demonstrated by Becker et al. (2012) with county-level evidence for Prussia in 1816. Ultimately, the process of human capital accumulation would induce a reduction in fertility rates as the growth rate of technological progress increases.

The decline in the gender gap is also considered a reinforcing mechanism impacting fertility rates. Galor and Weil (1996) investigate the relationship between fertility, gender gap in wages, and economic growth by explicitly assuming that men and women have different abilities and do different kinds of work. The authors postulate that technological progress and capital accumulation positively impact the relative wages of women along the process of industrialization, which increases the opportunity cost of raising children and ultimately leads to a reduction in fertility. Hence, economic growth would contribute to the closing of the gender gap in earnings, which would further lower fertility and reinforce economic growth. In a dynamic model with endogenous fertility, Iyigun and Walsh (2007) investigate how the evolution of spousal bargaining power within the couples' decision-making problem may trigger the decline in fertility.[9] Doepke and Tertilt (2009) study the opposite direction of causation. Based on a model with a quantity-quality trade-off on children, they investigate what economic forces may be at the origin of the progressive rise in women's rights throughout the process of industrialization. For Falcão and Soares (2008), it is the demographic transition that increases the supply of female labor and decreases the female-to-male wage gap. They show that gains in adult longevity increase the returns to human capital and reduce fertility. The subsequent decline in demand for household production (initially the specialization of women) increases the fraction of time spent by women in the labor market and reduces the gender earning gap. De La Croix and Vander Donckt (2010) employ the notion of intra-household bargaining power (called "welfare weight") and analyze how its variations may affect demographic and economic outcomes.

The progress of neoclassical growth models with endogenous fertility provides plausible explanations of the modern experience of economic growth in developed economies. Nonetheless, they do not provide a global understanding of the development process. They are unable to explain some of the most fundamental features of the process of development. They capture neither the recent negative relationship between population growth and income per capita nor the positive effect of income per capita on population growth and the economic factors that triggered the demographic transition. This left the door opened to a new generation of growth theorists (Galor and Weil 2000; Jones 2001; Galor and Moav 2002; Hansen and Prescott 2002; Doepke 2004; Strulik and Weisdorf 2008) to face the challenge of developing a theory consistent with the entire process of development.

[9]In this chapter, the authors do not focus on economic development and leave aside the question of how changes in gender heterogeneity may affect long-run growth.

The Unified Growth Theory

Unified growth theories are endogenous growth theories consistent with the whole process of development – accounting for empirical evidence that has characterized the growth process over longer time horizons in developed and less developed economies.

The Building Blocks of the Theory

Advanced first by Galor and Weil (1999, 2000) and developed by Galor (2005, 2010), the unified growth theory intends to capture, in a single framework, the main characteristics of the transition from the Malthusian era to the modern era, as well as the associated phenomenon of the Great Divergence and Demographic Transition.

The unified growth theory integrates the main features of the Malthusian economy in a context where the sizes of population and technology are linked. First, the increase in technological progress and the capital accumulation counterbalance the negative effect of population growth on income per capita highlighted by the Malthusian theory. As proposed by Galor and Weil (2000):

> . . .during the Malthusian epoch, the dynamical system would have to be characterized by a stable Malthusian steady-state equilibrium, but ultimately due to the evolution of latent state variables in this epoch, the Malthusian steady-state equilibrium would vanish endogenously leaving the arena to the gravitational forces of the emerging Modern Growth Regime.

Galor and Weil (1999, 2000) develop the idea that the acceleration in the rate of technological progress gradually increases the demand for human capital, inducing parents to invest in the quality of their offspring rather than in the quantity. Ultimately, the process of human capital accumulation induces a reduction in fertility rates in response to the increasing growth rate of technological progress. This leads to a demographic transition and sustained growth. The model, therefore, generates a transition from the Malthusian stagnation to the Modern Growth Regime. Later on, models incorporating new mechanisms emerge. Galor and Moav (2002) and Lagerlöf (2003) share similar intuitions by suggesting the existence of innate/inherited preferences in terms of children quality. Based on a unitary approach of the family, Lagerlöf (2003) explains how high-quality preferences may have spread over time and generate higher prosperity and lower fertility – considering changes in gender discrimination in education exogenous. In Cervellati and Sunde (2005), the authors introduce complementary mechanisms/channels based on the relations linking life expectancy, human capital, and technological progress. In a simple model, Strulik and Weisdorf (2008) provide a unified theory that captures the interplay between technological progress, mortality, fertility, and economic growth. Using a two-sector framework with agriculture and industry, the authors demonstrate how fertility responds differently to productivity and income growth between both sectors. Agricultural productivity and income growth make food, goods, and

therefore children, relatively less expensive, while industrial productivity and income growth, on the other hand, makes them relatively more expensive. Common to all these models (and to our model) is the central role played by the quantity-quality substitution in the phase transition. Empirically, the existence of a negative correlation between education and fertility has notably been demonstrated by Becker et al. (Becker et al. 2012) with county-level evidence from 1816 Prussia.

The unified growth theory generates the endogenous driving forces allowing the economy to experience a demographic transition that ultimately led to a takeoff from the era of stagnation toward a state of sustained economic growth. As highlighted in section "Introduction," Western countries experienced similar patterns of economic and demographic transition. This theory, which seems to be consistent with empirical regularities, is based on the interaction between four key elements: the building aspects of the Malthusian theory, the engines of technological progress, the origin of human capital accumulation, and the triggering forces of the demographic transition. The theory suggests that the acceleration in the pace of technological progress increased the importance of human capital. The rise in the demand for human capital and its impact on the accumulation of human capital led to a decline in fertility and to a rise in living standards.

However, one paradox persists. The French-English paradox (Chesnais 1992) raises a central question: why demographic development came so late in England and so early in France, while economic development was early in England and comparatively late in France. One underlying aspect of the development process may be missing.

Complementary Factors: The Role of Female Empowerment

Other central determinants of the development process have been left out of the first attempts at modeling a unified theory of growth. This left the door open to cliometricians and growth theorists to bring to light and explore additional and complementary mechanisms of the transition from stagnation to sustained growth. One such example is the issue of gender.

Gender-related issues have become central to the field of labor economics[10] and economic history (Goldin 2006). Empirical literature on the link between gender equality and economic development is rather abundant (Schultz 1995; Dollar and Gatti 1999; Klasen 2002; Knowles et al. 2002, among many others). However, the contributions remain rare in the field of economic growth. Few growth models explicitly consider the role played by gender on economic development: Galor and Weil (1996), based on the assumptions of different gender abilities; Lagerlöf (2003), taking gender differences as exogenous variables; or more recently De La Croix and Vander Donckt (2010), focusing especially on the pathways by which improvement

[10]Notably the pioneering work of Jacob Mincer (1962) that contributed to the development of economic analysis of the household.

in gender equality may affect fertility are among the few growth theorists who have integrated gender differentiation into their models.

Galor and Weil (1996) have engaged a first step toward a better integration of gender in growth theory by addressing the issue of the relationship between fertility, gender gap in wages, and economic growth with an inter-temporal dimension. Nevertheless, the model focuses on the modern era of economic growth and does not aim at providing a global framework of analysis for the evolution of economies over the entire course of human history. Lagerlöf (2003) sets up a model capturing gender stereotypes in which increasing gender equality can account for the important changes in growth rates of income per capita and population, in a unitary approach of the family. However, the model does not capture the notion of gender decisional empowerment, as noted by De La Croix and Vander Donckt (2010).

The role played by the rise in gender equality has been examined by Diebolt and Perrin (2013b). They argue that female empowerment has been at the origin of the demographic transition and engaged the takeoff to modern economic growth. More specifically, they develop a unified cliometric growth model capturing the interplay between fertility, technology, and income per capita in the transition from stagnation to sustained growth. The model suggests that gender empowerment is a crucial factor of both demographic and economic transition. In particular, the theory points out that the acceleration of skill-biased technological progress generates a positive externality on the level of gender equality. Both wages and gender equality are key variables in the education decision process of individuals. More specifically, higher gender equality reinforces individuals' incentives to acquire skilled human capital. In turn, female choices in terms of time and quality of educational investments increase their endowment in human capital and impact positively the fraction of the subsequent generation of individuals acquiring skilled education. In other words, improvements in technological progress, gender equality, and skilled human capital reinforce each other. Ultimately, the presence of a sufficiently high fraction of skilled individuals in the population yields to sustained economic growth. In the early stage of development, the low rate of technological progress does not provide any incentive to invest in skilled education. Therefore, the fraction of skilled individuals is low and the economy remains trapped in the Malthusian steady-state equilibrium, with low education, low standard of living, and low gender equality. Technological progress is assumed to increase monotonically from generation to generation. Therefore, as technological progress grows, we observe a qualitative change, and the subsequent income effect triggers (temporarily) higher fertility rates. After sufficiently many generations, increases in the returns from investments in skilled education (productivity growth) – driven by the rise in technological progress – makes investing in skilled education more profitable so that gender equality improves. The dynamic system of skilled human capital and gender equality is therefore characterized by multiple steady-state equilibria. Since gender equality becomes high enough, a substantially larger fraction of individuals acquire skilled human capital, which triggers rapid developments and reinforces gender equality. Due to larger educational investments (in terms of time units), the opportunity cost of having children increases and average fertility declines: The demographic transition occurs along

with the process of human capital accumulation. Ultimately, in later stages of development, gender equality and the fraction of skilled individuals converge toward their maximum. Thus, the economy is characterized by the Modern Growth steady-state equilibrium, where living standards are high, gender equality is high, and fertility is low.

Conclusion

The unified theory of growth has been developed as an alternative theory of exogenous and endogenous models that can capture the main characteristics of the process of development in a single framework. The unified growth theory sheds light on the driving forces that enable countries in a state of Malthusian stagnation to take off toward a state of sustained economic growth. In the Malthusian Regime, the economy remains trapped around a substantial level of output. During the Post-Malthusian Regime, the pace of technological progress accelerated under the effect of the increase in the population size and allowed economies to generate a takeoff. In the Modern Growth Regime, the output per capita increases along with the rate of population growth and human-capital accumulation (Galor and Weil 2000). Rapid technological progress, resulting from human capital accumulation, triggers a demographic transition with a constant decrease in fertility rates. The unified growth theory suggests that the transition from stagnation to sustained growth is an "inevitable by-product" (Galor 2011) of the process of development.

The purpose of future cliometric research in the growth theories area is to close the gap between *Geisteswissenschaften* and *Naturwissenschaften*, i.e., to move from the historical *verstehen*, or understanding, side to the economic *erklären*, or explaining, side. Even better, mixing both approaches, facts and stylized facts, may increase knowledge of the past, present and future economic and social development of developed and developing economies (Diebolt 2012; Diebolt and Perrin 2013a).

Preindustrial Economic Growth, ca. 1270–1820

Alexandra M. de Pleijt and Jan Luiten van Zanden

Contents

Abstract

This chapter presents an overview of the current state of the art regarding the trends and causes of preindustrial economic growth in Western Europe between ca. 1270 and 1820. In doing so, the chapter introduces measures of living standards – i.e., real wages and per capita GDP. The Low Countries and England showed more or less stable real wages after the increase in wages in the fourteenth century following the Black Death, whereas real wages elsewhere in Europe declined in the long run. This "Little Divergence" between the North Sea area and the rest of the continent is also evident from estimates on per capita GDP. On the continent, per capita GDP stagnated or declined, whereas Holland and England showed a lot of progress – they were substantially richer in 1750 than in 1500. There were two key

developments in this process. The first is the Black Death, which increased living standards in the countries bordering the North Sea regions due to well-functioning labor and capital markets. The second is the shift to premodern economic growth following the Black Death. The chapter summarizes the causes of the vast increases in living standards in the North Sea region between 1348 and 1820, including human capital formation and international trade.

Keywords
Preindustrial growth · Little divergence · Industrial revolution · North-Western Europe

Introduction

The British Industrial Revolution is arguably the most important break in world history. There is general agreement among economic historians on some aspects of the Industrial Revolution. For instance, the break that it represented was the appearance for the first time of continuous technological progress. However, its timing, location, and causes are a matter of debate. Can we explain the Industrial Revolution by looking at growth in the eighteenth century only, or is a much longer time-span required? Is growth a subnational/regional phenomenon, is the "nation"-state the appropriate unit of analysis, or is growth not limited by "national" borders? Were "efficient" institutions the main cause of the Industrial Revolution, or are there other important determinants of growth that need to be considered? These are highly relevant questions when studying the transition from an economy dominated by Malthusian forces to one characterized by "modern economic growth," as it supposedly occurred in Britain in the eighteenth century.

This chapter presents an overview of the current state of the art regarding the trends and causes of preindustrial economic growth in Western Europe between ca. 1270 and 1820. The first question that is dealt with concerns the location of preindustrial economic growth, for which the concept of the "Little Divergence" is relevant. A substantial body of evidence – starting with the real wage estimates of Allen (2001), and including the new generation of per capita GDP series (Bolt and van Zanden 2014; Fouquet and Broadberry 2015) – points to the fact that there was a divergence in levels of economic performance within Europe between 1500 and 1800. North-Western Europe, notably the Low Countries and England, showed more or less stable real wages after the increase in real wages in the fourteenth century following the Black Death, whereas real wages in Eastern and Southern Europe declined in the long run. In terms of per capita GDP, there is a similar divergence between the North Sea region and the rest of the continent: in the latter, per capita GDP stagnated or declined, whereas Holland and England showed a lot of economic progress: they were substantially richer in 1750 than in 1500 (Broadberry et al. 2015; van Zanden and van Leeuwen 2012).

The "Little Divergence" is also evident from other indicators of economic progress. The latest estimates on urbanization show that cities grew in the North Sea region, whereas city growth slowed down in the rest of Europe (Bosker et al.

2013). Similarly, the development of political institutions (measured by the activity of European Parliaments) declined almost everywhere in Europe between 1500 and 1800, except in the Netherlands and England (van Zanden et al. 2012b). Finally, estimates on per capita book production and rates of literacy and numeracy illustrate that the growth in human capital formation was faster in the North Sea region than elsewhere in Europe (Baten and van Zanden 2008; A'Hearn et al. 2009).

Economic growth between 1300 and 1800 was an international phenomenon originating in the region bordering the North Sea. Of this region, the Low Countries and England formed the core, but parts of Belgium, Northern France, North-West Germany, and Scotland were probably also experiencing growth. The North Sea region was strongly integrated. In the Late middle ages, England, for example, supplied the wool for the textile industry of the Low Countries, which was by then the main source of employment of the large Flemish cities. In the fourteenth–fifteenth centuries, Flanders formed the urban core of this economic system – and England its "periphery." In the sixteenth century, Antwerp took over the role of being the core. After 1585, the urban center moved to Holland, a switch that resulted in the Dutch "Golden Age" of the seventeenth century. After 1650 London gradually replaced Amsterdam as the central hub in the commercial network of North-Western Europe, and the urban core switched to England, as a result of which the Netherlands in the eighteenth century started to specialize in livestock products for the English market, thereby confirming its role as "new" periphery.

The second issue, concerning the beginning and periodization of the process of economic growth in the North Sea region, is related to the above. On the basis of the latest estimates of per capita GDP, a division into three periods can be suggested: before the Black Death ("classic Malthusian economy"), between 1347 and 1820 (slow but consistent growth that was limited to the regions bordering the North Sea region), and after ca. 1820 (rapid "modern" growth that started in England and from there spread to the rest of the continent). In explaining the transition from a Malthusian economy to modern growth, it is necessary to focus on two transformations: the Late Middle Ages, which prompted the "Little Divergence," and the early nineteenth century – the classic Industrial Revolution, which started in Britain and from there spread to the rest of Europe.

The third debate addressed in this chapter concerns the causes of preindustrial economic growth. There are numerous explanations. It has been characterized as "Smithian," as driven by the growth of trade and the increased division of labor made possible by it. The debate about its deep causes, however, focuses on the relevance of institutions – at the level of the state and/or at the level of the household – and the role of human capital formation in explaining the process.

Stylized Facts About Preindustrial Growth in Europe

There are two ways to measure economic performance in Europe in the long run. The first concerns the development of real wages. The classic paper is by Allen (2001), who estimated the real earnings of men in nine leading European cities from the Middle Ages up to the World War I. The second way to estimate levels of

economic development in the long run is per capita gross domestic product (henceforth GDP). This section briefly looks at the real wage series by Allen and the estimates of per capita GDP that have become available recently. Both indicators of preindustrial economic growth show that there was a "Little Divergence" in Europe between 1347 and 1800. Growth in this period was largely concentrated in the North Sea region, notably in Holland and England. The North Sea area was already dynamic during the Middle Ages, when Flanders became the urban center of North-West Europe. It continued to perform well in the one and a half centuries after the shock of the Black Death. In the sixteenth century, economic growth was likely concentrated in the southern parts of the Netherlands, and in the seventeenth century, the center moved to the province of Holland. In the second half of the seventeenth century/early seventeenth century, Britain took the lead. At the same time, living standards declined (e.g., Italy) or stagnated (e.g., Spain) elsewhere in Europe.

Real Wages

The divergence between the North Sea region and the rest of Western Europe is first of all clear from evidence on real wages. Allen (2001) developed a method to estimate the real wages of unskilled and skilled craftsmen (building workers) for nine leading European cities between 1400 and 1914. Figure 1 shows his results for six European countries. In the fifteenth century, real wages were relatively high across Europe, which can be attributed to the Black Death creating labor shortages.

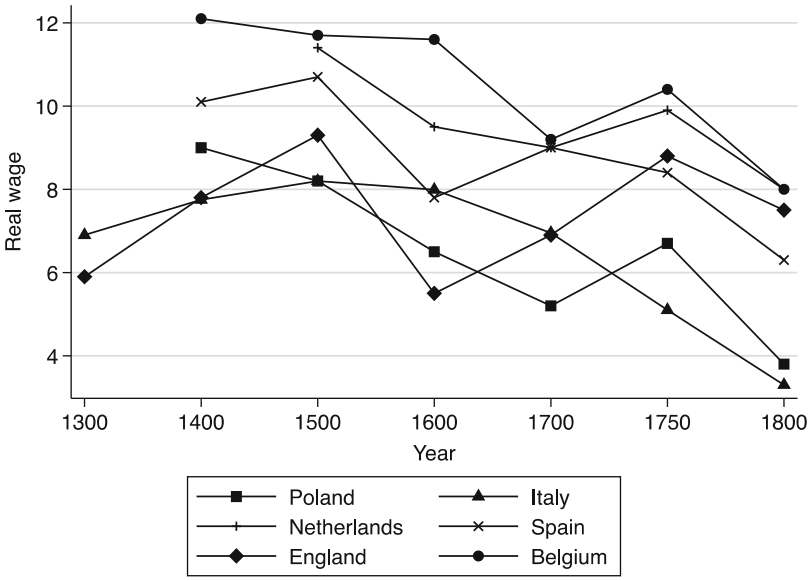

Fig. 1 Real wages in Western Europe, 1300–1800. (Source: Allen 2003)

Thereafter, however, there is long-term stabilization of living standards in the North Sea region (Belgium, the Netherlands, and England) in the centuries following the Black Death. Elsewhere in Europe, a long-term decline began and lasted into the late eighteenth century. According to Allen (2001), the Little Divergence started in the seventeenth century when the series for England (i.e., London) starts to show an upward trend. Pamuk (2006) and van Zanden (2009) date it earlier. The difference between the wages in the North Sea area and the rest of Europe already began to emerge during the second half of the fifteenth century.

The wage series by Allen (2001) has been challenged on several grounds. The real wages have been calculated by taking day wages and multiplying them by an assumed number of days worked per year (250) to determine annual income. This is then compared to the budget needed for a family of four people (man, woman, and two children) to derive the purchasing power of those wages over time and places. There are two versions of this basket. Initially, Allen reconstructed a respectability basket, close to what he assumed to be the actual budget in early modern Europe. When this basket was used in comparison with other regions of the world – such as Japan and China – it proved to be too generous, and a more austere barebones basket was constructed, which contained the basic essentials to survive (Allen et al. 2011). The problem with any standard of living is of course that it does not really fit the historical reality of all societies concerned – and perhaps, because it is some kind of average, no society in particular. This is inevitable in any attempt to make large international comparisons. It has been argued that the number of days worked per year (250) is too high (Hatcher 2011; Stephenson 2018b), or that the wage data used are not representative (Malanima 2011; Stephenson 2018a). Moreover, the wages used only capture the male population, and less is known about how much females worked and earned in the past. In a pioneering study, Humphries and Weisdorf (2015) have estimated the real earnings of women in England, and currently, attempts are being made to extend this research to Western Europe as a whole (De Pleijt and van Zanden 2018).

Per Capita GDP

Another way to measure economic performance in the past concerns per capita GDP. Economic historians since the rise of "New Economic History" have worked on a grand project to reconstruct the long-term evolution of the various parts of the world economy in the past millennium. Simon Kuznets in the 1950s and 1960s (building on work by, among others, Colin Clark) created the first international comparative studies to chart the development of GDP and its components in the long run (Clark 1940; Kuznets 1966). This work was continued by many economic historians. Angus Maddison became the central "hub" of this research, publishing various syntheses of the work in historical national accounting that was undertaken globally (Maddison 2001). This work is now carried out by the Maddison Project – a collaboration of the specialists in the field, coordinated by scholars from the University of Groningen (Maddison's home base). It synthesizes the research by many

economic historians who have combined data on population, employment structure, the rate of urbanization, nominal wages, prices, real wages, output levels in different industries, and many other sources to estimate GDP and its components for historical societies. Sometimes this is based on very rich historical sources – near-complete censuses such as the *Domesday Book* for post-Conquest England, the Catasto for Tuscany in 1427, or the Informacie for Holland in 1514. In other cases, indirect proxies have to be used to estimate the evolution of real income via, for example, real wages, which determine the demand for foodstuffs. Because different definitions of GDP via the output, demand, and income approach have to result in identical levels of real output and income, a lot of cross-checking of the results is possible, making the estimates more robust.

The Maddison project has resulted in a systematic comparison of estimates of GDP per capita, often going back to the (European) Middle Ages, which allows us to shed new light on the transition to modern economic growth. For England, the work by Broadberry et al. (2015) has produced annual estimates of GDP and its components from the 1270s up to the 1870s, as well as one point estimate for the year of the *Domesday Book* (1086). Likewise, van Zanden and van Leeuwen (2012) have collected comparable data for Holland between 1347 and 1807. Similar projects have been carried out for Italy by Malanima (2011), for Spain by Alvarez-Nogal and Prados de la Escosura (2013), for France by Ridolfi (2016), and for Sweden by Krantz (2017) and Schön and Krantz (2015). What is new about this research is that it has produced annual estimates of GDP per capita from the fourteenth century onward, making it possible to analyze the underlying trends more systematically than the "older" research that usually resulted in a number of benchmark estimates. We can now confidently observe breaks in growth and long-term performance trends.

As Fig. 2 shows, the "Little Divergence" is also very clear from the evidence on GDP per capita. The growth in real GDP per capita between 1300 and 1800 was largely restricted to the countries bordering the North Sea: Flanders, Holland, and England. In 1750, just before the start of the Industrial Revolution, the level of GDP per capita in Holland and England had increased to 2355 and 1666 (international) dollars of 1990, respectively, compared to 876 and 919 dollar in 1347 (just before the arrival of the Black Death) and 1454 and 1134 in 1500. Contrary to what happened in the North Sea region, there was no economic growth in Southern and Central Europe before the nineteenth century (Bolt and van Zanden 2014; Fouquet and Broadberry 2015).

The origins of the Little Divergence are of special interest because after the exogenous shock of the Black Death, real incomes in Britain and the Low Countries did not return to pre-plague levels, but remained much higher than before (ca. 20–40%), and, especially in the case of Holland, began to show a consistent rate of growth, which resulted in a doubling of GDP per capita over the next 250 years (not taking into account the effect of the Black Death). As Fig. 2 shows, the English growth experience was somewhat different. Between 1400 and 1600, real incomes fluctuated around a plateau of about 1000 dollars (against 700–800 dollars before 1347), and only in the second half of the seventeenth century did

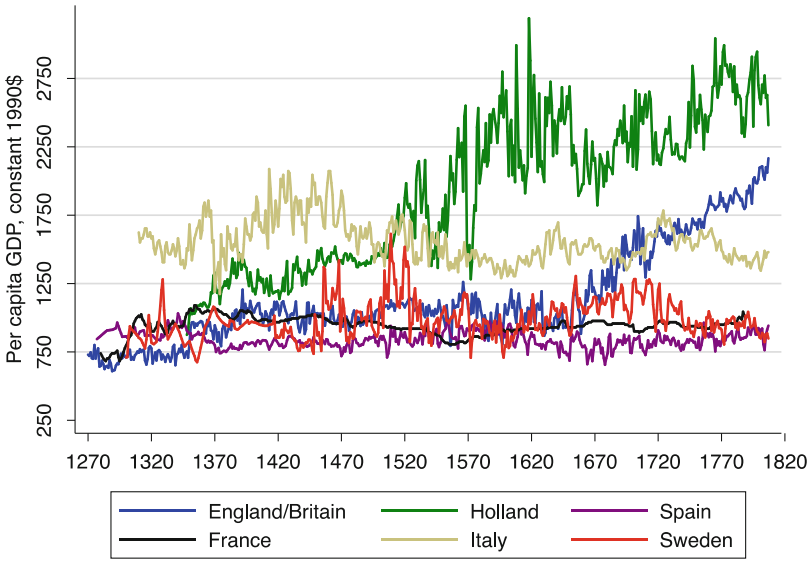

Fig. 2 Per capita GDP in Western Europe, 1270–1807. (Sources: Broadberry et al. 2015; Van Zanden and Van Leeuwen 2012; Malanima 2011; Alvarez-Nogal and Prados de la Escosura 2013; Ridolfi 2016; Krantz 2017; Schön and Krantz 2015)

growth really take off. Less is known about growth in Belgium, but the few point estimates that have been made by Buyst (2011) suggest that it followed a third pattern. Its level was fairly high at the start of the sixteenth century, there was some per capita income growth until the 1560s–1570s, but the late sixteenth and seventeenth centuries saw a decline of GDP per capita. In other parts of Europe (e.g., Spain), the collapse of population did not have similar positive effects on real incomes, which, as will be discussed below, tells us something about the quality of institutions in the North Sea region.

The per capita GDP series clearly demonstrate that the Black Death led to positive income growth in Holland and England/Britain. However, as Fig. 2 shows, a related phenomenon concerns the dynamics within the North Sea region itself. The late sixteenth and early seventeenth centuries saw a decline of GDP per capita in Belgium due to the loss of industrial and tertiary activities to the North of the Netherlands. The decline of per capita GDP in Belgium and the rise of the Netherlands were part of the same process, in which the urban core of the North Sea region moved from Antwerp to Amsterdam. The next shift in the urban system, from Amsterdam to London, started after about 1670 and had similar consequences – i.e., England started to grow, whereas Holland stagnated at a fairly high level.

Therefore, each country knew its separate growth cycles, characterized by a period of rapid growth followed by (and/or preceded by) long periods of stagnation. Flanders boomed in the Late Middle Ages, but declined after about 1560; Holland had its most spectacular growth spurt during its Golden Age (1585–1670), but slowed down in the eighteenth century; and, finally, English real incomes rose

rapidly after 1670. Sweden can be interpreted as perhaps demonstrating what happened to a region that (partly) belonged to the North Sea area but did not at any moment become the industrial and commercial core of the region.

Explanations for Preindustrial Economic Growth

Why did the Black Death led to an increase in per capita GDP in the North Sea region but not elsewhere in Europe? And what accounts for the phase of pre-industrial economic growth in the Low Countries and England between 1347 and 1800? This section gives a brief overview of the current state of the art.

The Black Death

To consider the effect of the Black Death, Fig. 3 gives a brief look at the "Malthusian" economy in the period before 1347. This series of GDP per capita reconstructed by Broadberry et al. (2015) shows no growth before 1348. The trend is slightly negative, mainly due to serious crises in the 1280s and the 1310s, and population growth seems to matter a lot. The population increases from 4.2 million in 1250 to 4.8 million in 1290, when GDP per capita registers a declining trend; after the crisis of the 1280s, the population starts to fall (to about 4.6 million in 1340), which results in a stabilization of real income, albeit with huge fluctuations, such as the "Great Famine" of the 1320s. In short, this economy shows distinct Malthusian

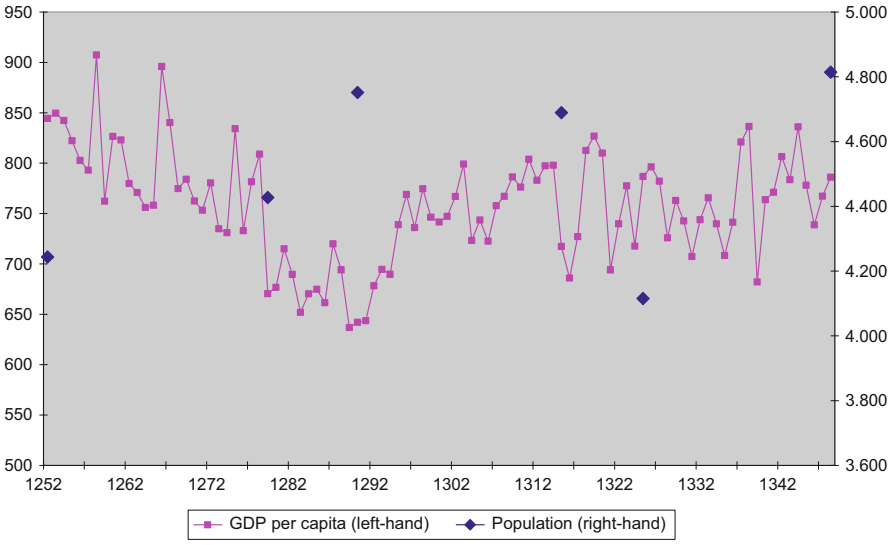

Fig. 3 English per capita GDP and population growth, 1252–1347. (Sources: Broadberry et al. 2015)

features, with a decline of real GDP during the (last stage of the) great Medieval boom (1080–1280), during which the population increased rapidly, and stability after the 1280s because population growth came to a halt. The level of GDP per capita is, however, clearly above subsistence levels, especially at the start of this century. During the 1250s, the English GDP per head of 800–850 dollars is between at least twice and almost thrice subsistence level (of 300–350 dollars) and quite high by international standards – only the more wealthy ancient economies reached similar levels, if one believes the recent estimates of pre-1000 GDP (Bolt and Van Zanden 2014).

The shock of the Black Death changed everything. As shown in the previous section, the average level of per capita GDP in Holland and England was significantly higher after the Black Death than in the period before. In England, it had increased from an average of 714 dollars before the arrival of the Black Death to 993 dollars in the period 1348–1500. Something similar happened in Holland. Van Zanden and van Leeuwen (2012) only have one point-estimate for 1347, but this suggests that it had increased from 876 dollars before the Black Death to 1301 dollars thereafter. In Spain, on the contrary, per capita GDP hardly responded to the decline in population: it fell from 900 dollars between 1270 and 1347 to 816 dollars between 1347 and 1500. The Black Death increased real incomes in Italy, but there, it gradually fell back to its pre-plague level over the course of the fifteenth century.

Why did the North Sea area respond so strongly to the population decline due to the Black Death, resulting in an immediate and sizable increase in GDP per capita? The population of Europe declined by about one-third to one-half, which led to major changes in relative prices. Wages went up, capital and land became relatively cheap, which, standard economic theory predicts, impacted the relative mix of inputs used. Labor productivity increased due to the larger availability of land and capital, and GDP per capita grew proportionally. This is arguably how a fully developed market economy would respond to such a crisis. That the North Sea area reacted in this way, therefore, meant that it behaved as a market economy. In other words, factor markets (markets for labor, land, and capital) and product markets were apparently developed to such an extent that the Black Death had such an impact on GDP (van Bavel and van Zanden 2004).

The point that the North Sea region in the Late Middle Ages was already characterized by highly developed factor markets has been made in the literature. A large part of the population – perhaps as much as 40–50% – was dependent on wage labor, both in the countryside and in the cities (Dyer 1989). Perhaps the rural labor market was even more developed than those in the cities (Van Bavel 2006). Both men and women were earning a wage income, and the gender wage gap was relatively low (women may have earned about 80% of the wages of men), stimulating the labor market participation of women (Van Zanden 2011; Humphries and Weisdorf 2015). Capital markets were also well developed, in particular in the Low Countries, with (after 1348 in particular) low interest rates (5–6% annually) and large-scale participation again by both men and women (Van Zanden et al. 2012a). Finally, on land markets, the leasing of land became increasingly popular, further adding to the commercialization of agriculture. Summing up, the fact that the

economies of the North Sea area responded to the shock of the Black Death in the way that it did appears to be rooted in an institutional structure with "thick" markets, which were used intensively.

The real issue is, arguably, why the other European countries did not respond in a similar way. The simple answer is that there were no comparable market economies. Alvarez-Nogal and Prados de la Escosura (2013) have addressed this issue for the case of Spain and conclude that the decline of GDP per capita after 1348 was due to the "frontier" character of the Spanish economy. The marketing system that had developed before 1347 could not be maintained anymore by the sharply reduced population. As a result, markets contracted, commercialization declined, and GDP per capita decreased. For Sweden, Krantz (2017) suggested a similar explanation of the absence of a Black Death bonus.

However, the marginalization of markets in a region with low population densities cannot be the explanation for the response of the Italian economy. According to the estimates by Malanima (2011), GDP per capita of Northern Italy (which is actually Tuscany in this period, as the data are from this region) initially increased by about 20–30% in the two decades following 1348 and then suddenly returned to the pre-1348 level for the rest of the fifteenth century. Larry Epstein (1991, 2001) has argued that institutional constraints related to the different relationship between city and countryside help to explain the relative stagnation of the fifteenth-century Tuscan economy. He argued that Florence was exploiting the Contado via taxation and other institutions that limited market participation in the countryside. Recent research seems to corroborate this view: the income gap between town and countryside was extremely high in Tuscany, and labor and land markets were relatively underdeveloped (Van Zanden and Felice 2017). In the countryside, the system of mezzadria, which spread rapidly in the fifteenth century, reflected those constraints, but it is equally striking that the rural labor market was extremely thin.

Summing up, the different responses to the Black Death were the consequence of different institutional settings and economic systems. Other studies that compared the impact of the Black Death on Late Medieval Egypt and England (Borsch 2005) or Central Europe and Western Europe/England (Brenner 1989) arrive at similar conclusions. The economic reaction of the North Sea area, where the well-developed market economy made possible a transition to a much higher level of GDP per capita, was probably exceptional. The deep roots of this peculiar development are probably not found in its specific political institutions, as these did not differ much between the North Sea area and the rest of Western Europe. The whole of Western Europe knew "feudal" sociopolitical relations, in which the power of kings, princes, and dukes was constrained by independent cities (strong in Northern Italy but also in the Low Countries) and by the integrative power of the Church (strong in all parts of the Latin West). The civil society of guilds, brotherhoods, and other religious and nonreligious institutions was not fundamentally different in the North from the South. An institutional "Little Divergence" between the North Sea region and the rest of Western Europe would only emerge in the sixteenth or even seventeenth century, when Parliaments acquired a much stronger position in the North-Western parts of Europe than in the rest of Europe, where absolutism arose (van Zanden et al.

2012b). Although political institutions may have enhanced the phases of growth after the sixteenth century, they do not seem to have made the difference in the centuries following the Black Death (de Pleijt and van Zanden 2016).

Explanations for the "Little Divergence"

Even more important than the response to the exogenous shock of the Black Death was the fact that it set in motion a process of preindustrial economic growth in Holland and England that persisted until the end of the eighteenth century. It is, as far as we know, the first time in world history that a region went through such an enduring process of sustained growth. Why were the Low Countries and England, already long before 1800, able to break through Malthusian constraints and generate a process of almost continuous economic growth? Various hypotheses have been suggested: institutional change (two versions: sociopolitical institutions such as Parliaments, demographic institutions such as the European Marriage Pattern); the impact of the growth of overseas – in particular – transatlantic trade (Allen 2003; Acemoglu et al. 2005); and the effect of human capital formation (Baten and Van Zanden 2008). Within the context of this paper, we can only briefly review some of the literature.

Premodern economic growth has been characterized as Smithian, after Adam Smith, who was the first to systematically analyze the process. He stressed the role played by the growth of international trade, urbanization, and specialization as the main drivers of the process. By contrast, growth after (and during) the Industrial Revolution is in this view primarily driven by technological change, the result of new ideas, and the application of science to production processes. In the Smithian approach, processes of structural change clearly played a large role (Broadberry et al. 2013). The North Sea region as a whole managed to capture an increasingly large share of international services and manufacturing output with high levels of value added. By 1300, only Flanders was highly urbanized – thanks to the combination of a highly specialized woollen textile industry exporting to large parts of Europe and international services mainly supplied by the commercial hub of Bruges. The ups and downs within the North Sea area in terms of GDP per capita are mainly linked to the spatial changes in the concentration of these high value-added activities – from Flanders to Antwerp to Amsterdam to London, respectively. At the same time, the relative size of these activities was growing, as the international markets for which they were catering expanded, until, in the seventeenth and eighteenth century, large parts of the world economy were linked to the central hubs in Amsterdam and London. The fact that other regions of Europe experienced GDP per capita decline – in particular, Northern Italy, but also Poland (Malinowski and Van Zanden 2017) – can be linked to the concentration of these activities in North-Western Europe, at the expense of Tuscany and Venice.

Another influential body of literature argues that it is the specific political economy of Western Europe, and in particular the balance of power between sovereigns and societal interests represented in Parliaments, that created the right

institutional conditions for Europe's specific growth pattern. Two versions of this hypothesis can be distinguished. The first one stresses the Glorious Revolution as the watershed between "absolutism" and some form of "parliamentary" government and sees this event as the main cause of the Industrial Revolution of the eighteenth century (North and Weingast 1989; Acemoglu and Robinson 2012). The other one argues that these institutions that resurfaced in 1688 had a much longer history and that forms of power sharing between the Prince and his (organized) subjects go back to the Middle Ages and are rooted in the feudal power structures of that period (Van Zanden et al. 2012b). The general idea shared by this literature is that the sovereign had to be constrained in order to protect the property rights of citizens. In republican systems with a strong Parliament, property rights were more secure than in states ruled by absolutist kings. This translated into, for example, lower interest rates at the capital market (Hoffman and Norberg 1994). Clark (1996) contests this view, arguing that there is little evidence of significant insecurity among private owners before 1688.

Mokyr (2002, 2009) does not refute the importance of efficient institutions for economic growth. However, he argues that the presence of efficient institutions alone was not enough for an economic takeoff to take hold: the Industrial Revolution was the result of an interaction between favorable institutions and the arrival of a new set of "ideas and beliefs." The Scientific Revolution of the seventeenth century produced "useful knowledge," such as knowledge about mathematics, that laid the foundation for "Industrial Enlightenment." This Industrial Enlightenment, which he defines as "the application of scientific and experimental methods to the study of technology" (Mokyr 2009, p. 29), connected the Scientific Revolution to the waves of technological innovations after 1760. In other words, the takeoff of England depended on what people knew and believed, which in turn affected their economic behavior.

An equally influential body of literature suggests that the root causes of "modern economic growth" should be found in an interplay of demographic and economic changes, affecting the "quality-quantity" trade-off (Becker 1981; Galor 2011) and resulting, on the one hand, in limitations on fertility and population growth and increased human capital formation on the other. The emergence of the European Marriage Pattern (EMP) in the North Sea area in the Late Middle Ages has been hypothesized as the crucial demographic change, which also resulted in increased investment in education of the fewer children from smaller families (De Moor and Van Zanden 2010; Voigtländer and Voth 2013). An important part of the mechanism was the increase in the average age of marriage of women (and men), which both limited fertility and increased opportunities for human capital formation.

The explanation focusing on the role of the EMP has, however, not been accepted generally. The data collected by Humphries and Weisdorf (2015) shows that wages for unmarried servants were developing less favorably than those of married women who worked for day wages in the century after the Black Death. From this they have concluded that it was not rational for women to postpone marriage. Dennison and Ogilvie (2014) were even more outspoken in their criticism of the European

Marriage Pattern, as they did not find a link between marriage patterns and economic performance in Early Modern Europe. Subsequently, however, Dennison and Ogilvie's results have been challenged. Carmichael et al. (2016) have argued that they did not conceptualize the European Marriage Pattern correctly. The focus of Dennison and Ogilvie was on the share of singles, the age of marriage of females, and the share of nuclear families, whereas attention should be on the broader context of how marriage responds to economic circumstances (Carmichael et al. 2016; Dennison and Ogilvie 2016).

Unified Growth Theory and related literature points to the importance of human capital formation for economic growth in general and the transition from Malthusian stagnation to Kuznetsian "modern economic growth" in particular (Galor 2011). From the Late Middle Ages onward, Western Europe saw a strong rise of literacy, numeracy, and schooling in general, which has also been attributed to social and religious changes, such as the Modern Devotion in the Low Countries (Akcomak et al. 2016) and the Reformation (Becker and Woessmann 2009). For England, a "first educational revolution" has been documented, which began in the fifteenth century and continued until the middle of the seventeenth century (Hoeppner Moran 1985; Orme 2006). But industrialization as such was not clearly related to rising literacy, as the English case demonstrates. There is increased evidence that in regions where the first Industrial Revolution was concentrated (in North-Western England), levels of literacy declined during the first stages of the process (Stephens 1987). In England, the eighteenth century was more generally a period in which levels of schooling stagnated, albeit at a relatively high level by international standards. This suggests that human capital formation may have played a role in creating the preconditions for industrialization but that this process itself was not driven by growing literacy and numeracy. Mokyr (2005) and Meisenzahl and Mokyr (2012) suggest that in this stage of industrialization, it was not the general level of education that mattered, but the skills of a small elite of educated and highly trained engineers and craftsmen, which played a key role in the wave of innovations in the eighteenth century.

Conclusion

This chapter reviewed the process of preindustrial growth, which occurred in the North Sea area between the Black Death and the onset of industrialization in eighteenth-century England. The latter process resulted in an acceleration of economic growth at about 1820, implying that the slow but sustained growth of GDP per capita that was characteristic of preindustrial growth continued between 1347 and 1820. The debate about the exact causes of the process is still going on, but institutional explanations, related to the organization of the state and the household, play a large role in it. Human capital formation, useful knowledge, the Enlightenment, and, last but not least, international trade also figure prominently in this debate about the "preconditions" of the Industrial Revolution.

The Industrial Revolution: A Cliometric Perspective

Gregory Clark

Contents

Abstract

The Industrial Revolution in England represented most importantly a change in the growth rate of the efficiency of the economy from close to zero in the years before 1800 to rates typical of those for modern England or the USA by 1860. This chapter details the overall change in productivity growth rates and shows also how this created an even greater increase in income per capita from induced capital accumulation. It also details the sectoral sources of this growth. Lastly, the chapter considers how this fundamental economic transformation might be explained as a function of institutions, ideas, demography, and human capital investments.

Introduction

Much is known of the story of the Industrial Revolution: the innovations in industry, the enclosure of the common fields, the turnpike trusts, the growth of cities, the spread of railways, the people, and the personalities. This essay, however, concerns the quantitative underpinning of the Industrial Revolution and what can be learned of its nature from such a quantitative analysis.

The first issue is the overall rate of growth of the macroeconomic aggregates for this period: output per person, income per person, the capital stock per person, the average wage, returns to capital, and land rents. The traditional approach to estimating output has been through estimating the sectoral outputs of the economy: agriculture, industry, transport, services, and government.[1] Table 1 shows these aggregate estimates for benchmark years. However, such estimates are still quite fragile in some areas.[2] Thus, Table 1 shows that the output-based estimates of GDP show a faster rise of output in the Industrial Revolution era than do estimates based on the payments to the factors of production: labor, land, and capital. The factor payments approach is based on an assumption of a constant number of hours worked per worker over the years 1700–1870. If hours increased in the Industrial Revolution era, then growth could have been somewhat faster than shown in Table 1. However, there is no strong evidence of any substantial increase in hours in these years. Already in the late eighteenth century, a day of work for building workers is assumed in accounts to be 10 h.[3]

Whatever series more accurately reflects the growth of output, the data is very clear that in the eighteenth century, economic growth was slow at a rate of less than 0.3% per capita per year (and likely only 0.17%) and only moved upward toward modern rates at the beginning of the nineteenth century. But even in the later years of the classic Industrial Revolution era, output per person was growing at only about a third the typical rate of growth in the modern economy.

The slow growth rates in the early years of the Industrial Revolution explains why none of the first generations of political economists had any idea of the momentous transformation of economic possibilities that was occurring all around them. None of Adam Smith's *The Wealth of Nations* (1776), Thomas Robert Malthus' *An Essay on the Principle of Population* (1798), David Ricardo's *On the Principles of Political Economy and Taxation* (1821), or James Mills' *Elements of Political Economy* (1821) contains any hint of the growth possibilities unleashed by the Industrial Revolution. Indeed, the very term *Industrial Revolution* did not enter currency until the 1880s.

[1]The contributors here included Deane and Cole (1962), Crafts (1985), Crafts and Harley (1992), and Broadberry et al. (2014).

[2]These estimates tend to assume large increases in agricultural output so that implied efficiency growth in agriculture is at a faster rate for the economy as a whole during the Industrial Revolution. Evidence from prices, wages, land rents, and capital returns in agriculture does not support such an optimistic assessment.

[3]Clark (2005).

Table 1 Estimates of growth in the industrial revolution era

Decade	N[a]	Real GDP[a]	Real GDP/N[a]	Net national income[b]	NNI/N[b]
1700s	100	100	100	100	100
1760s	122	144	117	133	110
1800s	176	234	133	195	118
1860s	381	807	212	610	170

[b]England

At the aggregate level, the transformation the Industrial Revolution represents is very simple. The growth of output per person in modern economies has two major proximate sources: more capital per worker and more efficiency in translating input into output. At the proximate level, all growth since the Industrial Revolution can be decomposed as

$$g_y = ag_k + g_A \tag{1}$$

where g_y is the growth of output per worker hour, a is the share of capital in national incomes, g_k is the growth of the capital stock per worker, and g_A is the growth rate of efficiency. Since the onset of the Industrial Revolution, the capital stock has grown roughly as rapidly as output. Also, the share of capital in all earnings has remained about a quarter. Figure 1, for example, shows the earning shares of labor, capital, and land in England 1750–2000. Thus, only about a quarter of all modern growth in income per person comes directly from physical capital. The rest is a steady rise in the measured efficiency of the economy.

The Industrial Revolution fits squarely into this modern growth pattern. Indeed, as Table 2 shows, efficiency was more heavily responsible for growth during the Industrial Revolution than at any time since.[4] Increased investments in physical capital per worker in England 1760–1860 were relatively unimportant in explaining the overall growth of output per worker. Capital per worker rose no faster than output per worker so that from the onset of modern growth, efficiency growth dominated.

While Eq. 1 suggests that efficiency growth and physical capital accumulation are independent sources of growth, in practice in market economies there has been a strong correlation between the two proximate sources of growth. Economies with substantial efficiency growth are also those with substantial growth rates of physical capital. Something links these two sources of growth.

Some economists, most notably Paul Romer, have theorized that this correlation derives from physical capital accumulation creating substantial external benefits not

[4]This is because a significant drag on the growth of output per person in the Industrial Revolution era was the decline in farmland per person. Since 1870, the landshare in all incomes became so modest that this drag became unimportant.

[b]England

captured by the investors in capital (Romer 1986). However, for this explanation to work, there would have to be $3 of external benefits accruing to physical capital investments for every $1 of privately captured benefit. Most of the modern physical capital stock, however, is still such mundane stuff as houses, shops, warehouses, factories, roads, bridges, and water and sewer systems. These types of investment we would not expect to generate substantial external benefits. So, if productivity advance is systematically associated with the growth of the stock of such physical capital, there must be another mechanism.

The most plausible one is that the association of physical capital accumulation with efficiency advance stems just from the effects of efficiency advance on increasing the marginal product of capital. In a world of relatively constant real interest rates since the Industrial Revolution, such a rising marginal product will induce more investment. And indeed, if the economy is roughly Cobb-Douglas in its production

structure, efficiency advances will induce a growth of the physical capital stock per person at a rate equal to the growth of output per person so that the capital–output ratio is constant. This is to a first order what we observe since the Industrial Revolution.

Thus, at a deeper level, all modern growth seemingly stems from this unexplained rise in economic efficiency as a product of a rise in knowledge about production processes. Somehow, after 1780, investment in such knowledge increased, or enquiry became much more effective in creating innovation.

Before the Industrial Revolution, we find no sign of any equivalent efficiency advances. This is true globally all the way from 10,000 BC to 1800, where we can measure the implied rate of productivity advance just from the rate of growth of population. In this long interval, average estimated rates of efficiency advance are 0.01% per year or less. We know this because we can assume before the Industrial Revolution, because of the Malthusian trap, that output per person and capital per person was in the long run constant. In that case, any gains in efficiency will be absorbed by population growth according to the formula[5]

$$g_A = cg_N \tag{2}$$

where c is the share of land in national income and g_N the rate of population growth.

We can thus approximate efficiency growth rates from population growth rates if we look at sufficiently long intervals. Table 3 shows these calculations at a world level. Implied rates of technological advance are always extremely slow even in the 250 years leading up to the Industrial Revolution.

But it is also true that implied rates of technological advance are also slow for those economies where we can measure actual efficiency levels before 1800 through measurements of the real payments to factors. Figure 2 shows the implied efficiency in England from 1250 to 2000 calculated from the formula

Table 3 Population and technological advance at the world level, 130,000 B.C. to 1800

Year	Population (millions)	Population growth rate (%)	Technology growth rate (%)
130,000 BC	0.1	–	–
10,000 BC	7	0.004	0.001
1 AD	300	0.038	0.009
1000 AD	310	0.003	0.001
1250 AD	400	0.102	0.025

Source: Clark (2007a, Table 7.1)

[5]For a more detailed explanation, see Clark (2007a, pp. 379–382).

Fig. 2 Estimated efficiency of the english economy, 1250–2000 (Source: Clark 2010)

$$A = \frac{r^a p_k^a w^b s^c}{p} \tag{3}$$

where A indexes economic efficiency, p is an index of output prices, r is the real return on capital, p_k is an index of capital goods prices, w is an index of real wages, and s is an index of land rents. a, b, and c are the shares of each input type in national incomes. As can be seen, there is, surprisingly, in England no sign of any significant improvement in the efficiency of the economy all the way from 1250 to 1800. Only around 1800 does the modern age of steady efficiency advance appear. Before that, the measured efficiency of the economy fluctuated, peaking around 1450 but with almost no upward trend.

The Industrial Revolution thus seems to represent a singularity, a unique break in world history but also an event where we know clearly what we have to explain. Why did the rate of expansion of knowledge about production efficiency increase so dramatically in England around 1800? Figure 3 shows that the upturn in productivity growth rates can be located to the 1780s/1790s. That upturn is preceded by seven decades in which the average annual productivity growth rate was a mere 0.14% per year, fast by the standards of the preindustrial world but glacially slow in modern terms. Overall, productivity growth rates from 1780–1789 to 1860–1869 averaged 0.58% per year, more than half way to fully modern levels.

We also know what sectors contributed most of the productivity advance during this period. For each sector, we can calculate an efficiency growth rate from the formula (3), in growth rate terms,

$$g_{A_j} = -g_{p_j} + a_j g_{r_j} + a_j p_{kj} + b_j g_{w_j} + c_j g_{s_j} \tag{4}$$

where j indicates each sector. To implement the formula by sector in this way, however, where we use output prices as p_j, would require being able to measure the capital, labor, and land embodied in all the inputs purchased by each sector. For coal mining, we would need to know the shares of capital, labor, and land embodied

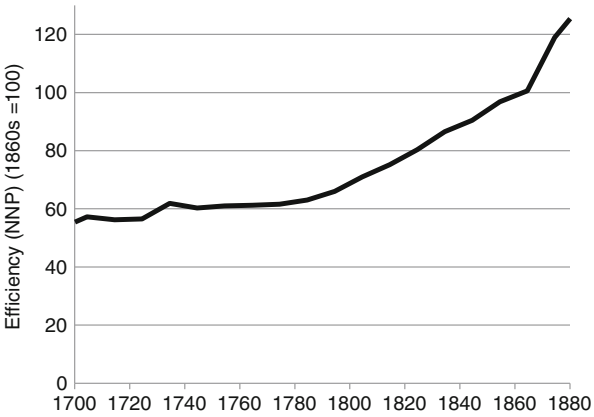

Fig. 3 Efficiency levels, England, 1700–1880 (Source: Clark 2010)

in horse feed, bricks, pit timbers, and steam engines. A more feasible procedure is one where we measure efficiency where p_j measures just the value added in the industry, the difference between the value per unit of output and the cost of purchased inputs.

In this case, national productivity growth will be related to productivity advances in individual sectors through the equation

$$g_A = \sum \theta_j g_{Aj} \tag{5}$$

where g_{Aj} is the growth rate of productivity by sector and θ_j is the share of j in total value added in the economy.[6] These results are shown in Table 4.

Textiles contributed nearly half, 43%, of all measured productivity advance. Improvements in transport, mainly the introduction of the railway, was the next biggest source of advance, contributing 20%. Agriculture, ironically, also contributed almost 20%. Coal, iron, and steel were in themselves minor contributions despite the fame of these sectors and their innovations in this period and despite the huge growth in coal and iron production. Productivity growth in the half of the economy not covered in Table 4 was modest, less than 0.20% per year.

[6]Another procedure to measure productivity growth at the sectoral level is to treat the major inputs in the same way as capital, labor, and land and measure efficiency growth as

$$g_{A_j} = -g_{p_j} + a_j g_{r_j} + a_j p_{kj} + b_j g_{w_j} + c_j g_{s_j} + d g_{m_j}$$

where d is the share of purchased inputs in all costs and m indexes the price of such inputs. In this case,

$$g_A = \sum \varphi_j g_{Aj}$$

where φ is the ratio of sales in each industry to national income. $\sum \varphi_j > 1$ since some output is used as input into other industries and not for consumption or investment. This approach to measuring Industrial Revolution productivity advance was pioneered by McCloskey (1981).

Table 4 Sources of industrial revolution efficiency advance, 1780s–1860s

Sector	Efficiency growth rate (%)	Share of value added	Contribution to national efficiency growth rate (% per year)
All textiles	2.3	0.11	0.25
Iron and steel	1.8	0.01	0.02
Coal mining	0.2	0.02	0.00
Transport	1.5	0.08	0.12
Agriculture	0.4	0.30	0.11
Identified advance	–	0.51	0.49
Whole economy	–	1.00	0.58

Source: Clark (2007a, Table 12.1)

The decomposition in Table 4 establishes some things already. The Industrial Revolution has been thought of by some as essentially consisting of the arrival of the first of what have been called *general-purpose technologies*, the steam engine. *General-purpose technologies (GPTs)*, a rather nebulous concept, have been variously defined. They can be loosely thought of as innovations that have pervasive application throughout the economy, that go through a prolonged period of improvement, and that spawn further innovation in the sectors in which they are employed.[7] Various GPTs have been identified such as steam power in the Industrial Revolution, the introduction of electricity, and the recent information revolution.

Steam power in England certainly permeated a number of areas in the Industrial Revolution. It was important in coal mining, on the railroads, and in powering the new textile factories. The steam engine itself underwent a long process of improvement in thermal efficiency and in the ratio of power to weight from its first introduction by Thomas Newcomen in 1707–1712 to the 1880s. The earliest engines had a thermal efficiency as low as 0.5%, while those of the 1880s could achieve thermal efficiencies of 25%. The steam engine was associated also with the widespread use of fossil energy in the economy to replace wind, water, and animal power sources in transport, home heating, and manufacturing. Output of the coal mining industry rose from Table 4 suggests, however, that whatever role steam power played in economy-wide productivity advance after the 1860s, its role up to then in the new productivity advance of the Industrial Revolution was minor. Coal mining and iron and steel production contributed very little to Industrial Revolution productivity advance, and most of the productivity advance in these industries did not stem from the introduction of steam power.[8] By the end of the eighteenth century, most coal mines used steam engines to do the winding of the coal and to pump water out from the workings. But horses were technically a viable alternative power source. Thus,

[7]Bresnahan and Trajtenberg (1996).

[8]Clark and Jacks (2007).

Table 5 Cost increase from absence of steam in mining, by epoch

Period	Share of costs coal for winding, pumping (%)	hph/ton	Cost increase (d./ton)	Cost increase (%)
1720–1759	6.0	1.6	0.4	1
1770–1799	4.4	2.0	5.3	14
1800–1839	4.9	4.8	12.2	20
1840–1869	3.0	2.9	6.2	10

Source: Clark and Jacks (2007, Table 4)

in the Walker colliery in the northeast coalfield in 1765, the deepest coal mine in England at that point at 600 ft, the coal was still lifted from the mine by a gin powered by eight horses.[9]

Table 5 calculates how much the absence of coal would have raised costs of production in each epoch. The method here is to calculate how many pounds of the equivalent of best coal were used at the colliery per ton of coal raised using the share of mining costs reported as coal consumed in winding or pumping. These pounds of coal were then translated into horsepower-hours per ton of coal, shown in column 3 of the table. The extra cost of supplying this energy as horsepower as opposed to steam power is given in column 4, and the percentage increase in production costs this would imply appears in the last column. The implication is that production costs in the nineteenth century would have risen by 10–20% absent the introduction and development of steam power in collieries. The absence of the new steam technology would not have crippled the industry even late into the Industrial Revolution.

Even in transport, a substantial part of the productivity advance is attributable to the improvement of the traditional road transport system, the introduction of canals, and improvements in sailing ships. The textile factories of the Industrial Revolution could, if necessary, have still been powered by waterwheels even as late as the 1860s. As in coal mining, power costs would have been higher in this case, but power costs were also a small share of total costs in textile mills. Advances in textiles and agriculture explain the majority of the Industrial Revolution.

Recent accounts of the Industrial Revolution, most noticeably in the work of E. A. Wrigley and Kenneth Pomeranz, would still make coal the key actor despite the absence of much sign of productivity growth in coal mining in Table 4.[10] Both argue that the switch from a self-sustaining organic economy to a mineral resource–dependent inorganic economy was central to the Industrial Revolution. Indeed, Pomeranz's account of the Industrial Revolution was dubbed "Coal and Colonies" by one reviewer.[11] Pomeranz argues that Britain, in contrast to China, had accessible deposits of coal near population centers. That, rather than differences in innovative potential, explains British success and Chinese failure. While the absence

[9]By 1828, three-quarters of mines in the Newcastle area were still less than 600 f. deep. Clark and Jacks (2007, Table 2).

[10]Wrigley (1988), Pomeranz (2000).

[11]Vries (2001).

of steam power would not have impeded growth much, would the absence of the coal deposits altogether have prevented the growth of the Industrial Revolution?

Coal output expanded enormously in the Industrial Revolution era. By the 1860s, it was supplying power for domestic purposes that was equivalent to the annual energy production of 25 million acres of woodland. This would have required nearly the entire farmland area in England in these years. Thus, if England had to depend only on its own supplies of energy, costs would soon have soared and the economy taken a very different path. There was, however, in the Baltic region alone a lot of wood available to the English economy throughout the Industrial Revolution era. By the nineteenth century, the Baltic was a major supplier of timber to England and the Netherlands. The regions bordering the Baltic produced enough energy in the form of wood to completely replace the energy supplied by coal for domestic purposes even as late as the 1860s. That energy would be more expensive, but the value of coal at the pithead in the 1860s in England was only around 2% of national income. But declines in shipping costs between the seventeenth and nineteenth centuries meant that the transport costs for this wood fuel in the 1860s would not have been much greater than the cost of domestic coal supplied to consumers in places like London. So total energy costs to the economy would likely have risen only modestly, and the gains in efficiency from textiles, farming, and transport would have been largely preserved.[12]

The diverse nature of productivity advance in this era makes the Industrial Revolution all the more puzzling. The revolution in textiles came through mechanical innovations that can be traced to a number of heroic individual innovators: John Kay, Richard Arkwright, James Hargreaves, Samuel Crompton, Edmund Cartwright, and Richard Roberts. But the improvements in agriculture stem from the advances of thousands of anonymous farmers in improving yields, mainly involving nonmechanical changes. Such celebrated figures of narrative accounts of the agricultural revolution such as Jethro Tull, "Turnip" Townsend, and Arthur Young on examination played no important role. Tull had no idea of what the sources of plant growth actually were.[13] Turnips were introduced into Norfolk rotations in the 1660s, long before Townsend, born in 1674, began farming.[14] Further, there is little sign that the new rotations promoted by Townsend and Young were themselves an important element in improved yields. Mark Overton looking at grain yields in probate inventories in the seventeenth century finds these to be no higher on farms which had introduced the new rotations.[15] Young made vigorous claims for the productivity benefits of such institutional reforms as the privatization of common fields and the ending of tithe payments. But the efficiency gains from enclosing common lands were miniscule. Even though a quarter of English farmland was

enclosed 1750–1830, the gain in farming efficiency would be less than 1%. And the tithe reforms of the 1830s had even smaller measured benefits.[16]

What is clear, however, is that at a fundamental level, the Industrial Revolution was driven by an upturn in the rate of technical innovation within the English economy.[17] This upturn, at least at interest in innovating, shows up clearly in English patent statistics, as summarized in Fig. 4. Clearly in the 1760s, before there was any general perception of an upturn in the rate of economic change and before the aggregate productivity data shows any signs of faster efficiency growth, more innovators were finding their way to London to file patent applications. What triggered this process?

The Problem of the Netherlands

When it comes to explaining why England was the first nation to experience modern productivity growth rates, the puzzle is deepened by the example of one earlier economy, the Netherlands, in the years 1581–1795. After a revolt that began in 1568, in 1581 the northern provinces of Flanders successfully attained independence from the Spanish Crown (in the form of the Hapsburg Empire). Despite a continuing military struggle against the Hapsburgs that ended only in 1648, the break was

[16]Clark (1998), Clark and Jamelske (2005).

[17]This is also the analysis of Mokyr (2003, 2012).

associated with a period of growth and prosperity known as the Dutch Golden Age, which spanned the seventeenth century. As one English commentator stated in 1669,

> Scarce any Subject occurs more in the learned discourse of ingenious man than that of the marvelous progress of this little state . . . which has grown to a height infinitely transcending all the ancient Republicks of Greece but not much inferior in some respects even to the greatest Monarchies of these latter Ages.[18]

The Netherlands economy was characterized by largely free markets internally for labor, land, capital, and commodities.[19] The Netherlands was also a very open economy, conducting extensive trade with the Baltic region (for grains and raw materials), the rest of Europe, and Asia. The political structure guaranteed property rights, contract enforcement, and freedom of movement of labor. As the Hapsburg forces recaptured Ghent, Bruges, and Antwerp, the Protestants of these cities, which included many skilled craftsmen and merchants, largely migrated north to Dutch territories. The Netherlands also welcomed Jewish refugees from the Iberian peninsula, both those continuing to practice Judaism and New Christians still treated as second-class citizens in their home countries.

By 1595, soon after gaining independence, Dutch merchants began sending ships to engage in the spice trade of the East, heretofore a Portuguese monopoly. Despite armed clashes with the Portuguese, the Dutch were able to force their way into the trade. After the formation in 1600 of the English East India Company with monopoly privileges in trade in the East, the Dutch set up their own East India Company in 1602, the *Vereenigde Oostindische Compagnie* (VOC). This proved an enormously profitable enterprise all through the seventeenth century. As a reflection of its scale, between 1602 and 1800 the VOC recruited almost a million men for work in Asia as traders, sailors, and soldiers. At this time, the population of the Netherlands was only around two million. In pursuit of spice trade profits, the VOC colonized the main islands of Indonesia for the Dutch. Its operations and profits were significantly greater than those of its main rival, the English East India Company.

This influx of talent made the Netherlands the leading economy of Europe in terms of living standards, science, intellectual life, and the arts by 1600. Real wages in the western Netherlands were the highest in Europe and maintained this position until well into the Industrial Revolution. Thus, de Vries and van der Woude estimate that in 1660, Dutch GDP per capita exceeded that of England by more than 30%.[20] By the mid-seventeenth century, trade and industry made up the bulk of the economy, with less than 40% of the labor force employed in farming. Along with its eastern trade empire, the Dutch developed, despite their high labor costs, a major shipbuilding industry with many technical innovations in ship design and construction. Its merchant shipping fleet was the largest in Europe in the seventeenth century.

[18] Aglionby (1669, pp. 3–4).

[19] The discussion below is largely based on De Vries and Van der Woude (1997), though see also Freist (2012) and de Vries (2000).

[20] De Vries and Van der Woude (1997, p. 710).

Again despite high labor costs, it had a major textile industry. It also had a number of industries based on the exploitation of cheap peat fuel such as ceramics (bricks, tiles, pottery, and clay pipes), brewing, and sugar refining.

Capital was unusually cheap in the Dutch republic as witnessed by the low rates of return on government debt, land, and housing.[21] This, along with the flat topography, allowed the Dutch to develop an extensive canal system linking all major cities. Canal boats would travel hourly between the major cities in much the way airlines now shuffle passengers between major US and European destinations.[22] The canal system also allowed for the cheap supply of peat fuel to industry and urban areas.

With the developments in trade, industry, and agriculture came innovation in finance. The Amsterdam Stock Exchange, established in 1602, is the oldest in the world. The Bank of Amsterdam, established in 1609, was a precursor to the central banks of the modern world.

The riches of the economy and the openness to immigration of talent from across Europe made the seventeenth century Netherlands a center for both the arts and scientific enquiry. By the seventeenth century, average levels of education in the Netherlands were as high, or higher, than those in Industrial Revolution England. One measure of this is the share of grooms and brides signing marriage registers. Table 6 shows the rates for the Netherlands circa 1620, 1700, and 1800 compared to the rates in England and elsewhere in Europe circa 1800. In the seventeenth century, implied literacy rates are, at worst, as good in the Netherlands as for Industrial Revolution England. And literacy rates in northern France and northern Germany exceed those of Industrial Revolution England.

The extensive developments above led Jan de Vries and Ad Van der Woude to title their 1997 book summarizing this history *The First Modern Economy*. However, while the Netherlands was modern in all the ways described above, in another respect it remained firmly a preindustrial and pre-Industrial Revolution economy. For while all the changes outlined above were significant and associated with economic growth and prosperity, the Dutch of the Golden Age never achieved any breakthrough in terms of productivity growth. This is illustrated in Fig. 5, which shows real wages in the western Netherlands from 1500 to 1799. The growth of the Golden Age was not accompanied by any rise in real wages. This implies that the overall productivity of the Netherlands economy expanded little in the years 1550–1650. The level of productivity is the weighted average of real wages, real land rents, and real returns on capital, with the weights equal to the share of each of these factors in incomes received.[23]

Given the failure of real wages to increase, given that wages would be half or more of all incomes, and given the declining returns on capital, even if real land rents

[21]By 1665 the State of Holland was able to reduce rates on its long term debt to 4%.

[22]De Vries (1978).

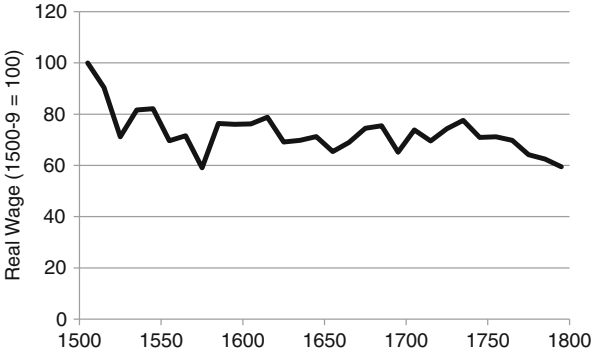

Fig. 5 Real wages, Western Netherlands, 1500–1799 (Sources: Based on the wage series in De Vries and Van der Woude (1997, pp. 610–611), with budget weights and cost of living as described in van Zanden (2008))

rose in this period, the overall gains in efficiency would be very modest. The Dutch had a Golden Age, but they did not have an Industrial Revolution.

The failure of Golden Age Netherlands to experience an Industrial Revolution suggests that most proposed explanations of the English Industrial Revolution are misguided. Robert Allen, for example, has recently proposed that the Industrial Revolution in England was driven by high labor and low energy costs in eighteenth-century England, leading to a replacement of hand labor by machines driven by steam engines.[24] Yet, 200 years earlier, we see in the Netherlands even higher wages than for England in 1780 and again low energy costs but no Industrial Revolution.

The example of the Netherlands is particularly a problem for the idea that the Industrial Revolution is the product of institutional innovation. A powerful modern school within economics is *institutionalism*, which asserts that institutions, formal or informal, explain most differences in economic outcomes and that systematically early societies had institutions that discouraged economic growth (see, e.g., Acemoglu et al. 2001, 2002, 2005; Acemoglu and Robinson 2012; DeLong and

[24] Allen (2009).

Shleifer 1993; Greif 2006; North 1981, 1994; North and Thomas 1973; North and Weingast 1989; North et al. 2012; Rosenthal 1992).[25]

The common feature that Douglass North and other such *institutionalists* point to in early societies is that political power did not derive from popular elections. In preindustrial societies, as a generalization, the rulers ultimately rested their political position on threats of violence. Indeed, there is a good empirical association between democracy and economic growth. By the time England achieved its Industrial Revolution, it was a constitutional democracy where the king was merely a figurehead. The USA, the major country with the highest GDP per person since the 1850s or earlier, has always been a democracy.[26]

Economic efficiency in any society requires that property rules be chosen to create the maximum value of economic output. In such a case, a disjuncture can arise between the property rules in the society that will maximize the total value of output and the property rules that will maximize the output going to the ruling elite. Indeed, North and others have to argue that such a disjuncture systematically arises in all societies before the Industrial Revolution. This idea has been restated recently as the replacement of extractive economic institutions designed just to secure income for a ruling clique with inclusive economic institutions designed to maximize the output of societies as a whole (Acemoglu and Robinson 2012).

One subset of such theories that has shown amazing persistence despite its inability to account for the most basic facts of the Industrial Revolution is that which links the Industrial Revolution to the earlier *Glorious Revolution* of 1688–1689. Thus, the recent widely read book by Acemoglu and Robinson, *Why Nations Fail*, has a chapter titled "How a political revolution in 1688 changed institutions in England and led to the Industrial Revolution" (Acemoglu and Robinson 2012).

The *Glorious Revolution* established the modern political system of the UK, a system that has been continuously modified but not fundamentally changed since then. The new political system made Parliament, the representative of the propertied classes in England in 1689, the effective source of power in what is nominally a monarchy.

A basic problem with placing political developments at the heart of the Industrial Revolution is that the *Glorious Revolution* of 1688–1689 had no discernible impact on economic efficiency before 1770, nearly three generations after the institutional change, as Fig. 6 shows. The figure shows the level of net national product per person across these years. It is also clear in the figure that even the earlier political and military disruptions of the Civil War of 1642–1649, when Parliament and the King were at war, and the Interregnum of 1649–1660 were not associated with any decline in the efficiency of operation of the economy in the seventeenth century.

[25]Clark (1996, 2007a, b) criticizes this approach.

[26]The recent rise of China is, however, an exception to the general association of growth and democracy.

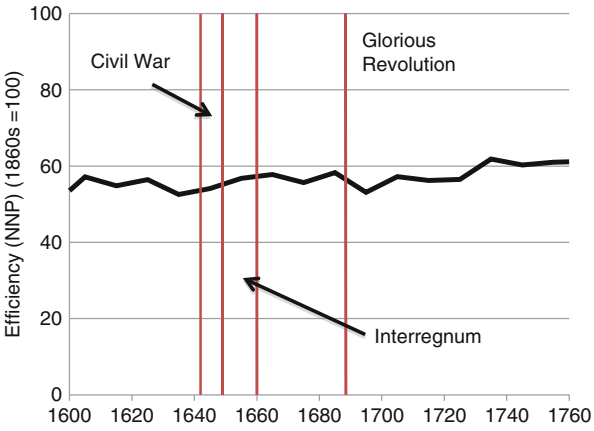

Fig. 6 Economic efficiency and political changes, England, 1600–1770 (Source: Clark 2010)

Further, there is no sign that private investors in England perceived a greater security of property even as a result of the Glorious Revolution. The return to private capital in the economy did not deviate from trend after 1689 (see Clark 1996). Private investors seem to have looked at the political changes with indifference. The return to government debt did eventually decline significantly after 1689 and had fallen to modern levels by the 1750s. This decline was no doubt driven in part by the enhanced taxing power of the government after 1689. But almost all of the money raised from those taxes went to finance the British Navy in the long struggle with France that ended only with the final defeat of Napoleon at Waterloo in 1815. Almost none of the tax revenues went into subsidizing innovation, investment, or education.

And we do see, long before the Glorious Revolution or the Industrial Revolution, societies that had stable representative political systems, the inclusive institutions of Acemoglu and Robinson, but little or no productivity advance. The Dutch Republic of 1588–1795 was, as discussed above, one such regime.[27] While the political system of the Dutch Republic had its tensions and contradictions and periodic instabilities, the leadership was responsive to the needs of the citizenry at city and national levels. The citizenry itself was mainly property-owning burghers. In most Dutch cities, you could become a citizen by inheritance of citizen status, by marrying the daughter of a citizen, by receiving the status as a reward, or by purchase. It is estimated that about half of adult males in cities would be citizens, but the large rural population was largely excluded from citizenship.[28] Even where town councils were not formally elected by citizens as in Holland, they were drawn from this milieu and subject to pressure through other organizations of burghers such as the militia. So the Netherlands was, par excellence, a property-owning democracy whose leaders had regard for the economic interests of the merchant and manufacturing classes.

[27]The Dutch Act of Abjuration of 1581 has been claimed by some to be the precursor of the Declaration of Independence of the USA of 1776.

[28]See Prak (1997), van Zanden and Prak (2006, pp. 121–122).

The Netherlands of the seventeenth century was just one of many earlier European societies that had property holder franchises. From 1223 to 1797, Venice was a Republic, with the government under the control of a mix of popular and patrician representatives. Policy was geared toward the needs of a trading and commercial empire. Venice developed an important trading empire in the Eastern Mediterranean with colonies and dependencies such as Crete, Cyprus, and Dalmatia. It also saw the growth of important manufacturing activities such as glass. But again, none of this institutional framework was reflected in the kind of sustained productivity advance seen in the Industrial Revolution.

Similarly, the free cities of the Hanseatic League were from the Middle Ages dominated by a politics that emphasized the needs of trade and commerce. Lübeck, for example, became a free city in 1226 and remained a city-state until 1937. After gaining its freedom in 1226, Lübeck developed a system of rule and government called Lübeck Law that spread to many other Baltic cities of the Hanseatic League in the Middle Ages such as Hamburg, Kiel, Danzig, Rostock, and Memel. Under Lübeck Law, the city was governed by a council of 20 that appointed its own members from the merchant guilds and other town notables. It was thus government by the leaders of the commercial interests of the cities. Though not democracy, this was government by interests that should have fostered commerce and manufacturing. Under such rule, the Hansa cities became rich and powerful, engaging in substantial manufacturing enterprises such as shipbuilding and cloth production as well as trade. But again, this was not associated with sustained technological advance.[29]

Property in Knowledge

If it is not insecure property rights in general that can explain the long delay in the arrival of the Industrial Revolution and its location finally in England, what about a more specific deficiency? Could it be that the problem was just that all earlier societies lacked the institution of allowing knowledge to be a kind of property?

In both ancient Rome and Greece, the concept that you could own property in ideas or innovations was missing. Thus, in both the Roman and Greek worlds, when an author published a book, there was no legal or practical way to stop the pirating of the text. Copies could be freely made by anyone who acquired a version of the manuscript (on papyrus rolls), and the copier could amend and alter the text at will. Texts might thus be reissued under the name of a new "author."[30] It was common to condemn such pirating of works or ideas as immoral. But writings and inventions were just not viewed as *commodities* with a market value.[31] It is frequently asserted

[29]There have been institutionalist arguments, however, about why Hansa institutions still deviated from those necessary for modern growth. See Lindberg (2009).

[30]This problem continued into at least the seventeenth century in England, where publishers quite freely pirated the works of authors.

[31]See Long (1991, pp. 853–857).

that the concept of intellectual property was alien to cultural norms in imperial China, with the first copyright law only being introduced in the late Qing era in 1910 under Western pressure. There were, however, some limited protections for publishers of block-printed books after the introduction of printing in China in the ninth century. But these seem to have been local and special protections within a legal environment where the idea of intellectual property rights was alien.[32]

While the European ancients and the Chinese may have lacked them, there were systems of intellectual property rights in place, however, long before the Industrial Revolution. The rudiments of a modern patent system were found already in the thirteenth century in Venice. By the fifteenth century in Venice, true patents in the modern sense were awarded regularly. Thus, in 1416, the Venetian Council gave a 50 year patent to Franciscus Petri from Rhodes, a foreigner, for a new type of fulling mill. By 1474, Venetian patent law had been codified. There is also evidence of patent awards in Florence in the fifteenth century. The Venetian innovation granting property rights in knowledge, which was very important to the famous Venetian glass industry, spread to Belgium, the Netherlands, England, Germany, France, and Austria in the sixteenth century as a consequence of the movement of Italian glass workers to these other countries. These workers demanded protection for their trade knowledge as an inducement to set up production in these other countries. Thus, by the sixteenth century, all the major European countries, at least on an ad hoc basis, granted property rights in knowledge to innovators. They did this in order to attract skilled craftsmen with superior techniques to their lands. The spread of formal patent systems thus predates the Industrial Revolution by at least 350 years.

The Netherlands in particular had a fully functioning patent system in place by 1590 and was issuing patents at a much higher rate than England in the early seventeenth century despite having a much smaller population. In the Dutch Golden Age, patent activity was much greater than in the eighteenth century, when the flow of patents slowed to a trickle just as the English patent issues were rising sharply.[33]

The claims of North and his associates for the superiority of the property rights protections afforded by the patent system in eighteenth-century England thus stem from the way in which the system operated after the Glorious Revolution of 1688–1689 established the supremacy of Parliament over the King. Under the patent system introduced in the reign of Elizabeth I, 1568–1603, the system was supervised by government ministers. Political interference led to the creation of spurious monopolies for techniques already developed or the denial of legitimate claims. After the Glorious Revolution, Parliament sought to avoid this by devolving the supervision of patents to the courts. Generally, the courts would allow any patent to be registered as long as no other party objected. No other major European country had a formal patent system as in England before 1791. But the system was in fact notoriously costly in terms of money and time, especially if the patentee wanted protection in Scotland and Ireland as well as England. The application had to pass

[32]Ganea and Pattloch (2005, pp. 205–206).

[33]De Vries and van der Woude (1997, pp. 345–348).

Fig. 7 Cotton spinning and weaving productivity, 1770–1869. *Note*: The *squares* show the decadal average productivities. The years 1862–1865 were omitted because of the disruption of the cotton famine (Sources: Cotton cloth prices, Harley (1998). Labor costs, return on capital, Clark (2010))

through seven court or government offices in London and a further five each in Scotland and Ireland.[34] Applications could be rejected on such technical grounds as the innovator having sold even one of the devices prior to the application. Also, as Fig. 4 shows, while the Glorious Revolution produced a brief increase in patent rates, there was no sustained increase in patenting rates until the 1760s, 75 years after the Glorious Revolution.

Another implausibility in the knowledge appropriability argument is the weak evidence for any increase in returns to innovators in England in the 1760s and later. The textile industry, for example, was in the vanguard of technological change in the Industrial Revolution period. Figure 7 shows efficiency in the production of cotton cloth measured in terms of value added to the cotton input per unit of land, labor, and capital. From 1770 to 1869, efficiency rose about 22 fold. Yet, the gains of the textile innovators were modest in the extreme. The value of the cotton textile innovations alone by the 1860s, for example, was about £115 million in extra output per year in England. But a trivially small share of this value of extra output flowed to the innovators. Table 7, for example, shows the major innovators in cotton textiles and the gains accruing to the innovators through the patent system or other means. Patents mostly provided poor protection, the major gains to innovators coming through appeals post hoc to public beneficence through Parliament. Also, the patent system shows none of the alleged separation from political interference. The reason for this is that Parliament could, on grounds of the public good, extend patents

[34]Khan (2008).

Table 7 The gains from innovation in textiles in the industrial revolution

Innovator	Device	Result
John Kay	Flying Shuttle, 1733	Impoverished by litigation to enforce patent. House destroyed by machine breakers 1753. Died in poverty in France
James Hargreaves	Spinning Jenny, 1769	Patent denied. Forced to flee by machine breakers in 1768. Died in workhouse in 1777
Richard Arkwright	Water Frame, 1769	Worth £0.5 m at death in 1792. By 1781 other manufacturers refused to honor patents. Made most of money after 1781
Samuel Crompton	Mule, 1779	No attempt to patent. Grant of £500 from manufacturers in the 1790s. Granted £5,000 by Parliament in 1811
Reverend Edmund Cartwright	Power Loom, 1785	Patent worthless. Factory destroyed by machine breakers. Granted £10,000 by Parliament in 1809
Richard Roberts	Self-Acting Mule, 1830	Patent revenues barely covered development costs. Died in poverty in 1864

Source: Clark (2007a, Table 12.2)

beyond the statutory 14 years to adequately reward those who made significant innovations. James Watt was the beneficiary of such a grant. But obtaining such Parliamentary grants depended on political patronage just as much as in the old days.

Productivity growth in cotton textiles in England from 1770 to 1870 far exceeded that in any other industry. But the competitive nature of the industry and the inability of the patent system to protect most technological advances kept profits low. Cotton goods were homogeneous. Yarn and cloth were sold in wholesale markets where quality differences were readily perceptible to buyers. The efficient scale of cotton spinning and weaving mills was always small relative to the market. New entrants abounded. By 1900, Britain had about 2,000 firms in the industry. Firms learned improved techniques from innovating firms by hiring away their skilled workers. The machine designers learned improved techniques from the operating firms. Thus, over time, the entire industry – the capital goods makers and the product producers–clustered more and more tightly in the Manchester area. By 1900, 40% of the entire world output of cotton goods was produced within 30 miles of Manchester. The main beneficiaries of this technological advance thus ended up being two parties: consumers of textiles all across the world and the owners of land in the cluster of textile towns, which went from being largely worthless farmland to valuable building sites.

The profit rates of major firms in the industry also provide good evidence that most of the innovation in the textile industry was quickly leaking from the innovators to other producers with no rewards to the innovators. Knick Harley has reconstructed the profit rates being made by some of the more successful cotton spinning and weaving firms in the early Industrial Revolution period (Harley 1998, 2010). The cotton spinners *Samuel Greg and Partners* earned an average profit from 1796 to 1819 of 11.7% per year, just the normal commercial return for a risky venture such as manufacturing. Given the rapid improvements in cotton spinning

productivity going on in the industry in these years, it suggests that whatever innovations were being introduced were spreading from one firm to another very quickly. Otherwise, leading firms such as *Samuel Greg* would have made large profits compared to their competitors.

Similarly, the firm of *William Grey and Partners* made less than 2% per year from 1801 to 1810, a negative economic profit rate. The innovations in the cotton spinning industry seem to have mainly caused prices to fall, leaving little excess profits for the firms that were innovating. From 1777 to 1809, *Richard Hornby and Partners* was in the handloom weaving sector of the industry, which had not yet been transformed by any technological advance. Yet, its average profit rate was 11.4%, as high as *Samuel Greg* in the innovating part of the industry.

The conclusion is that the host of innovations in cotton textiles do not seem to have particularly rewarded the innovators. Only a few, such as Arkwright and the Peels, became noticeably wealthy. Of the 379 people probated in 1860–1869 in Britain who left estates of £0.5 million or more, only 17 were in the textile industry even though, as noted, from 1760–1769 to 1860–1869, this one sector generated nearly half the productivity growth in the economy (Rubinstein 1981). The Industrial Revolution economy was spectacularly bad at rewarding innovation. This is why Britain has few foundations to rival the great private philanthropies and universities of the USA Its innovators captured little of the rewards.

A similar tale can be told for the other great nexus of innovation in Industrial Revolution England: coal mining, iron and steel, and railroads. Coal output, for example, exploded in England in the Industrial Revolution era. This coal heated homes, made ore into iron, and powered railway locomotives. Yet, there were no equivalents of the great fortunes made in oil, railways, and steel in America's late-nineteenth-century industrialization.

Though the first great innovations of the Industrial Revolution era did not offer much in the way of supernormal profits because of the competitive nature of the industry, the second, railroads, seemed to offer more possibilities. Railways have inherent economies of scale. At a minimum, one line has to be built between two cities. Once it is built, a competitor must enter with a minimum of one complete second line. Since most city pairs could not profitably support multiple links, exclusion and hence profits thus seemed possible.

The success of the Liverpool–Manchester line in 1830 – by the 1840s, shares on this line were selling for twice their par value – inspired a long wave of investment in railways. Figure 8 shows the rapid growth of the railway network in England from 1825 to 1869, by which time more than 12,000 miles of track had been laid across the tiny area of England. This investment and construction was so frenetic that so-called *railway manias* commenced in 1839 and 1846.

But again, the rush to enter quickly drove down profit rates to very modest levels, as Table 8 shows. By the 1860s, real returns, the return on the capital actually invested, were no greater than for very safe investments such as farmland or government debt. While new railway lines initially often had local monopolies, they ended up in constant competition with each other as additional links between nodes in the network were added.

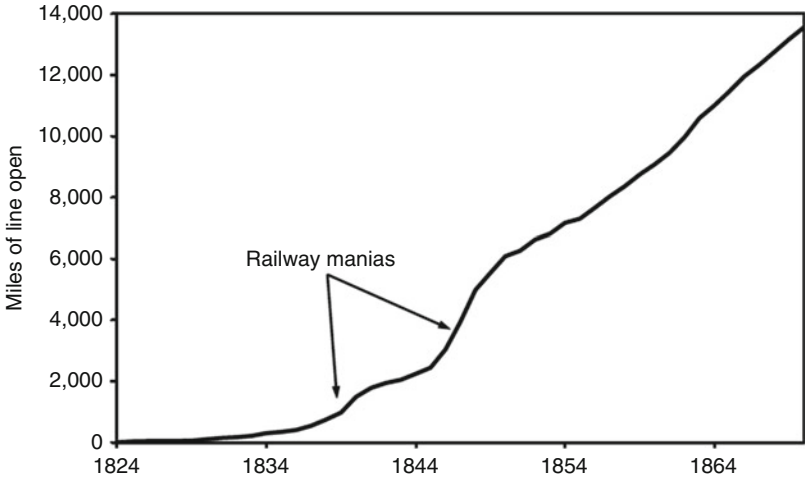

Fig. 8 English railroad construction, 1825–1869 (Source: Mitchell and Deane 1971, p. 225)

Table 8 Profit rates on the capital invested in British owned railways, 1860–1912

Period	Rate of return, UK (%)	Rate of return, British empire (%)	Rate of return. Foreign lines (%)
1860–1869	3.8	–	4.7
1870–1879	3.2	–	8.0
1880–1889	3.3	1.4	7.7
1890–1899	3.0	2.5	4.9
1900–1909	2.6	1.6	4.4
1910–1913	2.6	3.1	6.6

Source: Clark (2007a, Table 14.7)

Thus, while, for example, the Great Western may have controlled the direct line from London to Manchester, freight and passengers could cross over through other companies to link up with the East Coast route to London. Again, profits inspired imitation, which could not be excluded, and any supernormal profits were soon eliminated. Consumers were again the main beneficiaries. It is for this reason that in Britain, unlike in the USA, there are very few universities and major charities funded by private donors.[35] The new industrial priesthood, the engineers who developed the English coalfields, railways, and canals, made prosperous but typically moderate livings. Though their names survive to history – Richard Trevithick, George and Robert Stevenson, Humphrey Davy – they again captured very little of the social rewards their enterprise wrought. Richard Trevithick, the pioneer of locomotives, died a pauper in 1833. George Stevenson, whose famous locomotive *The Rocket* ran loaded at 15 miles an hour (an unheard-of speed for land travel in this era) in a trial in

[35]The industrialization of the United States created much greater private and family fortunes.

1829, did much better. But his country house in Chesterfield was, however, a pittance compared to his substantial contributions to railway engineering. But other locomotives competed in the famous trial, and soon, a swarm of locomotive builders were supplying the railway network. Humphry Davy died rich and celebrated. But he never patented his safety lamp for coal mining, giving the innovation to the industry for free.

Innovation in the Industrial Revolution era typically benefited mainly consumers in the form of lower prices. As coal output exploded, real prices to consumers steadily declined: the real price in the 1700s was 60% greater than in the 1860s. Coal, iron and steel, and rail carriages all remained highly competitive in England in the Industrial Revolution era. The patent system offered little protection to most of the innovations in these sectors, and innovations quickly leaked from one producer to another.

Textiles, the industry with the most dramatic productivity declines, became substantial exporters of products throughout the world, with about half of the production being exported by the end of the Industrial Revolution era. Thus, a large share of the benefits of the Industrial Revolution flowed abroad. This meant that real living standards in England in the Industrial Revolution period grew more slowly than did GDP since the price index for national expenditures grew more rapidly than the price index for national output.

One thing that is striking about the institutionalist explanations discussed above in general is the absence of any agreed metric for institutional quality. There is a belief in the physical sciences that a basic element in any scientific analysis of any phenomenon is to have a defined, objective, and shared system of measurement. There is no agreed metric for institutional quality. Institutionalists on this standard are still in the prescience world of phlogiston and other early theories.

Ideas and the Industrial Revolution

In search of what made England in 1800 different from the Netherlands in 1600 or France in 1800, some scholars have turned to culture. In particular, they have promoted a central role for ideas in germinating technological advance. Margaret Jacob has championed the thesis that the underpinning of technological advance in Industrial Revolution England lay in the grounding of English industrialists, mechanics, and engineers in Newtonian science.

> To be sure some makers of jennies and spindles were semi-literate, more visual than verbal, but by and large, the creators, installers and users of steam and hydraulic presses, the planners and builders of canals - the key players in the British Industrial Revolution - were mechanically literate and in possession of a distinctive cultural persona.[36]

[36]Jacob (2013, p. 8).

Similarly, Joel Mokyr explains the dynamism of the English circa 1800 versus the stasis of the Dutch circa 1650 as

> the advanced technology that helped propel the Dutch economy into unprecedented and even "embarrassing" riches in the seventeenth and eighteenth centuries was still mostly the traditional, pragmatic knowledge at the level of artisans or applied engineers: mechanically clever, well-designed techniques, but without much of an epistemic base in the deeper natural phenomena that made them work. As a consequence, technological progress ran into diminishing returns.[37]

Such propositions about the role of ideas and cultural forms are inherently difficult to test. It is easy, for example, to measure the level of education in different societies at the time of the Industrial Revolution, but measuring the extent to which elites were trained in Newtonian scientific ideas or had grounding in the principles of mechanics is intrinsically much more difficult.

Jacob, for example, has conducted detailed studies of the activities of Industrial Revolution entrepreneurs and innovators, showing their detailed knowledge of mechanical principles and careful attention to detail in introducing such things as steam power. Humphry Davy is one such paradigmatic figure. He grew up in Cornwall, far from major centers of learning, and had very little formal instruction in science, never completing grammar school or attending a university. But he was able to instruct himself utilizing the apparatus and libraries of a circle of local amateurs and professionals who took him under their wing. Thus, early in his career, he made the acquaintance of James Watt and of the Wedgwoods. Although he had no direct experience with the coal industry, when asked to solve the problem of underground explosions of firedamp sparked by the naked flames of lamps, he was able to utilize his scientific experience to rapidly create the Davy lamp in 1815.[38]

But at the same time, in response to the same disastrous underground explosion, George Stephenson devised a safety lamp on other principles. Stephenson had much more humble origins and less impressive scientific credentials. He did not learn to read until age 18. He learned his technical skills on the job as engineman at a colliery. But he became a successful locomotive designer, then railway projector, the father of the railway age.

Which was a more representative figure for the English Industrial Revolution: the scientifically immersed and inspired Davy or the unschooled practitioner Stephenson? Proponents of a culture of Newtonian science or of a British-style Enlightenment can certainly show that some of the leading innovators of the age were immersed in mechanical science and ideas of progress through rationality. But even for these individuals who may acquire more prominence than is their due because of their tendency to join scientific societies, to publish, and to leave private records, it is nigh impossible to demonstrate in most cases that their industrial achievements were the direct result of their scientific interests. Thus, the idea that

[37] Mokyr (1999).

[38] Jacob (2014, pp. 82–84). See also Jacob (1997).

the Industrial Revolution was the product of a particular intellectual culture in England in the eighteenth century is to a large degree untestable given current sources.

How Sudden was the Industrial Revolution? Revolution or Evolution?

One of the things that makes the Industrial Revolution so hard to explain is the apparent suddenness of the arrival of persistent efficiency advance in economies circa 1800. All other elements of the economy were seemingly evolving in a very slow manner in this era – the underlying institutional, political, and social variables were changing slowly if at all in England in the years 1700–1800 – so how could they produce the relatively abrupt change of the Industrial Revolution? See, for example, Fig. 9 showing literacy levels in England, 1580–1920. The Industrial Revolution did see a modest rise in male literacy rates and a more substantial rise for women. But the late nineteenth century was the period of much greater and more dramatic increases in literacy, long after the Industrial Revolution commenced. And for men, there is not much sign of major increases in literacy rates all the way from 1650 to 1800. What is true of literacy is true of many of the underlying variables in the economy in this period: wages, rates of return on capital, land rents, transport costs, population, life expectancy, and so on.

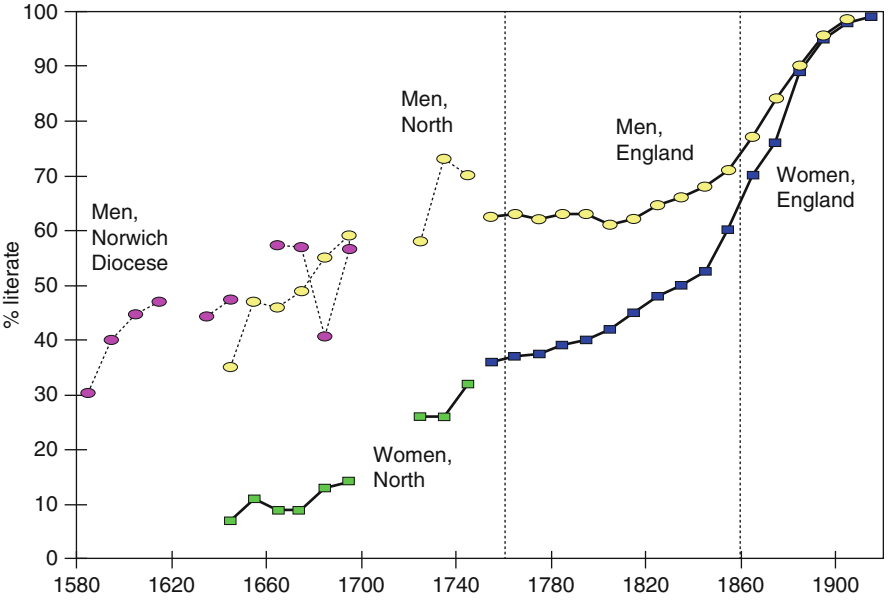

Fig. 9 Literacy in England, 1580–1920 (Source: Clark 2007a, Fig. 9.3, p. 179)

Viewed from the aggregate productivity level of the economy, the conclusion that the transition to modern growth was rapid seems to be at odds with the general historical picture of England from 1200 to 1780. England during this period was a society that was advancing in education, in scientific knowledge, in technical abilities in navigation and warfare, as well as in music, painting, sculpture, and architecture. England in 1780 was a very different place from England in 1250 even if the standard of living of the average consumer measured mainly in terms of their consumption of food, clothing, housing, heat, and lighting had changed little.

The reason for this mismatch is that as noted above in Eq. 4, national productivity growth will be related to productivity advance in individual sectors through

$$g_A = \sum \theta_j g_{Aj} \tag{6}$$

where g_{Aj} is the growth rate of productivity by sector and θ_j is the share of j in total value added in the economy. National efficiency advance is measured by weighting gains by sector with the value of output in that sector. The effects of innovation on national productivity measures is thus crucially dependent on the pattern of consumption.

Much of the technological advance of the period 1250–1780 had minimal impact on measured productivity at the national level because the share of expenditure on these goods was so small in the preindustrial economy. The printing press, for example, led to about a 25-fold increase in the productivity of written material between 1450 and 1600 in England. This was as great an increase in productivity as seen in cotton cloth production 1770–1870. But since the share of income spent on printed materials in the seventeenth century was only about 0.0005, the productivity gains from this innovation at the national level were miniscule (Clark and Levin 2001).

We can see in Fig. 10 that the production of such manufactured items as iron nails and glassware also saw significant productivity advances before 1780. But this efficiency advance would be a negligible contribution to national productivity advance because of the small share of total production value these goods represented in a preindustrial England. Iron nails had limited use, while glasswares were enjoyed only by the richest groups.

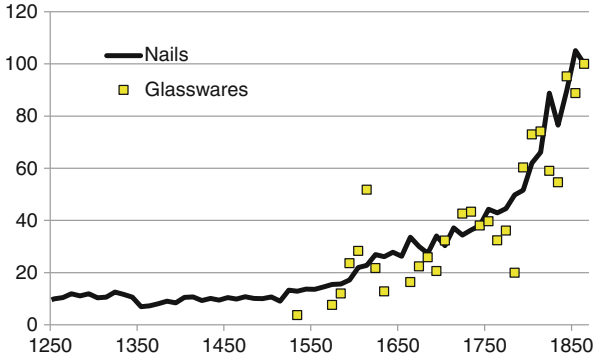

Fig. 10 Efficiency of production of nails and glassware, by decade, 1250–1869 (Source: Clark 2010)

Further, for many goods whose production was becoming more efficient through technological advances, no consistent series of prices can be calculated. There was, for example, a great advance in military technologies in European countries such as England over the years 1250–1780. The infantry of 1780 or a naval ship of that period would have swept the equivalent medieval force from the field. English troops of 1780 would have quickly overwhelmed the fortifications of 1250, but the fortifications of 1780 would have been impregnable even against medieval armies of major size.

For example, the evolution from the medieval crossbow to the arquebus in the late fifteenth century to the musket and then to the rifle in the nineteenth century saw a substantial increase in the firing rate and the force of the projectile. In the sixteenth century, arquebuses could sustain a rate of fire of only one shot every 2 min.[39] By the early nineteenth century, with flintlock muskets, as many as three shots per minute were possible.[40] But none of this would be reflected in conventional productivity measures. There is no allowance in these measures for the delivery of more effective violence by English armies and navies over the years.

There is no allowance also in the national productivity measure for improvements in the quality of literature, music, painting, and newspapers. These sources also do not reflect medical advances such as the one-third reduction in maternal childbirth mortality between 1600 and 1750.[41]

This makes it possible that the rate of technological advance in the economy measured just as a count of innovations and new ideas was actually increasing long before the breakthrough of the Industrial Revolution. But accidents of where these technological advances came in relation to mass consumer demand in the pre-industrial economy create the appearance of a technological discontinuity circa 1780. Suppose that prior to the Industrial Revolution, innovations were occurring randomly across various sectors of the economy – innovations in areas such as guns, gunpowder, spectacles, window glass, books, clocks, painting, new building techniques, improvements in shipping and navigation – but that just by chance, all these innovations occurred in areas of small expenditure. Then, the technological dynamism of the economy would not show up in terms of output per capita or in measured productivity in the years leading up to the Industrial Revolution.

To illustrate this, suppose we consider a consumer whose tastes were close to those of a modern university professor. Their consumption is much more heavily geared toward printed material, paper, spices, wine, sugar, manufactured goods, light, soap, and clothing than the average consumer in the preindustrial English economy. Based on their consumption, how would the efficiency growth rate of the economy 1250–1769 look compared to 1760–1869 and 1860–2009? Figure 10 shows the results, where efficiency is measured as an index on a log scale on the vertical axis so that the slope of the line measures the rate of efficiency growth. Thus,

[39]Shineberg (1971, p. 65).

[40]Townsend (1983, p. 6).

[41]Wrigley et al. (1997, p. 313).

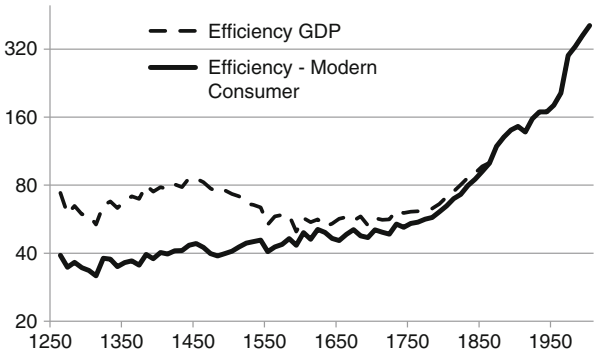

Fig. 11 Economic efficiency from the perspective of a modern consumer, England, 1250–2009. *Notes*: The weights in consumption for the modern consumer are assumed to be half from the consumption basket of the pre-industrial worker. But the other half is composed of books (.1), manufactured goods (.1), clothing (.1), sugar (.03), spices (.03), drink (.05), light (.05), soap (.02), and paper (.02) (Source: Clark 2010)

the upward slope of the line indicates efficiency growth rates. Now, in the years 1300–1770, there is an estimated efficiency growth rate of 0.09% per year for the goods consumed by a university professor. This is followed by efficiency growth rates of 0.6% per year 1760–1870 and 0.9% a year for 1860–2010. Estimated efficiency advance is still very slow for the preindustrial period, but there is a more than 50% increase in efficiency between 1300 and 1770. And this still excludes many of the gains that were discussed above. Thus, we can think of the economy in this period as going through a more protracted transition between preindustrial growth rates and modern growth rates (Fig. 11).

Framed in this way, the possibility opens of some more gradual transition to higher rates of technological advance starting in the medieval period or earlier. We can conceive of the Industrial Revolution as a more evolutionary affair with roots earlier than 1780. We can also think of the Dutch of the seventeenth century as having achieved significant technical progress though in areas such as painting, which leave little trace in aggregate measures of the efficiency of the economy.

Changes in People

Two things suggest that we should perhaps look at changes in people as the wellspring of the Industrial Revolution. The first is the lack of institutional or social barriers to innovation even in medieval England. The medieval economy was largely already a fairly laissez-faire system with modest taxation and few effective religious or social impediments to technological change. The second is the modest signs of any increase in returns to innovation at the time of the Industrial Revolution. If the barriers to innovation were unchanged and the financial rewards in England still modest and no greater than in seventeenth-century Holland or eighteenth-century

France, perhaps the transition was instead driven by changes in the aspirations and capabilities of economic agents.

We certainly see evidence within England that the behavior of economic agents had changed in significant ways between 1200 and 1800. Four changes stand out: a decline in impatience as revealed by a significant decline in the underlying interest rate, an increase in literacy and numeracy, a decline in interpersonal violence, and an increase in work hours. The levels of literacy and numeracy were high by the standards of the preindustrial world. Even the great civilizations of the past such as the Roman Empire or the city-states of the Italian Renaissance had general levels of literacy and numeracy that were surprisingly low by the standards of northwest Europe on the eve of the Industrial Revolution. Though, as noted in Table 6 above, while we can distinguish Industrial Revolution England in terms of literacy and numeracy from earlier societies and even from Japan and China in 1800, we cannot use such measures to explain why England, among many western European societies, was the creator of the Industrial Revolution.

Another caveat about the role of numeracy and literacy in the Industrial Revolution is that given the observed rates of return to schooling, the increased investment in countries like England in the Industrial Revolution period can account little for faster productivity growth rates. Thus, we can modify Eq. 1 to allow for investment in human capital to

$$g_y = a_k g_k + a_h g_h + g_A \tag{7}$$

where a_h is the share of income attributable to human capital investments and g_h is the growth rate of the stock of human capital. But the growth rate of the human capital stock in England from 1760 to 1860 implied by Fig. 9 is very modest: less than 0.4% per year. And even if we allowed one-third of all the 60% share of wage payments in income in Industrial Revolution England to be attributed to human capital, this would entail that human capital investments increased income growth rates by a mere 0.08% per year. If human capital lies at the heart of the Industrial Revolution, it must be because there are significant external benefits associated with human capital investments, as Lucas (1988) hypothesized.

We find interesting evidence that the average numeracy and literacy of even rich people in most earlier economies was surprisingly poor. A prosperous landowner in Roman Egypt, Isidorus Aurelius, for example, variously declared his age in legal documents in a less than 2 year span in 308–309 AD as 37, 40, 45, and 40. Clearly, Isidorus had no clear idea of his age. Other sources show he was illiterate (Duncan-Jones 1990, p. 80). A lack of knowledge of their true age was widespread among the Roman upper classes as evidenced by age declarations made by their survivors on tombstones. In populations where ages are recorded accurately, 20% of the recorded ages will end in 5 or 10. We can thus construct a score variable Z which measures the degree of "age heaping," where $Z = \frac{5}{4}(X - 20)$ and X is the percentage of age declarations ending in 5 or 10 to measure the percentage of the population whose real age is unknown. Z measures the percentage of people who did not know their true age, and this correlates moderately well in modern societies also with the degree of literacy.

Table 9 Age heaping

Place	Date	Type of community	Innumeracy rate
Ancient Rome	1–300	All	46
Medieval England	1270–1370	Landowners	61
Town of Florence	1427	Urban	32
Florentine Territory	1427	Rural	53
Corfe Castle, England	1790	Urban	8
Ardleigh, England	1796	Rural	30

Sources: Clark (2007a, Table 9.4, p. 178)

Among those wealthy enough to be commemorated by an inscribed tombstone in the Roman Empire, typically half had unknown ages. Age awareness did correlate with social class within the Roman Empire. More than 80% of officeholders' ages seem to have been known by their relatives. We can also look at the development of age awareness by looking at a census of the living, as in Table 9. Some of the earliest of these are for medieval Italy including the famous Florentine *Catasto* of 1427. Even though Florence was then one of the richest cities of the world and the center of the Renaissance, only 68% of the adult city population knew their age. Medieval England had even lower age awareness. The medieval Inquisitions post mortem, which were enquiries following the death of landholders holding property where the King had some feudal interest, show that the exact ages of the heirs to property was known in only 39% of cases. In comparison, a 1790 census of the small English borough of Corfe Castle in Dorset with a mere 1,239 inhabitants, most of them laborers, shows that all but 8% knew their age. In 1790, awareness correlates with measures of social class, universal knowledge among the higher-status families, and lower age awareness among the poor. But the poor of Corfe Castle or Ardleigh in Essex had as much age awareness as officeholders in the Roman Empire.

Another feature of the Roman tombstone age declarations is that ages seem to be greatly overstated for many adults. Thus, while we know that life expectancy in ancient Rome was probably in the order of 20–25 at birth, tombstones record people as dying at ages as high as 120. For North African tombstones, for example, 3% of the deceased are recorded as dying at age 100 or more.[42] Almost all of these 3% must have been 20–50 years younger than was recorded. Yet, their descendants did not detect any implausibility in recording these fabulous ages. In contrast, the Corfe Castle census records a highest age of 90, well within the range of possibilities given life expectancy in rural England in these years.

Why then did education levels rise in the centuries leading up to the Industrial Revolution? A theme of many of the previously mentioned economic models of the transition from Malthusian stagnation to modern growth is that there was a switch from quantity, or at least desired quantity, to quality in families as we moved to the modern world (see, example.g., Galor and Weil 2000; Galor 2011). This theme has been driven by the observation in modern cross sections, looking across countries,

[42]Hopkins (1966, p. 249).

that high-income, high-education societies are those with few children per woman. Also, within high-income societies, there was a period between 1890 and 1980 where lower-income families were those with more children.

Such theories face a number of challenges in modeling the actual world of Industrial Revolution England. The first challenge is that these theories are expressed always in terms of children surviving to adulthood. In the modern world, in most societies, child survival rates are high, and so, in practice, births and surviving children are closely equivalent. But in all known preindustrial societies including preindustrial England, large numbers of children did not survive even to their first year. In these cases, the distinction between births and surviving children becomes important. Measured in terms of births, Malthusian societies witnessed high fertility, with the average woman surviving to age 50 giving birth to 5 children. But in such societies, the average number of children surviving to adulthood could only be 2.

Further, since children who died in the preindustrial world tended to do so fairly early, the numbers of children in any household at any time in the preindustrial world would typically be 3 or less. For example, of 1,000 children born in England in 1700–1724, nearly 200 would be dead within 6 months (Wrigley et al. 1997). Preindustrial families would look similar to the families of the USA in the high-growth 1950s and 1960s. Preindustrial families thus faced remarkably similar trade-offs between the number and quality of children as do modern families. In some sense, there has been no change in fertility from the preindustrial to the modern world measured in net as opposed to gross terms.

The second challenge these theories face is that in England, the transition from high births per woman to lower levels of births per woman did not occur at the onset of the Industrial Revolution but only 100 years later – in the 1880s, after efficiency growth rates changed fundamentally.[43] Fertility in England did not show any decline at the aggregate level prior to 1880. Indeed, the opposite occurred, as Fig. 12 illustrates. Births per woman and also net fertility rose precisely in the period of the Industrial Revolution in England.

The third challenge is that in cross section in preindustrial England, there was a strong positive association between net fertility and the wealth or occupational status of families. Figure 13, for example, shows by 20 year periods the numbers of children alive at the time wills were made for married men in England between 1520 and 1879, where those leaving wills are divided into wealth terciles defined across the whole sample. The lowest tercile in wealth would still be men of above median wealth at death. Their implied net fertility is similar to that for men as a whole in England, as revealed by Fig. 13. But the men of the top wealth tercile marrying before 1780 were leaving on average 3.5–4 surviving children. The most educated and economically successful men in preindustrial England were those with the largest numbers of surviving offspring. Matching these men to parish records of births shows that this advantage in numbers of surviving children stems largely from

[43]France was the only country to experience a decline in fertility starting in the late eighteenth century, and France of course lagged Britain in terms of the onset of modern growth.

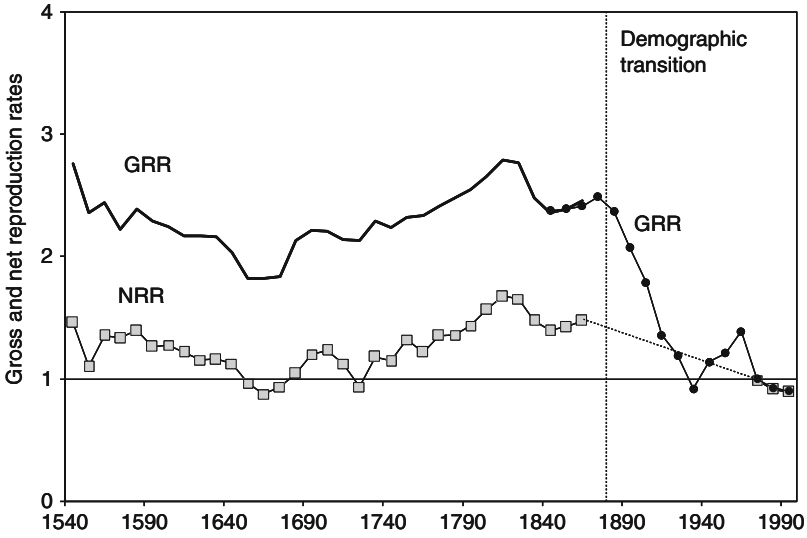

Fig. 12 The fertility history of England, 1540–2000 (Source: Clark 2007a, Fig. 14.6, p. 290)

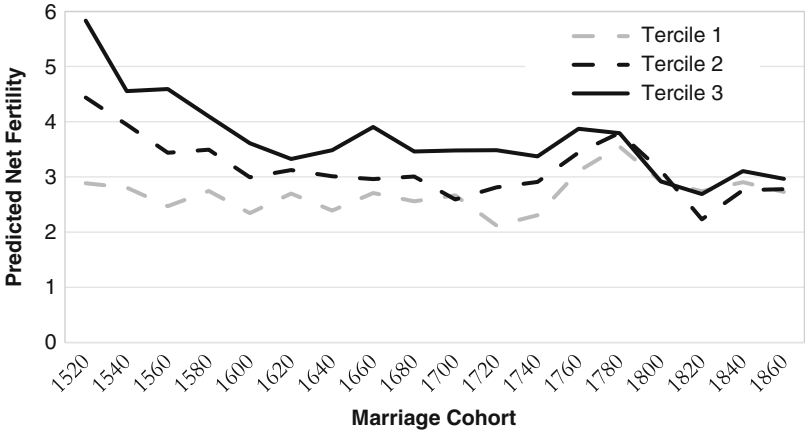

Fig. 13 Net fertility by wealth terciles, marriage cohorts, 1520–1879 (Source: Clark and Cummins 2015)

the greater fertility of the wives of richer men. Their gross fertility was equivalently higher. This positive association of economic status and fertility pre 1780 has been confirmed in an independent study of gross fertility in parish records in England from 1538 to 1837 by Boberg-Fazlic et al. (2011).

For marriages from 1780 to 1879, this pattern of high fertility by the rich and educated is more muted. Instead, we have an interval for most of the Industrial Revolution period where fertility is weakly positively linked to education, status, or wealth. Figure 14 shows the shift in pattern this represents, grouping married men by

Fig. 14 Net marital fertility by wealth decile, marriages 1500–1779 and 1780–1879. Note: The lines at the *top* of the *columns* indicate the 95% confidence interval for the net fertility of these groups relative to the decile of lowest asset income. All assets normalized by the average wage in the year of death from Clark 2010 (Source: Clark and Cummins 2015)

wealth deciles. However, the high overall fertility levels in England at the time of the Industrial Revolution meant that completed family size even for wealthier families continued to be large.

The delay in the decline in aggregate fertility levels in England until after the Industrial Revolution represents a formidable challenge for theories that seek to explain the Industrial Revolution through a quality–quantity trade-off and rising levels of human capital. For it implies that the agents making the Industrial Revolution were still typically from much larger families than in the modern world. Figure 15, for example, shows completed family size for marriages of richer families in England occurring from 1770 to 1879, where by completed size we mean children reaching at least age 21. While the average person in the modern middle class in Europe or the USA has only one sibling or less, this pattern of family sizes implies that the average middle-class person in England born before 1900 had four or more siblings. The engineers and the innovators who made the breakthrough of the Industrial Revolution were typically drawn from families that were very large by the standards of the modern era. Explaining the breakthrough of the Industrial Revolution by the operation of any quality–quantity trade-off in England thus seems a blind alley.

One reason the prosperous of Industrial Revolution England continued to have very large families may be that there is little sign that quantity had much effect on the quality of their children. For these richer families, one measure we have of quality in terms of human capital, though only for boys, is whether they enrolled at Oxford or Cambridge. We can thus estimate the coefficients of the regression

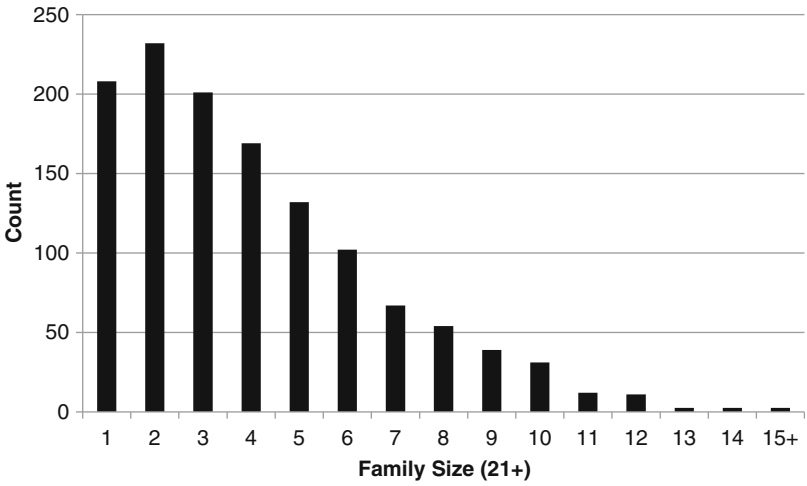

Fig. 15 The distribution of family size in english upper classes, marriages 1770–1879 (Source: Clark and Cummins 2014)

$$\mathrm{DOXB}_{t+1} = a + b_1\mathrm{DOXB}_t + b_2\ln(\mathrm{Wealth})_t + b_3N + e_t$$

where DOXB is an indicator variable for attending Oxford or Cambridge, t is the generation, Wealth is wealth at death, and N is the number of siblings. The estimated values of b_1 and b_2 are both positive and significant. Wealthier fathers who attended Oxford or Cambridge themselves are likelier to have sons who attend. But the coefficient on family size is insignificantly different from 0. There is no sign in education of any quantity–quality trade-off.

Longevity is another measure of child quality. In this sample, for example, sons who attend Oxbridge live on average nearly 4 years longer than those who do not attend. So we can also estimate the effect of family size on longevity, where in this case we can also include daughters. Thus, we estimate the coefficients of the regression

$$\mathrm{AGE}_{t+1} = a + b_0\mathrm{DFEM}_t + b_1\mathrm{PAGE}_t + b_2N + e_t$$

where AGE is child age at death (21+), DFEM is an indicator for a daughter, PAGE is the average of the parents' age at death, and N is again the number of siblings. There is a significant association between PAGE and AGE, but again, family size has no significant effect on age of death of children.

The final measure we have of child outcomes is wealth at death. Here, family size does play a role. We estimate the effect of family size on wealth through estimating the coefficients of the regression

$$\ln W_{t+1} = b_0 + b_1\ln W_t + b_2\ln N + b_3\mathrm{DFALIVE} + e_t$$

where N is family size, W indicates wealth, and DFALIVE is an indicator for when the father is still alive at the time of the son's death. DFALIVE is a control for the

effects of sons who die before fathers and thus likely receive smaller transfers of wealth from fathers. Such sons will also tend to be younger. And in this data, wealth rises monotonically with age until men are well past 60. With this formulation, b_2 is the elasticity of a son's asset income as a function of the number of surviving children the father left. N varies in the sample of fathers and children from 1 to 17. The coefficient b_1 shows the direct link between fathers' and sons' wealth independent of the size of the fathers' family.

For wealth, the coefficient on numbers of children is negative and strongly statistically significant. For sons, the estimated value is -0.43. However, it is much less in absolute value than -1. This implies that while additional children reduce the wealth at death of each sibling, inheritance cannot be the main force determining wealth at death for these children. Wealthy fathers tended to produce wealthy children independently of the actual expected value of the bequest to the child.

Hence, in the Industrial Revolution era, we find that family sizes for the educated classes remained large but seemingly had little effect on children's outcomes except for a partial dilution of their wealth at death. Thus, there is no sign that the Industrial Revolution was created by any move to reduce family size and correspondingly enhance child quality. The revolution was largely achieved in a world where average family sizes remained large for the educated share of the population.

These facts about the transition from preindustrial to modern fertility in England in the Industrial Revolution era represent a formidable challenge to those trying to model the Industrial Revolution in a child quality–quantity framework. Since some of these patterns such as the strong positive association of wealth and fertility in preindustrial England were discovered only in the last few years, many of these models fail to capture essential features of the fertility transitions (Clark and Cummins 2015; Boberg-Fazlic et al. 2011).

So, if changes in family size were not important, why were economic agents in England more effective after 1800? Clark (2007a) postulated that the excess fertility of the rich in the years 1250–1800 observed in England could itself be a factor changing the characteristics of the population across the preindustrial era. We know that all through English history, there is a strong correlation between children and their parents in economic success. So, as the population over many generations shifted toward the children of those achieving economic success, could this have raised the general economic abilities of the society? A full discussion of this issue would take us too far from the specific issue of the Industrial Revolution. But it remains an intriguing possibility that the societies we observe now all have a *deep history*, a set of social conditions over millennia that continue to exert influence on their current possibilities and abilities.

Conclusion

The Industrial Revolution remains one of history's great mysteries. At one level, the transformation is very clear and easily described. After millennia of extremely low rates of technological progress, England in the Industrial Revolution made the first

great step toward modern rates of technological advance. But why this monumental break with the patterns of millennia occurred on a small island of six million people on the periphery of Europe remains a mystery to this day. Attempts by economists to model this transition in terms of institutions and incentives have been so far largely unsuccessful. Changes in institutions and the incentives they generate seem to play little role in the transformation of England in these years. Such changes would also predict an Industrial Revolution much earlier in the seventeenth century in the Netherlands. There is also little sign of any major changes in the underlying parameters of the economy circa 1780 which would lead to changed behavior by individuals.

There is clear sign in England in the 500 years leading up to the Industrial Revolution that there were changes occurring in the basic behaviors of economic agents, changes that might explain an enhanced rate of technological advance. The underlying interest rate in England fell, for example, from 10% in 1300 to 4% by 1770. But what drove these changes remains mysterious. These changes occurred before any significant decline in realized family sizes for the English upper classes, so they do not represent the quantity–quality trade-off beloved by modern growth theorists. There is an intriguing possibility that they are the result of a logic inherent to the preindustrial Malthusian demographic regime, which predicts that the economically successful in any society will also be the demographically successful. But for this to explain an English Industrial Revolution, it would have to be the case that this process was more advanced in England than in other societies. This is an open-research question. We know, for example, that in Qing China, similar Malthusian demographic processes were at work, but we cannot yet quantify whether they had less force in China than in England.

So, 250 years after its first appearance, the Industrial Revolution remains one of the great puzzles of human history, a challenge for future generations of researchers in cliometric history.

The Antebellum US Economy

Gavin Wright

Contents

Abstract

In the antebellum era, the economy of the United States underwent an acceleration of economic growth. Cliometric studies have established not only that growth predated the Civil War but that many features prominent in later years – commercialization of agriculture, urbanization, the rise of manufacturing, and mass European immigration – were clearly visible in the antebellum period. This chapter reviews and summarizes this body of research. A notable dimension of this history is that growth and development transpired under two distinct regimes: the slave economy of the southern states and the family-farm, wage

labor economy of the free states. This experiment in comparative development has also been a focus of cliometric attention and thus provides a second theme for the essay.

Introduction

From the Constitution of 1789 to the secession crisis of 1861, the economy of the United States underwent an acceleration of growth, reaching annual rates of 1.7% per capita by the late antebellum decades. Cliometric studies have been instrumental in establishing not only that growth predated the Civil War but that many features of the growth process prominent in later years – commercialization of agriculture, urbanization, the rise of manufacturing, mass European immigration, and rapid adoption of new technologies – were clearly visible in the antebellum period. This chapter reviews and summarizes this body of research. Because Douglass North's *The Economic Growth of the United States, 1790–1860*, first published in 1961, was something a landmark in the rise of cliometrics; that book proves helpful in defining the issues and consolidating the results of more than a half-century of scholarship since then.

A notable dimension of the antebellum US economy is that growth and development transpired under two distinct regimes: the slave economy of the southern states and the family-farm, wage labor economy of the free states to the north. Although both regions shared in the antebellum growth spurt, patterns of geographic settlement and investment were strikingly different between them, with important implications for subsequent eras. This historical experiment in comparative economic development has also been an important focus of cliometric attention and thus provides a second theme for this essay.

Estimates of Gross Domestic Product, 1790–1860

Compiling estimates of national income and product over extended historical periods was one of the earliest and most important contributions of cliometrics. Simon Kuznets received a Nobel Prize for developing the modern framework for national income accounts in the 1930s, extending his estimates back to 1869 in subsequent work. Robert E. Gallman, a former student of Kuznets, constructed new estimates for 1834–1909, using figures for commodity production (agriculture, mining, and manufacturing) from the federal censuses of 1839, 1849, and 1859 as "major" benchmarks and extending the series to other years on the basis of state censuses (Gallman 1960, 1966). The results clearly showed that high rates of per capita growth predated the Civil War.

Gallman's figures had a solid basis in the national surveys of agriculture and manufacturing that began with the US Census of 1840 (reporting economic data for 1839). Estimates for early years have to be derived from much more fragmentary sources, prompting Paul David to label this era a "statistical dark age" (David 1967). David constructed new "conjectural" estimates by combining evidence on average agricultural productivity from Towne and Rasmussen (1960) with estimates of the agricultural labor force from Stanley Lebergott (1964) and assuming that the productivity ratio between the two sectors was constant across the period. The results showed little or no growth between 1800 and 1820, followed by a sharp spurt between 1820 and 1840. Alternative labor force figures developed by Thomas Weiss (1992, 1993) and supplemented by evidence from Kenneth Sokoloff (1986) on productivity growth in manufacturing pointed to a more gradual acceleration of growth between 1800 and 1840.

The subsequent literature raised a number of questions about the underlying evidence and interpretation of these estimates. Nancy Folbre and Barnet Wegman (1993) noted that the conventional definition of GDP descended from Kuznets excludes housework, childcare, and other nonmarket outputs chiefly (though not exclusively) produced by women and that women also contributed to marketed production on farms, though they are excluded from the labor force by convention. These concerns are particularly pressing for this historical era, when farms were organized as family enterprises and a large fraction of their produce did not pass through markets. Thus Weiss presents two sets of estimates of farm productivity, a "broad" output measure that includes home manufactures and improvements and a "narrow" version that counts only the market value of farm products. In 1800 the gap between the two was 17.5%, and by 1900 it had virtually disappeared. Using market values may be said to overstate growth, because some of the expansion represents a resource transfer from nonmarket to market activity. But because commercialization was itself a contributor to growth, neither alternative is unambiguously "correct." Both series, it should be noted, show an acceleration of productivity growth after 1850.

Another interpretation is suggested by a later set of estimates by David (1996). Abandoning the notion of a productivity "gap" between agriculture and manufacturing as inappropriate for the early American land-abundant setting, David constructed detailed estimates of hours of labor by sector. His conclusion is that more than half of the average annual growth rate of 0.9% between 1800 and 1840 was attributable to an increase in hours worked per year: a labor force "working harder" rather than "working smarter."

A genuine infusion of new evidence into this context was provided by Joseph H. Davis (2004), who compiled an annual index of US Industrial Production beginning in 1790. Drawing upon previously untapped sources such as state inspection records and local trade organization reports, Davis collected a total of 43 quantity-based series for mining and manufacturing, most entirely new. Many of these date from 1790, such as copper smelting, firearms, fire engines, shipbuilding, newspaper publishing, and pipe organs, while others enter the index at later dates. The Davis index shows almost continuous growth from 1790 onward. It is of

relatively limited direct value in estimating GDP per capita, because the index measures total production rather than productivity and because nonagricultural occupations (only partially covered by "industrial production") accounted for less than 25% of total employment in 1800. Nonetheless, the series has been used to interpolate GDP estimates based on benchmark dates and to improve knowledge of the timing and magnitude of fluctuations in economic activity (Fig. 1). Even the list of new industries entering the index (presumably because production first began or first became notable enough to be counted) such as whale oil refining (1793), salt production (1797), milled wheat flour (1798), fish curing (1804), gunpowder (1804), wool stockings (1808), hog packing (1809) make it evident that an economic development process was underway.

The most recent attempt to re-estimate antebellum growth is by Peter H. Lindert and Jeffrey G. Williamson (2016). Whereas virtually all other estimates are constructed directly or indirectly from the production side, Lindert and Williamson instead build their new figures from the income side, using the venerable methodology of "social tables": average incomes for various classes of society, such as officials, merchants, artisans, farm operators, and laborers. The authors draw upon the federal tax assessment of 1798 to estimate incomes for 1800 and then use the federal censuses to generate new figures for 1850 and 1860. Thus, they cannot address the debate about the timing of growth acceleration. But the new estimates confirm the finding of strong per capita growth across the entire period. Indeed, their point estimate of 1.42% average annual growth between 1800 and 1860 is higher than any previous estimate and higher than the growth rate of any other country during this period. The reasons for these differences are not clear, but caution is advisable, because the estimates by other scholars and for other countries were not generated by similar methods and may not be conceptually comparable. A prudent assessment would be that Lindert and Williamson confirm the broad consensus

Fig. 1 The left-hand axis is in 1996 dollars. The right-hand axis is an index set at 1849–1850 = 100, divided by the resident population. (Source: Carter et al. (2006), Series Ca11, Ca14, Ca19. The original source is Davis (2004))

among cliometricians that aggregate US production and incomes per capita grew at accelerating rates prior to the Civil War, putting the country on a path toward world leadership by the end of the century.

Napoleonic Wars, Embargo, and the War of 1812

Within 3 years of the new constitution, economic activity along the Atlantic seaboard began to accelerate. The problem with relating institutional to economic change is that the primary stimulus was external: the advent of the long period of European conflict known as the Napoleonic Wars, during which American shippers and shipbuilders took advantage of the nation's neutral status. As North wrote: "One need look no further than to events in Europe to account for nearly every twist and turn in the fortunes of the American economy during these years" (1961, p. 36). The growth in US foreign earnings came primarily from the carrying trade (shipping services), shipbuilding, and reexports of goods from the West Indies and other tropical sources (Fig. 2).

Cliometricians have debated North's assertion that "the years 1793–1808 were years of unparalleled prosperity" (p. 53). Claudia Goldin and Frank Lewis (1980) estimated that the surge of foreign demand across these years augmented US growth by an average of 0.22 percentage points. In contrast, Donald Adams (1980) noted that this period saw no sustained increase in real domestic imports per capita, perhaps because higher freight rates caused by pressures on capacity acted as a tax on American consumers. In the absence of reliable annual income figures, this debate may be impossible to resolve. But, North also argued that the period of seaboard prosperity fostered long-term developments in financial and urban infrastructure, laying "important foundations for the growth of the economy after 1815"

Fig. 2 The vertical axis is in millions of dollars. (Source: Historical Statistics of the United States, Colonial Times to 1970 (1975): Series U190, 192, 193)

(p. 53). Examples include the rise of banking and insurance companies, much of which serviced the shipping industry, and construction of warehouses and turnpikes, driven by growth of the urban population. Richard Sylla (1998) has shown that capital markets were active in Boston, New York, Philadelphia, and Baltimore far earlier than previously believed, with a strong surge between 1797 and 1811. It seems evident that the capital demands of shipping and urban growth were important forces behind this development.

What we do know is that the era of open trade with the warring nations came to a crashing close with Jefferson's Embargo of December 1807, which closed down all foreign trade. This effort to assert American rights on the high seas gave way to agreements that partially restored trade over the next 4 years, but the seaboard economy never returned to its former glories, and ultimately the US itself entered the conflict by declaring war on Britain in June 1812. From an economic standpoint, 15 years of open economy were followed by 8 years of closed economy, the most severe isolation coming during the later war years, when Britain blockaded the entire US coast. Davis and Irwin (2003) show that the composition of US industrial production radically shifted, from trade-dependent industries such as shipbuilding (which contracted) to domestic infant industries such as cotton textiles (which boomed).

Joshua Rosenbloom (2004) makes the case that the rise of the antebellum US cotton textile industry exemplifies a "path-dependent" historical process, whereby the 8-year break from foreign competition triggered developments with enduring consequences long afterward. The discontinuity in industry growth supports this interpretation: Even after the transfer of Arkwright's spinning technology to America by Samuel Slater in 1790, by 1807 the United States still had only 8,000 spindles; that number jumped to 31,000 in 1809 and to 300,000 by the war's end in 1815. Despite the devastating effects of renewed British imports in 1816, the industry's capacity never declined thereafter; within a few years, growth had resumed.

An important question for this thesis is: What was the basis for the industry's survival and growth in the postwar era? One set of factors may be classified as "learning": gains in skills and experience on the part of workers, managers, and machine-makers. We have little detailed knowledge of these matters for this early period, but we can point to one technological innovation that was critical to the industry's success in later years: adoption and improvement of the power loom by mechanic Paul Moody, who was employed by Boston merchant Frances Lowell at the Boston Manufacturing Company. The BMC was established in 1813 during the wartime boom, and its business strategy embodied features that became hallmarks of a distinctive American approach: large capitalization, integrated spinning and weaving under one roof, and commitment to long production runs of uniform products, coarsely woven but durable. The firm also innovated in its labor policies, recruiting young, unmarried women from the New England countryside, to be well-housed and supervised in dormitories under what was known as the "Massachusetts system." All of these innovations may be understood as adaptations of British technologies to the labor-scarce, resource-rich American environment.

A difficulty in presenting this case as a clear illustration of the "infant industry effect" is the postwar competitive setting, which was also reshaped by new protective tariffs, beginning with the Tariff of 1816 – another aspect of Rosenbloom's case for path dependence. Although New England's representatives favored free trade before the war, protests from failing textile owners pushed many of them toward protection in that year. One of the leading voices was Frances Lowell himself, who was instrumental in enacting a "minimum valuation" on imports of 25 cents per square yard. Because this principle effectively constituted a prohibitive tax on Asian cloth made of Asian cotton, the measure won a number of Southern votes. The industry thus received several more years of breathing space in their favored product lines (Temin 1988). Tariffs were increased still further during the 1820s, as emerging patterns of regional specialization became clearer, pushing erstwhile supporters of mercantile interests (such as Daniel Webster) into the protectionist camp. The "Tariff of Abominations" in 1828 and the Nullification Crisis of 1832 made clear that the tariff had become a major issue of regional conflict.

Transportation Revolution

The dramatic fall in the costs of transportation, associated with rapid extension of settlement and markets, was a defining feature of the antebellum economy. This phenomenon was central to the interpretation of Douglass North, who called it "the most pervasive influence affecting the. . .shift from pioneer self-sufficiency to a market oriented agriculture" (1961, p. 143). An interest in the role of government in promoting such "internal improvements" was in the air during the 1950s, as economic historians sought to explore the lessons of the US experience for countries pursuing development programs in our own times. Carter Goodrich of Columbia University should be considered one of the founders of cliometrics, in that his students H. Jerome Cranmer, 1960, and Harvey H. Segal, 1961, assembled statistical evidence to track the flow of investments in canals over time and to estimate the benefits of those investments for the economy (Cranmer 1960; Goodrich 1961). This was the intellectual background for the two landmark railroad books by Albert Fishlow (1965) and Robert Fogel (1964). (Fogel's book dealt primarily with the postbellum economy and hence will not be reviewed here.)

Turnpikes

The drive to improve transportation long predated the large-scale canal projects of the 1820s and the 1830s. Beginning in the 1790s, a network of toll roads known as "turnpikes" crisscrossed the northern and middle states, constructed in most cases by corporations chartered by the states for specific ventures. More than 70 such companies were created by 1800, rising to as many as 800 by 1830, comprising more than 11,000 miles of roads and accounting for between one-fourth and one-half of all business incorporations in these states. From an economic standpoint, a remarkable

feature of these corporations is that although they were chartered as profit-seeking enterprises, nearly all of them lost money. It is not unusual for entrants into a competitive industry to experience losses, perhaps because of overoptimistic expectations or severe competition. But when hundreds of firms enter an activity with a proven track record of losses, one is driven to the conclusion that they must have known what they were getting into. Despite the adverse prospects, stock subscriptions were typically broad-based in the affected areas. Daniel Klein (1990) describes the ways in which turnpike promoters persuaded community members to invest, invoking the shared interests of farmers, merchants, and land speculators to overcome free rider problems. The patterns illustrate the American "cooperative spirit" that so impressed Tocqueville but also Veblen's characterization of the American town as a form of collusion among "interested parties" whose social cohesion was enhanced by a common interest in its real estate values. Compared to the more densely populated United Kingdom, these "indirect benefits" of transportation investments were far more important in the United States (Bogart and Majewski 2008).

Canals

Turnpikes extended the range of markets, but they could not overcome a basic fact of economic geography for this period: the dramatic 10- to 30-fold differential between ton-mile rates on overland relative to water modes of transportation (Carter et al., vol. 4, p. 781). This gap gave rise to a demand for canals, "artificial rivers" to augment the nation's natural waterways. These larger-scale projects were typically beyond the reach of local governments, and so the states took the lead in the post-1815 era, beginning with New York's 363-mile Erie Canal, linking the Great Lakes to the Atlantic Ocean via the Hudson River. Begun in 1817 and opened on November 4, 1825, the Erie was a decisive turning point in transportation history, spawning as many as a hundred imitative projects and 3,000 canal miles by 1840 (Goodrich 1961).

John Wallis and Barry Weingast (2018) theorize that the states played the leading role in the antebellum era because the federal government was locked in a position of "equilibrium impotence": the US Constitution required direct taxes to be allocated on the basis of population, so the federal government was unable to develop a system of "benefit taxation" in which costs were borne by the areas that gained the most from transportation project. As a result, federal infrastructure expenditures tended to be collections of small projects broadly distributed around the country, such as lighthouses and rivers and harbors. In contrast, state governments (who faced similar problems of sectional rivalries) did use schemes that coordinated taxes and benefits. For example, in 1817 New York created a special "canal tax" to be levied on counties along the canal, if additional funds were required to service state bonds. Ohio in 1826 and Indiana in 1836 created new ad valorem property taxes to allocate the burdens more equitably and to align these burdens more closely with increases in land values that were the consequence of state projects. Wallis (2003) shows that Indiana's Mammoth system of canals, railroads, and turnpikes followed directly on this change in public finance.

This political economy analysis should not be understood as an argument that construction of the American canal network was efficient. No state replicated New York's Erie success in generating revenues sufficient to pay off the bonds early – a performance the state subsequently squandered by extending canals through many interior counties. One-fifth of all canal ventures were costly failures, contributing to the wave of defaults on state bonds during the depression in 1839–1843. Even for the survivors, canal abandonments continued during the 1840s, as many were soon rendered obsolete by the railroads. With all of these defects, however, the canal era in many respects launched the nation on the path to economic development. Lee Craig et al. (1998) show that location on a canal or river in 1850 raised land values by $2.68 per acre, a result confirmed by Wallis (2003) for Indiana a decade earlier. Treatment-control and difference-in-difference methods were anticipated by Segal (1961), who showed that canal counties experienced more rapid settlement and occupational shifts into commerce and manufacturing compared to non-canal counties. Andrew Coleman (2012) uses New York and federal censuses to develop a panel of households for 1825 through 1845, confirming that farm families with access to the canal reduced home production of cloth, in favor of commercial activity and factory-made goods. Coleman adds the interesting detail that new arrivals to the canal zone had lower home production activity than long-established residents. Eventually, however, the old-timers copied their neighbors and reduced home production to similar levels.

Steamboats on Western Rivers

An innovation that augmented the shift from land to water transportation was the steamboat, which radically reduced the time and cost of upstream river routes (Carter et al. 2006, vol. 4, pp. 878–880). Neither the steam engine nor the steamboat were US inventions, but from the time of Robert Fulton's commercially successful passenger service on the Hudson River in 1807, steamboating on internal waterways became an American specialty. Fulton and his partner Robert Livingston were granted a monopoly by Louisiana in 1812, but this proved unenforceable even before the Supreme Court confirmed exclusive federal authority over interstate commerce in *Gibbons vs. Ogden* (1824). Thus driven by competitive forces, round-trip travel times between New Orleans and Louisville fell from 30 days in 1815–1819 to 11.7 days in 1860. Haites et al. (1975) estimate that total factor productivity in western river steamboating grew at an average annual rate of 4.6–5.5% over the entire period 1815–1860.

Steamboats became faster and cheaper, but they were also hazardous. Paul Paskoff (2007) tallies 1,166 wrecks on US waters between 1821 and 1860. Highly publicized fatal explosions led to federal regulatory acts in 1838 and 1852, of uncertain effect. Although the absolute number and tonnage of losses increased over time with growing commerce, rates of loss clearly declined. Whereas Haites et al. attributed efficiency gains on the rivers almost entirely to private enterprise, Paskoff builds a persuasive case for the efficacy of the federal government's support

for removal of snags and other natural hazards, under the Rivers and Harbors legislation. This relative success contributed not just to safety but to the growth of total factor productivity by reducing losses, encouraging larger vessel size, and increasing steamboat longevity. As with virtually all phases of the antebellum transportation revolution, a combination of private initiative and public support was at work.

Railroads

US railroad mileage in the antebellum era was small relative to later decades, barely one-sixth of the total for the nineteenth century as a whole. Yet this amount was greater than that of any other country at that time, greater indeed than the rest of the world combined, and its effects were transformative, as recounted in Albert Fishlow's now-classic 1965 book. Digging deeply into industry records as well as government sources, Fishlow assembled detailed new estimates of railroad output, receipts, capital expenditures, employment, and profits and deployed these to address basic historical issues. Among these were the direct benefits of railroad transportation services, forward and backward linkages, and the impact of the railroad on regional patterns of domestic commerce.

Probably the most influential chapter was Fishlow's critique of Joseph Schumpeter's dictum that antebellum railroad building "meant building ahead of demand in the boldest acceptance of that phrase" (quoted in Fishlow 1965, p. 165). Restating this assertion as "an initial disequilibrium that is self-correcting over time. . .by induced shifts in the demand schedule" (1965, p. 166), Fishlow developed a series of tests: ex ante risk premiums for investment, ex post profits, and patterns of sequential construction and governmental assistance. On each count, he found that the hypothesis failed. During the 1850s, railroads first entered counties that already had higher population densities and wheat production than their neighbors. Most were highly profitable from the start; small sections of line typically opened as soon as they were completed, to the cheers of expectant farmers. Most tellingly, governmental aid during this period came mainly from local rather than state or federal sources, from towns and counties eager for a new rail line and fearful that they might be bypassed. An active recruiting and promotional role for such communities is the opposite of what one would expect to see if railroads were built ahead of demand.

There was one complicating factor, however, the phenomenon Fishlow called "anticipatory settlement." Settlers may have been on the ground waiting when the railroads arrived, but their choice of location was heavily influenced by expectations regarding the railroad's path. Anticipating the impact on land values, farmer-speculators wanted to "get in on the ground floor" ahead of their rivals. This consideration undermines the simple conceptualization behind the empirical tests, the notion that the issue could be answered on the basis of timing. As Fishlow wrote: "In a larger sense, therefore, railroads *were* a leading sector. . .[but] this interpretation takes us far from a simple Schumpeterian world. Indeed, it almost turns that

model on its head: instead of a heroic role for the railroad investor or even the state, the beneficiary of railroad construction displays the crucial attributes of foresight" (1965, pp. 165, 197).

Many subsequent cliometric studies have pursued issues related to antebellum railroads. The most recent use geographic information system (GIS) databases drawn from digitized historical travel guides, allowing authors to pinpoint railroad locations and timing far more precisely. Atack et al. (2010) deploy difference-in-difference methods to compare railroad with non-railroad counties, showing that the entry of railroads had a small effect on population density but a large impact on urbanization. As a robustness check, the authors use instrumental variables based on early (pre-railroad) government surveys of potential transportation routes. Atack and Margo (2011) extend this methodology to document an effect on agricultural improvement and farmland values.

Note that these questions differ from Fishlow's. Fishlow asked whether railroads were built before they were commercially viable, i.e., whether they induced settlement in a dynamic sense, while the later scholars set out to identify the "treatment" effect of railroads on economic outcomes. Their approach is to look for "credible exogenous variation" in rail access, and for this purpose, endogeneity in the geography of rail location is a source of bias to be corrected through instrumentation. Indeed, the first stage IV regressions confirm the very endogeneity that Fishlow described – biasing the DID coefficients downward – but the objective of the articles is to purge this effect rather than to analyze it. The new results would not surprise Fishlow, who argued throughout that antebellum railroads were transformative.

Atack et al. (2014) come closer to capturing Fishlovian dynamics in their econometric procedure. These authors link the GIS database to a census of banking, exploring the detailed timing of railroad construction and bank entry. They show first that railroads tended to link existing financial-commercial centers but next that new bank entry quickly followed (within 1–3 years) in the wake of rail construction. Their conclusion is that "financial and real factors interact[ed] to put a virtuous cycle of economic development in motion" (p. 943). The deeper implication is that the grass-roots foundations for transportation improvements were broadly similar from the turnpikes to the railroad era.

Productivity Growth in Agriculture

Because the great majority of the antebellum labor force was in farming, acceleration in growth for the economy as a whole would have to entail productivity growth in agriculture. Extending a methodology utilized by the US Department of Agriculture, William N. Parker developed productivity estimates for individual crops, by decomposing output per laborer into labor requirements per acre (distinguishing preharvest, harvest, and postharvest labor) and yields per acre. The results clearly pointed toward mechanization as the primary source, as proxied by the increase in acres per laborer (Parker and Klein 1966). Although the research sought to track

productivity growth over the long period from 1840 to 1910, it is evident that the trends toward mechanization and larger acreages were underway well before the Civil War.

One of the most widely discussed studies in cliometrics is Paul David's analysis of the diffusion of the mechanical reaper in antebellum Illinois (David 1966). Although the machines invented by Obed Hussey and Cyrus McCormick were available as early as 1833 or 1834, they were not widely adopted until the mid-1850s. David's explanation for this 20-year lag is that most Midwestern grain farms were too small in harvestable acreage to justify the fixed cost of purchasing a reaper. David estimated the threshold scale for reaper profitability as 46.5 acres using the factor prices of 1849–1853, whereas Illinois farms in 1850 averaged only 15 or 16 acres of wheat, oats, and rye. Between 1850 and 1860, however, harvest acreage grew as farm families continued their land-clearing operations, while the threshold size fell as reaper prices declined and the wages of harvest labor rose during the boom decade of the 1850s. The transversal of a falling threshold and a rising farm size distribution generated the sigmoidal adoption pattern commonly seen in diffusion studies.

Critiques across several decades have revised nearly all parts of this narrative. Alan Olmstead (1975) showed that the threshold calculation is highly sensitive to parameter assumptions, so that modest adjustments nearly doubled the estimated crossover point. Drawing on a sample of nearly 12,000 farms from the 1860 census, Jeremy Atack and Fred Bateman calculated a range of thresholds and found that only 41,000 reapers would have been profitable in that year, or 150,000 reaper-mowing machines (1987). Yet, Olmstead showed that as many as one-fourth of the reapers sold by McCormick were purchased jointly by two or more individuals, indicating that sharing arrangements were not infeasible. Olmstead's explanation for the lag in adoption was that the performance and reliability of the reapers improved considerably across the 20-year period. Olmstead and Rhode (1995) presented new evidence based on more than 1,000 reaper purchasers matched to the manuscript censuses. Their data showed that although the relative propensity to buy a reaper increased with small-grain acreage, the pattern was by no means discontinuous at a specific threshold. The authors went on to question the threshold concept more thoroughly, drawing on farm diaries to suggest that individual operators typically drew assistance from neighbors at peak times, offering their own labor at other times in exchange. In this view, effective use of mechanized equipment was less a micro-level choice by self-contained farm households than a community undertaking, reflecting norms of cooperation not unlike those of the turnpike movement.

The significance of the mechanization debate goes well beyond the detailed timing of reaper adoption. At issue is the characterization of the contrast between agriculture in the free and slave states. As proposed by Heywood Fleisig (1976), an essential feature of slavery was to provide an elastic supply of labor to individual farms, allowing them to expand acreage and production without mechanization. In contrast, free labor was scarce and unreliable, long-term contracts legally unenforceable. Olmstead and Rhode (1995) show that farmers were not limited to members of their own family, but this evidence does not gainsay the broader observation that in

the absence of slavery, acreage could not expanded indefinitely on the basis of hired labor. As Fleisig shows, the size distribution of farms under slavery extended well beyond that of the free states, and larger free-state farms had greater investments in implements and machinery.

To be sure, one cannot necessarily compare cotton and wheat farms directly, because these crops were quite different both in seasonality and technology. It is possible, however, to compare northern wheat farms with the slave-using wheat farms of Virginia. Despite the common belief that slave labor was not well-suited for wheat, the two were in fact closely connected in the fertile Valley of Virginia and the Piedmont, so much so that James Irwin (1988) published an article "Exploring the Affinity of Wheat and Slavery in the Virginia Piedmont." Irwin's data showed that slavery was more closely tied to wheat than to tobacco in that area and that slave-using wheat farms were larger and more productive than their smaller counterparts. A plausible explanation is that slave owners could mobilize virtually the entire captive labor force at the time of the harvest peak. As one ex-slave recalled: "John Fallons had 'bout 150 servants an' he wasn't much on no special house servants. Put everybody in de field, he did, even de women. Growed mostly wheat on de plantation, an' de men would scythe and cradle while de women come along an' stack" (quoted in Wright 2006, p. 119). On this reading, slavery and mechanization were alternative methods of expanding cash crop acreage.

Biological Sources of Productivity Growth

A more fundamental challenge to mechanization as the exclusive driver of productivity was provided by Olmstead and Rhode, in their 2008a book *Creating Abundance: Biological Innovation and American Agricultural Development*. The relative constancy of land yields over time led many economists to infer that farmers devoted little attention to improving crops, but Olmstead and Rhode show that this was far from the case. An 1840 survey found 41 wheat varieties under cultivation in New York State, and in 1857 the Ohio State Board of Agriculture identified 111 varieties that had been grown in recent years. One reason for diversity was that the geographic centers of cultivation were constantly changing, generating demands for new varieties adapted to new geo-climatic areas. Even within localities, static plants came under unrelenting attack from pathogens (such as rusts and other fungi) and pests, such as the Hessian fly, the grain midge, and the chinch bug. Maintaining constancy in land yields was itself a productive achievement requiring continuing effort – a phenomenon the authors call the curse of the Red Queen, after the Lewis Carroll character who declared that "HERE, you see, it takes all the running YOU can do, to keep in the same place." Olmstead and Rhode deploy their estimates of biological innovation to revise Parker and Klein on the sources of productivity growth, but the broader message is that such accounting exercises are misleading when inputs interact with each other in complex ways.

Olmstead and Rhode (2008b) extend their biological theme to the antebellum cotton economy. Economic historians have long noted the growth of cotton

production relative to the slave labor force, but this simple ratio reflects changes in the mix of crops and in the geography of cotton, as well as true productivity growth. Drawing from the records of 142 plantations, Olmstead and Rhode develop a panel dataset of picking rates between 1801 and 1862, reporting a fourfold increase, or a growth rate of 2.3% per year. To be sure, picking was not the only important labor activity in cotton farming, but it seems to have been the constraining task in most times and places. The authors argue that the principal force behind this productivity growth was the advent and diffusion of new cotton seeds, primarily those adapted from Mexican imports during the 1820s, and later hybrids. The new varieties sharply increased lint-to-seed ratios, while counteracting the adverse effects of plant disease (such as the "rot") and destructive insects (such as the boll worm and the cotton worm). This evidence confirms that cotton farmers were entrepreneurial and adaptive like their northern counterparts. It does not undermine the assertion that a substantial portion of southern growth was attributable to a shift onto superior cotton lands, but the authors argue that these natural advantages were augmented by technological changes that were both picker-friendly and regionally biased. This new quantitative evidence has played an important role in ongoing debates between cliometricians and the "new historians of capitalism" (Olmstead and Rhode 2018).

Manufacturing and American Technology

The biggest splash in the antebellum economy was the rise of manufacturing. From the barest of beginnings before 1815, manufacturing output grew to more than 30% of national commodity output by 1859 according to Gallman (1966), roughly 20% of GDP. Still more impressive, many of these industries displayed novel technologies by mid-century, drawing international attention at the Great Crystal Palace Exhibition of 1851. In at least one case (small arms), technology flowed eastward across the Atlantic in the 1850s, sparking discussions of a new American System of Manufactures.

Economic historians have analyzed this American Industrial Revolution from the beginning, but quantitative evidence has been unsystematic and scarce. A breakthrough came from Kenneth Sokoloff (1986), who used data from the 1820 Census of Manufactures, the 1832 McLane Report, and samples from the 1850 and 1860 Censuses of Manufactures (see Atack et al. 2006) to construct estimates of labor productivity and total-factor productivity for northeastern manufacturing firms, 1820–1860 (Table 1). The results showed positive productivity growth for all 13 industries studied, averaging 2.2–2.5% per year across the 40-year period. The figures suggested an acceleration of productivity growth during the 1850s, particularly in boots and shoes, woodworking, iron, flour milling, tobacco, and wool. Sokoloff suggested an evolution of productivity over time, from an early phase based on organizational change (such as the advent of the factory and the employment of women) to an acceleration based on sophisticated capital equipment embodying new technologies.

Table 1 Growth rates of labor productivity in selected manufacturing industries, 1820–1860 (percent per year). The figures are average annual percentage change in an index of real value added per equivalent worker. The ranges of estimates reflect the difference between figures derived from firm data and those based on aggregate data. Averages based on fewer than 13 industries (affected by missing values) are reported in brackets. (Source: Sokoloff 1986, p. 698)

	1820–1850	1850–1860	1820–1860
Boots/shoes	1.0–1.2	4.4–5.2	2.0–2.1
Coaches/harnesses	1.8–2.0	2.7	3.7
Cotton textiles	2.3–3.5	1.9–2.9	2.2–3.3
Furniture/woodwork	1.9–2.7	3.8–6.2	2.9–3.0
Glass	3.7	−0.7	2.5
Hats	2.1–2.3	3.0–3.4	2.4–2.5
Iron	0.5–0.7	4.6–4.6	1.5–1.7
Liquors	0.5–1.9	2.0–5.3	1.7–1.9
Flour/grist mills	−0.4–0.4	1.6–3.8	0.6–0.7
Paper	6.0–6.2	−1.2–4.0	4.3–5.5
Tanning	1.7–3.0	−1.7–0.4	1.2–1.7
Tobacco	0.1–1.0	6.3–8.1	2.1–2.4
Wool textiles	1.3–2.3	4.4–7.0	2.7–2.8
Weighted average	[1.8]–2.3	3.2–[3.2]	[2.2]–2.5

What were the characteristics of these new technologies? This question has been the object of a long-running debate, following the thesis advanced by Habakkuk (1962) that American producers developed labor-saving, capital-intensive techniques in response to pervasive labor scarcity. The discussion is too lengthy for full review, but a broad consensus has emerged that Habakkuk's simple two-factor framework is not adequate to capture the distinguishing features of American technology. What has emerged instead is a set of identifiable traits that differentiated American from British manufacturing practice. Some examples include:

1. Greater use of natural resources relative to both capital and labor. In the antebellum era, American machines and products tended to be made of wood, and the country became an early leader in woodworking technology (Rosenberg 1976). A case in point was the Blanchard lathe, invented in 1818 for shaping gunstocks but adapted over time for reproducing other irregular shapes such as shoe lasts, hat blocks, spokes, and oars.
2. Use of special-purpose machinery for long production runs of standardized commodities (Ames and Rosenberg 1968). Such products were well-suited to the utilitarian tastes of American consumers and the relatively equal distribution of income.
3. American manufacturing processes operated *faster* than their European counterparts, from machine speeds to the intensity of the work pace (Field 1983). Intense use of the capital stock foreshadowed the "high throughput" production systems of later eras.

4. American manufacturers did not necessarily substitute capital for "labor" generally, but deployed machinery to substitute unskilled for skilled craft labor. Early American factories relied heavily on women and children, subsequently on immigrants (Goldin and Sokoloff 1982). High mobility and job turnover were the norms, to which mechanization was a response.

These attributes and others may be considered adaptations of European technologies to the American setting. The crucial development was an indigenous technological community, its members pursuing individual goals but collectively shaping a new body of techniques and practices. American technological progress was a network phenomenon, unfolding over a longer time period but taking its shape and direction during the antebellum era.

Network relationships do not readily lend themselves to cliometric analysis. A classic work in this field is Nathan Rosenberg (1963), which described how specialized machine tools firms spun off from the machine shops associated with early textile mills, applying their skills to diverse new industries – sewing machines, locomotives, steam engines, turbine waterwheels, bicycles, and eventually the automobile. Although Rosenberg's paper had been invited by and presented to the Conference on Income and Wealth, it was dropped from the conference volume because it had no numbers! Yet the article, subsequently published in the *Journal of Economic History*, has been described as "the single most influential essay ever written" in the history of technology. What Rosenberg called "technological convergence" – the application of common technical principles to a wide range of industries – might today be reframed by identifying metal working and machine building as general purpose technologies. Equally important, however, was Rosenberg's depiction of machine tools firms as aggressively promoting and seeking out new markets for their accumulated knowledge and expertise.

Cliometric students of technology frequently work with data on patents. Kenneth Sokoloff and Zorina Khan (1990) credit the patent system for the "democratization of invention" in the United States compared to the United Kingdom and for the acceleration of productivity change in the late antebellum period. Whereas the British system was expensive, administratively cumbersome, and elitist, US patents were inexpensive and accessible to a much broader segment of the population. Particularly after the patent reform of 1836, which restored the examination system and established "the world's first modern patent institution" (Khan 2005, p. 53), US patenting rates per capita surpassed those of the United Kingdom. According to Ross Thomson (2009), as many as 36,000 individuals obtained patents in the United States between 1790 and 1865.

Patenting rates are a very imperfect measure of technological progress. Not only are many inventions patented but never used, but many important innovations were not patented. In a study of the 1851 London Crystal Palace Exhibition, Petra Moser (2005) found that only 11% of British exhibits and 16% of American exhibits were patented. Patenting rates varied significantly by industry, the highest being machinery at 36.4%. Thomson found somewhat higher patenting rates at the 1853 New York Crystal Palace Exhibition: three-fifths of Americans displayed patented

products, the highest shares in specialized machines for harvesting, woodworking, transportation, and firearms. Surveying international patterns, Moser suggests that patenting laws may have influenced the *direction* as opposed to the pace of technological change. But many types of innovation were not patentable during this era (such as seed varieties), and secrecy was a viable alternative to patenting in many others (such as chemicals and dyestuffs).

Despite their limitations, patenting data have proven useful for tracing network patterns among inventors and technologies. Thomson (2009) follows intricate lines of influence among textile machinists and steam engine innovators, while Meyer (2005) presents maps showing the clustering of innovation centers and paths of mobility for machinists and engineers. Thomson uses patent evidence to document a shift in the 1830s from own-industry inventions to crossover linkages passing through machine tools, largely confirming Rosenberg's account. Evidence of complex supply chains of specialized machinery, and of high mobility and job-hopping for skilled machinists, convey a powerful resemblance to modern "knowledge economy" clusters such as Silicon Valley. But, whereas Silicon Valley has remained highly concentrated geographically, the antebellum knowledge network was also a vehicle for diffusing technology and industry from the Northeast to the Midwest, which was developing an advanced manufacturing sector even in the antebellum era.

Economic Growth in Slave South and Free North

Accelerated growth in the antebellum era was shared by southern as well as northern regions. As North saw it, the cotton trade was the prime mover for the economy as a whole. He wrote:

> Cotton was strategic because it was the major independent variable in the interdependent structure of internal and international trade. The demands for western foodstuffs and northeastern services and manufactures were basically dependent upon the income received from the cotton trade. . .it was cotton which was the most important influence in the growth in the market size and consequent expansion of the economy. . .Cotton played the leading role (1961, pp. 67–68, 194).

This analysis has been revived by practitioners of the New History of Capitalism, in their efforts to show the centrality of slavery for American development. But it has largely been rejected by cliometric research.

Drawing on contemporary southern newspapers, railroad reports, and periodicals, Diane Lindstrom (1970) confirmed Fishlow's finding that the South provided only a limited market for imported foodstuffs: "the needs of the lower South for flour and corn were insufficient to absorb the output of these products from the upper South, to say nothing of their serving as a major outlet for western produce" (p. 113). The reason for this pattern is that most cotton plantations were themselves self-sufficient in food, planting ample corn crops to spread the fixed costs of slave labor across the

year and maintaining swine to feed the residents. The landmark Parker-Gallman sample of 5,229 farms from the 1860 manuscript census was developed specifically to test North's interregional trade hypothesis (Parker and Gallman 1992). (For a description of the sample, see Parker 1970.) Drawing upon the sample, Gallman (1970) concluded that "large plantations as a group produced more than enough grain to meet their requirements" (p. 20) and that "large planters in the cotton South were attempting to be self-sufficient in basic foodstuffs" (p. 22), typically satisfying this objective. Taken together, the evidence rejects the claim that "the growth of the market for western foodstuffs was geared to the expansion of the southern cotton economy" (North 1961, p. 68).

As a market for northeastern manufactured goods, the South was sizeable in the immediate aftermath of the War of 1812, but its role was never dominant, and it diminished over time. Using capture-recapture methods to analyze the coastal trade from New York City, Lawrence Herbst (1978) estimated that no more than 16.4% of northern manufacturing output went South in 1839, of which only a subset was attributable to surging exports of cotton. In her study of economic development in the Philadelphia region, Lindstrom (1978) found that manufacturers rarely sold goods in distant markets before 1840, and when they did, these markets were normally in the East. Longer-distance trade grew over time, but primarily along east-west lines. The transportation revolution hastened both western settlement and commercialization, together comprising the majority of demand growth for US manufactures. Financial connections between the slave South and the money markets of New York City were undoubtedly important. But northern financial centers were active and growing long before cotton became significant (Sylla 1998). Investment opportunities in western railroads were at least as attractive as southern slave plantations to northern capitalists. In short, the free states had their own growth dynamic, in which the South was largely peripheral.

If the two systems were increasingly divergent in their features, attention shifts to their comparative economic performance. Surprising as it may seem, economic historians have debated this issue for years, in a sense continuing an exchange that goes back to antebellum times. Northern critics observed that the South was far behind in cities and towns, transportation, manufacturing, population growth, and education. Southern apologists pointed out that the slave system avoided many unappealing features of capitalism (such as large cities, factories, and mass immigration), while generating large fortunes that free-state residents could only dream of. The cliometric debate has largely revolved around a set of regional income estimates developed by Richard Easterlin (1961). The data showed that in 1840, southern per capita income was only three-fourths the national average, while average incomes in the South Atlantic and East South Central regions were barely half those in the northeast. The South as a whole grew rapidly between 1840 and 1860, but much of this spurt was attributable to the shift of population from the low-income southeast to the high-income West South Central area, propelled in turn by surging world demand for cotton. True, southern per capita income levels would look more favorable if only incomes of the free population were considered, but dividing by total population is more appropriate for assessing the legacy of slavery for long-term regional development.

Lindert and Williamson (2016) have recently used their "social tables" approach to develop new regional income estimates. Although the resulting figures are not clearly comparable to those generated from the output side, patterns of relative regional income may still be informative. An interesting feature of Lindert and Williamson's account is the long-term relative decline of the South. After the region bore the brunt of the post-Revolutionary War economic collapse, southern per capita income grew at only 0.9% per year between 1800 and 1860, compared to 1.94% in New England and 1.66% in the Middle Atlantic. The authors attribute this relative slippage not directly to slavery, but to the emergence of a poor white class within the region, aggravating inequality within the free population. Because the components of regional performance in this new formulation are not yet clear, their significance for prevailing interpretations remains to be determined.

An alternative approach is to move away from volatile current-income estimates in favor of tracking the accumulation of tangible wealth, which may be viewed as a market valuation of future income streams from assets. Much of the dynamic of antebellum growth was driven by efforts to capture capital gains on land, as settlement and commercial development proceeded. Although this underlying motivation was presumably similar throughout the country, there was one major difference between the regions: southerners could accumulate wealth in the form of slave property while northerners could not. In 1860, the value of slaves accounted for nearly half of all tangible wealth held in the South.

According to the research of Alice Hanson Jones (1980) based on probate records, northern and southern colonies were virtually equal in nonhuman wealth per capita (real estate, livestock, equipment and inventories of producers' and consumers' goods) as of 1774 (Wright 2006). The South, however, had the advantage in total wealth, 20% greater in aggregate, nearly 40% on a per capita basis. At that point in history, one could not say that the use of slave labor had retarded southern economic progress in the colonial era.

Seventy-five years later, North and South were virtually equal in total wealth per capita, consistent with Lindert and Williamson's finding that northern growth was faster across this epoch. During the cotton-boom decade of the 1850s, the South surged to an 18% lead by this metric (Table 2). If slave values are included, the South

Table 2 Regional wealth 1850 and 1860 (in dollars). (Source: Wright 2006, p. 60)

	1850		1860	
	North	South	North	South
Physical wealth (billions of dollars)	4,474	2,844	9,786	6,332
Value of slaves (billions of dollars)		1,286		3,059
Nonslave wealth (billions of dollars)	4,474	1,559	9,786	3,273
Wealth per capita	$315	$316	$482	$569
Nonslave wealth per capita	$315	$174	$482	$294
Nonslave wealth per free capita	$315	$266	$482	$449
Wealth per free capita	$315	$483	$482	$868

was the wealthiest region. Note, however, that in both years the South was well behind in nonslave wealth per capita, a metric that better indicates how the regions would compare economically after slavery was abolished. The south-to-north ratios are 55% in 1850 and 61% in the peak census year 1860. These are not very different from the ratios of regional per capita income that prevailed in the postbellum era.

Perhaps more telling than the aggregate ratios is a calculation showing that wealth per slave owner was more than $2,000 in 1860, or more than four times the average for northerners. The average wealth of nonslaveholding white southerners, by contrast, was barely half that of their northern counterparts. This discussion has omitted intangible forms of wealth such as education, an indicator that would only accentuate the contrast between the regions – most obviously for the slaves but also for the free populations. On this reading, the origins of southern backwardness were firmly located in the antebellum era.

Conclusion

Cliometric studies have clearly shown the acceleration of economic growth during the antebellum era, for aggregated national measures of production and income per capita. Both slave and free regions shared in this growth, but the components and direction of economic change increasingly diverged. In the free states, growth was characterized by extensive investments in transportation and population recruitment, commercialization and mechanization of agriculture, and the emergence of a manufacturing sector with a distinctive technology adapted to American conditions, stretching over time from Northeast to Midwest. The slave South was highly successful in expanding cotton production and in generating wealth for the owners of slaves. But the region lagged in other dimensions of economic development, leaving it poorly positioned for ongoing progress after Civil War and emancipation.

Economic-Demographic Interactions in the European Long Run Growth

James Foreman-Peck

Contents

Abstract

Cliometrics confirms that Malthus's model of the preindustrial economy is a good description for much of demographic-economic history; increases in productivity raise population, but higher population drives down wages. A contributor to the Malthusian equilibrium was the Western European marriage pattern, the late age of female first marriage, which promised to retard the fall of living standards by restricting fertility. The demographic transition and the transition from Malthusian economies to modern economic growth attracted many cliometric models surveyed here. A popular model component is that lower levels of mortality over many centuries increased the returns to, or preference for, human capital investment so that technical progress eventually accelerated. This initially boosted birth rates and population growth accelerated. Fertility decline was earliest and most striking in late-eighteenth-century France. By the 1830s, the fall in French marital fertility is consistent with a response to the rising opportunity cost of children. The rest of Europe did not begin to follow until near the end

of the nineteenth century. Interactions between the economy and migration, mainly focused on the long nineteenth century, have been modeled with cliometric structures closely related to those of natural increase and the economy. Wages were driven up by emigration from Europe and reduced in the economies receiving immigrants.

Demographic transition · Economic growth · Malthusian economy · Migration

Introduction

For most of history until the industrial revolution and the onset of modern economic growth, living standards have been stagnant or periodically falling and rising around a stationary level in response to wars, famines, plagues, and climate change. In the absence of technological or social change, population has also tended to a long-term balance. Demographic transition is a stylized description of a shift from one type of social order to another. In phase 1, mortality and fertility are high and population is broadly stable. Mortality falls in phase 2, but fertility does not; consequently, population explodes. In phase 3, fertility drops so that population begins to stabilize at a much higher level (Chesnais 1992). Cliometric analysis (not necessarily under this banner) attempts to link these demographic changes with economic development by explaining fertility and human capital accumulation as the outcome of household decisions that are rational in their environments but that also influence the way their environments evolve. In so doing, the aim is to model the transition from a low living standard "Malthusian" economy to one with rising output per capita.

A country's population is potentially influenced not merely by natural increase – the excess of fertility over mortality – but also by migration. Simply establishing the size of historical populations has been a major challenge for historians, with migration an almost unknown magnitude, primarily seen as a source of bias in estimates of birth rates, marriage rates, and death rates. But from the nineteenth century, with more effective state control and interest in statistics, usable migration data becomes available. In this field, cliometric analysis has focused primarily on the vast movements across the Atlantic before the First World War. Because a survey has been recently published (Hatton 2010), the central concern here is with the commonalities of modelling population movement and population change through natural increase.

These themes matter because the size and quality of an economy's population have been critical for its military and economic success and even its survival. Population is a tax base and source of military recruitment. Some economies at various times have considered themselves overpopulated and encouraged emigration. Others have believed they were underpopulated and promoted immigration or family-friendly policies. The natural increase of national or ethnic groups has been and can be a source of social tension, as has immigration; one response has been legal restrictions on immigration, pressure for which has not disappeared.

Unusual in the early acknowledgement of some state responsibility for sections of the population in difficulty was England's 1601 Poor Law. Elsewhere in Europe, relief of these people was primarily left to charity or religious organizations. A question that exercised English social thinkers in the late eighteenth century still concerns some today; if the state gives financial support for families with low earnings, will this encourage indigence and a larger population? A related policy concern has been "will encouraging or permitting immigration lower domestic wages and employment and will encouraging emigration raise domestic wages and job opportunities?"

In the following survey, section "Data" discusses the sources and data used by the cliometric literature; section "Population, Natural Increase, and the Economy" presents the literature on natural increase of population in a simple Malthusian model framework; section "Demographic Transition and Economic Growth" considers the possible ways that a shift could be made to modern economic growth; section "Migration and the Economy" extends the Malthusian framework to selected cliometric migration literature; section "Identification and Estimation" considers approaches adopted to inferring parameters of interest from the historical data; and section "Time Series Analyses" outlines the distinctive approaches of some recent studies that use methods for data indexed in time order.

Data

How far cliometrics can proceed substantially depends upon the nature of the available evidence. The more distant past is generally more problematic in this respect than the more recent. Much effort over many years has been devoted to establishing the historical course of demographic and economic variables, with some surprising results. The Emperor Diocletian's Price Edict of AD 301 has allowed a comparison of Roman living standards with those of the medieval and modern worlds (Allen 2009). The culmination of work by Thorold Rogers (1866), Beveridge (1939), and Phelps-Brown and Hopkins (1955, 1956, and 1981) in Clark's (2005) annual English real wage (for builders, coal miners, and agricultural workers) series beginning in 1209 is no less remarkable. English real wages were apparently higher in 1209 than in 1800, and in 1450, they were higher than at both these dates.

Swedish data on real wages show even more extreme contrasts, suggesting that unskilled laborers were better off in the Late Middle Ages than in the mid-nineteenth century. After about 1540, the trend in real wages in Stockholm is downward so that by 1600, real wages were some 40% lower than in 1540 (Söderberg 2010). This remarkably strong fall occurs elsewhere in Europe as well (Allen 2001). The difference between Britain and the Netherlands on the one hand and Southern Europe on the other is that the first two countries recovered the 1450 peak by the mid-nineteenth century, but the south did not. Like the Swedish series, the German real wage series beginning in 1500 are derived from the builders' wages (Pfister et al. 2012). But experience in Germany differed because of the labor scarcity created by the devastating demographic consequences of the Thirty Years War. Over the first

half of the seventeenth century, the war period, the German real wage rose by 40%. By the end of the third quarter century, wages had climbed to the level at the beginning of the sixteenth century.

The foregoing wage series all refer to men's earnings. Humphries and Weisdorf (2015) have constructed indices of women's casual and contractual wages in England between 1260 and 1850 which show a different pattern from men's wages. Women's annual wages were held down by regulation more than males in the labor scarcity period of the fourteenth and fifteenth centuries, reducing the incentive to postpone marriage and reduce fertility. Married women gained from more buoyant casual wages and by accessing the better paid male labor market through their husbands. When industrialization began to impact on the labor market strongly, the position of the two types of female employment was reversed. Women who could not commit to annual contracts fared less well, increasing the reliance of married women on the male earner.

Human capital indicator series, that might eventually reflect the level of skill, are much more fragmentary, but no less important. Literacy, book production, subscribers to the Encyclopédie, and age heaping have all been enlisted as indicators (A'Hearn et al. 2009; Baten and van Zanden 2008; Squicciarini and Voigtländer 2015). Most series are distinguished by their tendency to rise strongly in early modern Europe – before the onset of sustained increases in national income. This may be why Allen (2003) finds no effect of literacy on economic development measured by wages, though perhaps the impact is concealed by the close link with urbanization which he does find important. In France, illiteracy rates fall sharply from 65% to 5% between 1720 and 1880 (Diebolt and Perrin 2013a).

Tax surveys or returns, private or national censuses, and listings for military, civic, or religious purposes have all provided the raw material for constructing estimates of population, fertility, and mortality.[1]

Perhaps the best known surviving early European census of population and assets is that of 1086 in England, in the Domesday Book. Prussia conducted a national official population census in 1725 (Wilke 2004) and Sweden followed in 1749. By the beginning of the nineteenth century, governments were beginning to undertake censuses regularly; the first French and British official censuses took place in 1801. But for the sixteenth to the nineteenth centuries, parish registers of baptisms, marriages, and deaths have provided the principal sources of key demographic variables through aggregation and family reconstitutions in Europe.

Family reconstitution entails tracing individuals from birth, through marriage and births of children to death. Adding up these individual reconstitutions across a parish potentially provides measures of life expectation, age at marriage, fertility, and other indicators. Drawbacks include the difficulty of linking names in the different

[1]When interpreting these materials, it is important to appreciate that aggregated data can conceal relations that are apparent in more disaggregated sources of information (Brown and Guinnane 2007). The Princeton Fertility Project in particular (for instance, Coale and Watkins 1986) has been criticized for drawing incorrect inferences from excessively aggregated data.

registers, migration reducing the continuity of experience, and the possibility that substantial portions of the local population were not included in the registrations, either because of shortcomings of the recorder or because some people were able to avoid registration, perhaps for religious reasons. Migration from parishes of birth can bias estimates of mean marriage age and life expectancy even when demographic characteristics of migrants and nonmigrants are similar (Ruggles 1992). Only those married in their place of birth are included in the family reconstitution. Late marriage is more likely to take place after migration and so to be systematically excluded from the data. Early deaths are overrepresented in reconstitutions because those who live longer and have time to migrate will die elsewhere – and be omitted.

Good-quality parish registers have a high survival rate in France, Spain, and Italy. Sweden and Finland supplement registers with listings of inhabitants by house with notes on religion, reading ability, and migration in the seventeenth century (Flinn 1981). For England, Wrigley and Schofield (1981) established mortality and fertility rates by family reconstitution of 404 Anglican parish registers of baptism, marriage, and burial, for which the earliest date from the beginning of registration in 1541.[2] Wrigley and Schofield also used the data from parish registers to calculate population by "Back Projection."[3] This involved back dating and revising the age structure of the 1871 population census at 5-year intervals by taking into account flows of previously occurring "events." Age at death was not stated in the register before 1813, so deaths were allocated to age groups by a model mortality schedule.

The high famine and plague-induced mortality of the fourteenth and fifteenth centuries is a critical demographic event for Western Europe.[4] The Great European Famine of 1315–1317 and subsequently in England, diseases of cattle and sheep, and drought (Dodds 2004; Stone 2014), followed by the Black Death of 1348, drastically reduced populations. Moreover, the plague returned in 1361 and 1369, as well as later, with diminished force. In Sweden, population fell from 1.1 million to less than one-third between 1300 and 1413. Not until the mid-seventeenth century did the population recover, and sustained growth only resumed in the later part of the century (historical statistics.org). In England, clearly there was a massive decline in population, perhaps until the middle of the fifteenth century. In the Durham area, tenant numbers imply that population fell to 45% of pre-Black Death levels by the end of the fourteenth century, and tithe evidence indicates a similar collapse of output (Dodds 2004). Clark's (2007) calculations from wage data reach a broadly comparable conclusion for aggregate English population. Tuscan population decline was apparently even more severe; between 1244 and 1404, the population of the Pistoian countryside fell to less than one-third of its former level, and the city

[2]The Cambridge team also published a much more detailed analysis based upon 26 English parishes (Wrigley et al. 1997).

[3]Lee and Anderson (2002) contend that the resulting population estimates are inaccurate for taking into account international migration, but a fair representation of population excluding migration.

[4]For an interpretation on film of the impact, see Ingmar Bergman's *The Seventh Seal*.

population fell to one-half (Herlihy 1965). In Germany, the Thirty Years War of the early seventeenth century was a comparable mortality crisis, with population falling by more than one-half (Pfister and Fertig 2010).

Population, Natural Increase, and the Economy

The literature survey is initially structured around Malthus's (1970) fundamental treatment, presented as a two-equation model. This allows a wide range of cliometric and related literature to be interpreted. Such was the importance of Malthus's theorizing about the relation of the economy and population that he earned the rare accolade of posthumous transformation into an adjective. His work is therefore the natural beginning for a historical survey of the interaction of demography and economy.

Malthus behaved like a true social scientist, combining empirical evidence and theory. Among other data sources, he utilized Alexander von Humboldt's observations of Spanish American population behavior and, indirectly, the US census to contrast with European demographics. Malthus's focus on the geometrical progression of population increase compared with the arithmetic progression (at best) of food increase, when there was little extra land that could be brought into cultivation, proved compelling. Whereas in the Americas, population doubled every 25 years because land was abundant, in the hilly or mountainous parts of Europe, like Switzerland or Wales, there was virtually no increase, because of "positive" or "preventive" checks.

Positive checks shorten the natural duration of life; they include poverty, famine, pestilence, great cities (with their high mortality induced by work, living, and leisure styles), and war. Bubonic plague was the biggest killer in Western Europe from the fourteenth to the seventeenth centuries. Thereafter, quarantine regulations kept it at bay. Typhus and smallpox then assumed preeminence (Flinn 1981, Chap. 4). Urbanization must also have contributed to holding up mortality as the severity and frequency of bubonic plague declined. In 1500, London was estimated to contain 40,000 people and Paris 100,000, but the populations of both cities exceeded half a million by 1700 (de Vries 1984). Another type of mortality check originated from the failure of two or more harvests in a row, as in Finland by 1697 or Ireland by 1846. Poor transport infrastructure and the high cost of moving food meant that these crises were likely to be localized, although the Great European famine of 1315–1317 was an exception. Movement of armies could generate mortality crises even in the absence of fighting. The Thirty Years War in Germany was as lethal for the civilian population as the Black Death, because of disease spread, crop and livestock destruction, and confiscation, by marauding troops.

Preventive checks act on the effective birth rate; for Malthus, these included delayed age at marriage, "unnatural passions," and abortion. Some combination of these checks constrains population to the fixed land resources of long-settled regions. Subsequent research (Hajnal 1965) showed that substantially delayed age at first marriage of females until around an average age of 25 was indeed the norm in

Western Europe at the time Malthus was writing and for some centuries before (de Moor and van Zanden 2010). Moreover, this custom was unique to Western Europe. Everywhere else, the average marriage age was lower. The customary justification for "restraint" in Western Europe was the need to accumulate or acquire sufficient resources to create a separate household for a married couple. The other form of preventive check, or "moral restraint," in Europe that was unusual by world standards was that perhaps 10% or more of females never married at all. In conjunction with social sanction that held illegitimacy to low levels – perhaps 2–5% – these "moral restraints" limited population growth and the level of population below the rates that otherwise would have prevailed. Using English data, Crafts and Ireland (1976) suggest that in the late eighteenth century, a rise of 3 years in the age at marriage could have at least halved the population growth rate.

A policy implication, Malthus maintained, was that raising Poor Law payments with the number of children in the family would incentivize a larger population and undermine independence. The attractions of the ale house, and of large families, he contended, would be diminished if the laborer knew there were no state handouts to fall back on. Cross-section regression of English parishes by Boyer (1989) indeed indicated not only that higher wages were associated with more births (an elasticity of 0.4) but child allowances stimulated more births; parishes that paid allowances with the third child had 25% more births than those that paid no allowances. Boyer tests Huzel's (1980) suggestion that the allowance system was more likely a response to population increase and finds, on the contrary, that the allowance system was exogenous to births.

On the other hand, Kelly and O'Grada (2014) establish that the disappearance of the positive check coincided with the introduction of systematic poor relief. They cite Malthus himself as an authority for the likelihood that government action contributed to breaking the link between harvest failure and mass mortality. On the European continent, where there was no Poor Law, men and women could not count on relief from hardship, unlike in England, and this had profound consequences for economic development (Solar 1995). They were unwilling to break their ties with the land and become the labor force of an industrial revolution.

Not only did Malthus identify long-run equilibria, or steady states of population and wages, but he also noted the likelihood of a population and wage cycle. "Overpopulation" drives down money wages and pushes up food prices. This reduction of real wages discourages marriage, and so population stagnates or declines. But low wages encourage the extension of cultivation and improvement of land already farmed until real wages recover with the stronger demand for labor, and population expansion resumes.

"This sort of oscillation. . ..may be difficult even for the most penetrating minds to calculate its periods." (Malthus 1970, p. 77)

These oscillations can be simulated in response to a mortality shock, for instance, to show a key feature of the Malthusian model. As an exercise in "deterministic calibration" they illustrate an approach that has proved popular in demographic-economic interaction modeling in recent years (albeit with more complex models). In a stylized discrete time model of the Malthusian process, the relevant single period

may be at least 15 years but perhaps double that. The wage in the current period (w_t) falls with the population in the current period (P_t) (which brings the labor force on to the market) due to the diminishing marginal product of labor, and the fixed available land.[5] Where u_t is a random disturbance term with mean zero and a and b are parameters,

$$w_t = a - b.P_t + u_t \quad a,b > 0 \tag{1}$$

Perhaps the strongest evidence for this relationship is the terrible European population mortality from plague in the fourteenth century which boosted wages for instance in England to levels not seen again until the nineteenth century (Clark 2005).[6] Pfister et al. (2012) for Germany from 1500 find a strong negative relationship between population and the real wage until the middle of the seventeenth century that probably reflects this relationship. A plausible estimate of b is 0.5 according to Lee and Anderson (2002). (This assumes an elasticity of substitution of about 1 and labor's share in national income of 0.5.[7]) Allen (2003) measures the effects of population in this type of equation by the land-to-labor ratio in a cross-European country panel beginning in 1300 and ending in 1800. He estimates an elasticity of 0.4, when the a parameter in (Eq. 1) above is a function of urbanization and total factor productivity in agriculture. Crafts and Mills (2009), using time series English data from 1540, estimate a much higher elasticity of 0.95 for b (compared with Lee and Anderson's (2002) $b = 1$). One source of the difference from Allen may be that the time series approach captures short-term relationships which are less responsive than the long-term coefficients obtained from the panel data. Another possible reason is that Allen includes a wider range of explanatory variables in his model, leaving less wage variation to be explained by population. Crafts and Mills also find the shift in a up to 1800 is an average rate of technological progress of 0.75% per annum using Wrigley and Schofield's real wage series and 0.4% when Clark's more broadly based series is employed. Cervelatti and Sunde (2005) extend Eq. 1 by distinguishing two wages, arising from the demand for skilled labor and the demand for unskilled labor, an approach also followed by Diebolt and Perrin (2013a).

A second, quite different, relation connects population and wages. Population in the current period *Pt* increases with the previous period wage because higher wages

[5]In practice, cultivated land area expanded a little with population in Western Europe, as less productive soils were brought into use. Broadberry et al. (2015) Table 2.10 estimate that in England, the cultivated land area only exceeded the medieval peak of 1290 by 1836, when population was several times greater than at the earlier date.

[6]Spain appears to be an exception in Western Europe (Alvarez-Nogal and Prados de la Escosura 2013)

[7]Defining W as log w and p as log P (the labor force), the marginal productivity condition is $W = a - 0.5(p - q)$ where q is the log of output and the elasticity of substitution between factor inputs is unity. An additional assumption is that there should be close-to-perfect competition in labor markets.

encourage earlier marriage and because children are "normal goods" (the diminution of the preventive check); as household income rises, more children become desirable.[8] As well as the effect on births, at low living standards, higher wages reduce positive checks to premature death.

For the moment, no theoretically distinction will be made between positive and preventive checks; both, and their net effect, may depend upon the level of wages.[9] Where v_t is a random disturbance term with mean of zero and c and d are parameters,

$$P_t = c + d.w_{t-1} + v_t \quad c,d > 0 \tag{2}$$

Allen (2003) estimates a long-run equation of this form for early modern Europe and finds a positive coefficient d for the Netherlands and England and Wales but no long-run response for the other European countries in his sample. Evidence from a version of (Eq. 2), distinguishing the effect of wages on birth rate from that on death rate, includes a median of 14 European countries' fertility response to wages from 1540 to 1870, estimated at an elasticity of 0.14 and for England, of 0.12 (Lee and Anderson 2002; Table 2). Mortality elasticities for England go down to −0.076 with an indication of higher rates – perhaps −0.16 – elsewhere in Europe. These numbers imply a positive population response to wages in England. In the long run, the coefficient d may tend to infinity, so that wages eventually return to some customary subsistence level after an increase in productivity. This would be consistent with Ashraf and Galor's (2011) findings.[10]

An alternative measure of (the inverse of) wages, which has the merit of exogeneity to annual population and birth and death rates, is food prices. After 1740, there was no response of death rates to food prices in France, perhaps a century later than in England (Weir 1984). French marriages were more responsive to price shocks than the English, but in the nineteenth century, there was a weakening of this French preventive check. In eighteenth-century Sweden, a 15% rise in rye prices was associated with at least a 3% increase in mortality the following year (Bengtsson 1993). Sweden also showed evidence of the preventive check in both centuries, with higher rye prices reducing marriage rates and fertility.

Lagerlof (2003) postulates that v_t (in Eq. 2 above) is primarily due to mortality shocks, the values of which play a critical role in the breakout from the Malthusian equilibrium. He also derives an analogy to Eq. 2 from household optimization of a preference function for surviving children, human capital, and goods. This theme is developed by Foreman-Peck (2011) who shows that a fall in child mortality

[8] In reality, there may be longer lags in this relationship, which in turn lengthens the periodicity of the cycle discussed below. Autocorrelated shocks or disturbances have the same effect.

[9] When birth and/or death rates respond to wages, as, for example, in Lee (1973), then Eq. 2 explains the change in population and should be modified by the addition of $-P_{t-1}$ to the right-hand side. In the interests of simplicity, this modification is not implemented here.

[10] And with Arthur Lewis' (1954) model of economic development with unlimited supplies of labor, although here, the perfectly elastic supply of labor comes from migration, rather than natural increase.

theoretically reduces target births but increases desired family size and population. Across late-nineteenth-century Europe and across English counties, lower mortality rates are actually associated with lower birth rates.

From Eqs. 1 and 2 (substituting out wages) and assuming the disturbance terms take their mean values, we obtain a first-order difference equation for P:

$$P_t + bd.P_{t-1} = c + ad \tag{3}$$

Given the initial condition, the population in the base year P_0, we can solve the difference equation:

$$P_t = \frac{c + ad}{1 + bd} + \left(P_0 - \frac{c + ad}{1 + bd}\right)(-bd)^t$$

The first right-hand-side component is the particular solution. In the limit, this is the steady-state value of population. The second right-hand-side term is the complementary function with a characteristic root equal to $-bd$. Population will oscillate around the steady state (particular solution) every period until it converges to the equilibrium level (as long as $|bd| < 1$).

The wage equation corresponding to the population Eq. 3 is

$$w_t + bd \;\; w_{t-1} = a - bc. \tag{4}$$

The solution to this wage difference equation is

$$w_t = \frac{a - bc}{1 + bd} + \left(w_0 - \frac{a - bc}{1 + bd}\right)(-bd)^t.$$

Higher living standards are achieved by larger values of a and lower values of c, b, or d. A higher marriage age lowers the population by reducing c and d. Exogenous population growth, measured by the growth of c, drags down wages. This could be due to falling mortality, as Boucekkine et al. (2003) postulate when they calibrate their model with mortality schedules from Venice 1600–1700 and Geneva 1625–1825. Quarantine regulations in this period were supposedly increasingly successful in diminishing outbreaks of plague in Europe (Chesnais 1992, p. 141). Conversely, if urbanization was sufficiently important to raise national mortality rates (Voigtländer and Voth 2013b), c would fall and wages would rise. Wrigley and Schofield (1989, p. 475) maintained that in the half century after 1820, the rapid increase in the proportion of the population urbanized contributed substantially to the failure of English life expectations to rise significantly (though this is after the Voth period).

Deterministic calibration typically chooses values for parameters $a - d$ so that the model tracks the historical series of interest. More ambitiously, the researcher may adopt parameter values that have been estimated. Based on the calibration $a = 1$,

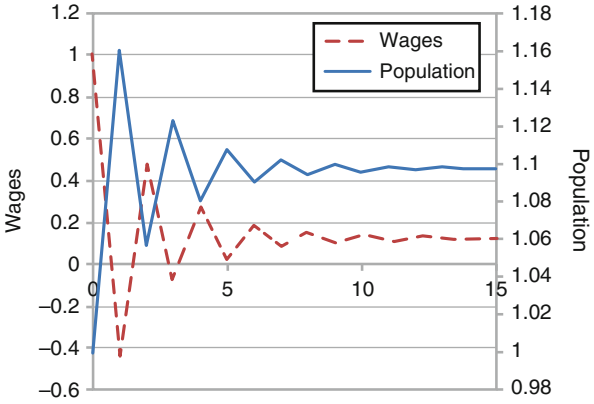

Fig. 1 Simulated Malthusian cycles

$b = 0.8$, $c = 1$, and $d = 0.8$, the steady state for wages to which the system converges is $w^* = 0.12$ and for population $P^* = 1.097$. The dynamics of the Malthusian process can be shown with an Excel spreadsheet[11] and by rearranging the system as follows:

$$P_t + 064P_{t-1} = 1.8$$

$$w_t + 0.64\ w_{t-1} = 0.2$$

Starting with values of 1, Fig. 1 shows the inverse fluctuations in population and wages in response to very large initial shocks, cutting population and boosting wages. The figure shows convergence on $w^* = 0.12$ and $P^* = 1.097$, getting quite close over 10 periods, perhaps 150 or 300 years (in the absence of other shocks, if each period is 15 or 30 years). The initial levels can be considered to represent a positive mortality shock, such as those of the fourteenth and fifteenth centuries in England or the Thirty Years War in Germany, cutting the population and boosting wages.

In summary, two features of this simple dynamic model are the very long-lasting oscillation and the inverse movements of wage and population. It is a homeostatic system returning to an equilibrium of population and wages. Are the theoretical cycles realistic? Lee (1993) maintains that at the macroeconomic level, homeostasis has only been a weak background force. The approximately 250-year European

[11]Enter the parameters of the population difference equation in say cells A1 and A2 (respectively, 0.64 and 1.8 in this case). Fill a column (say B) with a series starting at zero and increasing by one with each subsequent cell. Assign the column next to B for $P\,t$. The first value depends upon the shock to be considered. As a positive shock, use any number greater than 1.097 here. So entering 1 as the first cell in the C column will be a negative population shock. In cell C2, enter "= − A1*c1 + A2" and fill down column C. The series rises above the equilibrium level in period 1 and falls below it in period 2. The behavior of the equation can be studied by changing the parameters assigned to cells A1 and A2.

cycle was mainly driven by exogenous and probably autocorrelated shocks. On the other hand, there is much evidence that for most of history, there has been a stable Malthusian equilibrium of wages and population (Ashraf and Galor 2011). Across countries, land productivity and the technological level affected population density in the first to the sixteenth centuries, whereas the effects of land productivity and technology on income per capita in these years were not significantly different from zero.

Demographic Transition and Economic Growth

This Malthusian equilibrium might be defined as phase 1 of the interaction between demography and the economy. Phase 2 of the transition in Europe refers to the eighteenth and nineteenth centuries, when population generally increased strongly; real wages eventually no longer fell, and in due course began to rise. This last suggests an acceleration in the pace of technical change, represented in Eq. 1 by an increase in the a coefficient (and perhaps a fall in b). Malthus predicted that technical progress would be absorbed by greater populations, as birth rates rose. But real wages do not fall in this phase because advances in productivity offset the diminishing returns from population growth.

Lee and Anderson (2002) define the "population absorption rate" of an economy as the rate at which population can grow without a fall in real wages. This depends upon the growth in a relative to the growth in c (in Eq. 2). The balance was likely to change, and at diverse times in different countries. In eighteenth century England, strong growth in population in the eighteenth century no longer reduces wages. In Germany, the negative relation between wage and population size (Eq. 1) was weaker in the eighteenth than in the sixteenth century; the fall of the marginal product of labor was less pronounced, and the beginning of the eighteenth century saw a marked increase in labor demand (Pfister et al. 2012). German labor productivity experienced a strong positive shock during the late 1810s and early 1820s and continued to rise at a weaker pace during the following decades. Sustained economic growth began well before the beginnings of German industrialization, in the third quarter of the nineteenth century. French exceptionalism appears with the alternative to accelerating technical change; the widespread evidence of marital fertility control in France in the 1790s (reducing c and d), nearly 100 years before comparable evidence in England (Weir 1994).

In a version of unified growth theory (Galor and Weil 2000), rising population boosts technological advance, offsetting diminishing returns. The interpretation could be extended to include market widening, such as the European discovery of the Americas – Smithian growth (cf Acemoglu et al. 2005). Natural selection in favor of higher child quality (Galor and Moav 2002) cumulatively also has this consequence of raising technical progress, or increasing a.

By contrast, a permanent mortality shock reducing death rates could trigger offsetting behavior. Higher chances of child survival would require fewer births for desired final family numbers. And because fewer resources would be lost

investing in children dying before adulthood, larger family sizes can be afforded. The outcome would then be eventually lower wages as population increased, unless positive or preventive checks intervened (Doepke 2005).

However, longer life expectancy can raise the returns to investment in human capital because there is a greater period over which the benefits accrue. Eventually, accumulation can trigger an acceleration of technical progress (Boucekkine et al. 2003; Lagerlof 2003; Cervellati and Sunde 2005). Or higher child survival chances simply might increase parental investment in "child quality" (Foreman-Peck 2011). In this last case, higher female marriage age is hypothesized to increase the rate of human capital accumulation through greater investment in "child quality" as well. Assuming literacy is a partial measure of child quality and human capital, the hypothesis is supported by the finding that the proportion of single females aged between 25 and 29 negatively predicts illiteracy across Europe, controlling for schooling. Moreover, illiteracy in English counties in 1885 is negatively associated with age at marriage. Controlling for prior school attendance, literacy appears to boost output in a cross-Europe production function for the years 1870 to 1910.

The contribution of the later female first marriage preventive check to the breakout from the Malthusian equilibrium in Western Europe has been controversial (Dennison and Ogilvie 2014, Carmichael et al. 2016). Another hypothesized chain of events where marriage age matters is that mortality shocks of the fourteenth and fifteenth centuries induced higher male wages that switched demand towards meat, thereby encouraging the expansion of pasture at the expense of arable farming. Pasture was supposedly more conducive to higher women's wages which encouraged later age at marriage and lower fertility (Voigtländer and Voth 2013a). But women's wages in England do not seem to have conformed to this pattern (Humphries and Weisdorf 2015). A third suggested role for later age at marriage of females has been the general empowerment of females and this supposedly led to economic development (De Moor and Van Zanden 2010).

Inspection of Eq. 3 suggests Phase 2 of the transition occurs if a increases continuously; then population will eventually "take off." The same applies to the wage difference equation. Figure 2 shows the effect of continuous technical progress represented by a linear time trend superimposed upon the Malthusian population cycle. Initially, there is no noticeable effect; the cyclical response to the initial shock is similar. After period six, population is growing continuously, though obviously the strength of the time trend determines when the breakout occurs.

The fertility transition of the next phase, 3, has been interpreted either as an innovation – the spread of information about contraception – or as an adjustment, a response to changes in motivation and structural factors affecting preferences and choices (Carlsson 1966). These last include new economic conditions such as prohibitions of, or restrictions on, child labor, greater child costs, cultural change, higher incomes, and falls in mortality. Mortality reductions may *increase* target family size by lowering the number of births necessary to achieve a given target and thereby cutting the costs or price of a surviving child. But a fall in death rates may also contribute to fertility *decline*, simply because fewer births are necessary to achieve a given completed family size.

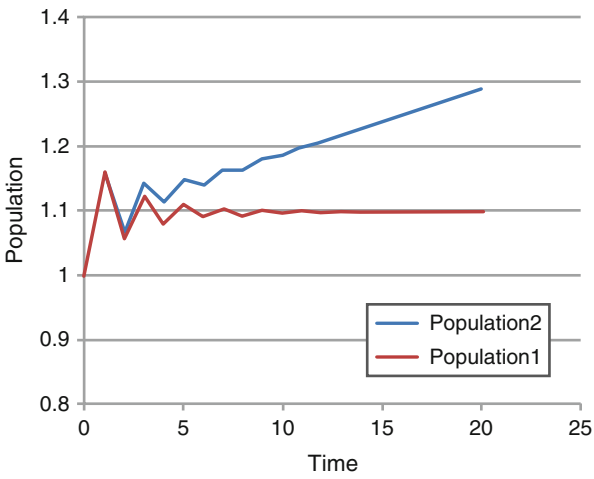

Fig. 2 Population in the break out from the Malthusian cycle

Galor (2012) maintains that a rise in the demand for human capital was the main trigger for the fertility transition. In terms of the simple model, a rise in demand for human capital stems from technological progress, reflected in continuous increases in a, which must raise real wages continuously. Since real wages are growing, the opportunity cost of children will be rising. This may reduce d, the response of population to wages. Other reasons for falling values of d include those mentioned above. When $d = 0$, population stops growing. However, wages continue to grow at the rate given by the growth of a. A "demographic transition" then is completed by the fall in d and perhaps c in Phase 3.

After 1830, French behavior is consistent with an adjustment; rising living standards reducing the demand for children for a slightly rising age at marriage was accompanied by falling marital fertility (Weir 1984). Not only living standards were driving the decline (Diebolt and Perrin 2013a, b). Empowerment increased the amount of time invested by women in their education, and fertility declined for this reason. Female literacy was associated with falling fertility in France in the period 1881–1911. In much of Bavaria, unlike France, only after 1900 did sustained fertility decline begin, when the rising opportunity costs of children became apparent (Brown and Guinnane 2002). Textile employment, a measure of nonagricultural opportunities for women, markedly cut fertility, as did higher women's wages. Conversely, women on small farms that relied primarily on family labor were more likely to have more children. For the British fertility decline Tzannatos and Symons (1989) find that fertility responded positively to income but was more than offset by the rise in cost of female time – that closely followed women's education (and implicitly, wages).

Belgian fertility decline was earlier among groups voting socialist, liberal, and communist in 1919 and later among those paying Easter dues to the Roman Catholic Church (Lesthaeghe 1977). These experiences suggest a role in fertility decline for ideology and ideological change creating a willingness to adopt more effective

contraception (Crafts 1984; Bhattacharya and Chakraborty 2017). Crafts (1984) maintained that the cheaper or more widely understood was contraception, the lower would be both illegitimacy and the legitimate fertility. Illegitimacy is then assumed to be an indirect measure of contraceptive costs. The approach shows that economic choice model of fertility can synthesize the "innovation" and "adjustment" processes, integrating contraceptive costs (broadly defined) into the decision to adopt birth control techniques.

Migration and the Economy

The Malthusian scheme also provides a conceptual framework to assess the impact of labor force/population growth induced by European migration. In the growing international economy of the nineteenth century, millions sailed from Europe to new lives across the Atlantic. These bursts of migration triggered lagged increases in building activity to absorb them and more rapid (extensive) economic growth than could be supported by natural increase alone. Much of the cliometric literature has been concerned with the forces of "push" from the country of origin, or "pull" by the destination, behind migration (Thomas 1973; Hatton and Williamson 1998, 2006; O'Rourke and Williamson 1999; Hatton 2010).

A technology shock (perhaps railway building) in the region of recent European settlement increases the demand for labor (a rises) and raises wages there:

$$w_t = a - b.P_t + u_t \tag{1}$$

Higher wages eventually mean (a "pull" for) higher immigration and therefore higher population in the recipient region:

$$P_t = c + d.w_{t-1} + v_t \tag{2}$$

This is the same model as that used to represent the Malthusian economy, but by the later nineteenth century, the Atlantic economy was expanding fast, with a continuously rising a parameter. There is a positive correlation of the real wage and the upswing. In the region without the positive shock, less labor and capital are supplied, because better returns are to be had elsewhere. In the booming region, the time necessary for building the infrastructure to take full advantage of the technology means that the flow of labor and capital continues for some years, until marginal returns are equalized again between regions (allowing for nonpecuniary differences and costs of migration), or other shocks occur.

An early cliometric calibrated cyclical model of this process for an export economy was presented by Parry Lewis (1960). The region of immigration exports "coal" (Parry Lewis had in mind later nineteenth-century Wales but probably today, the term would be replaced by "tradable goods"). Also, the economy has a "building" sector ("non-tradable (capital) goods"). When conditions abroad cause the demand for exports to oscillate or grow in a specific pattern, then the cycles and

growth would be reflected in building. If, in addition, exogenous population pressure abroad ("push") causes waves of emigration, then the building sector will fluctuate similarly. This endogenous cycle is heavily damped but endogenous immigration reduces the degree of damping.

Demographic impulses ("push" from the origin countries) as well as technology shocks promote the distinctive inverse cycles between the regions.[12] A case in point is the Napoleonic war "baby boomers" (a rise in c) that, in due course Thomas (1973) maintains, created the "hungry forties." Malthusian pressure in Europe pushed migrants to the USA; capital tended to follow them and the demand for housing in the USA rose (even though, in contrast to the positive technology shock, real wages in the receiving region fall, relative to what they would have been).

To the extent that the immigrants are complementary to the indigenous work force, wages will rise. More likely, as assumed above, is that some wages (say skilled) will rise and others fall – if, for instance, immigrants are unskilled. The more capital that flowed with the migrants, the stronger the economic growth they promoted and the less adverse the impact on wages. Taylor and Williamson (1997) calculated that in the absence of mass migration after 1870, real wages in 1910 would have been higher by 27% in Argentina, by 17% in Australia, and by 9% in the USA. The pervasive nineteenth-century innovation of railways was a major shift in technology for which immigration amplified the impact on output, while reducing output per head in Malthusian fashion (Foreman-Peck 1991, pp. 87–88). The more responsive immigration was to wages, the lower was steady-state output per head.

In the sending region, migration was a partial alternative to mortality as a positive check, for instance, in Ireland and Germany in the 1840s. In a Malthusian economy, emigration simply made space for a higher natural increase. In a neoclassical growth model economy on the other hand, with exogenous population growth and an unchanged savings ratio ($d = 0$ in the Malthusian scheme), output per head and wages would be raised by emigration. Emigration explained about half of the rise in wages across Swedish counties between 1870 and 1910 (Ljungberg 1997). Taylor and Williamson (1997) estimate that in the absence of emigration, real wages would have been lower by 24% in Ireland and by 22% in Italy but by only 5% in Great Britain and 2% in Germany.

Immigration restrictions in the two-equation model discussed have a similar effect to Malthus's prediction of a reduction in child benefit under the 1601 Poor Law. They reduce the population response to higher wages (reduce the value of d in Eq. 2). From the end of the US Civil War to the 1920s, European immigration provided strong competition to internal US migration from the southern states to the urban North and West. So, US immigration restrictions of the 1920s favored black

[12]Both types of shocks may be classified as originating on the supply side and as "real" rather than "monetary," consistent with real business cycle theory (Kydland and Prescott 1982).

migrants from the South who gained from the elimination of European competition (Thomas 1973; Williamson 2005).[13]

In Europe, the countries of emigration, the effects of the closure of the USA were less benign. Agricultural protectionism in Europe was encouraged by redundant work forces, unable to move to the USA, who were instead employed growing subsidized crops (Thomas 1973). Migrants were also diverted to Canada and South America, boosting output there.

Identification and Estimation

Much of the cliometric literature is inevitably concerned with how the values of the parameters of the favored model can be known or estimated. If an association in time series data between wages and population can be found, in principle, it could reflect relations generated by one or both of the equations in the model discussed above. The parameter values *a, b, c*, and *d* cannot be inferred from the estimated relation without further information; the original equations are not identified.

If shocks or variables affecting one equation, that do not affect the other, can be distinguished then there is a chance of identifying the parameters. A mortality shock because of plague might affect the demographic response to wages (Eq. 2) but not the Eq. 1, derived from the production function. In this case, the response of wages to the exogenous shift in population traces out the effect of the *b* coefficient of Eq. 1.

Clark (2007) and Scheidel (2010) use this principle to construct or infer population numbers. Scheidel observes that the second-century Antonine and sixth-century Justinian plagues of the Roman Empire were associated with higher Egyptian real wages, from which he infers that population must have fallen substantially on these occasions. Clark (2007) reconstructs English population back to 1200 with a peak of six million around 1300 from Eq. 1. An example is the inference from the rise in agricultural wages to population scarcity created by the mortality crises of the fourteenth century.

Harvest failures might lower real wages in a preindustrial society for reasons outside the model; they are u_t in Eq. 1, an exogenous shock. If so, they could be used to identify the demographic response (Eq. 2). Higher food prices lower the value of the real wage exogenously, and the effect on population change might be assessed, perhaps especially through changes in marriage rates. In this case, the lagged responses are a major potential problem because by the time population responds, other shocks with which the harvest failure may be confused will have struck the economy.

Subject to this qualification, if wages fall and population rises, the dominant shock must be demographic (Eq. 2). If both wages and population fall, the dominant shock is technological, such as harvest failure. But this classification only

[13]Williamson (2005) also discusses the corollary that the position of blacks deteriorated after 1970 because of competition from immigrants.

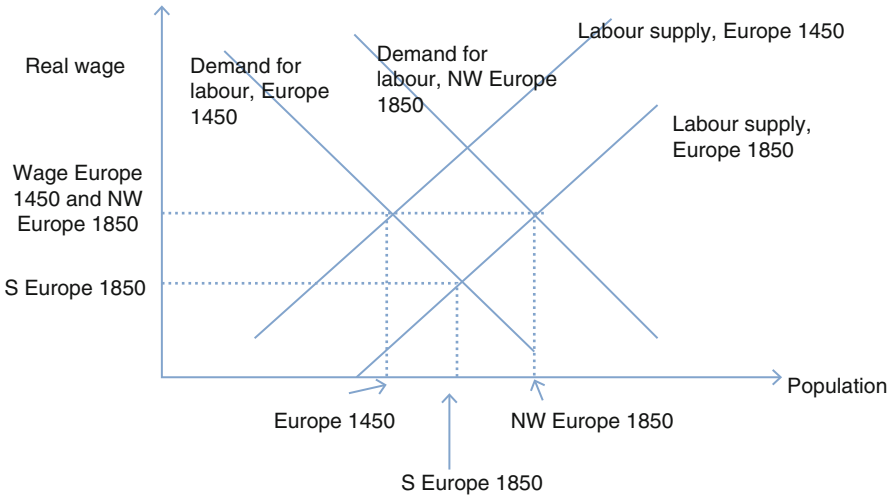

Fig. 3 Allen's (2001) interpretation of European divergence 1450–1850

distinguishes the dominant shock, not how much of the change in population and in wages is due to which type of shock.

An illustration of the identification problem arises in the interpretation of early modern European wage movements with the two-equation model. Real wages in the cities of northwest Europe tended to increase, or at least did not fall, by 1850 compared with 1450. But in Southern and Eastern Europe, they did decline, with few exceptions. Allen's (2001) interpretation, shown in Fig. 3, is that this was due to more vigorous economic development in northwest Europe – in Britain and the Netherlands especially. In principle, the divergence could have been due to a stronger exogenous growth of population in Southern Europe (a greater rightward shift of "labor supply" in the figure) with similar rates of economic development expanding the demand for labor. Apart from the qualitative evidence to the contrary, the stronger growth of population in the Netherlands and Britain compared with that in Spain or Italy identifies the greater shift as in the demand for labor. But we cannot conclude that there was no technical progress in Southern Europe, only that there was less than in the northwest.

With the more recent demographic-economic interactions, more variables are available for identification. For migration modelling, it is important to note that population is a stock and migration is a flow that adds to the stock in the same way as do births. Taylor and Williamson (1997) quantify how international migration in the Atlantic economy altered wages between 1870 and 1910. They estimate the demand for labor (Eq. 1) and utilize the many studies that provide parameter estimates for calibration. They assume that migration was exogenous to national populations or labor forces; it shifted Eq. 2, thereby identifying Eq. 1. Wage changes are then found from the change in population or labor force due to migration over the period.

Time Series Analyses

The econometric alternatives for estimating identified economic-demographic models are generally concerned with time series analysis. In particular, the study of preventive and positive shocks has utilized vector autoregressions (VAR) and impulse response functions. VAR analysis arose from the difficulties of identification, of finding any truly exogenous variables. Past values of every variable in the model are assumed to be potential influences on current values of these variables. In the two-equation model, the following equations would be estimated, although with more lags than written:

$$w_t = a + bP_{t-1} + cw_{t-1} + u_t$$
$$P_t = g + dw_{t-1} + fP_{t-1} + v_t$$

This system of equations can be thought of as encompassing several structural models in an unrestricted way; for example, the original equations only allowed past wages to influence population, whereas now, past population does as well.

The residuals u_t and v_t represent the unexplained movements in population and wages, reflecting the influence of exogenous shocks (i.e., shocks that arise outside the assumed model). These residuals are now an aggregation of the various exogenous shocks affecting the endogenous variables in the underlying structural model. Therefore, no economic interpretation can be derived from the residuals without transforming the equations. If movements of the endogenous variables within the VAR system reflect the effects of exogenous shocks or innovations, the VAR can be used to examine these shocks. Different shocks and their effects may be disentangled by placing identifying restrictions on the VAR.

Then a derived impulse response functions can give the response of birth and death rates (and therefore of population) to an impulse in wages. If there is a reaction of one variable to an impulse in wages, we may call the latter a "cause" of the former. This type of causality can be studied by tracing out the effect of an exogenous shock or innovation in wages on some or all the other variables.

A problematic assumption in this type of impulse response analysis is that a shock occurs only in one variable at a time. Such an assumption may be reasonable if the shocks in different variables are independent. Eckstein et al. (1984) in an early demographic-economic VAR study of Sweden 1749–1860 employ weather variables for this purpose. Shocks to weather affect other variables but are not themselves affected by shocks to wages or demographic variables.

Using the Wrigley and Schofield demographic series and the Phelps-Brown-Hopkins wage data, Nicolini (2007) finds that in England, contrary to the Malthusian model, positive checks disappeared during the seventeenth century and preventive checks vanished before 1740. In Germany, Pfister et al. (2012) from 1500 obtain a strong negative relationship between population and the real wage until the middle of the seventeenth century. On English data, Moller and Sharp (2008) estimate highly significant preventive checks working through marriages but agree with

Nicolini that positive checks were insignificant. They suggest that growing population enhanced income by increasing the size of the market.

Crafts and Mills (2009) establish that wages ceased to be "Malthusian" at the end of the eighteenth century, after which they grew strongly. They maintain that the preventive check cannot be found after the mid-seventeenth century, as in Germany, but unlike Moller and Sharp, they do not use a total marriages variable. Demographic growth was permitted by an expanding demand for labor of about 0.5% per annum. Crafts and Mills find no indication of positive feedback between population size and technological progress, contrary to the assumption of unified growth models (Galor and Weil 2000). For Sweden, Eckstein et al. (1984) incorporate more variables into their VAR system, albeit for a shorter period than with the English data. They include infant mortality and a crop index as well as weather variables. As Malthus postulated, Eckstein et al. estimate that a positive innovation in the general crop index, or in the real wage, increases fertility for several years and decreases infant and non-infant death rates over the same period.

For earlier periods, some of the key variables indicated by theoretical discussion are not available as continuous time series. An example is human capital accumulation that drives technical progress, a vital component of many models (Boucekkine et al. 2003; Cervelatti and Sunde 2005; Lagerlof 2003; Galor and Weil 2000; Foreman-Peck 2011). One approach to this problem is the Kalman filter (Lee and Anderson 2002). This can be illustrated with the (initially) two-equation Malthusian model – which has been shown to generate an equilibrium around a steady-state population and real wage. Technical progress or human capital accumulation in effect shifts the a parameter of the demand for labor equation in the Malthusian model. Lee and Anderson model the behavior of the disturbance terms u_t and v_t and the rates of shift of the parameters a and c. For expositional purposes, the simplest approach is to introduce only one more equation which explains unobserved H, human capital, say, by a disturbance term (summarized below by ε_t) reflecting other unmeasured factors.

$$w_t = a + H_t - bP_t + u_t$$
$$P_t = c + dw_{t-1} + v_t$$
$$H_t = f_t + gH_{t-1+\varepsilon_t}$$

All variables are endogenous in this system; it can be solved for each endogenous variable only in terms of lags and disturbance terms, because there are no exogenous variables. The second step is to use this system for prediction, beginning in the base period $t = 0$, assuming $u_0 = v_0 = \varepsilon_0 = 0$. Starting values of all the six parameters ($a - g$) must be postulated. The third step is to update the prediction in the light of the "new" data. Estimated w_1 and P_1 are compared with the actual values of w_1 and P_1 and new values of the six parameters chosen that maximize their likelihood.

This process is repeated for each period. When best estimates of all the model parameters are obtained, the effects of the human capital can be inferred from the values of f and g and the assumed unit effect on real wages. Lee and Anderson's

(2002) parameter estimates are very similar to those from the Crafts and Mills' VAR (as noted above). Foreman-Peck and Zhou (2018) use a related approach to demonstrate a jump in the English female marriage age at the end of the fourteenth century and the effect on human capital accumulation over the ensuing centuries. Their method, unlike the Kalman filter, does not depend on distributional assumptions for the disturbance terms, but only requires that variables have first and second moments.[14] But most importantly for their purposes, it enables them to estimate the economic-demographic model with different length time series, to use all the available information; the real wage series goes back to 1209, which provides many more observations than the mortality and birth rate series beginning only in 1541, than the even shorter celibacy and marriage age series.

Conclusion

Malthus's model of the preindustrial economy in which increases in productivity raise population, but higher population drives down wages, appears to be a good description of much of demographic/economic history. The Western European marriage pattern – the late age of female first marriage – promised to retard the driving down of living standards by restricting fertility. Otherwise, the positive check of mortality, induced by disease, war, or malnutrition, constrained population in regions that had been long settled by arable and pastoral farmers, despite high birth rates. Living standards then largely depended upon how recently mortality shocks had occurred. Cycles in the Malthusian economy may have been due to lags such as those in the response of fertility to wages, but shocks were perhaps more likely to be the drivers.

Since there is good evidence that population, or natural increase, responded to higher wages, it is likely that subsidy policies like those attributed to the English 1601 Poor Law would encourage fertility of those subsidized, as Malthus feared. There are indications that this happened and that the "social safety net" reduced premature deaths by breaking the link between harvest failure and mortality.

The demographic transition and the transition from Malthusian economies to modern economic growth have attracted many cliometric models, but as yet no consensus about the process has been achieved. Population expanded most rapidly in the most dynamic European economies, so fertility restriction was not obviously the key. Yet, the association of the Western European marriage pattern with economic development, combined with Malthus's emphasis on the vital necessity to balance population against resources, suggests there should be some connection. By the end of the nineteenth century, there was a European pattern that towards the east,

[14]Coefficients are not updated observation by observation as they are with the Kalman filter and the Kalman gain. Instead the recursive system goes all the way through the observations to get one vector of coefficients, minimizing the square of the distance between actual and forecast values of the variables.

mortality rates were higher and age at marriage lower than in the west. Mortality explained fertility statistically, and fertility explained age at marriage, across English counties and across Europe. Time series behavior was rather different because of lags in responses. French fertility control began at the end of the eighteenth century, earlier than elsewhere in Europe. Other European populations increased rapidly for perhaps a century, before fertility fell, with rising child costs and greater opportunity costs of time (in which children were intensive).

Interactions between the economy and migration have been modeled with cliometric structures closely related to those of natural increase and the economy. Similar problems arise with identification, of distinguishing cause from effect from contingent association. The historical focus of recent literature has, however, been different, even when bulk of the data has been available for the same period. Whereas the natural increase literature has been concerned with equilibrium and growth over many centuries, the bulk of the cliometric migration literature has focused on the great migrations from Europe of the later nineteenth century. These studies have yielded clear-cut and conventional results compared with the longer period studies; wages were driven up by emigration from Europe and reduced in the economies receiving immigrants. Policies of migrant restrictions therefore must have influenced wages similarly, if they were effective. Over all economies involved, if migration was an improvement in resource allocation, total output will have increased, but it is unclear how these gains were distributed between source and host economies.

The Golden Age of European Economic Growth

A Cliometric Perspective

Nicholas Crafts

Contents

Abstract

This chapter surveys cliometric research on economic growth in Western Europe from 1950 to the early 1970s, the so-called "Golden Age." Several hypotheses to explain the very rapid growth of that period are examined including those proposed by Abramovitz, Eichengreen, Janossy, and Kindleberger. Cross-country variation in growth performance is highlighted and explanations for it are

explored. Further insights into the Golden Age are obtained by considering the reasons for the subsequent growth slowdown. It is concluded that research in this area has made substantial progress in the last 30 years informed by ideas from new growth economics.

Keywords
Catch-up growth · Growth regressions · Relative economic decline · Social capability · Technological congruence

Introduction

The focal point of this chapter is the study of Western Europe's "Golden Age" of economic growth, which lasted from the early 1950s through the mid-1970s. The retrospective analysis of this period by quantitative economic historians only really began in the late-1980s although, obviously, this built upon the earlier work of applied economists. At that point, this historical research received a massive stimulus from the revival of interest in growth economics, which produced potentially appealing new theoretical ideas together with a much more empirical focus which was initially noteworthy in particular for its stress on issues relating to catch-up and convergence.

Hitherto, formal growth theory had been dominated by the neoclassical growth model in which long-run productivity growth was a result of exogenous technological change and changes in the investment rate only affected the level of output per person rather than its growth rate. The key feature of the endogenous growth models, which appeared during the 1980s, was that they made long-run growth rates a result of investment decisions (relating to a broad concept of capital) based on microeconomic foundations. Two different types of models were developed, namely, AK models of growth in which diminishing returns to (broad) capital accumulation were assumed away, and endogenous innovation models in which the rate of technological progress is a result of profit-seeking investments. Two well-known variants of the former type were Romer (1986), based on constant returns to physical capital, and Lucas (1988), where endogenous growth could be the result of human and physical capital accumulation combined, with the former generating externalities. Two well-known variants of the latter type were the quality-ladders approach of Grossman and Helpman (1991) and the Schumpeterian growth model of Aghion and Howitt (1992). The relevance of both these types of models is that well-designed institutions and supply-side policy can have positive growth-rate effects through their effects on incentives to invest and to innovate, rather than just levels effects as in the neoclassical growth model.

Empirical analysis of economic growth was also changing in the 1980s as new data sets became available, notably an early version of what became very well-known estimates of long-run real income levels for OECD economies (Maddison 1982), and a much improved version of the Penn World Tables (Summers and Heston 1984). These permitted more sophisticated international comparisons of

performance and underpinned the development of a huge growth regressions literature. Very early contributions to this by Baumol (1986) and De Long (1988) debated whether the historical record showed a general experience of convergence of income levels among advanced countries. Notions such as "conditional β-convergence" (Barro 1991) and "social capability" for catch-up and convergence (Abramovitz 1986) emerged as attempts were made to examine the roles that institutions and policies had played in growth outcomes.

Already in the 1980s, there were some excellent economic-history-textbook accounts of postwar European economic growth using a traditional approach, for example, Van der Wee (1986). The historiography also featured well-known interpretations of the Golden Age including Kindleberger (1967) and Olson (1982). Against this background, the cliometric contribution came in three main ways. First, it provided superior international and inter-temporal comparisons of growth performance based on much improved measurement techniques and a better articulated conceptual framework. Second, it pursued statistical testing of hypotheses that had previously been evaluated quite informally. Third, it developed more sophisticated ways of thinking about the role of institutions and policies in underpinning the Golden Age and explaining cross-country differences in growth outcomes.

Two (linked) questions are central to this topic, namely, "what explains rapid economic growth in Western Europe during the Golden Age?" and "why did Western European growth slow down so markedly after the Golden Age?" The first of these questions has produced a substantial body of work without by any means arriving at a complete consensus, but the second is still relatively underresearched by cliometricians. In each case, important insights can be gained from considering the variance of growth performance across countries and the correlates of relative success and failure.

Growth Performance

The basic data on growth are set out in Table 1 which is based on the original work of Angus Maddison, in particular with regard to establishing levels of real GDP measured at purchasing power parity. Several points should be noted. First, for European countries the growth rates of real GDP per person (Y/P) and of labor productivity (Y/HW) were much faster in the Golden Age than subsequently. The medians for 1950–1973 were 3.62% and 4.58% per year, respectively, compared with 1.76 and 2.54 during 1973–1995. Second, median European growth rates of Y/P and Y/HW were well above those of the United States in the Golden Age, but from 1973 to 1995 while labor productivity continued to grow faster in Europe than the United States, real GDP per person did not. Catch-up in income levels was rapid during the Golden Age but not thereafter. Third, in each period there is a clear inverse correlation among European countries between initial levels and subsequent growth rates of GDP per person so that in this special case the data exhibit unconditional β-convergence, as is confirmed by the regressions in Crafts and

Toniolo (2008).[1] The convergence rate was a little above 2% per year during the Golden Age but slowed to about 1.5% subsequently. Fourth, during the Golden Age, both the United Kingdom and Ireland underperformed in the sense that their growth was significantly slower than in countries with higher initial levels of income and productivity. For the UK, a prima facie verdict of "growth failure" in these years is reinforced by the evidence of being overtaken so that by 1973 levels of real GDP per person and of labor productivity were below those in many other European countries.

Table 2 benchmarks the sources of growth in labor productivity using a standard neoclassical growth accounting framework implemented in identical fashion for each country and permitting comparisons not only between Western European countries but also between the latter part of the Golden Age and the subsequent

[1]Their results show that this did not apply prior to 1950.

Source: Bosworth and Collins (2003)

Note: Estimates are for the whole economy and labor productivity is measured on a per worker basis. Growth accounting is based on assuming a Cobb-Douglas production function in which $Y = AK^{\alpha}(HL)^{1-\alpha}$ where H is the average educational standard of the labor force, A is TFP, K is capital and L is labor. This allows the following expression for the sources of labor productivity growth to be derived: $\Delta\ln(Y/L) = \alpha[\Delta\ln(K/L)] + (1-\alpha)[\Delta\ln(H/L)] + \Delta\ln A$

period of slowdown. The Golden Age era of rapid catch-up was indeed a period when both capital-deepening and TFP growth contributed greatly to labor productivity growth. Nevertheless, in most cases, TFP growth made the larger contribution and in countries with very rapid labor productivity growth the differential with the slower growing countries was much more due to TFP growth than capital deepening.

When TFP growth is as rapid as it was for Europe during the Golden Age, it can be expected that there is a substantial component from reductions in inefficiency, both allocative and productive. Maddison (1987) in a somewhat speculative exercise concluded that much of the Solow residual was typically attributable to some combination of labor quality, improved allocation of resources, changes in the utilization of factors of production, reductions in technology gaps and economies of scale, leaving only a modest share "unexplained" – and perhaps reflecting disembodied technical change. Maddison's list of the components of rapid TFP growth in the European Golden Age is broadly in line with conventional economic histories, but precise quantification is, of course, very difficult and there is no consensus on the details.[2]

[2]It should be noted that the results of a data envelopment analysis also give strong support to the claim that TFP growth during the European Golden Age was boosted considerably by improvements over time in the efficiency of factor use (Jerzmanowski 2007).

Table 2 reveals that the slowdown in labor productivity growth in Western Europe after the Golden Age reflected declines in both capital deepening and TFP growth in every country but that the latter was generally more important. The unweighted average decrease between 1960–1970 and 1970–1990 was 1.00 percentage points per year for the capital-deepening contribution but 1.75 percentage points per year for TFP growth, which was largely the result of the evaporation of transitory components mentioned above. The dramatic decline of TFP growth in Southern European countries reflects this point.

What Explains the Golden Age of European Growth?

This section of the chapter considers attempts by cliometricians to explain why growth was so much faster in these earlier postwar years than either before or since. Much of this work has entailed testing hypotheses put forward in earlier vintages of economic history. The focus will be primarily on research with a cross-country perspective, but at the end its implications for understanding the UK growth failure will be reviewed.

The Janossy Hypothesis

The conventional idea of the so-called Janossy Hypothesis, which is based on an interpretation of Janossy (1969) proposed by Dumke (1990), is shown in Fig. 1.[3] The basic idea is that after World War II the level of output in European economies was unusually low (at C) and that a period of super growth followed in which output first bounced back to its prewar level (CD) after which growth continued at a higher than normal rate (DE) until the normal growth rate resumed (at E). Obviously, countries varied in terms of how far the point C was below trend, and therefore in the scope for reconstruction and super growth, with West Germany often seen as an extreme observation and thus a good candidate for a *wirtschaftswunder*. This analysis raises two questions, which the cliometric literature has addressed: first, how much did reconstruction contribute to growth? and second, is it correct to see European countries returning to a pre-existing trend growth path?

Since a pioneering paper by Dumke (1990), the issue of the reconstruction contribution has been tackled by running what might be called augmented unconditional convergence regressions. In this approach, growth of real GDP per person is regressed against the initial level of income per person, a measure of the shortfall of the actual output level compared with an estimate of the level of trend output in the late 1940s (typically called "GAP") to capture the potential for reconstruction effects

[3]The graph embodies a trend-stationary view of the world. Arguably, Janossy himself believed in segmented trends where labour productivity growth in each period was underpinned by investment in human capital, see Vonyo (2008).

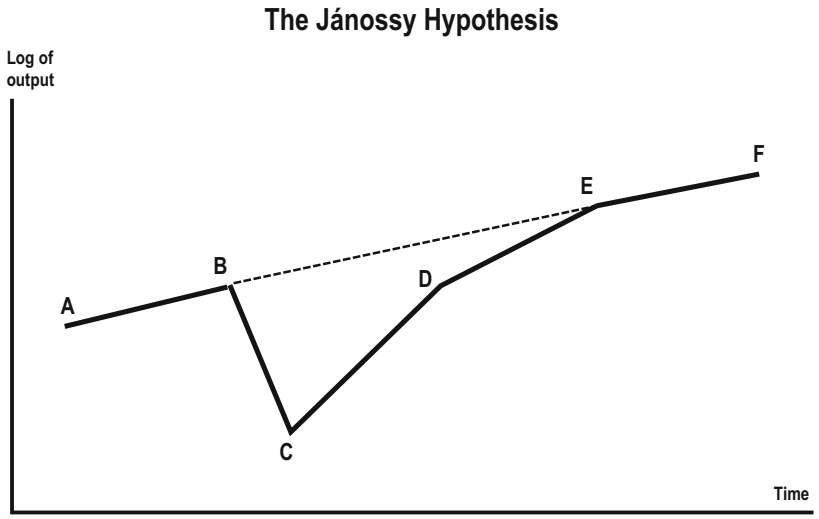

Fig. 1 AF, long run trend line; AB, pre-war output levels; BC, war induced shocks to output; CE, total length of the reconstruction period; CD, recovery of pre-war levels; DE, re-attaining the trend line; EF, output levels after reconstruction; Source: Dumke (1990)

and the share of the labor force in agriculture for a sample of European or OECD economies. Dumke (1990) estimated an equation of this type to explain average growth rates in cross-section for 1950–1980. He found that reconstruction was generally statistically but not economically significant and accounted for only about 5% of growth over the period. For West Germany, however, reconstruction did account for a large part of the difference between its growth and the average growth outcome and was complementary to conventional β-convergence.

A subsequent paper by Eichengreen and Ritschl (2009) echoed these findings for West Germany but argued that the output gap at the end of the war and reconstruction effect in the 1950s was somewhat bigger than Dumke had thought. They emphasized that this explained much of the extremely rapid TFP growth of that decade.[4] Temin (2002) estimated a similar equation for European countries for decadal growth during the 1950s through the 1990s but focused only on average performance. He found that reconstruction had a statistically significant positive effect only for 1950–1960 but not thereafter. Vonyo (2008) developed this approach further; his innovations included adding labor force growth as an independent variable and adopting a panel-data estimation setting. His results are summarized in Table 3. He found that reconstruction effects, which lingered through to the 1980s, were on average economically significant throughout the Golden Age with a very strong

[4]Eichengreen and Ritschl (2009) estimate that TFP growth in West Germany was 5.39% per year during 1950–1960 and it seems reasonable to infer from their discussion that as much as 3.5 percentage points per year may have been due to reconstruction.

Table 3 Contribution of reconstruction to growth of real GDP per person (% per year)

	1950s	1960s	1970s	1980s
Austria	2.18	1.60	1.02	0.44

Unweighted Average	0.97	0.71	0.45	0.20

Source: Vonyo (2008)

Note: Derived from panel estimation of two equations in one of which growth is regressed on initial income, labor force growth, GAP*Time, and a country fixed effect and in the other the fixed effect is regressed on GAP. GAP is the proportional difference between potential and actual output in 1948 where potential output is extrapolated from the 1938 level using the average annual growth rate from 1920 to 1938. The reconstruction contribution is obtained by adding the estimated impact of GAP in the two equations

impact in West Germany, but his results are notable also for underlining that in Sweden and Switzerland there was no reconstruction bonus.

Clearly, there is some support among cliometricians for Janossy's emphasis on reconstruction as an important factor in early postwar growth in addition to regular catch-up growth. It is also apparent that its impact varied greatly across countries. An implication of this is that international comparisons of growth performance during the Golden Age should attempt to normalize for differential scope for reconstruction, especially if they involve West Germany. The claim that the effects of reconstruction on growth still mattered in the 1980s should be treated with caution given the different results presented by Temin and Vonyo.

The second issue, relating to trend stationarity in long-run European growth, was investigated using time-series econometrics by Crafts and Mills (1996). They took the "pure-Janossy" hypothesis to mean that the return to normal growth would entail going back to the pre-1914 trend growth rate for real GDP per person by the end of the Golden Age. They found that the growth process could be modelled as segmented trend-stationary for all the European countries in their sample. On this basis they were able to reject the "pure-Janossy" hypothesis except in the case of Denmark. In the cases of Spain, Sweden, and Switzerland, a "modified-Janossy" hypothesis that after the Golden Age they had returned to the pre-1914 trend growth rate (but on a path at a higher income level) could not be rejected. This implies that all European countries except Denmark had higher real GDP per person at the end of the Golden Age than would have been predicted by extrapolating the pre-1914 trend.

This is very much what a reader of Abramovitz (1986) or Maddison (1982) would have expected given their emphasis on the unprecedented nature of rapid catch-up growth after 1950.

Macroeconomic Stability

It is widely recognized that the Bretton Woods era, which coincided with the Golden Age, was a period when macroeconomic fluctuations were relatively gentle (cf. Table 4), and it has been argued that this provided a highly favorable context for rapid postwar growth (Boltho 1982). Clearly, it was important that there was no repeat of the disastrous policy errors associated with the interwar gold standard which led to a lost decade for the gold bloc countries in the 1930s. The absence of banking crises in an era of capital controls and tight regulation of banks would also appear to be a positive feature of these years, as has been underlined by recent experience. Finally, the OPEC oil-price shocks only materialized in the 1970s. That said, some important caveats should be noted.

First, the hypothesis that volatility can harm growth has been somewhat controversial. One reason for this is that models were produced that had the opposite prediction, namely, that larger and more frequent business-cycle fluctuations can raise growth, for example, since the opportunity cost of productivity enhancing activities falls in recessions (Aghion and Saint-Paul 1998) and conflicting results have been found in empirical work. Nevertheless, the preponderance of evidence points fairly clearly to a negative effect on investment and growth of unexpected volatility, uncertainty, or the variance of innovations to a forecasting equation for growth (Bloom 2014; Rafferty 2005; Ramey and Ramey 1995), and this implies that a benign macroeconomic environment could have been beneficial for long-run growth outcomes in the Golden Age.

Second, the reconstruction of the world economy after World War II was based on the Bretton Woods Compromise (Rodrik 2000), which severely restricted international capital mobility while seeking to liberalize trade. This implied a new macroeconomic trilemma choice in which priority was given to scope for independent monetary policy to manage the domestic economy rather than the efficient allocation of capital. In the1950s and 1960s, average current account positions as a fraction of GDP were at an all-time low (1.3% in 1960–1973), and in cross-sectional Feldstein-Horioka regressions to predict investment/GDP the coefficient on savings/GDP is

Table 4 Real GDP growth: average for G7 countries in four macroeconomic eras (% per year)

	G7 Mean	G7 Standard deviation
1881–1913 (Gold Standard)	1.5	3.7
1919–1938	1.2	6.8
1946–1970 (Bretton Woods)	4.2	2.7
1974–1989	2.2	2.3

Source: Bordo (1993)

0.92 during 1946–1972 (Obstfeld and Taylor 2004). This imposed a domestic savings constraint on growth.

Third, the successful prevention of banking crises surely entailed lower growth in "normal years." Financial regulation reduced leverage in bank balance sheets and surely implied a higher cost of capital since Modigliani-Miller offsets are known to be imperfect (Miles et al. 2013). Capital controls also raised the cost of capital and adversely affected growth (Voth 2003). The period was characterized by high costs of adjusting capital stocks to the optimal level and also by high values of Tobin's *Q* in both West Germany and the United Kingdom (Crafts and Mills 2005). Overall, this suggests that investment and growth were constrained by the regulatory environment, but at present there is no study that quantifies the overall impact.

Structural Change

Some, but not all, European economies had substantial low-productivity agricultural sectors at the start of the Golden Age; for example, in 1950, 49% and 42% of employment was in agriculture in Spain and Italy, respectively, but only 5% in the UK. Kindleberger (1967) argued that in some cases fast growth could be understood in terms of a Lewis dual-economy model with elastic supplies of labor available to the industrial sector. Temin (2002) found that a statistically significant effect from adding the initial share of the labor force in agriculture to unconditional-convergence growth regressions for the 1960s and 1970s but not thereafter. He argued simply that this reflected the productivity gain from correcting a misallocation of resources.

The orthodox "shift-share" way to measure the contribution of structural change in employment to labor productivity growth is to calculate it as aggregate labor productivity growth minus a weighted average of intra-sectoral productivity growth rates based on initial employment shares, as, for example, in Maddison (1987). This assumes, however, that the intrasectoral productivity growth rates are unaffected by the labor transfer. This will not be the case, however, if there was surplus labor in agriculture (Kindleberger 1967) and/or the increased size of the manufacturing sector allowed economies of scale to be realized (Kaldor 1966) since one or both of the intrasectoral productivity growth rates will be increased. The problem facing cliometricians has been to evaluate this additional contribution.

Broadberry (1998) proposed a way to address the first of these issues. He suggested that in a declining sector, such as agriculture, a modified shift-share calculation should be used in which the actual should be replaced by a counterfactual labor productivity growth rate obtained by actual output growth minus national labor force growth. Table 5 reports the results of this method and compares them with those obtained using the orthodox method for a number of European economies. Not surprisingly, the contribution of structural change is much larger using Broadberry's method and is indeed quite large for Italy and Spain. Nevertheless, it must be accepted that although some correction for surplus labor probably is justified, this is no more than a rough and ready approach.

Table 5 Contribution of structural change to labor productivity growth, 1950–1973 (% per year)

	Orthodox measure	Broadberry measure
Denmark	0.24	1.10
UK	−0.12	0.31
Sweden	0.00	0.60
Netherlands	−0.31	0.29
France	0.00	0.52
West Germany	0.18	0.77
Italy	0.83	1.77
Spain	0.80	1.77

Source: Crafts and Toniolo (2008) who derived the estimates from data in van Ark (1996) based on Broadberry's methodology using a three sector (agriculture, industry, services) de-composition where agriculture is deemed to be the declining sector

Note: The orthodox approach considers the contribution of structural change equals $\Delta A_O/A_O - \Sigma \Delta A_i/A_i * A_i/A_O * S_i$ where A is labor productivity, S is share of employment, and subscripts o and i stand for the whole economy and sector i, respectively (Nordhaus, 1972). Broadberry (1998) modified this so that labor productivity growth in the case of declining sectors was measured using the overall national rate of labor force growth not the sectoral rate

The evidence on economies of scale in manufacturing is also far from satisfactory. Kaldor based his views on a belief in Verdoorn's Law which he interpreted as implying a positive relationship in manufacturing between the rate of growth of labor productivity and the rate of growth of employment. This could reflect various sources of economies of scale including learning by doing. On the whole, the literature has been rather skeptical of the validity of Verdoorn's Law and, in any case, most economists would look to better-specified estimating equations to try to infer the presence of scale economies.[5] The evidence from econometric investigations for European industries in the 1970s and 1980s is in fact somewhat mixed (Caballero and Lyons 1990; Henriksen et al. 2001) and might suggest that experience varies.

The best developed example of a structural change account of the Golden Age relates to Italy which experienced a major shift of labor from agriculture to industry and was able to expand internationally tradable manufacturing by sustaining a substantially undervalued exchange rate for about two decades. Rossi and Toniolo (1996) using a modified growth accounting technique pioneered by Morrison (1988) found evidence of significant economies of scale during the postwar period. Based on an approach suggested by Rodrik (2008), Di Nino et al. (2013) estimated that undervaluation contributed 0.6–1.2% per year to GDP growth in an economy where wage growth was lower than labor productivity growth in tradables in the context of a strong domestic flow of migrant labor. Putting these components together gives an account of Italian growth quite similar to that which a reader of Kaldor and Kindleberger might expect.

[5]Magacho and McCombie (2017) is a recent review which suggests that the proposition will be rejected by mainstream growth economists. Maddison (1987) attributed only a small part of the Solow residual during the Golden Age to scale economies, which he assumed amounted to 3% of GDP growth, but this was no more than a guess.

The Marshall Plan and the European Economic Community

The reconstruction of the European economy entailed not only investment but policy reforms. The Golden Age was notable not only for the Bretton Woods agreement but also for the Marshall Plan and the European Common Market. Both of the latter promoted European economic integration and it is this aspect which is the main focus of this section.

In terms of short-run static effects, trade liberalization can improve allocative efficiency and/or productive efficiency, i.e., given existing costs, factors of production are deployed more efficiently or production costs are lowered. Insofar as freer trade increases competition in product markets (through actual or potential entry), it may have both effects as market power is reduced and price-cost margins fall, while managers of firms are pressured to reduce costs to the minimum feasible (principal-agent problems are reduced). In terms of long-run dynamic effects, according to endogenous growth models, it is possible that the growth rate will rise as a result of economic integration. In a basic AK model, if investment (or more generally the rate of growth of the capital stock) responds positively, there is no tendency for diminishing returns to erode this initial effect so there is a "permanent" impact on growth. Perhaps more plausibly, if a larger market and/or more competition in product markets ensues from economic integration, this may raise the rate of innovation and total factor productivity (TFP) growth. Even so, in a perhaps more realistic (semi-endogenous) growth model, the trade-liberalization impact on the growth rate would be a transitory phenomenon reflecting a move to a higher level of output rather than faster trend growth.

Growth regressions can be used to estimate the effect of European economic integration on income growth. Here the most useful paper is Badinger (2005), which made an index of the level of integration for each EU15 country from 1950 to 2000, and in a panel-regression setting with suitable controls examined its relationship with growth and with investment. The integration index, which took account both of GATT liberalization and European trade agreements, shows that 55% of the protectionism of 1950 was eliminated between 1958 and 1975, a figure which then rose steadily to 87% by 2000. The results of the regressions were that changes in integration were positive for growth but that the level of integration had no effect and that changes in integration had somewhere between half and three quarters of their impact through investment with the remainder coming from changes in TFP. Across the EU15 as a whole, GDP was estimated to be 26% higher than if there had been no economic integration after 1950, with a narrow range from 21.6% for Sweden to 28.9% for Portugal. The peak effect on the level of income resulting from the rapid liberalization prior to 1975 would have raised the growth rate over the period by about 1% per year – impressive, but only about a quarter of the western European growth rate in a period of rapid catch-up growth (Crafts and Toniolo 2008). The implication of the results in Badinger (2005) is that European economic integration has had a sizeable impact on the level of income but has not had a permanent effect on the rate of growth. This amounts to rejecting the endogenous growth hypothesis and is line with investigations of the

impact of recent trade liberalizations using difference-in-difference approaches (Estevadeordal and Taylor 2013).[6]

The Marshall Plan was a major program of aid which transferred $12.5 billion from the United States to Western Europe during the years 1948–1951 and provided inflows to recipient countries which typically averaged about 2% of GDP per year.[7] It helped reduce the costs of the Bretton-Woods Compromise by speeding up European integration via trade liberalization and the conditionality that it entailed also promoted pro-market reforms that were conducive to growth. As De Long and Eichengreen (1993) stressed, rather than being a handout, the Marshall Plan was a "structural adjustment program" along the lines of the Washington Consensus – "the most successful ever" – which succeeded by raising productivity growth and steered Europe away from becoming Argentina, i.e., away from an inward-looking development strategy based on protectionism.

In particular, each country signed a bilateral treaty with the United States, which committed them to follow policies of financial stability and trade liberalization while the Organization for European Economic Co-operation (OEEC) provided "conditional aid" to back an intra-West European multilateral payments agreement; in 1950, recipients had to become members of the European Payments Union (EPU). This lasted until 1958 by which time intra-European trade was 2.3 times that of 1950 and a gravity-model analysis confirms that the EPU had a large positive effect on trade levels.[8]

The Marshall Plan worked by tipping the balance in favor of pro-market structural reforms that raised productivity growth rather than through a direct stimulus.[9] This analysis can be developed by thinking in terms of a 3-gap model (Bacha 1990). This takes into account that aid can have positive growth effects through relaxing savings, foreign-exchange, or fiscal constraints. Eichengreen and Uzan (1992) provided an analysis of this type. The bottom line is that the direct effect of an average inflow of 2% of GDP would have raised the growth rate by 0.3 percentage points during the years 1948–1951.

The establishment of the European Economic Community increased trade considerably. In 1958 the EEC was formed by the original six countries following the signing of the Treaty of Rome in 1957.[10] The signatories pledged to lay the foundations of "ever closer union" among the peoples of Europe and Article

[6]Estevadeordal and Taylor point to reductions in tariffs on capital goods with consequent increases in the capital to labor ratio as central to the positive levels effect of trade liberalization; for a similar argument applied to Golden Age Europe, see Cubel and Sanchis (2009).

[7]More details of how it worked can be found in Crafts (2013).

[8]See Eichengreen (1993) which also contains a detailed description of the logic and mechanics of EPU.

[9]Exclusion from the Marshall Plan and EPU postponed but did not necessarily preclude liberalization, as is shown by the 1959 reform in Spain which raised the growth rate by 1 percentage point per year for the next decade and a half (Prados de la Escosura et al. 2011).

[10]The six founder members were Belgium, France, Germany, Italy, Luxembourg and Netherlands.

2 committed members to form a customs union, to establish a common market and to harmonize policies. The EEC customs union was achieved in 1968, but the common market took much longer and awaited the Single European Act, which addressed nontariff barriers to trade, liberalized trade in services and ended capital controls and was (less than fully) implemented from 1992. Even so, trade costs between the six countries fell relatively rapidly (cf. Table 6). Using a gravity model, Bayoumi and Eichengreen (1995) estimated that intra-EEC trade among the original six members was increased by 3.2% per year between 1956 and 1973 implying that EEC membership may have raised income levels by 4–8% by 1970 (Eichengreen and Boltho 2008) based on the elasticity between trade volumes and income estimated by Frankel and Romer (1999).

Social Capability and Technological Congruence

These concepts are central to the explanation given by Abramovitz and David (1996) for the Golden Age. They emphasize that catch-up growth is not automatic but depends on "Social capability" and "technological congruence." Their approach is one of conditional convergence and their argument is that lack of social capability and technological congruence had held Europe back prior to World War II, but these constraints on growth were much reduced by the 1950s and 1960s (Nelson and Wright 1992). Technological congruence refers to the cost effectiveness of the leader's technology in the follower countries which can be undermined by differences in factor prices or market size. Social capability refers to the ability to assimilate new technology. Absorptive capacity is underpinned by education, skills, and economic competences including organizational effectiveness, appropriate business models, and training. Beyond this, however, social capability turns on institutions, economic policies, and the incentive structures that they imply, which affect the profitability of innovation and investment.

Table 6 Trade costs

	Germany-France	Germany-Italy	Spain-France	UK-France	UK-Italy	UK-Norway
1929	0.99	1.10	1.18	1.00	1.22	0.87
1938	1.33	1.12	2.26	1.21	1.54	0.98
1950	1.12	1.27	1.55	1.22	1.36	0.98
1960	0.91	1.01	1.52	1.22	1.25	0.91
1970	0.73	0.79	1.24	1.10	1.21	0.90
1980	0.55	0.61	0.89	0.74	0.86	0.69
1990	0.53	0.56	0.74	0.70	0.84	0.77
2000	0.61	0.66	0.70	0.75	0.90	0.88

Note: Trade costs are inferred using a gravity model and comprise both policy and non-policy barriers to trade; 1929–1938 estimates are not strictly comparable with those for 1950–2000; estimates that include Spain are for 1939 not 1938

There is strong evidence of a significant increase in the rate of technology transfer into Europe after World War II. Madsen (2007) estimated a model in which TFP is impacted by imports of knowledge embodied in high technology goods and concluded that this played a major part in the reduction of TFP gaps. Comin and Hobijn (2010) investigated diffusion processes and showed that adoption lags for new technologies became much shorter. These studies do not, however, account for the relative importance of increased social capability and technological congruence.

The best evidence on technological congruence was provided by Jerzmanowski (2007). He devised a method to decompose TFP gaps into a part due to inefficiency (distance from the production function) and a part due to technology (inferior production function due to inappropriateness of American technology). His results (Table 7) show that TFP gaps were still quite large in 1960 but that they were primarily due to shortfalls in efficiency rather than technology gaps. Subsequently, big reductions in these efficiency gaps by 1985 accounted for a good part of European catch-up. This tends to confirm both the importance of improvements in resource allocation and that American technology was congruent for early post-war Western Europe.

When he proposed the concept of social capability, Abramovitz (1986) stated that the problem was that no-one knew just what it meant or how to measure it. Since then, a good deal of progress has been made. Giorcelli (2017) provides an important example of improved absorptive capacity in Italy as a result of managerial training under the auspices of the Marshall Plan. She is able to compare firm performance where managers participated in sponsored visits to learn about American management practices with a control group that was excluded from the program. Productivity in the former grew by 52.3% relative to the latter over 15 years. This paper

Table 7 Decomposition of 1960 level of TFP into efficiency and technology components (USA = 1.00)

	TFP	Efficiency	Technology
Austria	0.60	0.64	0.94
Belgium	0.65	0.64	1.01

Note: TFP = Efficiency*Technology

indicates that management quality was important to realizing the potential of new technology and, especially in the context of research by Bloom and Van Reenen (2007), suggests that improvements in management might have contributed to enhanced social capability in postwar Europe. This is a promising area for more research.

Turning to institutions and incentive structures, when Abramovitz first put forward the idea of social capability, the fashionable thesis was that of institutional sclerosis as set out by Olson (1982). Put simply, this proposed that in the absence of shocks such as wars and invasions over time democracies tend to experience a proliferation of rent-seeking interest groups, which act as a constraint on growth. The logic of this argument would be that World War II and its aftermath significantly relaxed this constraint for some countries, notably, West Germany. This hypothesis has generated a large literature by economists and political scientists exploring cross-country evidence which has, on balance, been supportive of Olson (Heckelman 2007). European economic historians have, however, been distinctly skeptical. In the case of the prime example, Eichengreen and Ritschl (2009) summarized a literature emphasizing institutional continuity rather than change. Comin and Hobijn (2011) developed a neat test based on changes in the adoption lags for new technologies after World War II for technologies with and without a competing predecessor. They found that for the latter these fell by 13 years, whereas for the former they increased by 5 years. The Olson hypothesis predicts the opposite.

Another approach to assessing the impact of institutional and policy settings on growth has been to use indices of economic freedom. Countries that are economically free have secure property rights and effective enforcement of contracts, stable prices, low barriers to trade, and resources mainly allocated through the market. Because of data limitations, analyses incorporating an economic freedom variable in a growth-regression specification have examined post-1975 experience. On balance, papers that pay attention to issues of endogeneity (De Haan and Sturm 2000; Kacprzyk 2016) give some support to the hypothesis that either the level of or increases in economic freedom promote growth. Recently, Prados de la Escosura (2016) has developed a Historical Index of Economic Liberty that will allow the hypothesis to be tested for earlier periods. Table 8 shows a general tendency to increased economic liberty in Western Europe; this was the case comparing 1960–1964 with 1935–1939 for all countries except Greece and Norway. It seems possible that these data can be used to provide some further support for the Abramovitz and David (1996) claim that improved social capability was an important ingredient in the recipe for the Golden Age.

High Investment/Wage Restraint Cooperative equilibrium

The most striking hypothesis to explain enhanced social capability in post-war Western Europe is that of Eichengreen (1996) who argued that high investment rates which allowed successful exploitation of catch-up opportunities were facilitated by successful social contracts which sustained wage moderation by workers in

Table 8 Economic liberty (0–10)

	1935–1939	1950–1954	1960–1964	1970–1974
Austria	6.2	6.5	8.5	8.6
Belgium	7.4	8.0	8.4	8.0
Denmark	8.1	7.9	8.5	8.5
Finland	7.2	6.6	8.1	8.2

return for high investment by firms. To achieve a cooperative equilibrium of this kind, it is necessary to solve a time inconsistency problem. In the event of wage restraint, capitalists can go back on their promise to invest and raise dividends instead. On the other hand, if investment is increased, then workers can abandon wage restraint and seek to appropriate the profits. "Corporatist" arrangements provided institutions to monitor capitalists' compliance and centralized wage bargaining that protected high-investment firms and prevented free-riding by subsets of workers. A game theoretic analysis suggests that the central foundation of a cooperative equilibrium with high investment and wage moderation is that both sides are patient take a long-term view of the payoffs to their decisions and have reason to expect those payoffs to be substantial (Cameron and Wallace 2002).

Table 9 records the evolution of systems of industrial relations. Compared with 1925, in 1950 there were more countries classified as "corporatist" or "neo-corporatist," characterized by coordination in wage bargaining, and fewer with decentralized collective bargaining. In a growth-regression study, Gilmore (2009) found that coordinated wage bargaining may have had quite strong positive effects on investment and growth prior to 1975, but these were not found in subsequent periods. These results are supportive of Eichengreen's hypothesis. But this was not the only route to rapid catch-up growth as was apparent in the earlier discussion of the Lewis dual-economy model favored by Kindleberger. In Italy, for example, elastic supplies of labor to the industrial sector restrained wage increases and underpinned high investment at least until the late 1960s (Crafts and Magnani 2013).

If patience and optimism about large future rewards, rather than coordinated bargaining alone, are required to achieve the high investment with wage restraint cooperative equilibrium, then it may be quite fragile. As Cameron and Wallace

Table 9 A classification of industrial relations systems

	1925	1950	1963	1975
Corporatism	A,D,E	A,B,DK,N, NL,S	A,B,DK,N, NL,S	A,B,CH,D,DK,N, NL,S
Collective bargaining				
Neo-corporatist	CH	CH,D	CH,D	FIN
Decentralized	B,DK,N,NL,S, UK	IRL,UK	IRL,UK	IRL,IT,UK
Contestation	F, FIN, IRL	FIN,F,IT	FIN,F,IT	E,F,P
Authoritarian	IT,P	E,P	E,P

(2002) point out, the economic environment of the Golden Age was conducive to this outcome, whereas the turbulence of the 1970s was not. The cooperative equilibrium is more likely in a world of restricted capital mobility, fixed exchange rates, weak bargaining power for workers, and lots of scope for productivity growth. This describes the 1950s much better than the 1970s.

Relative Economic Decline in the UK

A brief look at the UK during the Golden Age is instructive. As was noted earlier, growth was relatively slow compared with other European countries. Some of this reflects less scope for catch-up including having an already small agricultural sector in 1950. But there was more to it than that notwithstanding the claim to the contrary by Temin (2002). So, while the Janossy and Kindleberger hypotheses are relevant to the British case and would, of course, predict that economic growth would be slower than West Germany and Italy, for example (cf. Tables 3 and 5), there is nothing in these models that would predict the UK's slide down the European ranking of labor productivity from 2nd in 1950 to 10th in 1973. In this context, being overtaken connotes avoidable failure even though simplistic growth regressions might seem to say otherwise. A case-study approach allows the cliometrician further insights, especially with regard to the role played by social capability.

Britain did not achieve the transformation of industrial relations that happened elsewhere in Europe which implied a considerable growth penalty. When it is not possible to write binding contracts, either the absence of unions or strong corporatist trade unionism would have been preferable to the idiosyncratic British system. This can readily be understood in terms of the Eichengreen model or an extension of it to incorporate endogenous innovation. In Britain, it was generally not possible to make the corporatist deals to underpin investment and innovation because bargaining took place with multiple unions or with shop stewards representing subsets of a firm's workforce who could not internalize the benefits of wage restraint. This exposed

sunk-cost investments to a "hold-up" problem.[11] In the terminology of Hall and Soskice (2001), the UK was a "liberal market economy," whereas a "co-ordinated market economy" was the foundation of the Eichengreen model.

Failure to successfully reform industrial relations was a major shortcoming of British governments from the 1950s through the 1970s. Throughout this period, there were continual efforts to persuade organized labor through an informal social contract to accept wage moderation in the interests not only of encouraging investment, but even more to allow low levels of unemployment without inflation at a time when politicians believed that this was crucial to electoral success after the interwar trauma. At worst, this was tantamount to allowing a de facto trade union "veto" on economic reforms and certainly obstructed industrial-relations reform. In any event, British supply-side policy, shaped by the "post-war consensus," was unhelpful towards growth in several respects.[12] These included a tax system characterized by very high marginal rates, described by Tanzi (1969) as the least conducive to growth of any of the OECD countries in his study; missing out on benefits from trade liberalization by retaining 1930s protectionism into the 1960s (Oulton 1976); a misdirected technology policy that focused on invention rather than diffusion (Ergas 1987); an industrial policy that ineffectively subsidized physical investment (Sumner 1999) and slowed down structural change by protecting ailing industries through subsidies (Wren 1996); and tariffs (Greenaway and Milner 1994).

A key feature of the Golden-Age British economy was the weakness of competition in product markets, which had developed in the 1930s and intensified subsequently. Competition policy was largely ineffective, protectionism continued through the 1960s, and market power was substantial. The evidence shows that weak competition interacted with the institutions, notably the systems of industrial relations and corporate governance, to undermine British productivity performance during the Golden Age (Crafts 2012). The rents resulting from weak competition were shared with trade unions partly through effort bargains that entailed overstaffing as was revealed in the 1980s when competition subsequently intensified (Machin and Wadhwani 1989). Nickell et al. (1997) estimated that for firms without a dominant external shareholder to control managers (the norm for big British firms at this time), an increase in supernormal profits from 5% to 15% of value added would reduce total factor productivity growth by 1 percentage point.

All this confirms that the emphasis of Abramovitz (1986) on social capability is well placed. It also goes beyond what has been possible with the growth regression

[11] In the endogenous innovation framework the "hold-up" arises when after a successful innovation workers use their bargaining power to extract a share of the profits. This reduces the incentive to innovate and thus the rate of growth. The more unions are involved in the bargaining, the more profits are reduced. The problem can be eliminated if a binding contract prevents renegotiation or there is no union or if a cooperative equilibrium is achieved with a single union. For a formal model and empirical evidence, see Bean and Crafts (1996).

[12] The concept of the "post-war consensus" should be understood as the set of policies regarded as feasible by senior politicians and civil servants given presumed political constraints (Kavanagh and Morris 1994). This implied a high degree of policy convergence but did not connote ideological convergence between the Conservative and Labour parties (Hickson 2004).

approach discussed earlier partly by flagging up the importance of competition and its interaction with institutions, but also by suggesting that the past places important constraints on institutional reforms and policy choices. The case-study approach allows a deeper analysis of the underlying reasons for success and failure in growth performance.

What Explains the Big Slowdown After the Golden Age?

After the early 1970s, growth slowed down markedly right across Europe. The end of the Golden Age had a number of unavoidable aspects including the exhaustion of transitory components of fast growth such as postwar reconstruction, reduced opportunities to redeploy labor out of agriculture, narrowing of the technology gap, and diminishing returns to investment. Moreover, the United States itself experienced a productivity growth slowdown. All-in-all, the scope for catch-up growth was considerably reduced although by no means eliminated. There were big reductions in the contributions of capital deepening and, especially, TFP growth to labor productivity growth (cf. Table 2). Although there were unavoidable reasons why productivity growth slowed down and European countries generally continued to narrow the productivity gap with the United States until the 1990s, it is clear that productivity performance could have been better after the Golden Age. Explaining this undue slowdown in productivity growth is a worthwhile future project for cliometricians in any case, but in addition, this later experience can provide further insights into Golden-Age growth.

Incomplete Catch-Up

The process of catch-up growth typically entails a series of ongoing reforms with the danger that at some point the political economy of the next step in modernization becomes too difficult. As modern growth economics stresses (Aghion and Howitt 2006), the institutions and policy choices that can galvanize a far-from-frontier economy differ in many ways from what is appropriate for a close-to-frontier economy. In particular, in the latter case, stronger competition in product markets and high-quality education become more important. A strong capacity for creative destruction matters more as countries become more advanced (Acemoglu et al. 2006). As new technologies come along, institutions and policies may need to be reformed (Abramovitz 1986). Yet, making the requisite adjustments may be problematic – history matters – and achieved only slowly and incompletely such that catch-up growth falters. Arguably, European countries needed reforms after the Golden Age to be well positioned for a later stage of growth but were slow to make this transition (Eichengreen 2007).

An important aspect of the changing nature of productivity growth as countries get closer to the frontier is that the weight of manufacturing in the economy declines while that of services increases. This typically contributes directly to a slowdown in growth as catch-up proceeds since the rate of productivity advance in manufacturing

Table 10 Contributions to labor productivity growth in the market sector, 1950–2005 (% per year)

	EU			USA

Market services	0.85	0.58	0.44	0.96	0.69	1.57
ICT production	N/A	0.33	0.42	N/A	0.52	0.81

Sources: Timmer et al. (2010); van Ark (1996)
Notes: Contributions are (%value added*productivity growth) for 1980–2005 and (%employment*-productivity growth) for 1950–1973. "EU" is aggregate of eight countries (Denmark, France, Germany, Italy, Netherlands, Spain, Sweden, and UK) in 1950–1973 and an aggregate of 10 countries (Austria, Belgium, Denmark, Finland, France, Germany, Italy, Netherlands, Spain, and UK) in 1980–2005. ICT production is included in manufacturing and market services in 1950–1973

generally exceeds that in services. It also has the implication that supply-side policies and institutions have to support a different type of economy. These issues are reflected in Table 10. European countries experienced a substantial decrease in the productivity-growth contribution of manufacturing after the Golden Age, as might be expected. In addition, however, the contribution from services was disappointing and, at the end of the century, Europe was unable to emulate the marked increase in productivity growth in market services achieved by the United States.

Social Capability in Different Technological Eras

In the 1950s and 1960s, Italy prospered and the UK floundered in the era of Fordist manufacturing, but in the ICT revolution at the end of the twentieth century, the opposite was true. This illustrates both that social capability depends on circumstances and that continued success in diffusion of new technologies may require reform. Each of these issues is ripe for cliometric research.

The acceleration in American productivity growth after 1995 was underpinned by ICT. For most countries, the main impact of ICT on economic growth comes through its diffusion as a new form of capital equipment rather than through total factor productivity (TFP) growth in the production of ICT equipment. The implication is that Europe had a great opportunity to significantly increase its productivity growth. However, growth-accounting estimates of the contribution of ICT-capital deepening to the growth of labor productivity show that European countries were generally much less successful than the United States in exploiting the potential of this new general purpose technology (Timmer et al. 2010). Interestingly, it was also true that American multinationals operating in Europe achieved significantly higher productivity from investments in ICT and used more ICT capital than other multinationals

or domestic firms, and that a major reason for this was their management practices (Bloom et al. 2012). In other words, the absorptive capacity of American-owned firms was bigger in the context of ICT.

Restrictive regulation of labor and product markets and, in some cases, shortfalls in human capital explain Europe's sluggish take up of ICT (Cette and Lopez 2012). Restrictive product market regulation deterred investment in ICT capital directly (Conway et al. 2006) and the indirect effect of regulation through raising costs was relatively pronounced in sectors that use ICT intensively. There was a strong correlation between product market regulation and the contribution of ICT-using services (notably in distribution) to overall productivity growth (Nicoletti and Scarpetta 2005). Notably, employment protection has been shown to deter investment in ICT equipment (Gust and Marquez 2004) because it increases the costs of reorganizing working practices and upgrading the labor force, which are central to realizing the productivity potential of ICT (Brynjolfsson and Hitt 2003). Since these forms of regulation have weakened over time, the story is not that European regulation became more stringent, but rather that existing regulation became more costly (and social capability decreased) in the context of a new technological era.

Italy has experienced major obstacles to the rapid diffusion of ICT for which it was not well positioned. The effective assimilation of this new technology has been hindered by the small size of firms, oppressive regulation, and shortfalls in human capital by comparison with the European leaders in the take up of ICT, as micro-economic studies confirm (Crafts and Magnani 2013). For the UK, success in ICT diffusion was an unintended and unexpected consequence of economic reforms in the Thatcher period. For the UK, the 1980s' de-regulation of services that are intensive in the use of ICT (notably finance and retailing), which reduced barriers to entry, and reform of industrial relations was important for its relatively successful response to the new technology. The move away from the postwar consensus removed any impetus towards employment protection, and rapid expansion of higher education proved timely (Crafts 2015).

Supply-Side Policy

There are two ways in which supply-side policy may bear some responsibility for the post-Golden Age slowdown. Reforms may have had an adverse effect on growth or there may have been failures to upgrade policies to sustain catch-up growth better. The literature has found examples of both problems.

Europe's route to catch-up growth brought with it increasing demands for social protection. Partly, this came simply as a result of raising income levels, but to a large extent it resulted from greater openness as European integration and globalization advanced (Lindert 2004). The median European economy spent 21.1% of GDP on social transfers in 1980 compared with 10.5% in 1960 and 1.2% in 1930. Managing these demands without undermining growth was an important challenge; insofar as they were financed by "distortionary" taxation, this became a drag on growth. Financing this expansion of government outlays by a different tax mix would have

been considerably better for growth (Johansson et al. 2008). The similar estimates of Kneller et al. (1999) indicate that the average 10 percentage point increase in the share of direct tax revenues in GDP between 1965 and 1995 could have entailed a fall in the growth rate of about 1 percentage point. In some countries, there were also marked increases in employment protection levels through the troubled 1970s. High levels of employment protection slow down the process of creative destruction and the labor force adjustment that it entails. The difference in employment protection between France and the United States could account for a difference of 0.5 percentage points per year in labor productivity growth in the 1980s and 1990s according to the estimates in Caballero et al. (2004).

From the 1970s through the 1990s, the impetus to economic growth from European integration continued, notably, through enlargements which expanded membership to 15 countries by 1995 and the inauguration of the European Single Market in 1992. An analysis based on a synthetic counterfactuals method suggests that the impact of EU accession on economic growth varied considerably across countries but was generally positive and in some cases provided a significant boost to growth (cf. Table 11). However, the impact of the Single Market has disappointed probably because nontariff barriers to trade have been lowered by less than might have been hoped. For example, Ilzkovitz et al. (2007) estimated GDP had been raised by 2.2% by 2006, well below the 4.8–6.4% projected ex-ante by the European Commission. Establishing a true Single Market in services could probably double this impact by reducing barriers to entry, but governments have had considerable discretion to maintain these barriers (Badinger and Maydell 2009). A recent estimate is that implementation of the Services Directive had raised EU GDP by about 0.8%, whereas full implementation would have tripled this (Monteagudo et al. 2012).

It is also relevant to look at the progress that European countries made in the upgrading needed as they moved closer to the frontier, in particular with regard to education and competition, the areas stressed by Aghion and Howitt (2006). A measure of cognitive skills shown, based on test scores, correlates strongly with growth performance (Hanushek and Woessmann 2012), and it is striking that the EU15 average for the late twentieth century is about 40 points less than Japan and

Table 11 Post-accession differences between level of actual and synthetic GDP per person (%)

	After 5 years	After 10 years
Denmark (1973	10.3	14.3

Note: First year for Netherlands is 1998 and for Spain is 2000. The index takes account of the independence of the competition authority and its resources, scope of investigative powers, and sanctions

South Korea which, according to the growth regressions for 1960–2000 presented in the paper, would mean growth was lower by about 0.5 percentage points per year.[13] The implication is that quality of schooling is an area where Europe could have done better. Woessmann et al. (2007) show that the variance in outcomes in terms of cognitive skills is largely explained by the way the schooling system is organized rather than educational spending.

Slowness to relax strict product market regulation (PMR) has raised mark-ups and lowered entry rates, thus reducing competitive pressure on managers with adverse impacts on both investment and innovation (Griffith and Harrison 2004; Griffith et al. 2010), and reduced European TFP growth relative to the United States in the late twentieth century by around 0.75 percentage points on average based on the estimates in Nicoletti and Scarpetta (2005). Similarly, in many European countries, competition policy remained much weaker than in the United States (Table 12). The econometric analysis in Buccirossi et al. (2013) found that this held back TFP growth; a reduction from a competition policy score of 0.69–0.36 (Sweden to Spain in 1995) is estimated to cut TFP growth by about 0.3 percentage points per year.

The Celtic Tiger

Ireland was, of course, a striking exception to the general picture of disappointing growth; far from slowing down, growth accelerated dramatically from the late 1980s to the end of the century. Table 13 reports growth data from the 1990s. It should be noted that GNP, which is a better measure of Irish performance, grew more slowly than GDP and that labor productivity grew less rapidly than GNP per person because hours worked increased considerably. Nevertheless, this is a very impressive performance reminiscent of other European countries in the Golden Age.

[13]Some countries have improved test scores quite rapidly, notably, Finland while elsewhere, for example, Italy, there is retrogression.

Table 13 Economic growth in Ireland, 1990–2000 (% per year)

Real GDP	7.5	Real GDP/Hour Worked	4.7
Real GNP	6.8	Real GNP/Hour Worked	4.0
Population	0.8	TFP	2.5
Hours Worked	2.8	Real GNP/Person	6.0

Source: Crafts (2014)
Note: TFP is on a GNP basis

At the start of the Celtic Tiger period, Ireland had considerable scope for catch-up growth. In 1987 labor productivity was 48% of the US level and only just above 50% of the European leaders. Unemployment was 17.2% of the labor force. Ireland had underperformed in the Golden Age partly because it was slow to abandon protectionism, had a malfunctioning labor market, and went through a period of macroeconomic disarray prior to a successful stabilization in the late 1980s. As we might expect, the rapid growth of the 1990s depended on favorable supply-side policies and good institutions. It was also predicated on the continuing globalization that characterized the late twentieth century.

At one level, the Celtic Tiger is just a story of delayed catch-up based on better policies and improved Social capability, but at the same time, there were key features which made Irish growth a special case. In this period Ireland had, by European standards, relatively low direct taxation and employment protection together with high quality education and had become a very open economy as a member of the EU (Crafts 2005). These features made Ireland an exceptionally attractive location for foreign direct investment (FDI) which was central to Ireland's development strategy. A major result of FDI was a very large ICT production sector which accounted for a much higher share of gross output than in any other EU country, including Finland, and contributed a little over 2 percentage points per year to TFP growth during the 1990s (van Ark et al. 2003).

Ireland's success in attracting FDI was based largely on its idiosyncratic corporate tax regime. It is clear from the literature that the semi-elasticity of FDI with respect to the corporate tax rate is quite high, perhaps of the order of −2.5 or even −3.5 (OECD 2007). At the start of the Celtic Tiger period, the Irish tax rate for manufacturing FDI was easily the lowest in Europe, and a study by Gropp and Kostial (2000) suggested that the stock of American manufacturing investment in Ireland was about 70% higher than if Ireland had had a tax rate equivalent to the next lowest in the EU. As trade costs fell, the impact of low taxes on FDI appears to have been accentuated significantly and their relative importance for location compared with proximity to demand increased (Romalis 2007).

Rapid employment growth in the 1990s came from a combination of large reductions in unemployment, which had fallen to 4.6% by 2000; a change in net migration flows that saw the tradition outmigration turn into net inflows that amounted to 67,000 between 1987 and 2000; and rising labor force participation, especially of women. The period also saw a large reduction in the NAIRU underpinned by wage moderation under the auspices of social partnership (Baccaro and Simoni 2007) and increases in human capital per worker (Bergin and Kearney 2004).

In the context of favorable shocks to labor demand, an unusually elastic labor supply prolonged the boom (Barry 2002).

Although it is not usually seen in this light, Ireland's success story has echoes of themes in the wider literature on the Golden Age. Three points stand out here. First, as in Germany during the 1950s, rapid growth was underpinned by putting unused resources back to work – in this case by substantially increasing the employment rate. Second, there was an elastic labor supply based on improvements in the workings of the domestic labor market and the historic switch from net emigration to net immigration. This encouraged wage moderation and helped sustain investment (Barry and Devereux 2006) and can be seen as having some similarity to the Lewis-type model favored by Kindleberger. Third, wage restraint was also achieved under the auspices of a social contract in which the quid pro quo was cuts in personal taxation. The standard and top rates of income tax fell by about 10 percentage points between the late 1980s and the late 1990s during which time tax cuts amounted to about a third of the growth in real take-home pay (Barry 2002). Here we see a permutation on the Eichengreen co-operative equilibrium.

Insights for the Golden Age

This research on the slowdown period highlights the potential importance of conditions favorable to rapid growth in the Golden Age which have not yet attained much prominence in cliometric work at least partly because they are hard to quantify for the early postwar years. These include the following: First, the importance of the quality of education and development of cognitive skills rather than just years of schooling in the accumulation of human capital should be underlined: Second, as the ICT revolution has highlighted, absorptive capacity of firms is a key determinant of the rate of diffusion of new technologies. In turn, this may be strongly influenced by the quality of management: Third, competition affects productivity performance, which not only means that competition policy deserves some attention but also may be an important aspect of the impact of European economic integration.

Conclusions

This chapter has considered two questions, namely, "what explains rapid economic growth in Western Europe during the Golden Age?" and "why did Western European growth slow down so markedly after the Golden Age?" It has focused mainly on the first of these questions on which cliometricians have made important contributions.

A number of (not mutually exclusive) hypotheses have support in the cliometrics literature. They establish a basis for understanding the rapidity of growth in the boom years, but the details vary in different countries. Reconstruction made a strong contribution to growth in some countries especially in the 1950s, as the Janossy hypothesis suggests, but while this had a big impact in West Germany it was irrelevant for Switzerland. In accordance with Kindleberger's analysis, the transfer

of labor out of agriculture had a significant impact on growth where it was feasible. For a country like Italy, this was a key component of Golden-Age growth, but it was of little consequence for the Netherlands. There is evidence also to support Eichengreen's model of a cooperative equilibrium featuring wage restraint in return for high investment based on coordinated wage bargaining in a sizeable subset of countries, but while this benefited Sweden it did not materialize in Ireland. Economic integration had a substantial impact on income levels, especially for those countries which signed the Treaty of Rome. The UK, a relatively slow-growing economy, did not benefit from any of these growth stimulants.

The notion of "social capability" has proved somewhat elusive in quantitative research, as Abramovitz expected. The Olson hypothesis of the absence of institutional sclerosis as a positive for some fast-growing countries has been viewed with skepticism, but it is surely the case that supply-side policy did matter and this seems to be borne out quite strongly by the examples of Ireland and the UK in the Golden Age during which both experienced serious policy failures and underperformed. Recent research has returned to the issue of absorptive capacity as a key aspect of technology transfer and this seems a priority area for future research.

The Keynesian hypothesis advanced by Boltho that macroeconomic stability was a key condition underlying the Golden Age has been neglected in cliometric research, although everyone would agree that the absence of financial crises or a depression was a big plus. In this context, a potentially important development is recent interest in, and improved methods for, measuring uncertainty as an important influence on investment. This methodology based on textual analysis could be a useful way to reconsider the role of the macroeconomic environment and policy framework. This also seems a good candidate for research effort.

The starting point for thinking about the post-Golden Age growth slowdown is to note that it did not simply reflect the exhaustion of transitory components, important though that was. The key lesson is that economic policy does matter and that many European countries were slow to make necessary reforms. The shining exception to this generalization was Ireland, which enjoyed fast growth in the late twentieth century on the basis of successful policy reforms which delivered an idiosyncratic and belated version of the Golden Age.

GDP and Convergence in Modern Times

Emanuele Felice

Contents

Abstract

In this chapter, I discuss historical estimates of GDP at both the national and the regional level and their application for assessing economic performance in modern times. Having been invented in (and conceived for) industrial capitalist societies, GDP has stronger informative power in those contexts where industry and services, and market exchange, retain the lion's share of production. In modern times, when comparing the series available for different countries, there are three major methodological problems to be acknowledged and possibly addressed: the dissimilarity of the quantity series and related proxies, deflation through purchasing power parities distant in time, and the differences in the base year used to construct GDP constant price (Laspeyres) indices (the latter issue may be less widely recognized, but it may have a remarkable impact). The way

the estimates are constructed also has a bearing upon the statistical tools and models we should use to interpret them; owing to the lack of reliable long-run series, cross-sectional techniques are often preferable to time series analysis; provided we have reliable estimates, growth accounting – decomposing GDP growth into productivity and industry mix effects – may provide important clues about the choice between theoretical approaches; not least for the quality of our data, cross-country convergence models based on conditioning variables should always be supplemented by historical information from qualitative sources and case studies. More generally, cliometricians should prove themselves capable of adapting their models to different historical contexts and relativizing findings to the limits of their estimates.

GDP · Convergence · Purchasing power parity · Neoclassical school · Endogenous growth · New economic geography

Introduction

To the extent that economics should use facts to verify theories, history is precious, being the fieldwork where empirical information can be found. Of course, information must be reliable: potential mistakes but also methodological differences can affect the results to the point that data cannot serve the purpose, all the more so in international comparisons. When we deal with historical GDP estimates – the primary indicator of any macroeconomic reasoning – what may appear less obvious is that in order to evaluate their soundness, we must rely not only upon historical knowledge but also on some basic expertise in quantitative techniques: economists may pick up a misleading series if they overlook the historical context, but non-quantitative historians can also accept the wrong figures if they are unable to assess the validity of the techniques used to produce them.

In this respect, quantitative economic historians – admittedly, a more comprehensive definition for cliometricians – are vital to both economics and more traditional history. From their historian backgrounds, they can provide a useful contribution to the former, insofar as they warn against a superficial approach to historical information (and estimates) based on the inattentive use of datasets and aprioristic assumptions about the past that do not meet the facts. They may even be able to contribute models that effectively account for historical change. Using their quantitative expertise, cliometricians may also help traditional historians understand why, and under which conditions, various models and estimates are useful descriptions of the past and tenable explanations for growth. In short, they can identify instances in which our historical interpretation should change according to the results proposed by quantitative history and economics. Such a double-sided task is not an easy one, because it implies that a good quantitative economic historian must have proficiency in both economics and history. However, the efforts have their rewards, as they may endow us with some of the most powerful instruments to understand the past.

GDP stands out among these instruments. It is virtually impossible for anyone studying economic growth to avoid using GDP estimates. Hence, it is important to understand how the series are constructed and what assumptions undergird the most popular growth models. However, it is also crucial to recognize that the choice of model and the interpretation of its results are informed and affected by the procedure employed to produce the figures. This chapter is dedicated to explaining and developing these issues. It reviews the procedures and uses of historical GDP estimates in modern times, roughly from the second half of the nineteenth century onward, at both the national and the regional level. In doing so, I highlight the main problems that can arise in terms of comparability between different estimates and make a case for improving explanatory models with an understanding of both the historical context and the GDP estimation procedures.

GDP: Concept, Limits, and Success

The production approach of calculating GDP considers it to be the sum of the final values of all the saleable goods and services produced within an economic system (a country or a region) over a certain period of time. Values are measured at market price, and they are final in the sense that they are net of the costs of intermediate goods and inputs to avoid duplication. According to the expenditure approach, GDP is the sum of consumption, investment, government spending, and net exports (exports minus imports). Finally, according to the income approach, GDP is the sum of all the incomes earned in that economic system (e.g., Lequiller and Blades 2006).[1] So many dimensions, into a single number: this is probably the ultimate reason behind its success. For instance, when divided by the number of inhabitants, total GDP corresponds to average income[2]; and when divided only by employment, it equals average per worker productivity. Production and expenditure, income, and productivity: the basics of any economic discourse cannot be addressed nowadays without GDP.

Less widely known is the fact that the most important measure of economic performance is a recent invention, at least from a historical perspective. It was born in the United States during the Great Depression in order to monitor the impact of the 1929 crisis and the time and pace of recovery (Carson 1975). It was then elaborated in the National Bureau of Economic Research, a private institute of empirically oriented scholars directed by Wesley Clair Mitchell, one of the leading figures in institutional economics (Schumpeter 1950). Further, it should be credited mostly to the work of Simon Kuznets: under his authorship, the first official estimates were

[1]For a country, GDP includes the incomes earned by the individuals not officially living in that country. Gross national production (GNP) includes instead the incomes earned abroad by the citizens of that country.

[2]To be consistent with the definition of the previous footnote, GDP should be divided by the population de facto (present population) and GNP by the resident population.

published in 1934, with reference to the US economy from 1929 to 1932 (Kuznets 1934). After World War II, in a western world governed by Keynesian policies (thus paying particular attention to cyclical fluctuations) and one strongly influenced by the economic and political power of the United States, GDP (and GNP)[3] turned into official statistics in Europe[4] and then throughout the world (although planned economies used a different system of national accounts). However, the origins of GDP should not be forgotten, at least from the point of view of cliometricians and economic historians, since they are essential in order to grasp the three basic features of the measure we are dealing with. First, GDP was conceived in an empirically oriented environment, as a sort of practical shortcut to solve the complex problem of how to monitor the economy, and thus it had strong theoretical limitations and even some related methodological contradictions. Second, it was born into an advanced industrial economy with the aim of measuring *that* economy, where industry (manufacturing) and services had by far the *magna pars* of national income to the detriment of agriculture (and mining) and where most of the production was sold and bought in the market. Third, it was created at a later stage in the history not only of the modern world but also of industrial capitalism as we have come to know it: it did not exist during the Industrial Revolution or in the first globalization era or at the time of World War I, not to mention medieval or ancient times.

There is now a vast literature on the theoretical limitations of GDP, which is of interest not only to economic historians and economists but also to social scientists and to an extent policymakers and the general public (Felice 2016). Nevertheless, some confusion on this should be sorted out. Some of the limitations of GDP are neither theoretical nor the result of a methodological contradiction. For instance, GDP is neither a measure of well-being nor the standard of living: it excludes the nonmonetary dimensions of well-being (from clean air to free time to the quality of affective life) while including other items that do not contribute directly to well-being but at best prevent it from falling (such as the expenditures on defense or on the administration of justice), and it does not consider the impact of the distribution of income on personal utilities. But there is no contradiction on this: GDP simply was not born for this purpose. GDP cannot be a measure of "human development" – at least as intended in the capability approach by Sen (1985) that was developed half a century after the creation of GDP – since it does not allow for other fundamental dimensions of human development, namely, education and longevity.[5] But again,

[3]The United States used GNP instead of GDP as late as 1991. By that time, virtually all the other countries had already adopted GDP.

[4]The first official estimates for the United Kingdom were made in 1941 by Richard Stone and James Meade. The former also was the main contributor to developing a standardized system that since 1952 was implemented in OEEC (Organization for European Economic Cooperation) countries (Stone 1956, 1961).

[5]However, many others are equally excluded: take, for instance, political and civil freedoms. Nussbaum (2000) increases up to ten the number of basic capabilities: (1) life; (2) bodily health; (3) bodily integrity; (4) sense, imagination, and thought; (5) emotion; (6) practical reason; (7) affiliation; (8) other species; (9) play; and (10) control over one's environment.

GDP was never designed to be a comprehensive measure of all the desired goals a human being can nurture, and so there is no contradiction or theoretical limitation in this. Rather, limitations are in those who regard GDP as the ultimate icon of human fulfillment. But even then, it is only fair to acknowledge that there is still no agreement about alternative measures to GDP that would better monitor non-monetary dimensions. Even the Human Development Index, which is gaining consensus among economic historians (Crafts 1997, 2002; Prados de la Escosura 2013, 2015), is far from undisputed for what concerns its formula, weights, and components (Prados de la Escosura 2010; Ravallion 2012a, b), let alone its theoretical foundations. This may be the fundamental reason why GDP, although *it is not* a measure of well-being and human development, was and still is often *considered to be one* or at least a measure of economic progress, broadly defined.

Similar arguments can be raised to oppose another well-known accusation brought against GDP: it excludes unpaid work (Waring 1988). This can have paradoxical effects, such as the often quoted textbook insight that having grandparents take care of children, instead of hiring domestic help, may cause a fall in GDP. But we need to remember that GDP was conceived when policymakers needed to contrast official unemployment, not unofficial employment. Less known but particularly telling is instead what happens with the mining sector, which actually represents a theoretical limitation (and even a methodological contradiction). At the time GDP was invented, the US census didn't ask firms owning their mines to declare the value of their reserves (Fenoaltea 2008). As a consequence, GDP does not compute the net value of production or value added (total mining production minus an estimate of the depletion of natural resources) but only the value of outputs. In other words, the more you consume your reserves, the more GDP (artificially) increases. The mining sector is important by itself, of course, but also for being part of a major problem. GDP has serious theoretical limitations in dealing with the environment. Not only does it not account for air and water pollution or land contamination, but indeed all these phenomena can even indirectly increase GDP, as long as they lead to the creation of specific counter-pollution activities in the market economy. This is probably the most worrying issue, which in the future may negate the ability of GDP to measure economic progress, at least until it is modified to account for some costs of pollution and the consumption of the planet's resources.[6] Of course, at the time GDP was invented, the concern for the environment was practically unknown in the United States or anywhere else.

The second and third characteristics of GDP should be of particular concern to cliometricians and economic historians. GDP was born in order to monitor advanced industrial economies, where most of the production comes from industry and services. In these sectors, there are two factors of production, labor (L) and capital (K), meaning that the standard growth model starts from the following production

[6]In this direction, some progress has recently been made, but with little or no heed, thus far, in the systems of national accounts: see Boyd and Banzhaf (2007) and Ferreira et al. (2008).

function: $Y = f(L, K)$. A widely accepted specification of this function is the Cobb-Douglas form

$$Y = A \times L^{\alpha} \times K^{\beta} \tag{1}$$

and in particular the one with $\alpha + \beta = 1$ (i.e., with constant returns to scale)

$$Y = A \times L^{\alpha} \times K^{1-\alpha}. \tag{2}$$

In both Eqs. 1 and 2, α and β (or $1 - \alpha$) are the output elasticities of labor and capital, respectively, and in Eq. 2, assuming perfect competition, α and $\beta = 1 - \alpha$ also are their respective shares of output (Douglas 1976). A stands for total factor productivity (TFP), a factor measuring the efficiency with which capital and labor are employed in production: this captures both the technological change not incorporated in capital and the gains of efficiency in production processes due to the reallocation of activities from one sector to another (Solow 1957). Provided that we find values for α, or for α and β, and that we reconstruct the amount of labor (number of workers or, better, number of hours of work) and the value of capital (the physical capital stock, in turn composed of machinery, infrastructure, and equipment; means of transport; nonresidential construction; housing), the growth rate of GDP (Y) can be decomposed into the contributions of increases in labor (L) and in capital (K) and of improvements in their combination (A). And even if we don't have values for α and β, whose historical estimates are usually far from undisputed, the formula clearly indicates that capital deepening (K) and TFP growth (A) bring about an increase in GDP per worker (Y/L). According to the simple equation $Y/P = Y/L \times L/P$, GDP per worker is in turn one of the two determinants of GDP per capita (Y/P), the other being the percentage of workers in the total population (L/P). In short, this means that technological progress (in its broader sense) leads to a rise in GDP per worker and hence GDP per capita. Thus it follows that, other things being equal, countries with higher GDP are more technologically advanced.

These conclusions do not necessarily hold in a preindustrial world where agriculture maintains a significant share of the total output. The agricultural production function includes land as a third factor of production. Furthermore, similar to the problem with mining, GDP does not compute land as a cost (again, in part as a consequence of the specific context in which it was created): in agriculture, when passing from gross saleable production to value added, a figurative sum to account for the extension of the land used to produce agricultural goods is *not* detracted, as if land was an inexhaustible resource. All of this means that a rise in GDP, either per worker or per capita, can be due not only to technological progress but also to an extension of the land cultivated. In turn, this implies that in the preindustrial world, we can have countries with high GDP – or with high standards of living – that are not technologically advanced. They may be rich simply thanks to a favorable relation between land and population (because they have high land per capita), but that land can be inefficiently used:

they would have low *per hectare* GDP (land productivity), but since they may rely upon a lot of land, relatively high *per worker* (and thus per capita) GDP. Obviously, in this situation, the standard coefficients of the Cobb-Douglas function do not hold. In addition, the assumption of perfect competition may be incorrect, at the very least because a significant proportion of preindustrial societies are not even market economies. These considerations make the use of GDP for eras and contexts radically different from ours, namely, for those preceding the Industrial Revolution, particularly problematic. At the very least, the interpretation we give to those GDP figures should be more cautious and not a mere replication of the interpretative framework we have assumed for the last stretch of human history. Because of such limitations, in turn I am limiting the present study to the use of GDP in modern times.

Even so, however, things are far from simple. And here we come to the third characteristic of GDP than any cliometrician or economic historian (but also any shrewd economist) should always have in mind. As discussed, the first official statistics of national income were produced in the United States in the 1930s. They progressively spread across the world only after World War II. For the previous periods, quantitative historians or applied statisticians – or "chipprephiles," as Maddison (1994) once named himself – had to reconstruct their own historical series of GDP by making the best out of several different sources and hypotheses.[7] When they were lucky, they could benefit from data on production, prices, labor force, and wages, but these data were not always comprehensive or exhaustive and often not even available. We may draw a line roughly at the mid-nineteenth century. For earlier epochs, available sources are scant, and GDP estimates often come from a handful of figures on urbanization and demography, related assumptions on the share of nonagricultural sectors (as most of Maddison's figures for the years before 1820), plus a few reliable series on prices and wages for a limited number of countries, and maybe some information about public revenues and tax collection. We cannot help warning once again against a too relaxed use of these shaky figures. Gregory Clark (2009, p. 1156) has efficaciously defined Maddison's pre-1820 estimates "as real as the relics peddled around Europe in the Middle Ages."[8] However, a more in-depth discussion of these issues would go beyond the scope of this chapter.

For the years after the mid-nineteenth century, which also coincide with our period of concern, historical data are much more abundant and solid: they usually include production series that are complete, or nearly so, and at times also extended price series, plus reliable and highly detailed data on wages and employment in some benchmark years (those of official censuses). This is true

[7]They could, of course, take advantage of a long tradition of income and macroeconomic estimates, dating back to the seventeenth century (for an outline, see Maddison 2007, pp. 393–401).

[8]However, some improvements on this are now on the way (Bolt and van Zanden 2014).

for Europe, at least, where following the Enlightenment and Napoleonic wars in the course of the nineteenth-century modern bureaucratic states replaced *ancien régime* governments. For other parts of the world, the colonial administrations notwithstanding, unless we are willing to use indirect procedures (such as import – export charts), more often than not we must wait until the second half of the twentieth century, when we are in the realm of the official GDP statistics.

In other words, historical GDP reconstructions are the result of ad hoc efforts by individual scholars[9] who had to make the best possible use of the available incomplete sources. The available information typically changes from one country to another, and even within the same country, it changes across years and economic sectors (e.g., Prados de la Escosura 2016). As a consequence, even for modern times, (country and regional) GDP series are often the product of different methodologies and hypotheses, and this has significant bearings on the results. Cliometricians need to be aware of the methodologies (and limitations) behind the GDP series they are using. The following section is intended to offer an outline of the main methodological problems we encounter when dealing with, and working on, historical GDP estimates in modern times.

Reconstructing GDP: Methods and Problems

In order to be able to assess the soundness of GDP figures, transparency is of course a preliminary condition: sources and methods must always be adequately described, ideally up to the point that results must be replicable. This may seem obvious, but actually it is not. For example, Italy's official historical series of GDP (beginning in 1861), one of the first in the world to be produced (Istat 1957), was a pioneering effort that also came to be famed for its lack of transparency in sources and methods, which did not help remedy the faults discovered by subsequent scholars (Federico 2003; Fenoaltea 2003; Felice and Carreras 2012). The original series has finally been replaced with a new one reconstructed almost entirely by economic historians (e.g., Baffigi 2013), more than half a century after it was originally published. Every country has its issues in this regard, and it would be impossible to review them all. The good news is that the standards have changed, and now an established rule of the scientific community is that GDP estimates must be transparent and replicable, which they are, for the most part. Maddison's magnum opus (1995, 2001, 2006), which presents GDP figures spanning the past 2000 years for most countries, also accomplishes this rule: although some of his assumptions for the nineteenth century

[9]For modern times, outstanding examples are Feinstein (1972) for the United Kingdom and Prados de la Escosura (2003) for Spain.

are questionable – or may simply look too crude[10] – an outline of the procedure is always provided, with further reference to the primary and secondary sources used; new contributions from the literature are also discussed and at times properly integrated.[11] The *Maddison project* was created[12] in 2010, the same year that Maddison died. Its aim is to revise and improve Maddison's original dataset as new information becomes available. The first results have already been produced, and they incorporate a great deal of the new statistical evidence and historical estimates that had become available in the meantime (Bolt and van Zanden 2014).[13] Other scholars are at work on comparative estimates for shorter periods of time or with a sectoral focus, producing data that can usefully complement and integrate those of Maddison. For its scope and accuracy, it is worth citing Williamson's (2011) *Project on industrialization in the poor periphery*, which, after reviewing and harmonizing a number of primary and secondary sources, presents estimates of industrial output for the period 1870–1939 at constant prices for the European eastern and southern periphery (12 countries), Latin America (7 countries), Asia (7 countries), the Middle East (Egypt and the Ottoman empire), and Africa (South Africa), plus three leaders (Germany, the United Kingdom, and the United States). As these works progress, it is possible to imagine a future in which we may be able to take advantage of an international GDP dataset whose problems of reliability and comparability will have been progressively reduced and perhaps even become negligible.

However, reaching such a goal will not be an easy task, and it is only fair to acknowledge that we are still far from it: information is lacking, and research is sparse not only for minor countries but also for the most important ones whose data

[10]Just a handful of examples: for Switzerland, per capita GDP growth from 1820 to 1951 is assumed equal to average for France and Germany (Maddison 2006, p. 409); for Italy, a "guesstimate" for 1820 is created, "assuming that GDP per capita grew at the same pace from 1820–1861 as from 1861–90" (Maddison 1991, p. 234; Maddison 2006, p. 408); but for this country, see Malanima (2006, 2011), his 2011 article having been incorporated in the updated version of Maddison's database (Bolt and van Zanden 2014). For Albania, per capita GDP from 1870 to 1950 was assumed to move in the same proportion as the average for Bulgaria, Romania, Yugoslavia, Hungary (!), Czechoslovakia (!), and Poland (!); but what is more worrisome, this same average should work also for the entire Russian empire (Soviet Union territories) from 1820 to 1870 and for Greece from 1820 to 1913 (Maddison 2006, pp. 407, 469–471).

[11]See, for example, the review of Good and Ma's (1999) proxy measures of per capita GDP for six Eastern European countries (Bulgaria, Czechoslovakia, Hungary, Poland, Romania, Yugoslavia) plus Austria, which are derived by regression by using three indicators (letters posted per capita, crude birth rate, and the share of nonagricultural employment in the labor force) and are accepted by Maddison only for some countries (Bulgaria, Poland, Rumania, Yugoslavia), owing to the lack of any other information (Maddison 2006, pp. 403–404, 471–472). For a comprehensive picture of Maddison's amendments to his previous (2001) estimates, see Maddison (2006, p. 624).

[12]The project consists of a small working party of four established economic historians and a larger advisory board composed of 22 scholars from around the world. See the website of the project: http://www.ggdc.net/maddison/maddison-project/home.htm.

[13]Despite the title of the article ("Re-estimating Growth Before 1820"), updated estimates referring to the last two centuries also are included.

surely look more robust. Moreover, even when we have *reliable* estimates, it is not assured that these are *comparable* between countries.

Indeed, comparability probably looms as the biggest challenge. At least three problems need to be recognized: one is about quantities, while the other two are about prices. However, at this point, before entering into further details, it may be useful to provide an outline of how GDP series are normally produced. As a general rule, since price data are not usually available throughout the period, but only for some reference years, GDP series are estimated at constant prices: a base year is taken (for which there are current-price GDP estimates) and that *current-price benchmark* becomes the year of the *constant-price series*. In order to do so, for each i sector and t year, it is assumed that

$$\mathrm{GDP}^{\mathrm{ti}}/\mathrm{Q}^{\mathrm{ti}} = \mathrm{GDP}^{(\mathrm{t+1})\mathrm{i}}/\mathrm{Q}^{(\mathrm{t+1})\mathrm{i}}, \tag{3}$$

where Q is the elementary physical series. In other words, it is assumed that for each elementary series, the relation between GDP and quantity, that is, unitary GDP, does not change throughout the years of the series, with respect to the unitary GDP of the baseline year. From Eq. 3, we obtain the formula used to produce constant (base year)-price estimates as

$$\mathrm{GDP}^{\mathrm{ti}} = \left(\mathrm{Q}^{\mathrm{ti}}/\mathrm{Q}^{\mathrm{yi}}\right) \times \mathrm{GDP}^{\mathrm{yi}}, \tag{4}$$

where y stays for the baseline year.

From this formula, the problem with quantities is almost self-evident. Ideally, the elementary physical series of each country must be taken at a similar level of decomposition. This in turn should be as high as possible, because within each country, the physical series should be homogeneous. For instance, we should not estimate textiles via the total amount of textiles produced; rather, we must include separately at least each major fiber (silk, cotton, wool, linen), and, indeed, even within a major fiber, at least the main production processes (spinning, weaving) should be broken down. On the basis of textiles then, one could argue that for each country, it suffices to use the official series (of production and trade), which would then produce the finest comparable aggregate national series. But what about other sectors, such as mechanics, a sector with a non-negligible and growing impact on total GDP? In the long run, productions have changed enormously; even within a single subsector and a single production (e.g., automobiles), there are different types whose prices significantly vary from one model to another. And even the models could change: some disappear and we find them replaced by others, both backward and forward in time. As a consequence, in practice, for each country we must rely on a different methodology in order to produce the elementary physical series: not only the level of decomposition varies, but we also often resort to different proxies within the same sector or the same series (say, raw cotton instead of yarn cotton) with different hypotheses to cover the unknown productions (say, different elasticities between the other textiles, or the rest of cotton, and the chosen proxy). Even within

each country, there may be problems of comparability between different periods. For example, a remarkable degree of decomposition has been reached for the Italian industry in the liberal age, for which about 200 elementary series have been produced (Fenoaltea 2003). But it was not possible to maintain the same level of decomposition in the interwar years, when "only" 90 industrial series could be produced (Felice and Carreras 2012). Moreover, how can Italy be compared with other countries for which only the major industrial sectors can be estimated?

Procedures also vary because there is no common rule to firmly guide us. One rule could be "disaggregate as much as you can," but this inevitably results in many country-specific procedures, following differences in the systems of national statistics as well as the accidental availability of supplementary sources. Alternatively, it could be argued that if our goal is to compare the performances of countries, we should shift from the rule of disaggregating (which comes from a very national-centered estimating approach) to a "lowest common denominator" approach that would work for the highest number of countries. For example, we could decompose industry into a few major sectors, each one estimated through its aggregate total production (in quantities, say, tons, weighted with prices) or its most important product. However, not even this would solve the problem, simply because the most representative productions would also vary from one country to another, with possible distortions. To sum up, we must resign ourselves to the fact that having perfect cross-country comparability in elementary series which span long periods of time is all but a chimera. Once this limitation is accepted, we can look with more indulgence at the current state of the elementary series used to produce the available historical GDP estimates, that is, a disparate collection of what has been done in different countries during recent decades, by separate scholars concentrating on their own sources and problems, unworried by the need for a common aggregating methodology.

When dealing with constant-price series, however, comparability in prices may even be a more serious issue. In the choice of elementary price data, we encounter more or less the same problems briefly discussed above for physical quantities (although these are usually limited by the use of a few benchmarks instead of long series). However, there is also a further significant distortion due to the way in which relative prices vary over time. From Eq. 4, in fact, it is true that for $i = 1 \ldots n$ productions, total GDP (GDP^N) is

$$GDP^{tN} = \sum_{i=1}^{n} \left(\frac{Q^{ti}}{Q^{yi}} \right) \times GDP^{yi} \tag{5}$$

In Eq. 5, we can see that to each physical series, a GDP weight has been assigned, which is constant over time and corresponds to the GDP weight of that single production in the base year: this depends on the unitary GDP and the quantity produced, again in the base year. As Fenoaltea (2010, p. 91) efficaciously pointed out, such a bold assumption "is done … with a bad conscience but with good

precedent: all sorts of scholars, similarly constrained, have done the same." In short, Eq. 5 is a Laspeyres quantity index number, which uses the GDP weights of a base (fixed) year to convert the component quantities to comparable values and, at the same time, to weight them. Actually, most of the available GDP series are Laspeyres quantity indices.[14] Of course, unitary GDP is the result of the price system in use that year, i.e., the relative price of that single production compared with the others, at a specific point in time. The problem is that relative prices (and thus unitary GDPs) do not remain constant over time. It is well known that prices and quantities are usually negatively correlated, on the demand as well as on the supply side, especially in the presence of technological progress, which reduces the unitary costs of production. Over the course of decades, in fact, some sectors and productions (e.g., chemicals and mechanics in the West between the late nineteenth and the twentieth century) grow faster than others thanks to technological progress. As a consequence, the early-weight price series, those based on a price system early in time (say, 1870 in an 1870–1913 GDP series), assign a higher weight to the sectors growing faster (whose quantities increase and relative prices decrease), and therefore, they grow more rapidly in the long run. For the same reason, the late-weight indices (say, a 1913-price series) grow less. This has become known as the "Gerschenkron effect," since it was reasoned by Alexander Gerschenkron (1947), soon after World War II, when analyzing Soviet indices of industrial production. Today, it is also simply known as the "index number problem" (Feinstein and Thomas 2002, p. 513).

Of course, the Soviet Union in the interwar years was an extreme case of accelerated growth in heavy industrial sectors, and thus the distortion caused by the "Gerschenkron effect" was fundamental. However, it is worth stressing that the index number problem is also serious in countries that modernized at a slower pace. For example, Italy from 1911 to 1951 ranked more or less in the middle among OECD countries.[15] For Italy, three indices of industrial production at three different price bases are now available, all made up of the same elementary physical series (only the relative weights in the unitary GDP, which are 1911, 1938, or 1951, change). From 1911 to 1951, the 1911-price index of industrial value added more than triples from 100 to 362; the 1938-price index goes from 100 to 264; and the 1951-price index doubles from 100 to 210 (Felice and Carreras 2012, p. 447). It is clear that such a major distortion cannot be ignored when it comes to international comparisons. If large differences are observable in the *same* series (i.e., series constructed with the same methodology and proxies), which differ only in their benchmark years, then when it comes to comparing *different* series belonging to different countries, a minimum requirement is that their base years be the same or at least relatively close.

[14]For a detailed discussion of Laspeyres indices and their properties as well as of the other main indices used in time series (see Feinstein and Thomas (2002, pp. 507–525)).

[15]For updated international comparisons of Italy's GDP with the rest of the world, in 10-year intervals from the unification of the country (1861) until 2011, see Felice and Vecchi (2013, p. 28).

Nevertheless, this is barely the case. Actually, Maddison's GDP estimates put together a large collection of different price bases, following once again the national accounting systems of every country and the work of separate scholars. Even a brief examination of the price bases that Maddison reports to have used in order to produce constant price GDP series offers a discomforting picture: Austria, 1913 (for the 1820–1913 series) and 1937 (1913–1950); Belgium, 1913 (1913–1950); Denmark, 1929 (1820–1947); France, 1870 (1820–1870); Portugal, 1910 (1851–1910); Switzerland, 1913 (1913–1950); Australia, 1910/1911 (1861–1938/39); the United States, 1929 (1890–1929) and 1987 (1929–1950); and the Soviet Union, 1913 (1870–1928) and 1937 (1928–1950). And this is an incomplete list (Maddison 2006, pp. 403–409, 450–457, 471).[16] This means, for instance, that for 1913–1951, Switzerland is barely comparable with Austria, and the same is true for Belgium in comparison with Denmark, for the Soviet Union in comparison with the United States, and so on.

It is worth noting that the "Gerschenkron effect" produces a distortion not only for what concerns international comparisons but also in terms of intra-sectoral comparisons within the same country: the GDP sectoral shares of a series at constant prices tend to remain very close to those of the base year, for obvious reasons (only quantities vary). Both these distortions (between- and within-country) would not be present if we were able to estimate GDP at current prices for each year of the series – as is done today. In order to have "real" GDP figures, current-price GDP series could then be deflated by using a single common deflator instead of sector-specific deflators as in Eq. 5: wages, for instance (Fenoaltea 1976). In this way, we would have constant-price series, unbiased toward the GDP composition of the baseline year and comparable between countries. However, such a procedure is too data demanding, and in the end, it may also turn out to be a chimera, not least because the choice of the deflation system is far from undisputed (e.g., wages would ignore the share of GDP going to capital gains, while a consumer price index would ignore the price of investment goods). What can be reasonably done is to estimate as many current-price benchmark years as possible for every country. From these, short constant-price series can be created. Finally, a long-run constant-price series can be produced by connecting the shorter series through chain indices: ideally, a chain index rebased every year (a Divisia index) could be created. Alternatively, a Fisher Ideal index can be produced: the early-year and late-year indices can be combined through a geometric average, with weights inversely proportional to the distance between the year of the series and the price basis, according to the formula

$$y_{i_{ini}\,\text{min prices}}^{\frac{i\,\max - i}{i\,\max - i\,\min}} \times y_{i_{ini}\,\text{max prices}}^{\frac{i - i\,\min}{i\,\max - i\,\min}} \tag{6}$$

[16]For further details and more countries, reference must be made to the previous version of Maddison's work (1995, pp. 126–139) and to the country-specific sources cited by the author.

where i is the year of the series y, imin is the early benchmark, and imax is the late one.[17]

The third problem when comparing international GDP series comes with purchasing power parities (PPPs), which is not at all a minor issue (indeed, it is probably more easily recognizable than the Gerschenkron effect). With the ambitious goal of comparing not only income and production but also the standard of living, Maddison converted all his country estimates into Geary-Khamis PPP 1990 international dollars. It goes without saying that any purchasing power converter is different from the official exchange rate, since it allows for differences in the cost of living. The procedure is simple: (a) each national GDP series, expressed in constant prices at its own national currency, is converted into an index; (b) at the same time, for the baseline year 1990, each national GDP, expressed in its own national currency and at current prices, is converted into 1990 international dollars by using Geary-Khamis PPP deflators[18]; and (c) with the index in (a), a new national series in Geary-Khamis PPP 1990 international dollars is then created. By using this method, all series can be converted into a comparable unit of measurement without changing the growth rate of each national series. In order to estimate PPP converters, different multilateral measures (and methods) can be used, but it must be acknowledged that Geary-Khamis is a suitable one because it assigns each country a weight corresponding to the size of its GDP and considers the United States, the most important economy, as the *numeraire* country (i.e., the 1990 Geary-Khamis dollar has the same PPP as the US dollar has in the United States in 1990).[19] However, of course, both the country weights and the purchasing power differences are those measured in 1990. In fact, Maddison's entire magnificent edifice is based upon the situation recorded in 1990, as if the relative purchasing power of currencies (both domestic and international) was fixed, rather than changing over time, especially in the long run, as both the underlying forces (namely, the domestic and international flows of goods and services) that govern the movement of prices and the basket of goods and services used to construct the PPP converter change. This problem becomes more serious if

[17]For an application of Divisia and Fisher Ideal indices, see Crafts (1985) for England, Prados de la Escosura (2003) for Spain (Fisher Ideal index), and Felice and Carreras (2012) for Italy (Fisher Ideal index). In Prados de la Escosura (2003, pp. 46–47), an application of the Paasche index can also be found: the Paasche index (which uses a changing set of prices to value the quantities) is used to produce price series, which are then combined with the Laspeyres quantity index to estimate GDP at current prices.

[18]The Geary-Khamis purchasing power converters for most countries can be found in Maddison (2006, pp. 189 (OECD countries), 190 (five East European countries and USSR), 199 (Latin America), 219–220 (Asia), 228 (Africa)). The reference year was always 1990 only for OECD, East European countries, USSR, Japan, and China; for the others, it varies from 1975 to 1993.

[19]Other multilateral measures either give all countries the same weight (such the EKS system used by Eurostat for political reasons), are a shortcut approach based on reduced information (such as ESCWA used for 8 West Asian countries), or employ as a numeraire a currency different from the US dollar (such the ESCAP measure used for 14 East Asian countries, which takes as a reference the Hong Kong dollar) (see Maddison 2006, p. 172).

we go further backward in our extrapolation, thus distancing ourselves from the baseline year. As Prados de la Escosura (2007, p. 18) put it:

As growth occurs over time, the composition of output, consumption, and relative prices all vary, and the economic meaning of comparing real product per head based upon remote PPPs becomes entirely questionable. Hence, using a single PPP benchmark for long-run comparisons implies the hardly realistic assumption that no changes in relative prices (and hence, no technological change) takes place over time.

Even over a period of four decades, the distortions from the use of a baseline benchmark distant in time are large, "above 5% and often much higher, while showing a high dispersion" (Prados de la Escosura 2000, p. 4). For these reasons, the use of a number of PPP converters at different points in time, following at least the main historical ages, would be preferable; but constructing PPP converters is a highly demanding task in terms of time and resources (Ahmad 1988) and one undermined in terms of feasibility (and reliability) by data scarcity for the period before World War II. Given the lack of reliable PPP converters for distant periods, Maddison's approach, which was actually pioneered by Bairoch (1976), still represents a viable, if suboptimal alternative. It has been argued, for instance, that the distortion caused by comparing real products on the basis of long-run PPP projections can be larger than that generated by using current nominal exchange rates (Eichengreen 1986); thus, even simple exchange rates could turn out to be a more practical shortcut.

And yet there is indeed a superior shortcut, which is based on the reasonable assumption that price levels between a country and the rest of the world move according to some basic economic characteristics (e.g., the share of international trade, income, or population). By further developing the method originally envisaged by Kravis et al. (1978), Prados de la Escosura (2000) tested a number of variables against the 8 available PPP benchmarks (spanning 1950–1990) for 23 countries, through panel regressions. As a result, he proposed a structural relationship for each country between its price level (defined as the ratio between PPP and exchange rates), on the one hand (y, dependent variable), and its nominal GDP per capita plus an additional set of explanatory variables (ratio of commodity exports and imports to GDP, population, area, a periphery dummy indicating if the country's nominal income represents half or less the US income), on the other ($x_{1,\ 2,\ 3,\ 4}$ and dummy independent variables).[20] By applying the estimated parameters to the independent variables recorded in past times for the same countries (when available) as a second step, Prados de la Escosura could calculate additional PPP benchmarks, spanning 1820–1938 (and for some countries, previously uncovered, up to 1990), and then propose comparisons of real per capita GDP at current historical PPPs. The author is aware of the limitations of his method that "even for the same group of countries" is based on "the application of a structural relationship derived from advanced western

[20]In that article, an excellent discussion of the literature about these issues and the different shortcut methods is also provided (pp. 2–8).

economies over the past 50 years to earlier and different historical contexts."[21] Nevertheless, the potential error is minor compared with that residing in Maddison's approach.[22] The latter retropolates a PPP without any adjustment; in Prados de la Escosura, we still have retropolation, but with adjustments for changes in the underlying economic structure based on an empirically tested relationship. Thus far, the results from Prados de la Escosura's method are available only for a limited number of countries. This may be the main reason why Maddison's data continue to be so widely used, even in papers published in top economics journals: they are the only available long-run GDP series for many countries (or, in any case, those more easy to pick up), their patent unreliability notwithstanding. Bad conscience, but good precedent. To clean our conscience or to make it feel even more guilty, it is fair to warn against this habit.

Convergence or Divergence? Measures and Models

Provided we have relatively sound estimates, we may then investigate the patterns of GDP growth in modern times. Did the country converge over time? A number of techniques are available to measure convergence, and different underlying theories are available to interpret the results. Techniques based on time series allow us to detect differences in cycles in trends and to identify country-specific break points. Unfortunately, they are more data demanding: any user should always check for the fact that the series at hand is not the result of some extrapolation or interpolation, as is often the case with historical estimates. Cross-sectional analyses allow us to test convergence when only a few benchmarks are estimated (possibly, each benchmark at its current prices) and therefore may result in more appealing long-run comparisons. Of course, they only consider the trend and for this can miss relevant information in between the two benchmarks.

Two concepts of convergence (Barro and Sala-i-Martin 1991) are generally accepted and used mostly – especially the second one – with benchmark data. σ-Convergence is a measure of dispersion in per capita GDP between different countries. The σ prefix comes from the standard deviation, which is used to quantify it. A simple test of σ-convergence is provided in Fig. 1. This figure displays the standard deviation of the logarithm of real per capita GDP for 20 countries, in selected benchmarks, from 1880 to 1990; the benchmarks are those for which the

[21] Prados de la Escosura (2000), p. 19

[22] As confirmed by the results. Just a couple of examples: in 1860, according to Maddison, Greece would have a per capita GDP higher than France (0.855 vs. 0.850), while according to Prados de la Escosura, France had a much higher GDP per capita (0.821 vs. 0.405) in 1860, 1870, and 1880. According to Maddison, Austria (at pre-World War I borders) would be above France, Germany, and Canada, while according to Prados de la Escosura, and much more plausibly, it would be below them (2000, pp. 24–25).

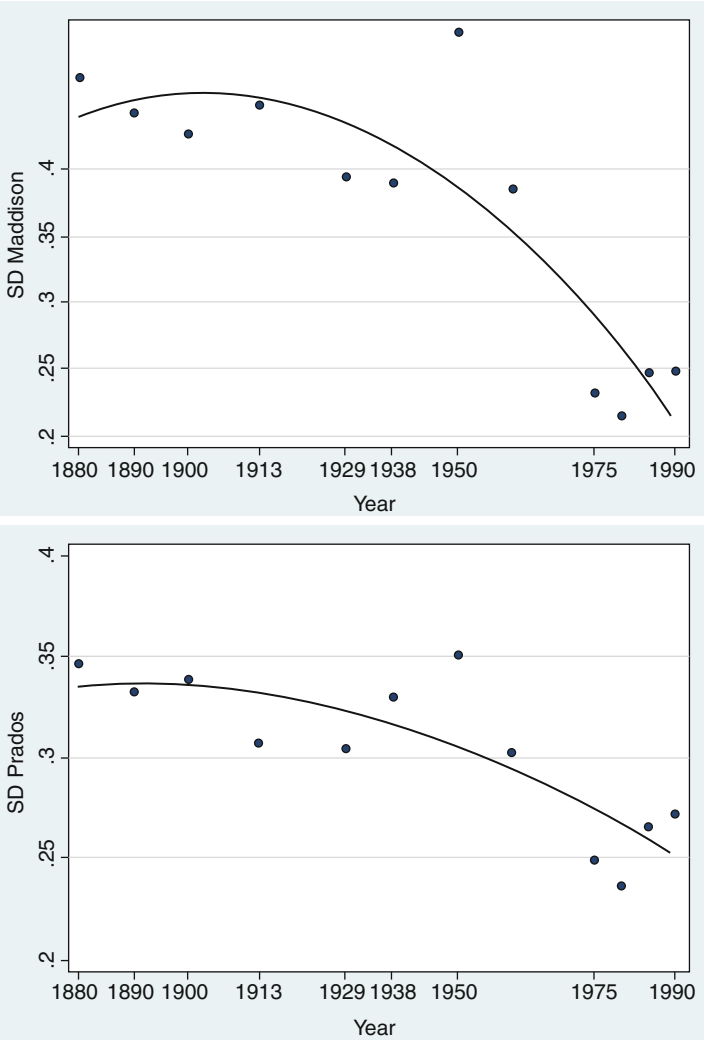

Fig. 1 σ-Convergence in GDP per capita from 1880 to 1990, according to different GDP estimates. (Sources and notes: see text)

estimates by both Maddison (upper quadrant) and Prados de la Escosura (lower quadrant) are available for an unchanged minimum number of 20 countries.[23]

[23]The countries are Argentina, Australia, Austria, Belgium, Canada, Denmark, Finland, France, Germany, Greece, Italy, Japan, the Netherlands, New Zealand, Norway, Portugal, Spain, Sweden, the United Kingdom, and the United States. The benchmarks are 1880, 1890, 1900, 1913, 1929, 1939, 1950, 1960, 1975, 1980, 1985, and 1990. GDP per capita is expressed in 1990 international dollars, but in the case of Prados de la Escosura, the figures are rescaled with his current price PPPs (2000, pp. 24–31).

As can be seen, the results can differ significantly. For the same countries, σ-convergence is much stronger using Maddison's estimates than it is when using Prados de la Escosura's estimates. This should not come as a surprise, given that differences in nominal GDPs and differences in PPPs are usually positively correlated. Both authors record convergence in GDP per capita, and this means that differences in this variable are lower in later periods; for this very reason, Maddison's differences in PPPs (which are for 1990), when retropolated, may also be lower than the real (historical) ones (say, for the nineteenth century). The latter are those estimated and employed by Prados de la Escosura, who then makes use of higher differences in PPPs in the early periods. This means that in early periods, the cost of living was lower in poorer countries than that supposed by Maddison, and therefore poorer countries had at that time higher real GDP; as a consequence, they converge less.[24] However, it is also worth noting that both authors report similar trends: most of the convergence took place from 1950 to 1975, but then it came to a halt and even reversed.

The fact that poorer countries grow faster than richer ones is usually regarded as a precondition for a decrease in dispersion. Technically, this is known as β-convergence, which can be conditional or unconditional. The prefix in this case derives from the coefficient of the regression model used to measure it (Eq. 8). β-Convergence can be tested by regressing the growth rate of per capita income with its initial level; if there is a negative correlation, then countries with higher per capita GDP are growing less. It is worth noting, however, that when we have unconditional (or absolute) β-convergence, we may not necessarily also have σ-convergence. For example, the initial GDP of a country may pass from 0.6 to 1.6 (the average being 1), implying β-convergence but also an increase in dispersion (σ-divergence). The opposite, however, is not true, namely, if we have σ-convergence, we always have β-convergence. If a country goes from 1.6 to 0.6, we record both σ- and β-convergence. For the same countries as in Fig. 1, β-convergence is tested in Fig. 2, where the growth rate from 1880 to 1990 in real per capita GDP is regressed on the logarithm of initial income.

As expected, β-convergence is stronger in Maddison's than in Prados de la Escosura's estimates: in the former, R^2 is considerably higher, and, as a consequence, the standardized β-coefficient is also more elevated (−0.869 vs. −0.738). Figure 2 also provides information about the relative performances of individual countries, namely, which grew above average, *given their initial income*, and which grew below; the former position themselves above the fit line, whereas the latter are below. For example, in both cases, Argentina records a disappointing performance, while Japan is the big winner. The entire European northern periphery (Sweden, Finland, Norway, Denmark) has been growing above the average, and today it is no longer periphery. Instead, the southern periphery (Portugal, Spain, Greece), with the exception of Italy, is below the average.

[24]It should be reminded that all are expressed in logs. In absolute terms, the standard deviation of real GDP per capita increased in both Maddison and (more) in Prados de la Escosura.

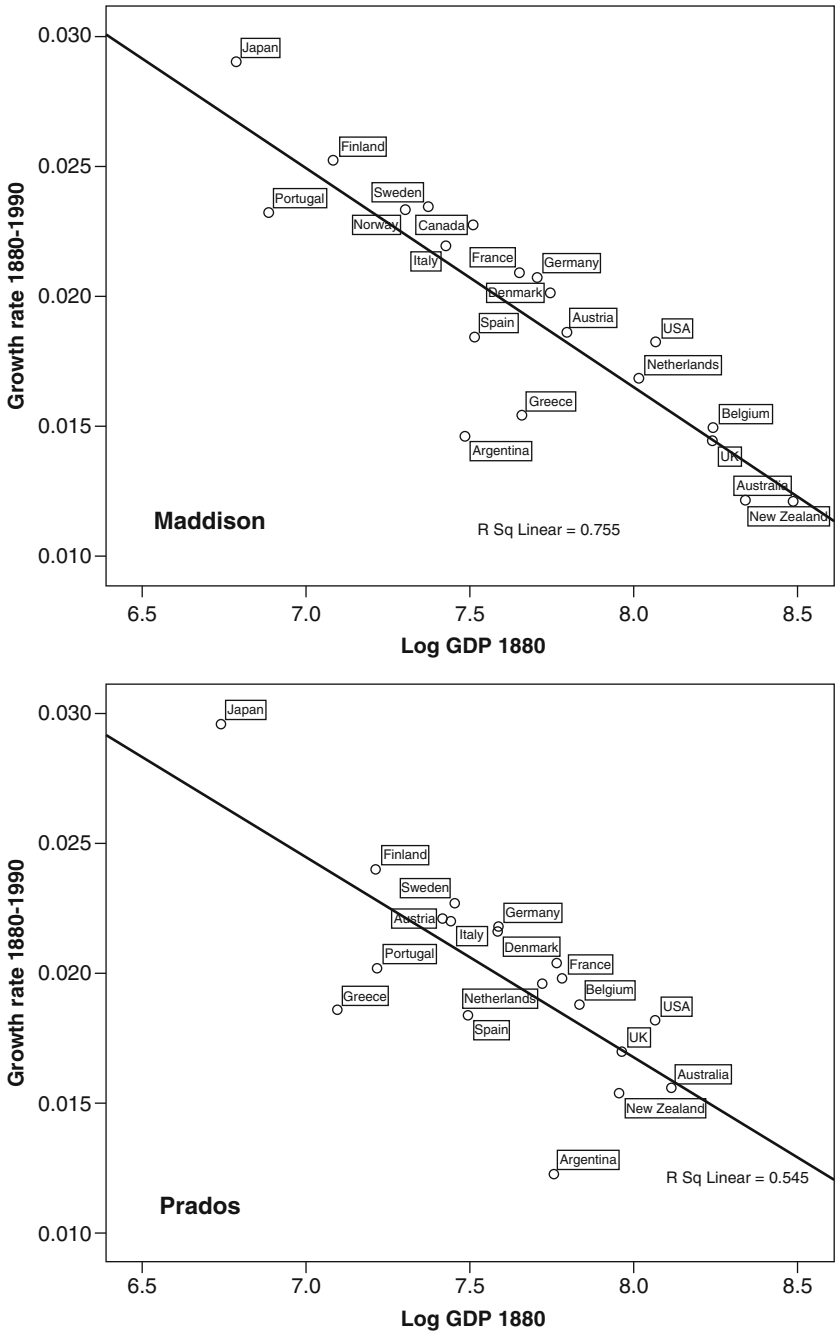

Fig. 2 β-Convergence in GDP per capita from 1880 to 1990, according to different GDP estimates. (Sources and notes: see text)

Why do some countries converge more than others? Economic theory is replete with elaborate models to explain the observed patterns. In the space of a few pages, it is impossible to review all of them thoroughly, but we may provide a sketch of the most important (and popular) ones. β-Convergence, both conditional and unconditional, can easily be incorporated in the neoclassical approach. This is based on the assumption of diminishing returns to capital or, in other terms, the downward slope of the savings curve. According to Solow (1956) and Swan (1956), in a closed economy where savings are equal to gross investments, the growth rate of capital stock would be

$$\gamma_k = s^* Af(k)/k - (\delta + n) \tag{7}$$

where s is the constant savings rate, ranging from 0 to 1, k is the capital stock per person, Af(k) is the production function in per capita terms, δ is the depreciation rate of the capital stock, and n is the exogenous rate of population growth. Thus, δ + n is the depreciation curve, a horizontal line, and s*Af(k)/k is the savings curve, a downward-sloping line. The argument for convergence holds that, given diminishing returns to capital, each addition to the capital stock generates higher returns when the capital stock is small. Of course, the capital stock determines per capita GDP, or income, via productivity. Thus, output and income should grow faster in countries or regions with smaller capital, i.e., with smaller income. It is worth stressing, however, that in order to satisfy this condition, the neoclassical model needs many collateral qualifications: the most important ones are that all economies must have a similar technology (considered in a broader sense to include taxation, property rights, and other institutional factors) as well as similar savings and population growth rates. These assumptions are anything but realistic in long-run cross-country comparisons. This is not a problem in itself, provided we always remind ourselves to use the models as they should be used: not as something true or false to be verified, in order to corroborate a theory, but as an analytical instrument useful to describe facts in a simplified way. In other words, we must always remind ourselves that theories are confirmed by facts, not by models, and that models rather serve us to draw the contours of the most relevant facts.

Using a Cobb-Douglas form of the production function, following Barro (1991), cross-country growth regressions may be expressed as

$$\gamma_i = \beta \log y_{i,0} + \psi X_i + \pi Z_i + \varepsilon_i \tag{8}$$

where γ_i is the growth rate of an i country, $y_{i,0}$ is its initial level of per capita GDP, X_i represents other growth determinants suggested by the Solow model apart from the initial level of income, and πZ_i represents those determinants not accounted for by the Solow model.

We have unconditional β-convergence (as seen in Fig. 2) when

$$\gamma_i = \beta \log y_{i,0} + \varepsilon_i \tag{9}$$

with the negative sign of the coefficient β.

Otherwise, we do not have *unconditional* convergence. We can still have *conditional* convergence, however, if after adding other variables to Eq. 8, the β coefficient becomes negative (Barro and Sala-i-Martin 1992). The basic idea behind conditional convergence is that differences in per capita incomes are not permanent only because of cross-country structural heterogeneity, that is, because the model does not satisfy collateral qualifications. This can be due to different resource endowments, institutions, and migration rates, as well as to human and social capital disparities, among others things. In the growth regressions, each of these factors can be a conditioning variable, coming either from within the Solow model variable group X i (i.e., human capital, institutions or social capital, if we consider technology in its broadest sense) or from outside the Solow model from the Z_i variable group (think of climate, but usually variables of this kind are much less common in the literature, while spanning an impressive range of categories). Once we have checked for the effects of structural heterogeneity, there can still be convergence; however, this is not convergence to a single common steady state, but rather the convergence of every country to its own steady state, given its own conditioning variables (i.e., *conditional* convergence). It has been called *convergence*, but truly this model does not measure convergence across regions or countries, since different regions or countries may have different steady states.

A major problem with this framework is the multiplicity of possible regressors, given that the conditioning variables that can be run are practically countless. Durlauf et al. (2005) classified about 150 independent variables used in growth regressions (in almost 300 articles) plus about 100 instrumental variables. In short, the number of possible regressors exceeds the number of cases, thus "rendering the all-inclusive regression computationally impossible" (Sala-i-Martin et al. 2004, p. 814). One reason for the multiplicity problem may lie in the analytical and theoretical weakness of the Cobb-Douglas function, which is valid only in the presence of a vast number of assumptions and has been verified only in a limited number of cases (namely, for the United States in the interwar years). There are two approaches to cope with the multiplicity problem: one is to take advantage of information from qualitative and case study research, while the alternative is to resort to econometrics in order to automatically sort out the irrelevant regressors. Bayesian models, which attach probabilities to each regressor, are an answer to the multiplicity problem safely within the second approach. Among these, the Bayesian Averaging of Classical Estimates (BACE) model, which makes use of the classical ordinary least squares (OLS) estimation, may be the most appealing technique. However, results from BACE models are far from convincing. To date, probably the most comprehensive exercise has been carried out by Sala-i-Martin et al. (2004), who proposed a BACE approach in order to sort 67 explanatory variables in cross-country regressions. Some of their findings look reasonable: for instance, they found primary school enrolment to be the second most important explanatory variable for 1960–1990 GDP growth rates. However, others don't. According to their model, the most significant explanatory variable was the dummy for East Asian countries. This outcome can be accepted only if we recognize that these regressions indicate a simple correlation; but if we are in search of an explanation (i.e., causation), what the model tells us is that South Korea grew because. . .it was South Korea. And there

are more problems with the results from that BACE model. For example, the socialist dummy is not correlated with (negative) growth. While the authors apparently do not note the tautology about the East Asian dummy, in the case of the socialist dummy, they discuss the unpersuasive result and specify that it "could be due to the fact that other variables, capturing political or economic instability such as the relative price of investment goods, real exchange rate distortions, the number of years an economy has been open, and life expectancy or regional dummies, capture most of the effect" (Sala-i-Martin et al. 2004, p. 829). Nevertheless, the ultimate determinant of most of these variables, as well as the particular political and economic features of those countries, was the socialist regime and the correlated planned economy: an econometric model concealing this evidence may lead to distorted interpretations of both history and the determinants of economic growth. These examples have been made to illustrate that the first approach must not be overlooked and, indeed, is often preferable. Historical knowledge, sensitivity to case studies, and country-specific characteristics should serve as a compass in order to choose among conditioning variables as well as be seen as an indispensable complement to any econometric analysis.

There is still the possibility that countries do not converge because initial conditions determine different outcomes in the long run, that is, the hypothesis that there are no decreasing returns to capital, for example, because the production function is not of a Cobb-Douglas form. A simple linear technology AK, instead of the neoclassical technology Af(k), would transform Eq. 7 into

$$\gamma_k = s^* A - (\delta + n) \tag{10}$$

where the savings curve is no longer downward sloping, but a horizontal line, just like the depreciation curve. Thus, two economies with different initial capital stocks would not converge even with all other conditions being equal. If technology or other parameters differ as well, these economies could still converge, but indeed they could also further diverge. They would converge if A or s are systematically higher in the poorer economy, if the depreciation line is systematically lower, or if other determinants of growth not included in the model are systematically higher as well; however, to quote Sala-i-Martin (1996, p. 1344), "there is no a priori reason why this should be the case." On the contrary, there is evidence that the savings curve is not even horizontal, but upward sloping. For example, because of economies of scale, increasing returns to capital have frequently been called into question to account for the rise in the United States during the second half of the nineteenth century or the rise of China in recent decades.

With the hypothesis of increasing returns to capital, we have entered the field of cumulative approaches. Following Myrdal (1957), this approach claims that growth is a spatially cumulative process that requires a minimum threshold of resources in order to start and thus may indeed increase cross-country disparities. Different schools refer to cumulative approaches. Among those worth mentioning are endogenous growth models (Romer 1986) that can still be regarded as a derivation from

the neoclassical approach and link economic growth to levels of human capital. Also important is new economic geography (NEG) (Krugman 1991), where the key determinants are either the economies of agglomeration (divergence) or the costs of congestion (convergence), and thus the size of the market plays a central role.

In practice, it is not easy to distinguish the increasing returns of endogenous growth models from the lack of collateral conditions of traditional (exogenous) neoclassical models. When there is no convergence, it may be difficult to conclude whether the traditional neoclassical model can still be valid with some qualifications to be satisfied or, on the contrary, that cumulative endogenous growth should be regarded as more suitable. Moreover, in historical analyses, crucial data, such as estimates of capital, are often lacking or unreliable. Furthermore, the models of increasing returns can easily be extended to predict convergence, such as in Eq. 10 by endogenizing the savings rate on the assumption that it would decrease with higher levels of capital (Sala-i-Martin 1996). Such a hypothesis is not at all implausible: think again of the opposite cases of China and the United States (the latter with higher capital but a lower savings rate). Thus, a unified long-term production function based on increasing returns could still be plausible in the case of convergence. On the other hand, some conditioning variables, such as the stocks of human (or even social) capital, can be seen alternatively as initial conditions in exogenous growth models, such as by decomposing K into physical and human capital (Mankiw et al. 1992).

Attempting to distinguish between the NEG approach, on the one hand, and the two neoclassical approaches, on the other, might be a more fruitful approach. Indeed, in terms of implications, it may be even more appealing. Broadly speaking, NEG models focus on the demand side. The resulting divergence in per capita GDP should be due to differences in "within-sector" productivity, brought about by economies of scale. The other two models, both the exogenous and the endogenous growth versions, are instead based on the supply side, namely, on imbalances in factor endowment. Divergence should refer to the "industry mix" effect, i.e., differences in the allocation of the working force between economic sectors. A simple algebraic calculation that decomposes GDP per capita into the product between GDP per worker (productivity) and workers per capita (employment rate), and then in turn decomposes the growth of productivity into "within-sector" productivity and the "industry mix" effects, may provide us with an (approximate) answer. This is also appealing in terms of interpretation given that, arguably, NEG growth can be explained by forces beyond human control (position, population density, and infrastructures that impact transportation costs, though they are at least in part the result of human decisions) in a larger portion than exogenous or endogenous neoclassical growth, which would typically include human capital, social capital or culture, and institutions as conditioning variables. Caution is warranted once again, since a significant proportion of the results may depend not only on the reliability of the estimates but also on the level of sectoral decomposition: within-sector productivity differences may be present between single industrial productions, but concealed at the aggregate level.

Besides these empirical difficulties, all three approaches seem to have theoretical limitations. Although the shift from divergence to convergence is usually allowed for and widely accepted, the economics literature has mostly neglected the possibility of a further reversal of fortune, namely, convergence to be followed by divergence again. This is common to all three models: there may be divergence at the beginning, because of either conditional exogenous variables, endogenous differences in factor endowments, or economies of scale, but then at a certain point convergence begins. Because differences in conditioning variables have been removed, factor endowments have converged, or congestion costs have exceeded economies of scale. Once progress is at work, it should go on until convergence is achieved. A renowned paper by Robert Lucas (2000) may be taken as paradigmatic of this frame of mind. Lucas argued that sooner or later a country will start industrial development and then converge. The problem is only to establish when, not if. However, once a region has embarked on economic growth, the process of convergence (in the long run) cannot be reversed. Nevertheless, how tenable is this argument? Many examples suggest that convergence may be stopped or even overturned. Take the cases of Western Europe and Japan (toward the United States) in the past two decades or of Southern Europe (toward Northern Europe) in recent years. The reason for the inadequacy of theoretical models can be explained by the fact that they are all static, in the broadest sense of the word: they are all based upon a single production function, which is supposed to be valid throughout the period of analysis. However, in reality – and especially over the long term – the shape of the production function may modify, following, for instance, technological progress. Think of human capital. Primary education was surely a fundamental ingredient of growth in the initial phases of the Industrial Revolution, while higher education may have made the difference in later phases. Other conditioning variables may change, too: natural resources may still have been important in the first Industrial Revolution, as testified by the geographical distribution of industries in nineteenth-century Europe. However, social capital has probably become more important in the current post-Fordist age, as far as it helps reduce transaction costs among a multiplicity of small firms. Some institutions (namely, authoritarian ones) may be effective in promoting growth at their early stages, but not at more advanced ones. Generally speaking, dynamic economics seem to be reconcilable with history better than static ones, since history too is essentially dynamic. But there is little or no use of dynamic models in the long-run analyses of GDP convergence.

A Further Step: From National to Regional Estimates (and Models)

In recent times, the reconstruction of GDP has been extended from the nation state to its regions and provinces. For these cases, the same caveats illustrated for national accounts apply, while methodological problems (and differences) are often even more serious due to the lack of data at the subnational level. A common methodological framework has been proposed and applied to produce comparable regional GDP figures for Europe (Rosés and Wolf 2014). The method elaborates on an idea

originally put forward by Geary and Stark (2002): at a sectoral, and hopefully sub-sectoral, level, national GDP is allocated by regional employment; the preliminary results are then corrected through regional nominal wages, which should approximate differences in per worker productivity; then, to have real GDP estimates, nominal figures should finally be rescaled by differences in the cost of living. Such a procedure is based on the assumption that capital gains are distributed along the lines of incomes from labor, namely, that the elasticity of substitution between capital and labor is equal to one. Moreover, the method is all the more effective the higher the degree of sector decomposition. For the reasons exposed in previous sections (namely, the Gerschenkron effect) , the national GDP to be allocated should be at current, rather than constant, prices. Another issue is that detailed figures on regional employment before World War II are available only from official censuses, which are usually taken at 10-year intervals. As a consequence, the production of regional GDP series is almost impossible. And even so, for some important sectors, census data may be misleading. For example, agricultural production may significantly vary from 1 year to the next, especially at the local level, without significant changes in the official labor force. At least in the primary sector, direct estimates (which are not impossible to find, even at the subnational level)[25] should be preferred.

The analytical tools are also similar to those briefly examined in the previous section, with only a few differences. First, at the subnational level, techniques based on benchmark estimates are de facto the only ones utilizable, at least for international comparisons. Since the subnational series of GDP for periods before World War II are often a product of interpolation,[26] with some possible exceptions at the sectoral level,[27] time series econometrics should be avoided. Second, when we measure σ-convergence, it may be useful to weight the regions with their population.[28] As long as we are interested in discussing the performance of national economic policies, we may treat different countries as statistical units with the same weights (thus giving the same importance to each national policy) and, at the same time, treat regions within a country with different real weights (thus measuring the overall dispersion of income within a national polity).

[25]See Federico (2003) for Italy.

[26]See, for example, the regional series for Italy estimated by Daniele and Malanima (2007), which have been produced by interpolating through the available regional benchmarks the national cycles of agriculture, industry, and services.

[27]For instance, the industrial production of Italy in the liberal age (1861–1913) (e.g., Ciccarelli and Fenoaltea 2009, 2014). In fact, time series techniques have been applied to the Italian regional construction movements during the liberal age (Ciccarelli et al. 2010). Even in this case, however, it must be pointed out that although the regional series by Ciccarelli and Fenoaltea running from 1861 to 1913 are indeed very accurate, they are estimated at constant 1911 prices, with possible distortions in interregional comparisons for the early years.

[28]Different population-weighted standard deviation measures are available and can be used, from the Williamson (1965) to the Theil (1967) index.

In addition, we can compare regions using an extension of the intercountry comparison models, with only a few qualifications. From a neoclassical perspective, the search for convergence within nation states should be simplified by the fact that here structural heterogeneity plays a minor role, given the usually common macroeconomic and institutional context. In fact, neoclassical scholars tend to be more optimistic about regional convergence than they are about convergence at the national level. For instance, Sala-i-Martin (1996) investigated unconditional β-convergence by applying the Solow-Swan growth model in five large European countries (Germany, the United Kingdom, France, Italy, Spain), plus Canada, Japan, and the United States, mostly for the years running from 1950 to 1990,[29] and found a similar rate of convergence, around 2% per year. Of course, this may not always be the case: at times structural heterogeneity can be hard to overcome, even within nation states, as is arguably the case for Italy, whose regional rate of β-convergence in the long run (1871–2001) has been found to be lower, barely 1% (Felice 2014)[30]; on the other hand, the forces of NEG should work better within a nation state provided there are no institutional barriers. The neoclassical approach of equalization in factor endowments and the increasing returns of the NEG have been both tested and compared for the Spanish regions by decomposing historical estimates (1860–1930) of regional per capita GDP in productivity and industry mix effects. The results suggest that they somehow reinforced each other, following the model by Epifani (2005), which combines both: from 1860 to 1930, the between-sector component was predominant, but NEG forces were gaining momentum in the last stretch, once industrialization had arrived in a considerable number of regions (Rosés et al. 2010). Furthermore, it should be considered that within nation states there may be regional development policies at work. Thanks to the common institutional framework, these can be more effective than development policies carried out at the international level (for least developed countries), and they may significantly change the pace of convergence, at least in specific periods.[31]

The descriptive model proposed by Williamson (1965) can be used to illustrate the observed patterns at the regional level. This is an extension of the Kuznets model (1955) of the evolution of personal income within a nation state. As for the personal income distribution, the relationship between national income and inequality would take a functional inverted U shape and a subsequent double movement: rising in the first phase, when industrialization begins and tends to concentrate in the strongest areas, then decreasing as industrialization spreads to the rest of the country. Williamson was mainly concerned about industrialization and structural change,

[29]Data for the United States run from 1880 to 1990, those for Canada from 1961 to 1991, and those for Spain from 1955 to 1987; data for Japan start in 1955.

[30]The results from panel models, for the years 1891–2001, are even lower: 0.5% (random effects GLS regression) (Felice 2011). The growth rate of convergence increases to 2% only once fixed effects are considered, that is, when we pass from unconditional to conditional convergence (Felice 2012).

[31]For Italy, the western country where the most impressive regional policy (in terms of expenditures as a share of GDP) was carried out (see again Felice (2010)).

and therefore his model focused on the supply side, and it is more easily reconcilable with the neoclassical approach (differences in conditioning variables would prevent industrialization spreading until they are removed). However, from a NEG perspective, the pattern would be similar (with rising inequalities due to economies of scale and then decreasing inequality due to congestion costs). There is some confirmation of the Williamson inverted U shape for the United States. The estimates suggest divergence between the late nineteenth and early twentieth century, as industrialization increased in the northeast and spread mainly to the northern and central regions. In the second half of the twentieth century, the southern and western states industrialized as well and thus converged (Kim 1998). When looking at Europe, we have confirmation for the Spain case, with divergence from 1860 to 1920 and then convergence from 1920 to 1980 (Martínez-Galarraga et al. 2014). For Italy, however, the inverted U shape is observed in the Center-North, but not when the southern regions are included (Felice 2014). Moreover, in many cases, regional convergence seems to have come to a halt in recent decades. This finding suggests that the long-run evolution of regional inequality may follow an N movement (divergence, then convergence, followed again by divergence) (Amos 1988), but on this issue, both empirical investigation and theoretical models have barely begun.

Concluding Remarks

The chapter reviewed the most common methods employed to produce historical GDP estimates at the national and the regional levels and the use of GDP to compare economic performances in the long run. The first point to be highlighted is that GDP estimates, even when relatively sound and well informed, are more suitable for measuring economic performance from the Industrial Revolution onward. GDP was born in the United States in the aftermath of the 1929 crisis, within an empirically oriented environment. It was designed for industrial advanced economies and may not correctly approximate material standards of living in preindustrial societies, where most production is from agriculture (for which the amount of land is a fundamental ingredient that GDP does not consider) and a non-negligible proportion is not even exchanged in the market (and thus is not included in GDP accounting). Moreover, for preindustrial societies, we often lack the minimum information required to produce reliable national accounts.

In modern times, when making cross-country comparisons, we should always make sure that the adoption of different estimating methodologies does not significantly affect the results. By themselves, national estimates can be reliable or made so given the available information, but this is not the point. For cross-country (and cross-regional) GDP comparisons, it is crucial that three basic conditions are satisfied. First, the decomposition level of the quantity series must be relatively homogeneous from one country to another. Even more important, and less generally acknowledged, the base year of constant-price series must be relatively close. Third, when considering real GDP figures, the PPPs used to compare countries must be as close as possible to the period of concern: as a consequence, the

renowned Maddison estimates at 1990 PPP international dollars may be not reliable for years before World War II, as illustrated by a contrast with the alternative PPPs proposed by Prados de la Escosura (2000).

Convergence tests may be significantly affected by the cumulative effect of these distortions. The way estimates are constructed also impacts upon the models used to interpret and describe the results. For instance, in international and (even more so) interregional comparisons, cross-sectional techniques are preferable to time series analysis, because the former are less data demanding even though they may be less informative. Provided we have reliable estimates, decomposing GDP growth into productivity and industry mix effects may yield important clues for distinguishing between the role of factor endowments and structural heterogeneity, on the one side, and market access, on the other. However, such clues should always be handled with care, for example, by searching for confirmation in the patterns of individual countries or regions. It also needs to be stressed that given the quality of the data, convergence models based on conditioning variables as well as more statistically refined ones such as the BACE techniques can be trustworthy only up to a certain point. They should always be supplemented by sound historical information, including qualitative sources and case studies, which should also help sort among the best conditioning variables to be tested, given the multiplicity of possible predictors.

In short, cliometricians should make an effort not to rely exclusively on statistical tools when searching for the determinants of growth but to complement them with historical expertise. They should also have a broad view of the available models, from exogenous to endogenous growth to NEG (and others that may or may not combine ideas from the three we have outlined), and be flexible enough to adapt both the models and the statistical techniques to the different historical settings and to the quality of their data.

Cliometric Approaches to International Trade

Markus Lampe and Paul Sharp

Contents

Abstract

This chapter gives a broad overview of the literature on the cliometrics of international trade and market integration. We start by motivating this by looking at the lessons from economic theory and, in particular, through the work which considers the effect of trade, openness, and trade policy on growth. Here theory, as well as empirical results, suggests no clear-cut relationship and points to the richness of historical experiences. We then turn to the issue of how to quantify trade and market integration. The former usually relies on customs records and the latter on the availability of prices in different markets. We then go one step back and look at the determinants of trade, usually tested within the framework of the gravity equation, and discuss what factors were behind periods of trade increases and declines and of market integration and disintegration. Finally, as one of the most important determinants of trade, and perhaps the most policy relevant, we include a separate section on trade policy: we both consider the difficulties of constructing a simple quantitative measure and look at what might explain it.

Cliometrics · International trade · Market integration · Tariffs

Why Look at Trade?

International trade can be considered a "biased" iceberg that stands out from the national economy and extends into foreign countries. As a topic in economic history, it has spawned a huge literature and with good reason. Adam Smith (1776) argued that trade would increase the "extent of the market," allowing for increased specialization and economic growth. David Ricardo (1817), inspired by the Methuen Treaty between Portugal and Britain which caused some specialization in port wine in the former and textiles in the latter, developed the concept of comparative advantage. He demonstrated, using the first mathematical model in economic theory, that since the opportunity costs of producing a good will differ in different countries, they can gain by trading and specializing according to their comparative advantages. Based on the trading patterns of the nineteenth century, which we will examine in more detail in the next section, Heckscher (1919) and Ohlin (1933) elaborated on the concept of comparative advantage, arguing that it was based on the relative endowments of different factors of production. More recently, new trade theory, particularly associated with the work of Paul Krugman (1979), has demonstrated how modern trade leads to trade in similar but differentiated goods, which is a gain for consumers, who have a love of diversity, although recent work for the case of Germany by Hungerland (2017) suggests that the welfare gains from increasing product variety were actually greater for the period before the First World War than today. Lastly, in as much as openness to trade leads to the spread of knowledge between countries, it can also lead to permanent gains in the growth of economies, rather than the one off gain from the exploitation of comparative advantages through a movement from autarky to free trade.

Economic history can also allow us to nuance the work of economic theorists, however. It has been pointed out that the UK and the USA both developed under protectionist regimes, and similar points have been made more recently on the emergence of the so-called tiger economies of Southeast Asia. Thus, even the father of the Washington Consensus, John Williamson (1990b), concluded that one exception from the general rule that free trade is always best is infant industry protection, whereby emerging industries are offered temporary protection so that they can enjoy the so-called dynamic comparative advantages which are not available at the initial stages of production. If these industries then allow for greater productivity growth than traditional sectors and they have spillover effects on the rest of the economy, then such temporary protection should increase incomes in the long run.

Thus, while no sensible economic theory offers the conclusion that autarky is preferable to an open economy, there are studies that argue for potentially positive outcomes from selective temporary protection of specific sectors under the "infant industry" and similar arguments (see Rodríguez and Rodrik 2000, pp. 267–272; O'Rourke 2000 for overviews). Such arguments highlight that specialization on the

production of "non-dynamic" (e.g., agricultural) commodities can, despite yielding static welfare maximization, lead to lack of development possibilities. Widening the domestic industrial base and aiding the self-discovery of nontraditional productive activities can lead to the evolution of new, more dynamic comparative advantages, which under direct world market pressure could not be effectively developed. If the resulting economic activities lead to higher economic growth and domestic knowledge development with concurrent spillovers – in the tradition of "new" endogenous growth theory – then temporary protection would be justified for the sake of long-term growth and development. However, as has already been highlighted above, foreign trade can also be a channel for knowledge transfer, and hence, trade barriers would act as barriers to the world technology pool and hence retard domestic productivity growth, so that successful "infant industry" protection would require both a wider growth-promoting macroeconomic environment and minimization of trade policy distortions.

Economic theory has thus been shaped by historical developments, and trade has been central to the development of economies over time and space and is thus a worthy focus of the efforts of cliometricians. In the following, we have surveyed papers from 2008 through 2017, plus older papers which were particularly relevant, although this is by no means a comprehensive study, and we rely on existing surveys where possible.

In relation to the cliometrics of international trade, we start by assessing the consequences of trade, which, according to standard theory, is directly related to understanding the sources of trade, since the standard textbook comparison of "autarky" and "free trade integration" predicts that adjustments in welfare, productive activity, factor remunerations, etc. will reflect these underlying sources. Hence, there is space for studies trying to assess the effect of trade, besides other "domestic" factors, on economic performance, as well as indirectly through the determinants of the latter (technological progress, technology transfer, institutions, and politics) and changes in the former (such as capital accumulation, natural population growth, and relative remunerations of factors of production), apart from the interplay between factor movements (foreign investments, migration) and trade. In the following, we provide a relatively concise survey focused more on methodology than on findings, since a recent chapter by Meissner (2014) in the *Handbook of Economic Growth* provides a comprehensive treatment of "Growth from Globalization," and Donaldson (2015) provides a similar survey on the "The Gains from Market Integration."

Turning to the big questions of the effects of international integration, two large questions stand out, to which economic historians have provided quantitative answers for the late nineteenth and early twentieth centuries: Does trade cause economic growth? And were trade and factor mobility substitutes or complements?

Regarding the first question, Irwin and Terviö (2002) use an identification strategy developed by Frankel and Romer (1999) to evaluate the impact of trade openness on growth net of the trade-enhancing effect of economic growth. This method consists of using standard gravity variables (distance, population, area, border, landlocked – see below) in a first stage to create "exogenous" trade shares

(aggregating bilateral trade per country) to be regressed onto income levels. Irwin and Terviö find that the coefficient for the trade share in their second-stage regressions for 1913, 1928, and 1938 is always positive but significant in only a few regressions, which might in part be due to small samples of 23–41 observations.

As for the second question, Collins et al. (1999) find that between 1870 and 1940, it is difficult to assess whether trade, capital flows, and international migration were substitutes or complements; although they quite clearly reject that trade and labor mobility were substitutes, for capital flows the findings are more ambiguous between complementarity and substitutability. They also highlight that both trade and migration policy might have influenced the actual historical outcomes. Both papers thus hint at history being richer and more complicated than standard theory might predict.

However, the Heckscher-Ohlin framework of relative factor prices and factor price convergence as a consequence of commodity market integration (see below) to explain the nineteenth-century globalization was behind the hugely successful research program leading to O'Rourke and Williamson's (1999) seminal monograph on *Globalization and History*. The underlying papers (O'Rourke and Williamson 1994, 1995, 1997; O'Rourke et al. 1997; O'Rourke 1997) have shown that commodity market integration went along with factor price equalization, especially regarding the ratio of wages to land rents, which increased in labor-abundant, land-scarce Europe but decreased in the land-abundant, labor-scarce New World, thanks to international migration, trade, and investments. Despite some criticism, for example, of the underlying data and interpretation of the Swedish case (Bohlin and Larsson 2007; Prado 2010), this account has become the standard reference in research and teaching of the nineteenth-century globalization.

Another central line of research focuses on the evolution of the early modern Atlantic economy, in which trade was not necessarily positive for welfare and development: Nunn (2008; see also Nunn and Puga 2012) finds that the slave trade had a clearly negative effect on the economic performance of the African regions that were most affected, not so much due to classical "direct" allocation effects but through the indirect impact via two not necessarily exclusive channels – boosting ethnic fragmentation and debilitating state capacity formation. This, of course, hints at the interplay between trade and domestic institutions and politics, a central topic in recent empirical growth economics. Acemoglu et al. (2005) find that, in Western Europe, the "central corner" of the Atlantic triangle, related trade was not large enough to directly boost economic growth significantly via capital accumulation or static gains from trade, but it increased the weight of merchants in political processes and thereby helped to tilt the political equilibrium toward institutional arrangements that favored trade and eventually economic growth via North and Thomas' (1973, p. 1) "efficient economic organization" via property rights and related "inclusive institutions."

This literature adds new layers onto an older literature regarding the role of trade in the "Great Divergence" with the "Rise of Western Europe," on the one hand, and African, Asian, and Latin American "backwardnesses" on the other. The relatively small importance for this trade on the European side has been highlighted by

O'Brien (1982) and is mirrored in Acemoglu et al. (2005), the O'Rourke and Williamson (2002b) assessment of the sources of early modern trade growth, as well as most recent discussions of the sources of the British Industrial Revolution. The latter often discard an important initial role for trade (Harley 2004; Mokyr 2009; McCloskey 2010), despite updated accounts on the volume and the working of the triangular trade (Inikori 2002) as well as selected links with welfare and economic activity in selected British ports (Draper 2008 for London shipbuilding, Richardson 2005 for Bristol), and for inventions and productivity in certain industries (Zahedieh 2013 for the British copper industry).

In an attempt to quantify the possible welfare losses for Britain from significantly reduced access to international markets, Clark et al. (2014) show in the context of a static standard computable general equilibrium model that relatively small welfare losses of 3–4% would have occurred in 1760, while increasing dependency on foreign trade, especially by the rapidly growing textile industry, would have implied substantial static welfare losses of 25–30% in 1850 by reducing access to foreign endowments and markets substantially. Beyond highlighting the importance of trade for the deployment of the industrial revolution, Allen (2003, 2011) has highlighted that the centrality of Britain in early modern international trade bore an important direct responsibility for the development of energy-intensive, labor-saving innovations that became a central feature of the industrial revolution, by raising real wages and making labor relatively expensive in Britain.

It is not only cliometricians of the British Industrial Revolution who have worked on the causal link between trade and economic performance and the role of international supply and demand versus domestic forces. A variety of studies with different approaches have emerged for mostly "peripheral" players in the emerging international economy of the nineteenth and early twentieth centuries. For Italy, Pistoresi and Rinaldi (2012) use cointegration analysis to assess (Granger-)causal relationships between imports, exports, and GDP. Bajo Rubio (2012) and Guerrero de Lizardi (2006) have conducted similar analyses, explicitly testing for the existence of balance of payment constraints to economic growth in Spain and Mexico, respectively, that is, structural limitations to conduct necessary imports for balanced economic growth. Other studies using cointegration analysis of the effect of trade on domestic economic activity include Greasley and Oxley (2009) on the pastoral boom in New Zealand after the invention of refrigerated long-distance transport and Boshoff and Fourie (2010) on the importance of both provisioning for ship traffic around the Cape of Good Hope and travelers stopping there during their journey to the East Indies, an early form of tourism, for agricultural activity in the Cape Colony. Somewhat connected to Allen's argument, Huff and Angeles (2011) show that globalization had a causal impact on urbanization in Southeast Asia prior to World War I, without leading to industrialization, simply by increasing demand from industrializing markets in the center of the world economy, fomenting commercial production and infrastructure investments, and accompanying overhead services in administrative and commercial centers.

Other authors have used different versions of input-output analysis to assess the relative importance of foreign versus domestic demand and supply forces in

structural models: Bohlin (2007) looks at Sweden before World War I and Kauppila (2009) at Finland during the Great Depression, and Taylor et al. (2011) show, using Leontief's original 1947 input-output table, that (mostly US financed) exports to Europe in the immediate postwar years (1946–1948) helped to avoid increasing US unemployment during the reconversion from a war-oriented to a civilian economy (Leontieff 1953). Ljungberg and Schön's (2013) comparative assessment of the drivers of industrialization in the Nordic countries shares a similar analytic framework but uses shift-share analysis.

Returning to internationally comparative studies and channels between trade and economic growth, Liu and Meissner (2015) derive a new, theoretically consistent measure of market potential and assess whether differences in domestic and foreign markets contribute to explain productivity differentials between the USA and the other countries on the eve of World War I. They find that productivity/GDP per capita is significantly related to market access but that its substantive significance vis-à-vis other factors is relatively minor. Madsen (2007) has shown that bilateral trade was a decisive channel for technology transfer and hence total factor productivity (TFP) growth and convergence for current OECD countries over the 135 years from 1870 to 2004, thereby extending findings by Coe and Helpman (1995) beyond recent periods. López-Córdova and Meissner (2008) examine the link between trade and democracy, and Huberman and Meissner (2010) show that bilateral trade was a diffusion channel especially for the adoption of basic labor protection legislation, such as factory inspection and minimum work ages for children. Vizcarra (2009) demonstrates how the Peruvian guano boom helped the country to return to international capital markets despite domestic political instability and a history of defaults. This finding seems to suggest that at least some forms of trade, controlled by foreign customers and investors, can be substitutes for "real" political and institutional reforms, a recurrent theme in the literature on modern commodity booms and the "resource curse" in developing countries. The importance of institutions[1] is also emphasized by Pascali (2017), who finds that the 1870–1913 globalization benefited only the small number of countries which were characterized by more "inclusive" institutions and thus was one of the main drivers of the economic divergence between rich and poor countries in that period. He identifies this effect by measuring the changes in trade distances brought about by the introduction of the steamship, which he also finds had a large effect on the patterns of trade worldwide.

In this context one final strand of literature, related to specialization resulting from international trade, merits attention: the debate on the role of the specialization in primary commodities for the growth perspectives of developing countries. This topic, promoted in economic history by Jeffrey Williamson and coauthors, for example, in his 2011 book on *Trade and Poverty* (Williamson 2011), has three strands: first, the original Prebisch-Singer finding of falling secular terms of trade for primary commodities that structurally harm the purchasing power of primary

[1]See also the survey by Nunn and Trefler (2014).

producers. Here, one recent comprehensive article by Harvey et al. (2010) underlines that over the last four centuries, for 11 out of 25 commodities studied, relative price trends were significantly negative, while for none was a significantly positive trend found, underlining that Prebisch-Singer forces are at work (Prebisch 1950; Singer 1950). A second strand focuses on deindustrialization and losses of dynamic development possibilities resulting from such specialization via Dutch disease forces or because of forces modelled, e.g., in Matsuyama (1992) and the infant industry literature. Hadass and Williamson (2003) and Williamson (2008) offer a comprehensive assessment of the effect of terms of trade on economic performance before World War I. Third, recent literature has highlighted that more than long-run trends in relative prices, the higher volatility of prices for primary products versus manufactures has harmed economic performance, investment, etc. in developing countries (Blattman et al. 2007; Williamson 2008; Jacks et al. 2011b). Country studies, conducted by Williamson and coauthors (e.g., Dobado González et al. 2008 for Mexico, Clingingsmith and Williamson 2008 for India; Pamuk and Williamson 2011 for the Ottoman Empire) and others (Federico and Vasta 2012 for Italy, Beatty 2000 for Mexico), serve to complement these comparative-econometric findings with historical case studies of channels, mechanisms, and their importance relative to domestic forces. For China, Mitchener and Yan (2014) find that as that country opened up to trade in the early twentieth century, its exports became more unskilled-intensive and its imports became more skill-intensive and identify this effect using the exogenous shock of the First World War, which led to greater demand for Chinese unskilled industries in particular and an improvement in its terms of trade. This might explain the decline in Chinese wage inequality over this period, in contrast to findings for developing countries during the recent globalization.

The impact of trade policy (to which we return in the last section) on the economy has been investigated in different frameworks. The first, already mentioned above and discussed in more detail below, is the gravity equation and the question whether tariffs and other trade policy components affect (reduce or divert) imports or exports. In a similar vein, researchers have asked if trade policy affects relative prices and factor incomes and, as exemplified in O'Rourke's (1997) study of the grain invasion, have found that this is normally the case. These findings imply that trade restriction via trade policy normally works, although trade policy might not translate 1:1 into the desired effects due to varying elasticities of demand and substitution between international and import-competing goods, both on the side of domestic suppliers and the preferences of domestic consumers.

In economic history, several studies since the seminal and controversial contribution of Bairoch (1972) have run growth regressions to estimate the impact of "average tariffs" on growth. The main finding is that of a "tariff-growth paradox" following the widely cited article by O'Rourke (2000) and subsequent papers by Vamvakidis (2002), Clemens and Williamson (2004), and Jacks (2006b). The robustness of these findings has been challenged by results with different methodologies and samples, including Foreman-Peck (1995), Irwin (2002), Athukorala and Chand (2007), Madsen (2009), Tena-Junguito (2010a), Schularick and Solomou

(2011), and Lampe and Sharp (2013).[2] Recent research has moved toward a clearer identification of the underlying channels of an existing or nonexisting tariff-growth paradox: Lehmann and O'Rourke (2011) find that before 1914, tariffs on manufactured goods were growth enhancing, while tariffs on agricultural commodities were probably harmful, and revenue tariffs on luxury goods and "exotic" products had no effect on growth. Tena-Junguito (2010a) finds that the skill bias of tariffs, one of the measures developed to assess not the average level but the structure of tariffs, is significantly related to growth before 1914. Lampe and Sharp (2013) have highlighted that the other side of a potential reverse causality circle is also of interest, since in many countries, tariff liberalization was preceded (and "Granger caused") by higher-income levels, presumably due to their effect on increased fiscal capacity to generate non-customs revenues (see, e.g., Aidt and Jensen 2009).

A novel investigation using prehistoric data by Maurer et al. (2018) suggests that locations on the Mediterranean which were better connected during the time of the Phoenicians, who were among the first to systematically cross the open seas, are associated with the location of Iron Age archaeological sites, suggesting that these areas were more developed due to trade. Otherwise, on a country level, Athukorala and Chand (2007) have studied the tariff-growth relationship for Australia over more than 100 years. Broadberry and Crafts (2010) have surveyed the interplay between trade openness, labor productivity, and structural change in Britain since 1870. Ploeckl (2013) shows that Baden's adhesion to the German Zollverein in 1836 had "traditional" effects on economic performance via increased market access but also led to the investment of Swiss entrepreneurs in Baden due to the higher external tariff Swiss exports faced toward the new customs area. Kauppila (2008) has studied the impact of tariffs on industrial activity and prices in interwar Finland. Tirado et al. (2013) combine new economic geography and an assessment of tariffs in their study of the effect of a gradual closing of the Spanish economy between 1914 and 1930 on the evolution of the regional wage structure. In the case of Spain, the post-Civil War (1936–1939) dictatorship under Generalísimo Franco is an especially interesting field of study, since it tried to run the country on an autarky basis. The macroeconomic consequences of this and the stepwise reforms during the 1950s have been ingeniously investigated by Prados de la Escosura et al. (2012); Martínez Ruiz (2008) has studied the impact of autarky policy on industrial efficiency (in 1958) via the domestic resource cost (DRC) indicator; and Deu and Llonch (2013) focus on the technological backwardness of the Spanish textile industry as a consequence of closed channels for embodied technology transfer. A related topic is import-substituting industrialization (ISI) in Latin America, whose strategies and results have been systematically investigated in Taylor (1998). Debowicz and Segal (2014)

[2]Lampe and Sharp look at a large number of individual country level ECMs for data on average tariffs and growth, identifying a multitude of different relationships for different countries and different periods. A similar framework has been adopted recently by Federico et al. (2017) for the trade-growth nexus, with similarly diverse results.

shed new light on the role of ISI for structural change and industrialization in a dynamic computable general equilibrium model for Argentina.

Finally, a few studies have used cliometric methods to study the effect of specific tariffs on the emergence of individual industries. The classical studies in this case are Head's (1994) study of the protection of US steel rails and Irwin's (2000) assessment of the US tinplate industry, which contrary to other iron and steel products faced a rather low tariff due to a misplaced comma in the 1864 tariff law. More recently, Inwood and Keay (2013) have studied the role of trade policy in modernizing and expanding the Canadian iron and steel industry in a comprehensive design including a novel identification strategy, and Juhász (2018) finds that regions in the French Empire which became protects from trade with the British during the Napoleonic Wars witnessed advances in the cotton spinning industry. Finally, Henriksen et al. (2012) demonstrate the relevance of the cheese tariff for the profitability of the Danish dairy industry before its eventual takeoff after 1880.

Having established the importance of trade in an historical context, we proceed by dividing this chapter into three further sections, which might be considered to follow a reverse causal structure. Thus, in the next section, we consider the extent of trade over time and space. How do we measure it? What different trade regimes can we identify in history? This, of course, can differ over both time and in the cross section and can be considered both in terms of trade volumes and in terms of market integration, which is measured by looking at prices in different markets. It also connects to the literature on the historical extent of "globalization." The section "What Determines Trade?" goes back one stage further and asks what is behind these different regimes, for example, institutions, technology, and trade policy. The latter deserves a particular mention given its importance for the pattern and extent of trade, as well as its central role, particularly in history, for the economic debate. Especially in the nineteenth century, politicians believed that by regulating trade, they were managing their whole economies. We thus devote the section "And What About Trade Policy?" to the issue of how to measure trade policy and its determinants.

Measuring the Extent of Trade and Market Integration

Before we can examine the effects of trade as discussed above, we need to be able to measure it. Thus, in this section we discuss the measurement of trade and market integration.[3] Clearly, the most direct way to measure the extent of trade is to look at the historical records of trade flows, which were often compiled by the customs authorities. Alternatively, or as a complement to this, cliometricians often measure the extent of market integration, which relies on price information.

[3]We ignore the sizeable literature on domestic market integration here, even though it obviously has a bearing on international trade, and the literature has contributed much to the methodological debate.

In very general terms, cliometricians have argued that the extent of market integration should be measured in terms of adherence to the (transaction cost adjusted) law of one price,[4] i.e., that integrated markets should enjoy an arbitrage-induced equilibrium, whereby prices cannot vary by more than the transaction costs of trading between them. Since market integration should be accompanied by more trade because of lower transaction costs, it should also lead to the effects outlined in the previous section.

The related work on globalization – a major part of the market integration literature – was inspired particularly by the new globalization of the late twentieth century, and the interest of cliometricians soon focused on the late nineteenth century, which they termed the "First Era of Globalization" (much of the early literature is summarized by O'Rourke and Williamson 1999). Exactly how to define globalization was, and is, a moot point. Clearly it should at least involve intercontinental trade, but the work by O'Rourke and Williamson cited in the introduction emphasized in particular that increasing *volumes* of trade were not a sufficient criterion for implying the presence of globalization – after all, intercontinental trade had expanded in previous eras, particularly perhaps with the European "discovery" of the Americas. Nor should it be defined by low-volume, high-price products such as the famous spices from the East, which have been traded for centuries. Instead it should be about the market integration of important, but basic, commodities, such as grains. Thus, in this literature, market integration was taken as an indicator of the increasing interdependence of markets and thus also their "globalization," and globalization is thus simply market integration on a global scale.[5]

To measure the extent of market integration, we simply need prices from different markets. The extent of trade and market integration is clearly linked, although markets might appear integrated even without trade, and there can be large volumes of trade with little market integration, as we discuss below. An important aspect of this is that trade regimes do not simply vary across time, for example, in the sense that the interwar years were more protectionist and with lower levels of trade and less market integration than the late nineteenth century. They also vary across space, so that, for example, Britain and Denmark were more free trading and consequently more internationally integrated in the late nineteenth century than France, the USA, and Sweden, for example. The market integration literature is heavily biased toward an understanding of the time dimension in the sense that many studies look at country pairs, or averages of several countries, and ask whether market integration is increasing or decreasing over time.

Turning first to the measurement of trade, much of the historical metrics have concentrated on tasks prior to the analysis of trade flows and their consequences,

[4]See the useful discussion on this in Persson (2004).

[5]This definition is not uncontroversial. De Vries (2010) distinguishes between soft globalization, which encompasses many things, and might well be applied to the changed trading world after 1500, and hard globalization, or "globalization as outcome," for example, market integration.

that is, the construction of databases and the examination of reliability and usefulness of key sources on cross-border trade. Starting with the most complex task, measuring the growth and geographical composition of world trade in the period prior to international statistical bodies like the UN, IMF, and World Bank and their classification (such as the Standard International Trade Classification) has been undertaken by a series of scholars, with the most recent estimates coming from Klasing and Milionis (2014), Federico and Tena-Junguito (2016), and Fouquin and Hugot (2016).

Klasing and Milionis (2014) calculate a world degree of openness (the ratio of imports and/or exports to GDP) for 1870–1949, which can then be chained with series from other sources such as the Penn World Tables. They contribute little to the understanding of the evolution of trade volumes, since they are aggregating available data from the Correlates of War database built by political scientists (Barbieri et al. 2009; Barbieri and Keshk 2012). Nevertheless, they provide a valuable service as they aim to derive non-PPP-adjusted estimates of national GDPs comparable to the non-PPP US-dollar-denominated trade flows they use; that is, they aim to undo Maddison's (2001) PPP adjustment based on a shortcut method for deriving the relationship of the difference of national to US price levels from a structural equation inspired by Prados de la Escosura (2000).

On the other hand, Federico and Tena-Junguito (2016) actually revise the whole literature on international trade flows from the beginning and succeed in the construction of comparable series from at least 1850 to 1938 based on a broad base of the cliometric literature and a more comprehensive use of historical statistical material. They also estimate world levels of (export) openness, using national export price indices to deflate trade series to make them comparable to Maddison's GDP series. Their work also gives a more detailed overview of previous estimates and yields annual growth rates of world trade and trade for the major regions from 1815 to 1938. In addition, they provide a large variety of price series and estimates of average transaction costs derived from CIF-FOB differences, which they show to be fairly constant over time (at about 7% of commodity values), apparently due to an increase in the average distance commodities traveled as a consequence of falling transport costs for given distances.

Such efforts are built upon two interrelated traditions: one of aggregating national statistics (Bairoch 1973, 1974, 1976; Maddison 1962; Lewis 1981) and the other, more relevant in the present context, of understanding the shortcomings and peculiarities of trade statistics as sources that economists often tend to brush over, while historians may in contrast have exaggerated (Platt 1971; Don 1968). Investigations of national cases like the Netherlands (Lindblad and van Zanden 1989), Belgium (Horlings 2002), Spain (Tena-Junguito 1995), Italy (Tena-Junguito 1989; Federico et al. 2012), China (Keller et al. 2011), and Argentina (Tena-Junguito and Willebald 2013) in the nineteenth and early twentieth centuries have unearthed a variety of peculiarities, most notably (Lampe 2008) underreporting due to smuggling or lack of legal requirement to declare, for example, duty-free imports or exports; differences in the definition, especially in differentiating retained ("special") imports and exports of domestic production from transit and reexport; unreliable practices of gathering

values or converting collected data on quantities into values; and different practices in recording countries of origin and destination, often proxied by last land border or port of consignment, as well as problems with port city entrepôts such as Hamburg for Germany or Hong Kong for China. For a comparative account on the international comparability of origins and destinations, the pioneering study is by Morgenstern (1963) for the first half of the twentieth century, reexamined later by Federico and Tena (1991) as well as Carreras-Marin (2012), Folchi and Rubio (2012), and Carreras-Marín and Badia-Miró (2008) for subsets of countries and commodities over the same period. Lampe (2008) offers a similar investigation for six European countries and the USA in the 1850s–1870s.

For the period prior to the nineteenth century, the problems are even greater since data on port entries, shipment manifests, customs revenues, etc. were in many cases not aggregated at a national level. As a result, they are often difficult to interpret and integrate into a meaningful picture. This leads to generally more qualitative than cliometric accounts, though national experiences and the relative endurance of their researchers provide differences in the state of knowledge.[6] Recently, sophisticated descriptions of international trade flows and shifting comparative advantages for individual countries have received renewed input through studies on Italy (Vasta 2010; Federico and Wolf 2013) and China (Keller et al. 2011), a study that also assesses changes to the intensive and extensive margin (number of available products and product varieties) over time. For late-Victorian Britain, Varian (2016) reaches the perhaps surprising conclusion that that country was at a marked comparative *dis*advantage in a number of manufacturing industries.

Finally, cliometricians are also now discovering the post-1945 period, where international statistics are easier to collect, and comparative accounts for countries and sectors can be more readily constructed. Examples for this include Serrano and Pinilla (2011) and Hora (2012).

Turning now to market integration, relatively little has been written on the general accuracy and usability of available price series. Although the issue is sometimes discussed in individual works, more often than not cliometricians work with "whatever they can get." A couple of useful studies by Brunt and Cannon (2013, 2014) have adopted a more critical stance, however. In the first, they offer a careful evaluation of the so-called *Gazette* prices of grain in England, which have been used in a vast number of studies. They find them to be of generally high quality, but they identify a number of limitations as a general indicator of the levels of prices due to fluctuations in quality, changes in the consumption share of domestic grains, and changes in the definition of the units of observation. In their second study, Brunt and Cannon build on this in order to examine the biases introduced to market integration studies when not taking the weaknesses of the statistics into account.

[6]See, for example, the comparative account of sources and knowledge on Spanish and British colonial trade as a subset of total foreign trade in Cuenca-Esteban (2008), work on Spanish cotton imports in the eighteenth century by Thomson (2008), and the export series for the British American colonies reconstructed by Mancall et al. (2008, 2013).

In particular, this problem arises from using infrequent data to measure the half-lives of price shocks, as we will touch on in the following discussion.

The literature on market integration and how to measure it is vast, and it is difficult to improve on the excellent survey provided by Federico (2012a). The following draws heavily on this. His survey includes everything written on market integration, including working papers, before 31 December 2009, and the reader is referred to this for a more complete survey of the literature prior to this date. Thus, we now summarize this literature and its conclusions but update it with the contributions of the last 5 years.

Within the market integration literature, a multitude of methodologies has been used to provide an econometric estimate of the extent of market integration. Likewise, conclusions differ about the extent of market integration, and a perennial question concerns that of "when globalization began." We start with the methodological debate. One of the main points Federico makes regarding this is that in order to understand market integration, there must be a clear theoretical framework. In particular, it should be understood that it consists of two, separable aspects[7]: first, that the equilibrium level of prices should be identical (the law of one price) and, second, that prices should rapidly return to this equilibrium after a shock (what he terms "efficiency").

Testing the first condition leads to the obvious problem that it is rarely if ever met in practice due to imperfect markets and the presence of transportation and other transaction costs. O'Rourke and Williamson (2004) suggest that the best approach is to look at trends and see whether or not prices are converging over time. However, although this works well for two markets, it becomes rather more complicated as the number of markets increases, and for this reason, most cliometricians have concentrated on price convergence between two markets. Thus, authors such as Persson (2004), Metzler (1974), and O'Rourke and Williamson (1994) have looked at simple graphs or have estimated simple regressions of price gaps or relative prices on trends.

Federico's preferred method, since it allows for the aggregation of price information from a number of markets simultaneously, is to calculate coefficients of variation and to regress these on a trend: a negative and significant coefficient implies integration (σ-convergence).The contribution of groups of markets to changes in dispersion can be calculated using simple variance analysis (Federico 2011, Sharp and Weisdorf 2013). Federico (2012a) notes, however, that inferences on the extent of market integration based solely on prices are risky, except with the addition of other information, particularly on the existence of trade. This is because a decline in the price gap *might* reflect a decline in transaction costs between the two locations, but it might also (or instead) reflect an increase in efficiency or availability of information, or it might reveal indirect arbitrage via other markets between which transaction costs have fallen.

Tests of "efficiency," i.e., the strength of arbitrage forces, on the other hand, follow a number of approaches, each of which also has particular weaknesses. First,

[7]Following Cournot (1838)

cointegration implies that the price differential will return to equilibrium after a shock due to arbitrage. Using the Vector Error Correction Mechanism (VECM), it is possible to both test for the presence of a cointegrating relationship and to estimate the half-life of a shock (see, e.g., Ejrnæs et al. 2008). As Taylor (2001) explains, however, this can lead to an overestimation of the size of the correction as long as transaction costs are positive. Thus, alternative approaches such as the threshold autoregressive (TAR) model have been suggested, which implies that prices only converge up to the "commodity points," i.e., the difference in prices beyond which arbitrage becomes profitable after the payment of transaction costs.[8]

The second approach, co-movement, implies that prices move together due to arbitrage. In its simplest form, this corresponds to the calculation of the coefficient of correlation between two prices or an OLS regression between them. To avoid bias if these prices share a common trend, the data can be de-trended, for example, by first differencing.[9] More recently, a Bayesian approach has also been applied (Uebele 2011). Third, variance tests can reveal that arbitrage has reduced the effects of local shocks, thus decreasing the volatility of prices,[10] although as Federico notes, such declines in variation could also be the result of changes to the weather or technology, for example.

Besides their weaknesses as discussed above, Federico is pessimistic about all these measures of efficiency, since they provide no indication of how to determine the relative strength of market integration (e.g., how close should the correlation between prices be before we claim "strong" integration?). Moreover, successful inference requires that it is possible to distinguish trading and non-trading locations, so we must be certain that common shocks unrelated to arbitrage are not biasing integration measures upward and that models that assume constant parameters (often over very long periods) are well specified. Moreover, it is not clear how the results for several country pairs, e.g., the correlation coefficients of their prices, can be aggregated into a more general and coherent picture. Other difficulties Federico notes are with the available data, which are often too infrequent to measure the speed of adjustment satisfactorily and only available for certain, possibly nonrepresentative, commodities (often grains), a point taken up again more recently by Brunt and Cannon (2014), who also measure the extent of the bias using data for England.

In the following we abstract from the more technical debate about how to test for market integration, and what exactly it means, and summarize some of the most important results from the literature. Federico (2012a) notes that most papers testing for market integration cover relatively short time periods and that there is a preponderance of work on the long nineteenth century, i.e., from the Napoleonic Wars to World War I. He explains that the results can be summed up quite simply. First, before the early modern period, there were waves of integration and disintegration

[8]See, for example, Obstfeld and Taylor (1997), Jacks (2005, 2006a, b).

[9]See, for example, Chartres (1995), Ljungberg (1996), Peña and Sánchez-Albornoz (1984), and Bessler (1990).

[10]See, for example, Shiue and Keller (2007), Persson (1999), and Bateman (2011).

both within Europe and between continents. Second, integration increased in the first half of the nineteenth century, but the process was slowed by increasing protectionism toward the end of the century, culminating in the well-known market disintegration of the interwar years. As Federico (2012a) also noted, the literature on the interwar market integration is perhaps surprisingly thin.[11]

Unfortunately, this generalization masks some debates. For example, although O'Rourke and Williamson (2002a) argue that there was no transatlantic integration in the early modern period, Rönnbäck (2009) sees waves of integration and disintegration, with great variation depending on which routes and commodities are being studied. Jacks (2005) was the first to suggest that markets started to integrate before the mid-nineteenth century. This is supported for the classic example of the trade between North America and Britain by Sharp and Weisdorf (2013), who document evidence for the importance of imports of wheat from the USA to Britain already in the middle of the eighteenth century, but with market integration being continuously disrupted, in particular by the French and Napoleonic Wars.[12] Similarly, but looking more generally at Europe and the Americas, Dobado-González et al. (2012), using a new methodology[13] to test for grain market integration between Europe and the Americas over the eighteenth and nineteenth centuries, find gradual integration with some setbacks. Going back further, more recent work by O'Rourke and Williamson (2009) demonstrates that the European Voyages of Discovery of the fifteenth and sixteenth centuries led to the integration of both European spice markets with those of Asia (despite the attempt to monopolize spice markets) and those within Europe. They would not, of course, classify this as evidence of globalization. De Zwart (2016) finds evidence of commodity price convergence between Europe and Asia for goods traded by the Dutch East India Company (VOC), although much of this was due to the ability of the VOC to control commodity markets. Federico and Tena-Junguito (2017) describe trends in trade and openness for the period 1800–2010, finding that the first globalization started around 1820 and was over by 1870 after which trade continued to grow (apart from during the Great Depression), but openness (and gains from trade) fluctuated greatly. It was only after 1970 that openness again resumed a steady upward trend. Finally, Fouquin and Hugot (2016) use a new database of historical trade 1827–2014 and a theory-based measure for assessing bilateral trade costs (an inverse measure of changes in trade), which are then aggregated as indices along various trade routes. They find evidence that globalization had already begun around 1840 (although it was mostly associated with a greater regionalization of trade patterns) and thus question the role of late nineteenth-century improvements in transportation technology and liberal trade policies.

[11]See the recent paper by Hynes et al. (2012).

[12]The effect of wars is also taken up by Jacks (2011), who looks at England during the French Wars to examine the effect of war on market integration and finds that it was mostly through the disruption of international trade linkages and the arrival of news regarding wartime events. This finding is supported by Brunt and Cannon (2014).

[13]Their methodology makes use of the residual dispersion of univariate models of relative prices between markets.

A similar debate exists for market integration within Europe, with Özcumur and Pamuk (2007) arguing against integration before the nineteenth century and Persson (1999) arguing for grain market integration across Europe already in the eighteenth century. More recent work by Bateman (2011) suggests that markets were as integrated in the early sixteenth as in the late eighteenth century, but with a severe contraction in between, while Chilosi et al. (2013) use a large database on grain prices for 100 European cities to demonstrate that market integration was gradual and stepwise rather than sudden for the period 1620 until World War I.[14]

What Determines Trade?

Trade theory, as outlined briefly above, provides the framework within which economists and cliometricians can understand the reasons for the patterns of trade which they observe. Direct tests of trade theory are, however, rare and often inconclusive, not just in a historical perspective but also for more recent periods. Estevadeordal and Taylor (2002) provide a series of tests of the Heckscher-Ohlin-Vanek theory of trade, that is, whether predicted and observed factor contents of trade for 18 countries, disaggregated by industry, correlated in 1913. For the standard factors of production, capital, and labor, correlations between predicted and observed factor contents are low, while for (especially nonrenewable) natural resources, their findings show that factor abundance and observed trade patterns seem to fit quite well.

A similarly motivated literature examines whether the factor endowment theory in its price version holds, that is, whether "autarky prices" of goods whose production uses a relatively abundant factor are relatively cheap. Normally, autarky prices cannot be observed, so the literature focuses on whether market integration, that is, a reduction in barriers to trade, leads to commodity and factor price convergence following Heckscher-Ohlin arguments. The main exponent of this literature is O'Rourke and Williamson's (1999) Globalization and History and its background papers. However, Bernhofen and Brown (2004, 2005, 2011) have used the actual opening of the isolated Japanese economy after 1853/1857 and its abundant available data for a direct evaluation of the autarky prices of its revealed exports after opening, finding that Heckscher-Ohlin type predictions cannot be rejected or are confirmed by this natural experiment.

Beyond this more or less strictly Heckscher-Ohlin-oriented literature, researchers trying to explain the growth of trade have used empirically less restrictive designs, mostly based on the gravity model, both to explain the growth of world trade in specific periods and when inferring determinants of trade from the immense variation to be obtained from comparing bilateral trade flows in cross section

[14]Analyses of markets outside Europe have generally been neglected, but see the recent study by Panza (2013). With a particular focus on the cotton industry, she shows that the Near East integrated into the global economy at the end of the nineteenth century.

or panel designs. The gravity model departs from a simple but theoretically micro-founded idea borrowed from Newtonian physics: the size of trade flows between two countries is (log) proportional to the size of their respective economies and the economic (geographical, institutional, cultural) distance that separates them. However, theoretical motivations and econometric applications have shown that the simple, "naïve" gravity equation, following Head and Mayer (2014, Eq. 4, p. 138)

$$X_{ni} = GY_i^a Y_n^b \phi_{ni} \tag{1}$$

where the *Y*s are importer and exporter GDPs, ϕ is distance, and *G* is a gravitational (cross-sectional) constant, has important flaws. Based on arguments prominently brought forward first by Anderson and van Wincoop (2003), empirical trade economists now recommend including proxies for the so-called multilateral resistance, that is, country-specific characteristics related to the idea of a "home bias" that make them more or less reluctant to trade internationally. Since these are normally assumed to be time varying, the typical approach is then to include country-year fixed effects, which, however, eliminates any other variable from the regression that is determined annually on the country level – such as GDP, GDP per capita, etc.

Thus, Estevadeordal et al. (2003) have used the gravity equation to assess the drivers behind the "Rise and Fall of World Trade" by first estimating gravity models including transport costs, tariffs, and the currency arrangement of the gold standard and then using the estimate to calibrate counterfactual situations for 1870, 1900, 1929, and 1938, in which these variables take their 1913 values. They find that world trade in 1870 would have been five times larger and world openness (trade/GDP) doubles the actual value. The higher counterfactual versus actual openness would be explained mostly by the spread of the gold standard and lower transport costs, as well as some income convergence, especially before 1900, while tariff changes played no role. The almost 60% higher counterfactual trade and 141% higher counterfactual openness in 1939 estimated by Estevadeordal et al. would have been achieved by avoiding increasing transport costs in the interwar period, maintaining the gold standard at its 1913 level, and avoiding the increases in tariffs that followed, especially after 1929. Some of these results have been reexamined in subsequent studies focusing on individual trade determinants, such as Jacks and Pendakur (2010), surveyed below.

O'Rourke and Williamson (2002b) provide a similar assessment of the drivers of a 1.1% annual growth rate in Europe's intercontinental trade between 1500 and 1800 but have to rely on much scarcer data, combining information on quantities and price gaps. They conclude that between half and two thirds of the post-Columbus trade boom is not explained by decreasing transport costs – which they find to be unstable and negligible due to "monopoly, international conflict, piracy, and government restrictions" (p. 426) – but by increases in European surplus income (i.e., land rent growth) spent on "exotic" commodities. This gave rise to a number of papers discussing "When did globalization begin?" which we survey in the context of the price-based market integration literature below.

For the period from about 1850 to 1940, as well as subperiods motivated by the research question of each study, researchers have used data on trade volumes in the context of the gravity model to investigate the significance and importance of different determinants of trade flows. The following offers a short survey of this literature. Although all gravity models include some proxy for country size (GDP) or productivity/purchasing power (GDP per capita), apart from Estevadeordal et al., the focus of the gravity-based literature is not directly on income growth or convergence as the main determinants of bilateral trade performance.

Distance, by contrast, has attracted considerable attention, especially since the now classical account of the late nineteenth-century globalization. O'Rourke and Williamson (1999) give (exogenous) innovations in transport technology, such as railways and steamships, as the main drivers of market integration during this period. The easiest way of incorporating distance, as done by Estevadeordal et al., is to calculate "effective distance" by multiplying geographic distance with a transport cost factor, traditionally taken from Isserlis' (1938) maritime freight rate index and improved by Mohammed and Williamson (2004). This, however, assumes homogeneity of trade cost developments across routes or actual mode of transportation.[15] Jacks and Pendakur (2010) use more refined data on transport costs by different routes and plausible instrumental variables to argue that it was not transport cost reductions which caused trade to increase but that increased bilateral trade led to increased demand and lower costs for transport services between 1870 and 1913. They then recalculate the sources of trade growth over this period, attributing 76% of it to income growth, 18% to income convergence, and relatively small shares to the gold standard (6%) and declining exchange rate volatility (2%), while the mild increases in average tariffs over the period would have contributed negatively (−1.4%).

However, in subsequent research, Jacks and coauthors (Jacks et al. 2008, 2010, 2011a) have derived a gravity-based measure of trade costs, which theoretically include all costs of conducting international trade as compared to national trade, that is, all determinants of bilateral trade increases not corresponding to income growth. They show that these costs vary significantly between country pairs and for the average of trading partners of individual countries, as well as over time; they are also significantly higher than existing ad valorem freight rate estimates for corresponding connections. For the period 1870–1913, they declined on average by 33%, increased (with considerable fluctuations) by 13% between 1921 and 1939, and decreased by 16% between 1950 and 2000 (Jacks et al. 2011a, pp. 190–192).

When estimating the determinants of these trade costs, distance, tariffs, the gold standard, the British empire, and joint railway density turn out to be significant determinants in the 1870–1913 period (Jacks et al. 2010, p. 135) as well as wider measures of fixed exchange rate regimes, common language, empire membership,

[15] A similar approach has been pursued more recently for the case of Argentina during the Belle Epoque by Pinilla and Rayes (2017), who find an important role for transportation costs for Argentinian export success but a less important role for tariffs.

and shared borders for all three periods (Jacks et al. 2011a, p. 194). Of the 486% growth in world trade between 1870 and 1913, 290% can be explained by the fall in trade costs and the rest mostly by increased output. For the period 1921–1939, they find a 0% increase in world trade, to which an increase in trade costs that would have led to a trade decline by 87% contributed negatively, while an almost equal contribution of income growth nullifies this (Jacks et al. 2011a, p. 195; cf. Jacks et al. 2008, p. 534). The Jacks-Meissner-Novy trade cost measure cannot be used as a measure of economic distance in gravity equations, since it is calculated based on the gravity equation itself. Assessing the importance of its components for systematic changes in trade would therefore imply first calculating the trade cost measure and its quantitative importance for trade and then estimating the determinants of trade costs and proceed from there to indirectly identify their effect on trade. So far, the literature in this direction has not extended beyond the initial contributions described here.

Researchers have, however, estimated the effects of all sorts of trade cost-related determinants of bilateral trade flows in the gravity framework. Related to transport and transaction costs, this includes physical transport infrastructure (railway mileage/density, e.g., in Lew and Cater 2006; Mitchener and Weidenmier 2008) and communication infrastructure to facilitate information flows and shipping coordination (telegraphs as proxied by the bilateral sum of telegrams sent in Lew and Cater 2006). To date nobody has included costs of information transmission or actual volumes of international traffic or information flows, although both, in the sense of Jacks and Pendakur (2010), might be endogenous to trade flows.

The role of exchange rate regimes, especially the gold standard, has also been central to the debate, given its prominence in accounts of both pre-World War I globalization and post-World War I instability and the Great Depression. For the first period, López-Córdova and Meissner (2003) find that the gold standard had considerable trade-enhancing effects: countries on the gold standard traded "up to 30% more with each other than with countries not on gold," so that, had the gold standard not spread widely, world trade in 1913 would have been approximately 20% below its actual level. In a similar fashion, Flandreau (2000), in what seems to have been the first cliometric gravity paper, and Flandreau and Morel (2005) assess the impact of the Scandinavian and Latin Monetary Unions and the Austro-Hungarian currency union on trade flows, finding insignificant effects for the Latin Monetary Union but a significantly positive contribution of the apparently more tightly coordinated currency unions in Austria-Hungary and Scandinavia on trade flows. Timini (2018) zooms in on the Latin Monetary Union and confirms the overall lack of significant trade effects but shows that in the earliest period (1865–1874), the Union had effects but that these were concentrated on the trade between France as its "hub" and the rest of the member countries as "spokes" but were negligible between the latter.

For the interwar period, the formation of trade and currency blocs has been analyzed with special care. Eichengreen and Irwin (1995) found that members of the Commonwealth [Ottawa signatories] and the Reichsmark bloc already traded more with each other in 1928, that is, before they formed "blocs" as a consequence

of the Great Depression. Ritschl and Wolf (2011) have reassessed the issue more formally, modelling endogeneity based on optimum currency area arguments. They essentially confirm that naïvely estimated trade creation among members of the different blocs disappears when accounting for the countries' self-selection into these blocs. Political scientists Gowa and Hicks (2013) have recently revisited the issue with a larger dataset. They confirm that none of the blocs increased trade between their members as a whole and underline political conflict and cooperation between the great powers (and "anchors" of the 1930s blocs) as an important component for understanding interwar trade patterns.

Recently, Eichengreen and Irwin (2010) have shown that, at least in the 1930s, flexible monetary policy and trade restrictions were substitutes, with trade restrictions being used when monetary policy, e.g., under the "straitjacket" of the gold standard, is limited when addressing domestic concerns. This leads us to the next classical determinant of foreign trade: trade policy. Studies have investigated two strands, tariffs (normally proxied by the average ad valorem tariff discussed below) and the effects of trade agreements, proxied by dummy variables. For the former, studies are limited, although Lampe (2008), Flandreau and Maurel (2005), and Estevadeordal et al. (2003) find indications of a significantly negative relationship before World War I. For the same period, Jacks (2006b) shows that both levels and changes of tariffs are positively correlated to a positive balance of payments (scaled to GDP), while Madsen (2001) finds a significantly negative impact of tariffs on trade in the interwar period. Regarding trade agreements, both the benign bilateralism of the mid- to late nineteenth century and the pernicious bilateralism of the interwar period have been evaluated using gravity models.

For the nineteenth-century most-favored nation clause trade agreements, both Accominotti and Flandreau (2008, period 1850–1880) and Ly most-favored nation clause (2003, period 1870–1913) find insignificant coefficients, with the former concluding that seeing the Cobden-Chevalier treaty of 1860 as a cornerstone of the nineteenth-century globalization would therefore be unjustified. Lampe (2009) has reexamined the evidence at the commodity level, arguing that nineteenth-century bilateralism did not actually intend to increase world trade but to exchange preference for specific commodities, for which he does find commodity-specific trade-enhancing effects for the first wave of the European Cobden-Chevalier network (1860–1875).

For the interwar period, apart from the literature cited above, de Bromhead et al. (2019) evaluate the effects of the British increase in tariff rates and quantitative restrictions from 1932 and its shift to imperial preference in the Import Duties Act of 1931 and the Ottawa Agreements of 1932. They show with a detailed commodity-wise database that increased protection explains about one quarter of the fall in British imports but over 70% of the shift in imports toward the production from the British Empire in the 1930s. In this case, protection did matter for total trade, but even more for its geographic composition. Similarly, Gowa and Hicks (2013) find, in a study with aggregate trade flows, that while the Imperial Preference System does not seem to have increased or redirected trade among members significantly, the trade of the UK within the system seems to have been redirected toward the

preference group. In contrast, Jacks' (2014) study of the effects of the 1932 Ottawa Agreements on Canadian trade patterns at the commodity level uses a difference-in-difference approach on trade flows at a quarterly frequency and shows that the Imperial Economic Conference had substantial anticipation effects on Canadian trade with the other signatories but very unclear direct effects once it was in place, leading him to conclude that "the conference was a failure from the Canadian perspective."

Another potentially transaction cost-reducing military-politico-economic institution related to the interwar trade blocs and imperial preference systems discussed above is colonialism, which, due to common economic and legal frameworks, bureaucratic practices, and preferential market access and potentially due to emigration, settlement, and homogeneous culture, might be trade enhancing. Mitchener and Weidenmier (2008) have examined the trade-enhancing consequences of colonial relationships using a large bilateral trade flow dataset for the 1870–1913 period (more than 20,000 observations) and find that empire membership had significantly positive effects on trade, with trade more than doubling between empire members as opposed to nonmembers. These were apparently largest for the relatively small empires of the USA and Spain but also substantial for the British, French, and German colonial empires. In a second step, they reestimate their models with a set of transaction cost (common language, years in empire, imperial currency union) and trade policy-related (empire customs unions and preferential market access proxies) variables and show that all of them are significant determinants of trade, confirming the trade cost decreasing function of empires. Head et al. (2010) have shown that these tend to persist even after independence but decrease over time, probably because of depreciating "trading capital."

Another form of changing political ties is the redrawing of national borders. The Versailles settlement after World War I provides a quasi-natural experiment, especially for parts of prewar Germany, the dissolution of the Habsburg Empire; the independence of Czechoslovakia, Hungary, and Poland; and the formation of Yugoslavia. Border effects are normally estimated from price data, but in a series of papers, Schulze, Wolf, and coauthors (Trenkler and Wolf 2005; Wolf 2005, 2009; Heinemeyer 2007; Schulze and Wolf 2009, 2012; Schulze et al. 2008, 2011) have estimated the effects of old and new borders on new and old political entities using trade statistics on railway shipments between regions and across old and new borders. Two central findings are that borders both tend to be endogenous and their effects persistent over time and, here, ethno-linguistic composition, that is, cultural ties, seems to play an important role for explaining trade flows (Schulze and Wolf 2009; see also Lameli et al. 2015).

Conflicts and military alliances have also been shown to be important determinants of trade flows. Gowa and Hicks (2013) highlight the importance of certain military alliances in the interwar period, while Rahman (2010) assesses the effects of being allied to central naval powers between 1710 and 1938. Glick and Taylor (2010) deal with the relationship between trade and wars and show that wars have a significantly negative impact on trade up to 8 years after they were fought and influence not just trade between opposed parties but also their trade with third

countries. They use their results to quantify the trade loss as a share of world GDP resulting from World War I and World War II at 10% and 17.6% of the respective prewar GDPs, with a corresponding trade-related GDP loss of 4.4% and 4.2%, respectively.

Related to this, some studies have also shown that democratic countries trade more with each other (Gowa and Hicks 2013). The importance of national institutional factors for trade orientation has also been stressed in papers with methodologies different from the gravity equation: Sánchez et al. (2010) have shown that lower levels of land conflicts and more secure land property rights helped raise investment in export-oriented coffee trees and production of coffee in the nineteenth- and early twentieth-century Colombia. Rei (2011) examines the determinants of institutional choices that determined the performance of early modern merchant empires in the long run.

What does the market integration literature contribute to this literature? Clearly, many of the factors identified as being determinants of trade, such as trade policy and wars, will also impact on market integration. Following Harley (1980), O'Rourke and Williamson (1999) are particularly associated with the idea that it was falling transatlantic transport costs which led to the globalization of the late nineteenth century, although Persson (2004) and Federico and Persson (2007) argue that it was largely domestic American transport costs that fell, particularly with the extension of the rail network, rather than transatlantic shipping costs. Their basis for so doing is the calculation of "freight factors," i.e., the cost of shipping a unit of a good divided by the price of the good. This can be considered as an ad valorem measure of shipping costs, equivalent to ad valorem measures of tariffs (see below), and a more accurate indicator of the impact of shipping costs on market integration than standard indicators of real freight rates.

Beyond transport costs, the market integration literature has largely focused on demonstrating the fact that markets integrated and disintegrated, rather than testing and estimating the factors behind this, although reasons are usually suggested. For example, O'Rourke (2006) demonstrates that mercantilist conflicts restricted commodity market integration in the eighteenth century, and Sharp and Weisdorf (2013) identify trade policy, war, and politics as being behind the fluctuating experience of market integration between America and Britain in the eighteenth and nineteenth centuries before the revolutionary changes in transport technology, which to a large part has inspired the nineteenth-century globalization literature. For Europe, specifically the Baltic Sea Region, Andersson and Ljungberg (2015) have demonstrated that the role of distance for market integration disappeared for wheat and rye (although not oats and barley), as it became integrated into the Atlantic Economy. At the other end of the First Era of Globalization, Hynes et al. (2012) show that the disintegration after 1929 was caused by trade barriers, the collapse of the gold standard, and the difficulty of obtaining credit.

A particularly notable contribution to this debate is Jacks (2006a), who directly focuses on the question of what drove commodity market integration in the nineteenth century. Using an impressively large panel of grain prices, he finds econometric evidence for the importance of transport technology, geography, monetary

regimes, commercial networks/policy, and conflict over both the cross-sectional and temporal dimensions. In more recent work, Ejrnæs and Persson (2010) have demonstrated the improvements in market efficiency between Chicago and Liverpool after the establishment of the transatlantic telegraph due to faster arbitrage (efficiency) and quantify the gains in terms of reduced deadweight losses. Steinwender (2018) takes this approach further, finding that the smaller information frictions after the telegraph led to greater, but more volatile, trade flows due to more efficient responses to demand shocks. Finally, using data from the transatlantic slave trade, Rönnbäck (2012) suggests that some of the market integration in the early modern period was due to the increased transit speed of ships, a finding somewhat backed up by Solar and Hens (2015), who find that the duration of voyages to Asia by English East India Company ships fell by between one fourth and one third between the 1770s and the 1820s, largely due to the adoption of copper sheathing, which both increased speed by around 11% and obviated the need for a stop at the Cape. Similarly, Kelly and Ó Gráda (2018) use a large database of daily log entries to estimate daily sailing speed from 1750 to 1850, finding that British, in contrast to Spanish and Dutch ships, saw steady progress.

And What About Trade Policy?

As mentioned in the first section, a key feature of trade in economic history and modern economics is the existence of policy barriers to trade. In principle, trade policy is any policy that affects the volume and value of imports coming into or exports leaving a country. This can be by levying tariff duties and other commodity-specific taxes, which, if not corresponding to exactly equivalent domestic taxes, will introduce changes in the relative prices between imported and domestically produced goods and probably also between the relative prices of different sorts of goods, depending on the rates of these duties and the elasticities of demand, supply, and substitution. Ideally, in order to study trade policy, we would wish to create an aggregate measure of all the various forms of duties, as well as accompanying legislation on related trade costs, such as monopolies, port duties, river and strait/sound tolls, prohibitions, regulations, etc. This is, however, theoretically difficult and practically impossible with the existing historical data.

Most studies thus proxy trade restrictiveness by the so-called average ad valorem equivalent tariff rate (AVE), which, as the name suggests, should proxy for the average ad valorem duty corresponding to the wide range of weight- or volume-specific rates and other duties importers or exporters would have to pay at the toll house or the customs office. In practice, this is normally estimated as the ratio of customs receipts to total imports, whenever possible separating import from export duty receipts. Among economic historians, this measure has received wide criticism on several accounts. First, it does not account for nontariff barriers, that is, prohibitions or restrictions like quotas or red-tape requirements that discourage trade. Second, it effectively weights rates for individual commodities by their share of imports, which would be affected by the structure of tariff rates if this is not perfectly

balanced out to be non-distortionary (Estevadeordal 1997, pp. 91–93). Third, it does not distinguish between protective tariffs, which effectively distort the domestic-to-world market price relationship, and the so-called fiscal tariffs, levied on demand-inelastic goods, and often those which are not produced domestically as an easy way to collect an indirect tax on the consumption of "luxury goods." This final point is particularly important in the nineteenth century, when large parts of government revenue in many countries are raised from such import duties (Tena-Junguito 2006a, 2010a), although the solution is not obvious, since the "fiscal commodities" taxed in this way should have had some domestically produced substitute and hence fiscal duties would distort prices in favor of the producers of those substitutes.

In practice, the wide use of AVEs is generally justified for a couple of reasons (see, e.g., Eichengreen and Irwin 2010, pp. 881–882; Lampe and Sharp 2013). First, given the data constraints, it is extremely difficult to imagine how superior measures might be calculated. Second, AVEs have been shown to correlate significantly with theoretically more consistent measures, both within one country (the USA over the nineteenth to mid-twentieth centuries (Irwin 2010)) and among a wide cross section of countries in the present (Kee et al. 2008). For researchers interested in using AVEs, the standard databases are those underlying Clemens and Williamson (2004), Schularick and Solomou (2011), and Lampe and Sharp (2013).

Alternative measures do exist, however. These are constructed to be more theoretically consistent and have been calculated for certain countries and periods. They include the so-called effective protection rates (Balassa 1965), trade restrictiveness indices (Anderson and Neary 2005), the nominal rate of assistance (Anderson et al. 2008), and Leamer's (1988) trade intensity ratio.

Effective protection rates combine information on tariffs for individual goods with input-output tables to assess the structure of protection between final products, primary materials, and intermediate inputs and weigh these rates accordingly in an overall index. Federico and Tena (1998, 1999) and Tena-Junguito (2006b, 2010b) have calculated effective protection rates for Italy and Spain in selected years between the 1870s and the 1930s based on individual tariff rates for 400–500 commodities and different input-output tables. Bohlin (2005, 2009) has undertaken similar work for Sweden.

The trade restrictiveness index (TRI) by Anderson and Neary (2005) in its simplified Feenstra (1995) and Kee et al. (2009) version is motivated by a computable general equilibrium framework and combines data on tariffs of individual commodities and import demand elasticities, thereby establishing a uniform ad valorem tariff rate calculation equivalent to the same welfare level as the existing structure of varying tariff rates; it can be converted straightforwardly into GDP-share equivalent static deadweight losses (DWLs) from protection. Irwin (2010) and Beaulieu and Cherniwchan (2014) have calculated TRIs and estimated DWLs for the USA and Canada over long periods since the mid-nineteenth century. Irwin (2005, 2007) developed a similar measure based on price data to assess the DWL of the Jeffersonian trade embargo of 1807–1809 (about 5% of US 1807 GDP) and the intersectoral transfers resulting from high tariffs in the USA in the late nineteenth century, for example, the classical transfer from consumers to producers via higher prices for import-competing goods.

Similar considerations are behind the "nominal rate of assistance," developed mainly to assess the degree of agricultural protection as "the percentage share by which government policies have raised (or lowered) gross returns of producers above what these returns would have been without the government's intervention" (Swinnen 2009, p. 1501) by comparing domestic to world market prices for individual goods, adding, if necessary, domestic subsidies to the calculations. Swinnen (2009) has calculated these for a variety of agriculture and animal husbandry products in Belgium, Finland, France, Germany, the Netherlands, and the UK from about 1870 to 1970.

Finally, Estevadeordal (1997) presents results on the "trade intensity ratio" of 18 countries in 1913. This measure estimates a Heckscher-Ohlin-based structural equation for trade flows based on endowments and compares the sum of predicted bilateral trade flows to the actual trade per country, interpreting the residual as a measure of protection (or openness) for the market of each country.

Recent research has also focused on assessing relative rates for different commodity groups, not overall average measures of protection, as in Tena-Junguito (2010a) and Tena-Junguito et al. (2012), who compare manufacturing tariffs and their potential skill bias for a large sample of countries in the nineteenth century, and O'Rourke and Lehmann (2011), who distinguish between agricultural, industrial, and revenue tariffs.

A different but related literature looks at tariffs for individual goods, sometimes only in one country. The major examples here are the British Corn Laws and their sliding scales (Williamson 1990a; Sharp 2010), discussed in a comparative perspective by Federico (2012b), or the US tariff on cottons (Irwin and Temin 2001) and a possible optimum export tariff on American raw cotton exports (Irwin 2003), a topic also worked on for interwar Egypt (Yousef 2000). That constructing comprehensive and comparable time series for individual tariff rates in the long run is a time-consuming and often complicated task is illustrated by Lloyd (2008), who estimates Australian tariffs on road motor vehicles, blankets, and beer from 1901–1902 to 2004–2005.

Other nontariff barriers to trade like prohibitions, quotas, licenses and capital constraints, import and production monopolies, marketing boards, etc. are normally only included in regression designs via proxies. At least for the period between the dismantling of mercantilist policies in the early nineteenth century and the introduction of all sorts of protective measures in the 1930s, nontariff barriers are generally said to have been small, at least outside a small group of commodities like live animals and meat, where public health concerns sometimes led to trade restrictions. For prohibitions, ad hoc adjustment assumptions have sometimes been made, such as twice the rate when imports started being permitted (Tena-Junguito et al. 2012) or 1.5 times the highest rate in other countries (Lampe 2011). Regarding nontariff barriers in the 1930s, Eichengreen and Irwin (2010) provide a summary of the scarce data available on quotas and exchange controls as a part of the trade and payments system. Finally, Ye (2010) investigates the political economy of US trade policy regarding the countries of the Pacific Rim from 1922 to 1962. Other measures of trade policy, like membership of trade blocs or trade agreements and most-favored nation status, have normally been proxied by dummy variables.

Despite the difficulties in defining the extent of trade policy as a simple numerical estimate, we might want to answer what explains it. The consensus seems to be that it emerges mainly as a result of political interest groups reacting to the changes brought by trade on national-, local-, and industry-specific "initial conditions." Thus, explaining trade policy involves disentangling the relative importance of these factors. This is normally done through contemplating just one sector or a relevant sample of the industries which are most affected in order to assess the specific impact on them and their reactions alongside the possibilities to affect policy making at the national level. In this sense, the studies by the political scientist Rogowski (1989) and the cliometrician O'Rourke (1997) on the European reaction to the late nineteenth-century grain invasion are outstanding examples of comprehensive trade policy studies, including initial factor endowments, changes in relative prices and factor incomes due to the inflow of cheap grain, formation of coalitions in policy formation, and trade policy outcomes. As Lehmann and Volckart (2011, p. 29) have summarized it, "Kevin O'Rourke (. . .) argued that where agriculture was concerned, the political choices of governments were related on the one hand to how the grain invasion affected land rents, and on the other to the weight of agricultural interests in domestic politics."

Thus, the key variables to describe agricultural trade policy are (following Swinnen 2009) the weight of agriculture in the economy, the relative income of agriculture, and political institutions and organizations, both as regards the level of democracy and the organization of agricultural interest groups. O'Rourke and Rogowski discuss and evaluate all of them in their comparative framework; Federico (2012b) provides a summary of the relevant forces behind an earlier central episode in agricultural trade policy, the repeal of the British Corn Laws, and parallel and subsequent liberalization of agricultural market access in Continental Europe, thereby summarizing a larger literature with important cliometric contributions (Kindleberger 1975; Bairoch 1989; Schonhardt-Bailey 2006; Montañés Primicia 2006; van Dijck and Truyts 2011). Recently, Lehmann (2010) and Lehmann and Volckart (2011) have studied voting behavior in key elections in Germany in the 1870s and Sweden in the 1880s and found that "agriculture," including small farmers, peasants, and rural workers, at least in Imperial Germany, voted "en bloc" for protection, hinting at low perceived possibilities for intersectoral mobility in the economy (a "specific factor model") by large parts of the rural population, as opposed to the opportunities of workers which might be derived from free trade and structural change. For Sweden, the results are less clear, apparently at least in part due to a much more restrictive franchise.

When assessing trade policy of more than one sector, the issue gets complicated by the fact that now not just the level of protection (e.g., on agriculture) has to be taken into account but also its level in comparison to protection or lack thereof for other sectors, i.e., the structure of trade policy. Thus, the political arena is much more complex. Pahre (2008) has written a whole book on the issue, offering a comprehensive theory of tariff setting, leading to six hypotheses on prices, interest group influence and compensation, country size and transport costs, two corollaries on tariff and price volatility, and several findings regarding the endogeneity and

exogeneity of fiscal revenue constraints and their dependence on customs duties and the interplay between democracy and tariff levels. The second step of his theory, regarding bilateral trade policy negotiations, is discussed below.

Blattman et al. (2002), Williamson (2006), and Clemens and Williamson (2012) provide systematic assessment of correlations between a wide set of variables and the "average tariffs," as measured by AVEs. They find population size (related to relatively low dependence on foreign trade), railroad penetration, urbanization, tariffs of other countries, and tariff autonomy (i.e., political independence versus formal or informal foreign control of trade policy) to be significantly and substantially correlated with tariff levels.

O'Rourke and Taylor (2007) investigate the link between tariffs and democracy and show that the relationship is contingent on the relative factor endowments of the national economy in question. In the case of the nineteenth-century globalization, the land-labor ratio is the most fitting operationalization. Irwin (2008) has highlighted that the use of tariff revenue for infrastructure provision was decisive for the American West to enter into a coalition with the North for high tariffs in the 1820s and 1830s and to swing toward more liberal trade policy later. Eichengreen and Irwin (1995, 2010) have shown that protective tariffs and otherwise restrictive policy can also emerge if no other opportunities for dealing with structural balance of payments deficits are available, in their case the unwillingness to or impossibility of devaluation under the interwar gold standard in the 1930s. Another recurrent aspect, especially in political science, is the importance of "hegemony" (McKeown 1983; Nye 1991; Coutain 2009) or the spread of "ideology" (Kindleberger 1975; Federico 2012b). The latter is especially difficult to measure. Finally, Chan (2008) has elaborated and indirectly tested an institutional economic model to explain the trade policy choices of the Chinese Song and Ming dynasties in the light of a trade-off between economic efficiency (and trade tax revenues) and political authority, a question motivated by the famous Needham puzzle of why modern economic growth did not start in China (Lin 1995).

Bilateral or multilateral negotiations to change trade policy have seldom been the subject of cliometric research, and if they have, the focus has been on their impact on trade flows as discussed above. In his book on the Agreeable Customs of 1815–1914, Pahre (2008) formulates nine hypotheses, three corollaries, two remarks, and one conjecture on the likelihood that individual countries cooperate in bilateral trade treaties and finds that, among other things, larger countries and countries with lower tariffs are more likely to cooperate and that "real" exogenous revenue constraints resulting from low fiscal capacity make cooperation less likely, while endogenous (i.e., politically chosen) revenue constraints increase the scope for cooperation. Lampe (2011) offers an assessment of the political and economic determinants of the Cobden-Chevalier network of bilateral MFN treaties in the 1860s and 1870s in the light of both Pahre's theory and recent contributions by economists Baier and Bergstrand (2004) and Baldwin (1995) as well as the political scientist Lazer (1999), and Lampe and Sharp (2011) use this framework for a cost-benefit analysis of bilateralism, the latter for Denmark, which, despite figuring as a free trader in classical accounts, concluded no substantial trade treaties during

this period. In the context of the effects of trade bloc formation in the 1930s, Ritschl and Wolf (2011) and others discuss its origins in the context of evaluating the endogeneity of these blocs and the resulting econometric challenges.

Conclusion

In this chapter we have argued for the importance of trade in economic history, in particular through its impact on growth. Today, domestic sources of growth play a much more important role, but trade might still be important – by establishing constraints, increasing competition, affecting coalitions and institutions, etc.

After discussing how to measure trade and its related concept of market integration, we then went one step back and discussed what factors were behind different examples of trade increases and declines and of market integration and disintegration. Finally, we honed in on trade policy as one of the most important determinants of trade, as well as perhaps the most policy relevant.

The literature is vast, but important questions remain. Moreover, much work is still being done on collecting trade databases and improving our measures of trade costs.[16] The cliometricians of the future will certainly have plenty of opportunities to make important contributions, not only for economic history but for economics in general.

Market Integration

Giovanni Federico

Contents

Abstract

This chapter outlines the main advances in the literature on market integration in the last 5 to 10 years. After a short review of the definition of market integration and of the main statistical tools to measure it, each of the three following section addresses one major issue. Section "The First Wave: Measurement" deals with the measurement of integration, updating and expanding the earlier review of Federico (2012) to integration in non-European countries and to transoceanic integration. Section "The Second Wave: The Causes of Integration" surveys the literature on causes of integration, arguing that changes depended mostly on political decisions about barriers to trade, with a substantial contribution of technical progress in the nineteenth and twentieth century. Finally, Section "The Third Wave: The Effects of Integration" deals with the effects of integration. Most papers quote the benefits from integration in the motivation for the choice of the issue, but there are very few and very partial attempts to measure them.

Section "Conclusion: Taking Stock" concludes with a short summary of the main findings, stressing the relevance of recent work to integrate spatial and intertemporal arbitrage.

Keywords
Market integration · Market efficiency · Smithian economic growth · Gains from trade

Introduction

Economists at least since Adam Smith have argued that markets and trade are essential for the smooth functioning and development of economic systems, and thus it is not surprising that economic historians have shown a keen interest in their development. A comprehensive research program should address three main questions: (1) the measurement of the process (when and by how much did market develop?), (2) its causes (why did markets develop?), and (3) its effects (how did market development affect welfare and growth?). It is almost impossible to address these issues in historical perspective with data on trade. Reliable series of international trade are available only since the nineteenth century (Federico and Tena 2016), and data on domestic trade flows are extremely scarce before the late twentieth century, an exception being Germany (Wolf 2009). Thus, economic historians have turned to prices. Series of prices, especially of cereals, are available in Europe since the Middle Ages, and their collection had started in the 1930s by the International Committee for the history of prices. Asian sources, once tapped systematically, have proven to be as rich as European ones, at least from the eighteenth century onward. This chapter will survey the price-based literature on market integration, leaving to other chapters the parallel quantity-based literature on growth of trade.

Some pioneering scholars started to use prices to study market integration as early as the 1960s, but the issue leapt forward as a hot topic in economic history in the late 1990s. The first wave of research focused on levels and trends of integration within Europe and the Atlantic economy at large (i.e., question 1 above). A survey (Federico 2012) quotes 61 works published before December 2009. Since then, researchers have continued to pursue this line of research, but recently they have begun to deal with the causes and, to a much lesser extent, the effects of integration – i.e., questions 2 and 3. In spite of their efforts, we are still far from having a comprehensive view of integration in the long run. Some works deal jointly with measurement and causes, and very few with measurement and effects, but remarkably, only Bateman (2012) in her work on early modern Europe addresses all three questions with statistical tools.

This chapter will deal with the quantitative works and not on the literature on market institutions and/or the causes of their change, such as Epstein (2000) and Van Bavel (2016). These works provide important insights to interpret quantitative results, but their discussion would exceed the remit of this survey. Furthermore, the chapter makes three clear and somewhat painful choices in the interest of page

constraints. First, it focuses on the integration of markets for commodities, neglecting integration of factor markets. Wage convergence has been studied, although not so extensively, in the literature on migrations, while the integration of capital markets in early modern Europe has attracted a lot of interest in very recent years (Volckart and Wolf 2006; Chilosi and Volckart 2011; Li 2017; Chilosi et al. 2018). Second, the chapter relies as much as possible on Federico (2012) for the literature on measurement of integration in Europe, updating it when necessary. In contrast, it will survey in more detail the measurement of integration on other continents (most notably Asia) and across continents and, above all, the literature on the causes (question 2) and effects (question 3) of integration. When appropriate, we will consider also works from the parallel literature on gains from trade (Donaldson 2015). Last but not least, unlike Federico (2012), this chapter does not aim at being systematic. Rather, it will focus on papers that add novel methodological insights or bring major new results.

The next section deals with the theory of market integration. It reviews the basic concepts of integration and sketches out the main statistical methods, integrating Federico (2012), with a discussion of the recent methodological developments. Each of the three following section addresses one of the issues – the measurement of integration (Section "The First Wave: Measurement"), the analysis of causes (Section "The Second Wave: The Causes of Integration"), and the estimation of its effects (Section "The Third Wave: The Effects of Integration"). Section "Conclusion: Taking Stock" concludes with a short summary of the main findings and some general remarks on the future agenda for research.

The General Framework: What Is Market Integration and why it Is Relevant

The definition of market integration was first put forward almost 200 years ago by French mathematician Cournot. He characterizes an integrated market as "an entire territory of which the parts are so united by the relations of unrestricted commerce that prices take the *same* level throughout with *ease and rapidity*" [emphasis added] (Cournot 1971: 51–52). In other words, (i) the equilibrium level of prices must be equal (the law of one price) and (ii) prices must return easily and quickly to this level after any shock. Those two conditions are clearly separable, as prices can return slowly to the same level or quickly to a different level. Both conditions are necessary but not sufficient for a fully integrated market, and each of them must be tested with a different set of statistical tools. Unfortunately, as we will discuss in section "The First Wave: Measurement," this good practice is not always followed. Many authors focus on one condition only and label their own results a test of market integration. Thus, before delving into historical results, it is necessary to briefly review the key features of the available statistical tests in relation to the basic theory of market efficiency (see for more details and additional references Federico (2012)).

Testing the law of one price is apparently simple: what can be easier than comparing prices of the same good in two different locations at the same moment?

Alas, the results are likely to be seriously misleading. If the two locations trade, the law would almost always be violated, even for perfectly homogeneous goods. The price differential in any given time would be at least equal to transaction costs (or commodity points) and could exceed them in case of temporary disequilibria while reabsorbing location-specific shocks. On the other hand, if the two locations do not trade, the difference may move randomly between the commodity points or be determined by trading with a third market (Coleman 2007; Federico 2012). One might argue that the law should not be taken literally and define as integrated market if violations are small or, as suggested by some authors (e.g., Stigler and Sherwin (1985), Ejrnæs et al. (2008)), if the price gap is equal to transaction costs. Both solutions are not appealing. Any threshold for distinguishing small violations from substantial ones would be unavoidably arbitrary, while computing all transaction costs and the implicit risks is a challenging task to say the least, as shown by the excruciatingly careful estimate of gold points in the nineteenth-century transatlantic currency markets by Officer (1996). Even if this computation were possible, the method would label as (equally) well-integrated markets with hugely different price gaps (say 1 percent or 100 percent or even 1000 percent).

The obvious alternative to a static comparison is a dynamic approach, focusing on trends rather than on levels. A market is integrating (rather than integrated) if the price gap between two locations shrinks (price convergence) and vice versa. However, the interpretation of results can become cumbersome if the number of locations, and thus of possible pairs, increases above a (small) figure. Some authors have suggested selecting some representative pairs of locations or focusing on the convergence of prices of a number of peripheral markets toward a central one (Ravaillon 1987). The easiest solution, which has become a standard in the literature, is to measure σ-convergence by computing the coefficient of variation across all locations in each year. The results are likely to be imprecise if quality differs, but not necessarily systematically biased (Federico 2011). The coefficient of variation, as a dimensionless measure, is easily comparable in time and space, and the sequence of coefficients can be analyzed with time-series analysis looking for discontinuities and estimating long-run trend. The cumulated change as a percentage of the initial dispersion is a simple measure of the extent of integration (or lack of it), while detected discontinuities could be related to specific events, such as changes in trade policy or in transport infrastructure.

Cournot's second condition can be restated in modern terms as a test for market efficiency. As it is well known, a market is defined as efficient if prices take into account all available information and thus there are no opportunities for profitable arbitrage in space or time. The price gap between two trading locations must be equal to transaction costs and the difference between current and future (expected) price to the storage costs. The standard framework in the market integration literature assumes that agents know the local conditions and prices of the commodity in other locations and set the prices accordingly. If a shock causes price differentials to exceed from their equilibrium level, arbitrage by profit-maximizing traders would push the gap back to the equilibrium level. The faster this process, the more efficient is the market. The early works tested Cournot's second condition indirectly by

looking at co-movement of prices: the faster the adjustment to an exogenous shock, the closer that prices would move together. The workhorse of these early "integration" (or more precisely efficiency) tests was the pairwise coefficient of correlation between prices in different locations. Some authors have preferred to run an OLS regression, possibly adding distributed lags to capture the dynamic component of the adjustment (see, for a recent example, Panza (2013)). This latter approach introduces the additional hypothesis of a hierarchy between two markets, the central one where prices were set and the other, to which prices were transmitted via arbitrage à la Ravaillon (1987).

The co-movement tests share two shortcomings. First, by construction, they have to be estimated with a minimum number of observations and yield a single coefficient. Implicitly, they thus assume transaction costs to be fixed in the period, in contrast with the whole research agenda on market integration. No matter how carefully the author could choose the period of estimation, there is risk that changes in transaction costs return an invalid estimate. The shorter the period and thus the higher the frequency of the data are, the smaller this risk is. Unfortunately, in very many cases, authors are forced due to the availability of sources to use low-frequency data. Second, the results will be biased upward if the series feature a common trend or are subject to the same shocks (e.g., from weather). Scholars used different strategies to tackle this problem, such as computing correlations of first differences (e.g., Li (2000), Studer (2008)) or detrending price series (e.g., Dobado et al. (2012), Chilosi et al. (2013)). Furthermore, the interpretation of the results needs a somewhat arbitrary decision on the minimum coefficient for an integrated market. Is a coefficient of correlation of 0.6 enough? In a nutshell, how big is big?

Since the 1990s, this traditional indirect approach to testing efficiency via co-movements has been sidelined by advances in time-series econometrics. The co-integration test offers a simple answer to the general question whether a market was integrated. It is possible to compute the key parameter for Cournot's second condition (the speed of adjustments) by running a simple AR (1) model, such as

$$\Delta \left(P_{it} - P_{jt}\right) = \rho \left(P_{it-1} - P_{jt-1}\right) + \varepsilon_t \quad (1)$$

The speed of adjustment is conventionally defined as the half-life of a shock, or $\lambda = [\ln 0.5/\ln (1+ \rho)]$. This parameter, as the coefficient of correlation, can easily be compared across time and space, although there is not an accepted threshold for distinguishing a fast from a slow adjustment.

There are many variants to eq. 1. It is common practice to add dummies for specific shocks (e.g., wars), while Bernhofen et al. (2016) add changes in the average price across locations as a measure of common shocks. It is also possible to explore the pattern of diffusion of shocks and hierarchies of markets with a vector error correction model or VECM (Lampe and Sharp 2015). On the other hand, the AR framework has a quite serious flaw as a test of efficiency. It implicitly assumes that prices would converge even if the price gap is smaller than the transaction costs, when arbitrage would be unprofitable. This logical shortcoming can be addressed by

running so-called threshold auto-regression models (or TAR). They assume that prices converge only when their gaps exceed the commodity points and that the process stops when the gap is equal to transaction costs. Within commodity points, prices move randomly. On top of this, the TAR software estimates the most likely commodity points with a grid-search procedure, which can be used in further analysis.

The co-integration revolution has marked a great leap forward in the analysis of efficiency, but it is not trouble-free. First, as the co-movement measures, the co-integration tests need a minimum number of observations, which correspond to a period of time inversely related to the frequency of data (240 observations correspond to 20 years with monthly data, to four and half years with weekly data, and to less than 1 year with daily data). They return one coefficient which would be unbiased only if transaction costs do not change in the period of observation. Second, the estimated speed depends on the frequency of the data (Brunt and Cannon 2014). Results would be biased upward if the frequency of data is lower than the actual speed of adjustment – e.g., if data are monthly and adjustment takes 1 week (Taylor 2001). They would differ according to the nature of the data – i.e., whether they refer to a specific point in time, with its specific shock, or rather are obtaining averaging prices, thereby smoothing shocks. Last but not least, the TAR assumes that its estimate of commodity points coincides with the actual transaction costs. This assumption would not hold if price gaps are smaller than the commodity points because the two locations do not trade, but also if they systematically exceed the commodity points, because the market is not (weakly) efficient. This case is not so implausible. Traders might rationally decide to overlook opportunities for arbitrage if they perceive that risks (e.g., from fluctuations in exchange rates) outweigh the potential gains from arbitrage. In both cases, the estimates from the TAR would be biased, respectively, downward or upward, relative to actual transaction costs. Furthermore, one should note that the whole co-integration approach implicitly rules out the possibility that agents in a location have information on the conditions in other locations other than the prices (i.e., that the markets were "semi-strongly" efficient). This restriction is somewhat implausible but relaxing; it implies a quite different process of price setting. Traders are likely to react similarly to the same information on events which can affect prices (a war, a failure in harvests), and thus price gaps would not change. In a perfectly efficient market with perfect information for a homogeneous good, price differentials between markets would remain constant as long as transaction costs remain stable.

A parallel strain in the literature has measured integration with the variance of prices for a single market or, as suggested by Engel and Rogers (1996), the ratio of prices in two locations. This approach assumes that integration could reduce price volatility relative to a closed economy, where prices are inversely related to domestic production, and fluctuations are larger, the less elastic is consumption. This assumption is supported by the results by Clark (2015), for England in the Middle Ages, and Studer (2015) for Switzerland in the early modern period. They run a very simple model of price determination as function of local supply conditions (as measured by yields or weather fluctuations) and find that adding

nationwide prices, or prices in other markets, reduced the coefficient of the local supply variable. These results, however, may not be sufficient evidence for the variance-based measures of efficiency. They refer to very specific cases, and in general price volatility depends on many factors, most notably the elasticity of substitution with other goods, the covariance with their prices, and the extent of storage or intertemporal arbitrage (Foldvari and van Leuuwen 2011). Furthermore, any interpretation of decline in variance as evidence of increasing efficiency assumes that the size of underlying shocks is constant. This is by no means sure (see Brunt and Cannon (2014) for an example). For instance, irrigation or other modern technology may reduce the effect of weather on crop yield and thus the size of weather-related price fluctuations.

The recent literature has suggested a number of important, although not earth-shattering, improvements to these traditional measures of efficiency. Dobado et al. (2012, 2015) suggest the use of variance residuals from AR(1) models of price ratios, rather than the variance of the series, to highlight shocks. On the same line, Brunt and Cannon (2014) distinguish the transitory from the permanent component of price movements with a two-market VECM model and decompose the former into location-specific shocks, common shocks, and adjustment. Others have introduced the possibility of changes in parameters, either by using time-variant specifications of the baseline AR model (Craig and Holt 2017) or a rolling stock approach (e.g., Hynes et al. (2012), Bernhofen et al. (2016), Federico et al. (2018)). The most relevant addition to the statistical toolkit is the dynamic factor analysis (Uebele 2011; Anderson and Ljunberg 2015; Federico et al. 2018). It can be interpreted as a sophisticated version of the traditional co-movement measure. Instead of computing pairwise correlations between price series and averaging them somehow, the procedure extracts one single series, or common factor, which captures all common movements. The ratio of its variance to the overall variance of location-specific series measures the extent of co-movements and thus the efficiency of the market. Furthermore, the common factor can be used as a proxy for reference prices for the area, as an endogenous alternative to the a priori selection of a central market à la Ravaillon (1987),

The most relevant methodological improvement is arguably the integration of intertemporal arbitrage in the modeling of spatial arbitrage. By definition, intertemporal arbitrage is possible only if commodities can be stored for future consumption. The technology for long-term conservation of perishables, such as dairy products, is quite recent, but storage is as old as agriculture, as cereals and some other annual crops have to be stored for consumption throughout the year. In theory spatial and intertemporal arbitrage are substitutes: agents can decide to withhold products from the market if they expect future prices to exceed current ones by more than storage costs. In this case, storage would reduce market supply, causing the current prices to return to their intertemporal equilibrium level. If the market is efficient, expected prices would change only if new information is available. Steinwender (2018) introduces storage in her analysis on the effects of the telegraph on transatlantic cotton trade, as a fluctuation-smoothing mechanism. In her model, cotton was stored only in the destination market (the United Kingdom), and

sales from stocks met additional demand, dampening price increases until the arrival of additional supply from the United States. The latter depended on the combined time for transmission of information about excess demand from the United Kingdom to the United States and for actual shipping of cotton. The telegraph reduced the time of transmission and thus the need for storage. In another very recent paper, Craig and Holt (2017) attribute the decrease in the speed of adjustment of egg prices in the United States in the late nineteenth century to the introduction of refrigeration (cold storage). Without storage, traders had to sell immediately, irrespective of their expectations about future prices. Refrigeration made it possible for traders to withdraw the product from the market if they expected prices to rise above storage costs and thus reduced the local supply for arbitrage.

A different and more radical approach was first suggested by Shiue (2002) and then formalized by Coleman (2009). Unlike Steinwender, he assumes perfect information on prices and focuses on the difference between equilibrium conditions with and without storage. In his model, prices in origin markets (Chicago in his example) at any given time are equal to the expected prices in destination markets (New York) at the time of arrival, t + n. These latter are equal to prices in New York at time t plus storage costs. In equilibrium, Chicago prices are equal to New York spot prices less transport costs (the standard condition for spatial arbitrage) plus storage costs – i.e., the gap in prices is equal to transaction costs less storage costs. Therefore, the spatial-cum-intertemporal commodity points are narrower than spatial-only points. In this case, spatial arbitrage would be unprofitable as long as the demand in the destination market could be met by reducing inventories. The information that inventories are going to run down at the time of arrival causes prices in the destination market to rise, and thus the price gap to exceed transaction costs, triggering arbitrage. Thus, in theory, the model implies regular spikes in price gaps, which could be detected with high-frequency data. In practice, if the period n is short enough, the difference between commodity points with and without storage is likely to be small, and thus the results of the spatial plus intertemporal arbitrage model will not differ much from those of the standard spatial-only framework.

The First Wave: Measurement

Federico (2012) summed up results of almost 40 years of research on the integration of European markets by pointing out the difference between the early modern period and the "long" nineteenth century, from Waterloo to World War One. There was a wide consensus on a massive integration process along Cournot dimensions, price convergence, and growing market efficiency in the latter period and a substantial disagreement on the movements before the French Revolution. Recent work has confirmed the view of the nineteenth century as a period of integration [integration, nineteenth century] and has shed some light on previous trends – or lack thereof. First, Chilosi et al. (2013) have explored the geographical pattern of integration in

Europe from 1620 to 1913, by allocating their sample of about 100 cities in regions (from 7 to 11 according to periods) with a principal component analysis. The size of regions and the pattern of price convergence depended mostly on geography. The area around the North Sea, which benefitted from easy and cheap sea communications, was already quite well integrated at the beginning of the period, while landlocked regions were smaller and less integrated. In the long run, also the landlocked areas joined the European market, with the exception of Spain, which remained isolated well into the nineteenth century. Federico et al. (2018) have expanded the period back in time to the early fourteenth century and the size of the database to almost 600 locations, with up to 300 prices in the mid-eighteenth century. Unfortunately, most of these series are quite short, thus authors rely for the very-long-run analysis on a core sample of 15 cities, mostly from North-Western Europe, with some cities in Southern France and Northern Italy. In the early modern period [integration early modern period], price dispersion for the core sample fluctuated widely: it was fairly low in the fifteenth and sixteenth century, jumped in the early seventeenth century, declined again from about 1650 to the French Revolution (the period covered by Chilosi et al. (2013)), and soared during the Napoleonic wars. A dynamic factor analysis shows that efficiency varied much less than price dispersion in the early modern period and started to rise in the late eighteenth century. After Waterloo, prices started to converge and efficiency continued to grow, so that around 1870 the European market for wheat achieved an unprecedented level of integration along both dimensions. Federico et al. (2018) supplement this analysis by building larger samples for 80-year periods, selecting cities from their database with a grid procedure to be as geographically representative of the whole continent as possible. These additional data confirm the result from the 15 cities sample but shows that convergence outside the core areas was slower and less complete. Last but not least, Federico et al. (2018) show that, taking distance into account, the level of integration in England and the Netherlands was not exceptionally high in the sixteenth and early seventeenth century and soared afterward. These two papers provide a broadly consistent story on European integration in the long run. Unfortunately, the story is quite complex, with substantial differences between areas and periods and between trends in price dispersion and efficiency. These differences can explain how the earlier literature, using different statistical tools on small samples of differently located cities for different periods, had reached quite divergent conclusions.

The conventional wisdom about intercontinental integration has been deeply shaped by the research by K. O'Rourke and J. Williamson. They have argued, in different papers, that:

1. The opening of a new route to Asia at the beginning of the sixteenth century caused a small decline in real prices of spices in Europe and a modest increase in correlation among European markets (O'Rourke Williamson 2009).
2. In the seventeenth and eighteenth centuries, price wedges between Europe and Southeast Asia remained stubbornly large, well above the transportation costs, even factoring for the risks of the trip (O'Rourke and Williamson 2002).

3. The Atlantic economy integrated during the nineteenth century, with far-reaching consequences on facto incomes and distribution (O'Rourke and Williamson 1994).
4. The interwar years featured mixed trends, with some divergence in prices, but no major loss of efficiency (Hynes et al. 2012).

The recent works suggest a more sanguine view of the intercontinental integration in the early modern period. Dobado et al. (2012) and Sharp and Weisdorf (2013) show that the Atlantic wheat market was already quite efficient in the eighteenth century. Both Ronnback (2009) and de Zwart (2016) criticize the conclusions by O'Rourke and Williamson as based on a small number of series for a limited period. They find that levels of dispersion and trends in convergence differed substantially among routes and between products along the same route. In particular, de Zwart (2016) shows that price gaps between Europe and Southeast Asia started to decline for some goods (e.g., cloves) already in the seventeenth century, and that convergence extended to the majority of commodities, with exceptions such as mace and nutmeg, in the eighteenth century. In the early 1810s, the markups on Asian products in Europe were still quite large, from 70% to 220%, and substantially greater than the price gaps for American products (Chilosi and Federico 2015). The convergence of the first half of the century was correspondingly faster and deeper in the Indian Ocean than across the Atlantic.

Most of the early literature on market integration deals with Europe, but there were some pioneering studies of the integration of Asian markets in the 1970s and 1980s (Hurd 1975; Latham and Neal 1983; Brandt 1985; Bessler 1990). The number of such studies has substantially increased in the last year. Dobado et al. (2015) argue, with their preferred variance-based measure, that domestic rice markets in Japan were quite efficient already in the eighteenth century. In contrast, the admittedly much bigger Indian market showed neither price convergence nor increase in efficiency before the second half of the nineteenth century (Studer 2015). The integration of the Chinese domestic market has attracted much attention as part of a wider debate on the economic conditions of China in the eighteenth century. The so-called California school argued that China was as advanced as Western Europe in the eighteenth century according to almost all indicators, including the development of markets, and diverged only in the nineteenth century (Pomeranz 2000). This sanguine view did not tally well with the disintegration of the market for wheat and millet in the Northern province of Hebei, which included Beijing, from 1738 to 1911 (Li 2000). On the other hand, Pomeranz's optimism was buttressed by a very influential paper by Shiue and Keller (2007), who compared China and Europe in the eighteenth century according to three different static measures of efficiency (volatility of prices, average coefficient of correlation, and t-statistics of stationarity of residuals of a pairwise regression of prices). They argued that China as a whole was no less efficient than Western Europe, although China's most advanced area, the Lower Yangtze valley, was less integrated than England. China and Europe diverged in the nineteenth century when massive integration in Europe was not matched by a parallel process in the Heavenly Empire. Further work has given mixed results,

possibly because of the use of different measures of efficiency. The residual-based variance measure by Dobado et al. (2015) shows that the market for rice in three locations in "advanced" China was as efficient as the English market and that efficiency was growing until the 1840s. In contrast, Bernhofen et al. (2016), with an augmented AR model, confirmed the results by Li (2000) for the markets for wheat in North China (80 cities) and rice in South China (131 cities). The half-lives of price shocks were growing (i.e., the market was becoming less efficient) already toward the end of the eighteenth century, well before the mid-nineteenth-century crisis, and, in stark contrast with Shiue and Keller (2007), they were on average about six times longer than in the (admittedly smaller) European "national" markets for series of comparable frequency.

Integrating temporal and spatial arbitrage [intertemporal arbitrage], although theoretically sound, has proven to be empirically challenging due to the lack of data. The economic history literature has largely ignored Coleman's (2009) plea for storage-adjusted commodity points, although some authors have tried to assess the relevance of storage from price data. Shiue (2002) has argued that the resort to storage can be inferred from the impact of a weather variable (an index of low rain) on local prices. The coefficient is positive and significant but declining in time. Thus, she concludes that in the eighteenth century China's intertemporal smoothing via storage was imperfect but improving. This inference is not robust, however, as her specification does not control for the effect of spatial integration on prices by including prices in other locations. She only points out that the effect of weather was stronger in inland areas, which were less spatially integrated than the coastal ones. Clark (2015) argues that in Medieval England storage was widespread because prices were correlated across years (while output fluctuated randomly), and intertemporal arbitrage was efficient because the increase of prices over the crop year was aligned to storage costs.

The Second Wave: The Causes of Integration

It would be unfair to state that economic historians have been so obsessed by measuring integration as to neglect its causes altogether. Almost all of them discuss the issue, but the majority infer the causes of integration combining the results of measurement and anecdotal evidence on changes in trade costs, without any formal test. All authors explain the nineteenth-century price convergence with the joint effect of liberalization of trade and technical innovation in transportation: the steamship and railways. Some authors have tried to support their conclusions about the likely causes of integration with some simple statistical testing. Quite a few of them have grouped (pairs of) markets according to distance to show how transportation costs affected domestic integration. For instance, Studer (2015) finds that in India before 1830 the average coefficient of correlation among first differences of wheat prices was very high for close-by markets (less than 35 kilometers apart), but it dropped to almost zero beyond 70 km. After 1860, the correlation was 0.46 for pairs over 1500 km. – i.e., as high as for the 35–70 km bracket in the first

period but still well below the correspondent figures for Western Europe in the same years. This approach requires the setting of thresholds to classify pairs of markets, and is suitable only for analyzing domestic integration, which depends only on transport costs. Federico and Persson (2007) suggest a way to disentangle the domestic from the international components of change in price dispersion with a variance analysis [causes of integration, variance analysis approach]. The two components accounted for almost the same share of long-run convergence of wheat prices in Europe from the early 1750s to 1870, but all short-term changes were driven by the international component, which clearly reflects political shocks, such as the outbreak of the Napoleonic wars or the abolition of British Corn Laws (Federico 2011). Last but not least, Dobado and Marrero (2005) explore the effects of railways on domestic integration in the nineteenth-century Mexico by comparing the speed of adjustment before and after the construction.

All these computations, while clearly an improvement over inferences from visual inspection, still need a selection of relevant causes and/or thresholds. Thus, in recent times, scholars have moved to formal testing of the effects of changes in trade cost using a panel regression approach [causes of integration, panel regression approach], broadly inspired by gravity models in international trade. In their classical paper on the issue, Anderson and van Wincoop (2004, pp. 691ff) define trade costs as "all costs incurred in getting a good to a final user other than the marginal cost of producing the good itself: transportation costs (both freight costs and time costs), policy barriers (tariffs and non-tariff barriers), information costs, contract enforcement costs, costs associated with the use of different currencies, legal and regulatory costs, and local distribution costs (wholesale and retail)." This definitions implies a general model such as

$$\mathrm{MI} = \mathrm{f}(\mathrm{Tc},\mathrm{B},\mathrm{I},\mathbf{E},\mathbf{X}) \tag{2}$$

where MI can refer either to price convergence or efficiency; Tc measures transport costs, B barriers to trade, I information flows, and **X** all other trade costs; and **E** is a set of dummies to capture unusually large shocks (e.g., wars). In this setting, the expected sign of explicative variables varies according to the dependent variable: a positive sign corresponds to less integration if the dependent variable is a measure of dispersion (e.g., price gaps between two markets) and to more integration if the dependent variable is a measure of efficiency (e.g., the speed of adjustment or the coefficient of correlation). Furthermore, results may differ to the extent that the same causes could affect the two Cournot conditions (equilibrium price gaps and the speed of adjustment) differently.

By far the most common measure of convergence in formal testing is the ratio of prices between pairs of markets. Federico (2007) uses also the coefficient of variation as the dependent variable, but the main alternatives are the estimates of transaction costs as obtained from a TAR model. As noted earlier, each TAR estimate yields a single set of points, but one can get several sets by running the model for overlapping periods (Jacks 2006). In contrast, there is a wide range of pairwise measures of efficiency, such as the coefficient of correlation (Shiue 2002), the

variance of relative prices (Engel and Rogers 1996), and of course the speed of adjustment (Jacks 2006). Brunt and Cannon (2014), in the most detailed analysis so far, uses as dependent variable(s) the standard deviation of gaps between prices of pairs of neighboring markets (i.e., the Engel-Rogers measure) and four different measures of location-specific shocks (speed of adjustment, size, pairwise ratio, or correlation between shocks in two locations).

Measuring trade costs has proved to be challenging. Only a few authors have been able to find series of actual transport costs or duties, and none has actual data on information costs. Nevertheless, economic historians have been quite imaginative in substituting them with proxies, with varying success.

The standard measure for transport costs (Tc) in gravity trade models is birds' fly distance, and indeed it is quite common also in the literature on market integration. Buyst et al. (2006) measure the effect of transport costs in the Southern Low countries in the eighteenth century with distance, distance squared, and dummies for access to water (rivers or sea). Distance affected the commodity points significantly, and not linearly, but not the speed of adjustment. By their nature, time-invariant measures such as distance and location dummies can explain the level of integration, but not their changes in time. Indeed, most authors try to capture changes in infrastructure endowment with dummies for the existence of a rail or road connection between two cities or, more generally, for the access to the network. The results confirm the expectations about the positive effects of infrastructure on integration, but with a lot of variations that offer important insights. For instance, Buyst et al. (2006) find that the existence of a paved road at the beginning of the period of estimation (1765) made adjustment significantly quicker, in all likelihood by improving the circulation of information, but it did not affect the commodity points. This latter result might reflect the omission of roads built after 1765, itself a consequence of structure of estimation (one single coefficient, no panel), or simply the existence of tolls on paved roads. Brunt and Cannon (2014) find that in the late eighteenth-century England, better transportation, as proxied by the density of paved road and dummies for canals, reduced the volatility of prices and the size of shocks and increased their correlation, but it had mixed effects on the speed of adjustment**.** Paved (free) roads reduced the gaps in rye prices in Westphalia in the central decades of the nineteenth century, while the effect of waterways was mixed, and railroads had little impact, possibly because the network was not yet fully developed (Uebele and Gallardo-Albarran 2015). Railroads have a very special position in this literature as the main factor of integration of domestic markets. Keller and Shiue (2008) estimate that building railways accounted for about four fifths of price convergence in Germany in the nineteenth century. The case of Italy was somewhat different (Federico 2007): the building of railways substantially reduced the price gaps between landlocked markets in the North, but had little impact for the rest of the country, where rail transportation was outcompeted by coastal trade. For the whole continent, Jacks (2006) confirms that the mere existence of a railway connection between two locations reduced price gaps by 5%, while the effects on efficiency are mixed: the speed of adjustment is positively related to the existence of a connection but negatively to its length. The effect of railways on integration of Indian markets

has drawn special attention within the debate about the economic benefits of British rule. Hurd (1975) argued that railways were the main driver on integration by comparing trends on coefficients of variation for counties with and without railroads and Studer (2015) concurs, although without a formal test. This conventional view has been questioned by Andrabi and Kuelhwein (2010), who find that convergence in cereal prices started before railway building and estimate that railways accounted for only a fifth of the overall decline in price gaps. They infer that most of the convergence can be explained by other integrating forces, such as a common currency, language, and administration, but that one could put forward an alternative interpretation. They use retail prices of cereals; thus the (likely) stable markup on wholesale prices may have dampened the effect of a decline of trade costs on wholesale prices. Indeed, the interpretation seems inconsistent with the recent estimates by Donaldson (2018) on the costs of transporting salt from a common source to the whole of India by different means. He estimates that the elasticity of trade costs to distance was around 0.25 and that both road and, somewhat surprisingly, river were more expensive than rail transport, by eight and slightly less than four times, respectively.

The econometric analyses have largely confirmed the relevance of changes in barriers to trade to foster or hamper the integration of commodity markets. The abolition of Piedmontese [duties] duty, the only relevant one, in 1849 accounted for about a fifth of the price convergence among Italian states before the unification of the country in 1860 (Federico 2007). Keller and Shiue (2014) estimate that the entry of a state into the Zollverein reduced the wheat price gaps with other Zollverein cities by 28% on average, although this decline cannot be interpreted exclusively as the consequence of the abolition of trade barriers because there are no data on duties on wheat before the accession. Chilosi and Federico (2015) find that the Corn Laws had a significant effect on price gaps between the United States and England. Finally, for the whole of Europe, Jacks (2006) finds that outright prohibition or protection against imports increased dispersion in wheat prices and slowed down the adjustment after a shock.

The effects of another trade barrier, the monopoly that European trading companies [European trading companies, monopoly], such as the Dutch *Vereenigde Oost-Indische Compagnie* (VOC) and the British East India Company (EIC) enjoyed on commerce with their Asian territories, has attracted a lot of attention and some very interesting controversy in recent times. O'Rourke and Williamson (2002) argued that only these restrictions could explain the huge gaps in spice prices between Asia and Europe in the seventeenth and eighteenth centuries. Their hypothesis tallies well with the situation of the spice market in Europe in the early sixteenth century, when the competition between the Portuguese and Venetians increased the correlation in spice prices in Europe and caused real prices to decline (O'Rourke and Williamson 2009). Along the same line, de Zwart (2016) interprets the differences in price convergence of various products between South Asia and Europe as a consequence of different market conditions. Prices converged earlier and faster in competitive goods, including pepper, while gaps remained wide in products such as cloves and nutmeg, where the trading companies succeeded in enforcing their monopoly. The

impact on welfare ultimately depended on the relative importance of these goods on total consumption. Chilosi and Federico (2015) show how trading monopolies still mattered in the first half of the nineteenth century. The French competition had disappeared, while the EIC maintained its monopoly on trade with India until 1815, and the Dutch recreated the monopoly of the failed VOC with the Nederlandsche Handel-Maatschappij (NHM) in the 1820s. The dummies for these companies are positively and significantly related to price gaps between England and the Netherlands for a wide range of commodities. In contrast, most commodity-specific market interventions in the interwar years, such as the Agricultural Adjustment Act (1933) or the Dutch marketing board for sugar (VSP and later NIVAS), had little impact on price gaps.

Information costs play an essential role in integration, especially efficiency, but measuring them has proved exceedingly difficult. Brunt and Cannon (2014) measure the proportion of cities with at least one local newspaper as a proxy for diffusion of news in the late eighteenth- to early nineteenth-century England. The variable has no effect on the speed of adjustment, but it is negatively related to the volatility of relative prices and positively to the correlation of shocks. In other words, prices in different locations reacted in the same way to presumably common news. Chilosi and Federico (2015) capture the impact of the telegraph on transatlantic price gaps with a simple dummy, which is negative (the telegraph reduced gaps) and significant. Steinwender (2018) explores in detail the impact of the reduction in the time for transmission of information (from about 10 days before the telegraph to less than 1 after it) on daily prices of cotton in New York and Liverpool. As expected, she finds that the telegraph reduced the information-adjusted price differentials (i.e., the gap between the New York price and the latest known Liverpool price). She also finds that the faster information increased the average and volatility of daily shipments but finds little support for the hypothesis that the telegraph affected storage.

The set of controls $\mathbf{X}$ includes a potentially boundless list of factors that might affect integration, which in panel regressions are lumped together in the fixed effect under the implicit assumption that they did not change in the period of estimation. Several authors have tried to be more specific, adding additional variables (or, more frequently, proxies and dummies), which can be grouped into four main categories:

1. Monetary factors. Currency fluctuations increase risks for arbitrage, and thus one would expect integration to be greater, ceteris paribus, under fixed exchange rates. Several authors have tested this by including monetary variables, such as exchange rate volatility (Jacks 2006), or dummies for monetary unions (Keller and Shiue 2008; Jacks 2006) or the gold standard (Jacks 2006). As a rule, results tally with expectations.
2. Ethnicity. Common ethnicity is expected to foster integration by increasing trust among traders. Usually it is proxied by common language, and, indeed, linguistic fractionalism increased price dispersion in Austria-Hungary (Schulze and Wolf 2009), and common language reduced price gaps between pairs of European cities and increased the speed of adjustment (Jacks 2006).

3. Measures of institutional quality. It is highly likely that efficient and universally fair legal systems fostered integration, but only Bateman (2012) tries to test this hypothesis for early modern Europe. She proxies quality with indexes of fiscal centralization or the activity of (traditional) parliaments, but neither variable is significant. This result should not be considered as conclusive, as these variables are arguably poor proxies for the efficiency of the legal system.
4. The existence of a political border. Engel and Rogers (1996) pioneered this measure by adding a dummy for pairs of markets in the United States and Canada to highlight the impact of institutional and other unaccounted-for differences on the volatility of relative prices. Jacks (2009) has reproduced their simplified model for a large number of markets, adding only volatility of exchange rates and, as expected, finds a long-term decline in the border coefficient in the long nineteenth century. Also, Andrabi and Kuelwhein (2010) find a significant effect of borders between British India and the princely states on price gaps. By its residual nature, one would expect the border dummy to be more relevant in bare-bone specifications. In fact, it comes out insignificant and wrongly signed in the analysis of integration of the Italian market by Federico (2007), which features among explicative variable yearly series of transport costs and duties. It is thus somewhat puzzling that the border dummy is still significant in the article by Jacks (2006), which features a rich set of proxies for other trade costs. Furthermore, the variable is positive in both regressions – i.e., ceteris paribus a border increased price dispersion as expected but also, unexpectedly, reduced efficiency.

By their nature, trade costs have a potentially permanent effect on integration, while wars are by definition temporary, if not exceptional, events. The effect of wars on price gaps is unambiguously negative, while there is a margin of uncertainty on their effect on efficiency. Wars disrupted the orderly working of markets, but in some cases, especially of backward societies, they could increase circulation of information, with positive effect on efficiency. Jacks (2006) tests the effect of six different cases of domestic and foreign war, with no-war as the default. In all these combinations except "neutral" (defined as the combination of a market in a neutral country and another in a country at war), the war dummy is significant: wars increased dispersion and, more tellingly, slowed down the adjustment. Chilosi and Federico (2015) systematically test the effect of a number of political events on intercontinental price gaps. The results are mixed. Some events did disrupt trade (the anti-slavery campaign in the 1830s for sugar, World War One on routes for India and Indonesia), while others (the Java war of the 1820s, the Indian mutiny, US Civil war, and World War One across the Atlantic) had no significant effect. The last result does not necessarily imply that these events did not affect price gaps. In fact, the regression includes a yearly series of trade costs, so the dummy captures additional effects, such as the shortage of ships for Asian trade during World War One.

This short review highlights two points. First, the same variable yields different results in explaining convergence or efficiency. This is not really surprising and is fully consistent with the results of measurement (cf. e.g., Dobado et al. (2012),

Hynes et al. (2012), Federico et al. (2018)). In an efficient market, a shrinking in commodity points, as a consequence of a decline in transport costs or of the abolition of barriers to trade, causes convergence, but does not necessarily increase the speed of adjustment after a shock.[1] On the other hand, an improvement in information flows (a decrease in costs or an increase in speed of transmission) or in institutions may increase the speed of adjustment, but does not necessarily affect the equilibrium price gaps. They might affect the measured price gaps to the extent that price differentials are computed as averages of actual prices, inclusive of periods of disequilibrium. The average gap would shrink if the latter become shorter because arbitrage is more efficient and/or less risky, even if the underlying equilibrium gaps remain constant.[2]

Second, a list of significant variables is not a sufficient answer to question two without an idea of their relevance. It is necessary to know how big is big or to borrow the title of a paper by Jacks (2006) "what drove market integration?" The question could be properly addressed only by including in the regression measures or proxies for all main drivers of integration. As is clear from previous survey, Jacks (2006) work is by far the most comprehensive, as he tests the effect of no less than 19 variables on convergence and efficiency. In Table 5, he sums up his results by ranking separately the impact of continuous variables (as measured by the impact of standard deviations on the dependent variable) and dummies (as measured by their coefficients). This division makes the comparison between the two categories of variables difficult. The author nevertheless concludes that "trade costs seem to be more responsive to changes in the choice of monetary regimes than changes in the underlying technology of transport," while "speeds of price adjustment present a more balanced account as transport, monetary, and commercial variables all seem to play a part" (Jacks 2006: 405). Federico (2007) and Chilosi and Federico (2015) estimate the contribution of each explicative variable to total price convergence by multiplying the coefficients from a log-log specification by the actual changes of the underlying variables (omitting nonsignificant ones). The results highlight a major difference between the first half of the nineteenth century ("early globalization") and the period from about 1870 to World War One ("heyday of globalization"). The early convergence was mostly determined by changes in barriers to trade, such as the abolition of trading monopolies by Western companies (the British EIC in 1815–1816 for India and the Dutch NHM around 1850) and the liberalization of British imports of wheat in 1842. After 1870 prices continued to converge, thanks to the telegraph lines and to technical progress in sea transportation, but the political decisions mattered more because most total convergence predated 1870.

[1]Note that a reduction in commodity gap increases ceteris paribus the likelihood of co-movements as it shrinks the scope for independent movements. However, this appears as an increase in efficiency only because co-movement measures are imperfect measure of efficiency.

[2]As stated earlier, in principle, the TAR models should solve the problem by endogenously selecting the "normal" observations to estimate the equilibrium commodity points. However, the results can be interpreted as effective equilibrium transaction costs on the twin assumptions of efficient markets and constant transaction costs in the period of estimation.

It may be premature to draw any conclusion from this still ongoing work, but the results so far point to an explanation for the difference between the early modern period and the "long" nineteenth century. This latter was the golden age of integration because of the coincidence of trade liberalization and a spurt of technical progress. The latter lowered transportation costs, especially overland, and increased the speed of transmission and the amount of available information, which increased efficiency first by increasing the proportion of common shocks (as determined by common information) and later, after the telegraph, also by speeding the adjustment.[3] But throughout history, waves of integration/disintegration were determined mainly by political decisions, such as barriers to trade, and by political events, most notably wars.

The analysis of causes has made impressive strides in the last 10 years, but its results have to be taken with an (abundant) pinch of salt. First and foremost, in most cases, the lack of data makes it impossible to consider potentially relevant causes. A major example is the role of the network of state granaries in China, set up by the Qing dynasty in the second half of the seventeenth century. Several scholars attribute to it the high level of "integration" (or efficiency) of Chinese domestic markets in the eighteenth century and to its decadence the disintegration of the early nineteenth century. This inference is plausible, as the system was designed to reduce the effect of local harvests on local supply and thus on price fluctuations. The inference would also be testable with information about the location and activities of granaries. Unfortunately, these do not exist, or at least have not been exploited so far.

Finally, there are three specific econometric issues, about endogeneity, the choice of market pairs, and the measurement of trade costs.

First, endogeneity is a widespread concern in modern-day econometrics that also affects the literature on market integration. Quite a few authors have used instrumental variables to address two potential sources of reverse causation. Existing trade flows may have determined the choice of railways or roads to be built, and political decisions, such as access to the Zollverein (Keller and Shiue 2008, 2014). In addition, transportation costs could be endogenously determined by the amount of trade (Jacks and Pendakur 2010). In these cases, a simple OLS regression might overstate the contribution of new infrastructures or liberalization of trade to integration. These concerns might be excessive. It is surely plausible that total trade affected the railway planning but less likely that trade in a single commodity (most frequently cereals) was so important as to determine it. It is even less likely that any specific commodity/route flow was large enough to affect the level of freights in the competitive world market for shipping.

[3]Let's assume that a war started in – say – Germany. Newspaper would transmit the news roughly at the same time in Amsterdam and London, and agents were likely to react in the same way by raising prices. This movement would appear as a common shock in the Brunt and Cannon (2014) framework and would increase the share of explained variance in DFA (Federico et al. 2018). In this case, there would be no market-specific shock to adjust to. Newspapers did not cut the time of reaction to any such market-specific shock, which still depended on the physical transmission of pieces of paper in the days before the telegraph.

Second, in contrast with the concern for endogeneity, most authors do not seem to bother about the existence of trade flows between each pair of locations, even if, as discussed earlier, this is an essential condition for price gaps to be a meaningful measure of integration. There are exceptions. For instance, Brunt and Cannon (2014) explicitly state that they prefer to run their VECM models only with pairs of neighboring counties, which were more likely to trade than faraway ones. They can afford to be so restrictive because their database includes a very large number of nearby counties to work with. To be sure, data on trade flows between specific cities are often unavailable, but the anecdotal information is abundant, and thus authors should defend their choices of market pairs beyond the obvious ones (e.g., nobody would doubt that Amsterdam and Konigsberg traded in the seventeenth century).

Third, the frequent resort to proxies for trade costs [trade costs, proxies for], admittedly quite common in gravity models, may introduce biases in estimation. For instance, using a common dummy for protection would yield imprecise coefficients if the duty is similar across pairs of markets and constant in time and a biased estimate if duties differ substantially among countries or change in time. This was the norm in the nineteenth century: Italian duties on wheat were first imposed in 1887, at about 10% of the world price, rose to a peak around 50% in the mid-1890s, and declined back to 30–35% on the eve of WWI. The problem is even more serious for transportation costs. By definition, distance is time-invariant and thus is a bad proxy for measuring the contribution of declining costs to integration. Unfortunately, precisely measuring transportation costs, especially overland ones, is difficult. The task is comparatively easy for water transport: the distance is fixed (although the length of a meandering river can exceed the distance by bird fly), and data on seaborne freights is readily available, although not necessarily route- and commodity-specific. In contrast, the distance of land transport depended on the shape of the network (the opening of a new road or of a new rail line could shorten it), and the data on unit costs are either scarce, as for road transportation, or very abundant, but often difficult to collect and unwieldy to manage, as for railways. The evidence suggests that the costs of road transport did not change that much before the diffusion of the internal combustion engine in the twentieth century, but the utilization of roads depended on the competition from railways. The productivity of railways was growing and thus one would expect rates to decline fairly steadily if the market were competitive. In most countries, this was not the case, thus the gains accrued to railway owners, including in quite a few cases the state, rather than being transferred to customers. Thus, one should look at actual fares, which differed by product, route, size of shipment, and so on. This combination of changes in network and in unit fares causes total costs of rail transportation to vary considerably. For instance, consider the case of rail transportation between Genoa, the main Italian port, and Rome. The distance as the bird flies and by sea is about 400 km. The first railway link via Florence, Bologna, and Turin (905 Km) was established in 1866, and the length of the connection was slashed by 40% (to 553 km) after the opening of the new line along the coast in 1875. The combined effect of shorter rail distance and cuts to unit fares lowered the total cost of rail transportation in 1890 to 22% of its 1866 level (Federico 2007). A dummy for rail connection in 1866–1890 would

measure only the initial impact of rail, and miss the subsequent decrease, thus understating the overall effect of railways on convergence. Most authors simply ignore the issue, while others use simple solutions such as interacting dummies (or rail distances) with time trends (Jacks 2006, 2009), segmenting the period of observation to get different coefficients for dummies (Uebele and Gallardo-Albarran 2015), or using ruggedness as a time-invariant proxy for railway costs (Keller and Shiue 2016). It is unclear whether these solutions can address the issue.

One might expect that the combined effect of poorly measured dependent variable and massive use of not so accurate proxies would yield poor results. As is evident from this review, this is not the case: most authors get significant coefficients from their imperfect measures. Either they are quite lucky,or underlying effects are quite large.

The Third Wave: The Effects of Integration

Authors in the market integration literature routinely motivate their interest in the field by reminding that the division of labor was a major driver of ("Smithian") economic growth in the past. Consequently, one would expect a massive effort to estimate the gain from integration benefits. Indeed, social savings from railroads had just such a prominent role in the early years of the cliometric revolution, and standard trade theory offers a wide range of estimation techniques. Price gaps depend on barriers to trade, and adding the impact of transportation costs is straightforward. Yet, somewhat contradictorily, estimates of benefits from integration [benefits from integration, estimates] are few and somewhat on the fringe of the literature.

Ejarnes and Persson (2010) and Steinwender (2018) focus on efficiency gains from the layout of telegraph cables between Europe and the United States in July 1866 with a broadly similar framework. Ceteris paribus, the amount of trade was positively related to the speed of transmission of information, as uncertainty in prices at destination led to a reduction in shipments. The fall in the time of transmission reduced this uncertainty and thus increased American exports to the United Kingdom. The authors use different specifications for different goods (wheat and cotton) with different data (monthly versus daily), but the results are strikingly similar – an increase of exports by 3–8% relative to their pre-telegraph level. The figure may seem impressive, but they correspond to an increase of 0.10–0.20% of American GDP in the 1860s.[4]

Gains from price convergence can be estimated by adjusting the standard partial equilibrium analysis of the welfare effects from trade liberalization to the more realistic case of a partial cut rather than a complete abolition (Hufbauer et al. 2002). It implies adding to the well-known Harberger triangles another term,

[4]The figure is obtained assuming that value added accounted for 90% of the export price of cotton and wheat, that wheat and cotton accounted for half of American exports, and that the export/GDP ratio was about 0.05.

where gains from integration of a given product are proportional to the absolute difference between shares of that product on consumption and output of the country. Thus, the benefits from integration are greater the more relevant the product and the more specialized it is. Federico and Sharp (2013) estimate the losses from the regulation of American rail fares, which prevented a full transfer of productivity gains to consumers and an adjustment to collapsing prices for agricultural products during the Great Depression. They ranged from 0.6 to 3.1% of GDP in the 1930s, depending on levels of specialization and demand and supply elasticities. Chilosi and Federico (2016) deal with the benefits from transatlantic price convergence in the nineteenth century. Gains were similar for the United Kingdom (1–3% of GDP in 1913), India (1.2–1.7%), and Indonesia (0.6–2.2%), while they were much lower for the United States (only 0.10–0.3%).

One might argue that gains below 3% are small, and consequently market integration was less economically relevant than assumed. However, this conclusion would seem too hasty, for three reasons.

First, the estimate refer to few, albeit important, products only, and changes in trade costs although sizeable (a decline by a third in costs) are much smaller than other historical ones, such as the convergence in domestic prices after the introduction of railways. It is likely that more extensive coverage of individual products would augment the size of total benefits, although it would be rash to mechanically extend the product-specific estimates to all goods. The effect of unit changes in transportation costs on price gaps depended on many factors, most notably the bulkiness of products. As a result, gains were likely to be smaller for manufactures than for commodities such as wheat. On the other hand, barriers to trade in manufactures were often higher.

Second, all estimates are partial-equilibrium static models, thus neglecting both the static general equilibrium effects and the dynamic benefits from Smithian growth. Donaldson has put forward two different strategies to estimate general equilibrium effects of market integration [benefits from integration, general equilibrium estimates], both broadly inspired to new trade theory. Costinot and Donaldson (2016) use a linear programming approach to estimate the differences between maximum potential and actual yields and local and New York prices in each American county for benchmark years from 1887 to 1997. Then they measure the gains from market integration (technical progress) by comparing the actual output with a counterfactual one, which they compute as prices (yields) of the current year times the yields (prices) of the next benchmark. The results are quite impressive: market integration increased agricultural output in the United States by 62% from 1887 to 1920 and by 55% from 1954 to 1997, about as much as technical progress (respectively, 30% and 70%). The first figure implies that market integration accounted for about a tenth of total growth in American GDP before 1920.[5] Donaldson (2018) uses a three-step regression-based approach to estimate the effects

[5]Agriculture produced about 27% of GDP in 1890, and the additional gross output corresponded to about 18% of GDP (assuming a GDP/output ratio around 0.90).

of railways on agricultural output of Indian districts (quite a good proxy for GDP in the case at hand) from 1870 to 1939. He shows that his price-based estimate of trade costs determined trade flows; the existence of a railway connection increased district level agricultural income by 16%; and that about 85% of this increase is explained by the additional trade from railways.

Finally, the lack of estimates of the benefits of integration for economic growth [benefits from integration, dynamic estimates] is hardly surprising, given that economists have not yet found a way to get country-level estimates. The market integration literature faces the additional problem of a dearth of measures of local GDP. Yet, at least two authors have tried to use the standard growth regression approach for market integration, using different proxies for GDP. Keller and Shiue (2016) use total population as a proxy for the level of development of each German city in the nineteenth century and find it to be inversely correlated with the average size of price gaps with all other cities in the sample. Bateman (2012) has estimated the effect of price gaps and volatility on level and trends of real wages and urbanization rates in early modern Europe. In her case, the results are poor as the integration variables are not significant. Neither results are really conclusive, given the poor measure of GDP and the well-known shortcomings of the growth regression approach.

Conclusion: Taking Stock

Federico (2012) concluded his survey of the literature on European integration in a "less than upbeat" tone. He pointed out the almost exclusive focus on measurement (question 1 from the introduction), the high proportion of studies on cereals (as opposed to other commodities and above all to manufactures), the limited size of samples, the prevailing interest in state-of-the-art econometric technicalities, and, by contrast, the insufficient attention to economics of arbitrage (as shown by the confusion between Cournot's two conditions). He also argued that price convergence may be more important than an increase in efficiency. An efficient market increases welfare by making adjustments to external shocks faster and easier, but does not affect the allocation of factors and consumption by much (unless the starting point is a totally inefficient market, which prevents prices from adjusting to changes in trade costs). In contrast, convergence would affect relative prices in the long term, with potentially massive effects on agents choice and ultimately on the economy. Last but not least, he put forward an ideal (and perhaps too ambitious) research agenda for measuring integration.

Seven years later, these shortcomings are still quite evident, but there are reasons for hope. There is potentially a more comprehensive theoretical framework, integrating time, via storage, with spatial arbitrage. The most recent works on measurement of integration rely on substantially larger samples of cities for longer periods of time, and have extended the range of goods, most notably to spices, even if they might not be representative (Solar 2013; De Zwart 2016). The literature on causes of

integration is flourishing with a common (albeit still somewhat questionable) framework, and some authors have started to measure effects. We know much more than before, and the new research suggests a more complex and nuanced, although not so different, story.

Markets have become more integrated in the long run, but the process has been far from steady. In pre-industrial Europe, price dispersion and, to a lesser extent, efficiency featured huge fluctuations with large differences across areas, and it is very difficult to find any clear common trend. There is some evidence of price convergence in Asian trade and of increasing efficiency in the late eighteenth century both in Europe and in the Atlantic market, which could compensate for the disintegration of the Chinese domestic market. A massive process of integration almost everywhere, with the likely exception of mainland China, characterized the nineteenth century. Integration most likely peaked sometime between 1860 and World War One and remained close to that peak until the Great Depression. The disintegration of the market during the Depression appears less devastating from the point of view of prices than of quantities, possibly because commodities were less affected than manufactures by the protectionist backlash.

There is widespread consensus on the importance of technical progress in transportation and transmission of information for price convergence in the long nineteenth century and possibly for the increase in efficiency since the late eighteenth century. In contrast, technical change does not seem to have played a major role in determining integration in the early modern period, although this statement is based more on circumstantial evidence than on quantitative testing. Thus, most authors explain the fluctuations in the level of integration in general, and especially in dispersion, in the early modern era to changes in barriers to trade. Furthermore, liberalization of trade was in all likelihood as important as technical progress for the nineteenth-century spurt. Thus, political decisions may have been the driving force of integration in the very long run.

The research on gains from market integration is still beginning. There are very few estimates, which yield fairly small figures. In all likelihood they represent a lower bound, for a number of methodological and empirical reasons.

The measurement of the benefits of integration is arguably the most difficult, but also the most rewarding topic in the field. The partial equilibrium static models are useful as a first approximation, but their results downplay the true benefits of integration. On the other hand, adding spatial dimension for all integrating areas into classical CGE models seems very difficult. Models from new trade theory are promising, but it is too early to tell how helpful they will be. A fortiori this conclusion holds true for the dynamic effect of integration. The growth regression approach, even if perfect data were available, is plagued by the twin problems of collinearity and too many potential explicative variables. On the other hand, there seems to be no simple alternative approach.

The second main task seems to be the improvement of the databases. The progress in coverage by product and area is substantial but still insufficient, and the work on explicative variables is rather backward (a problem that also bedevils the

macroeconomic literature on trade). Poorly measured explicative variables may be significant and still give misleading results about the importance of different factors of integration.

More generally, in spite of all progress so far, the ambitious agenda by Federico (2012) is far from fulfilled. There is still a lot to do.

African-American Slavery and the Cliometric Revolution

Richard Sutch

Contents

Abstract

This chapter explores the significant contributions to the history of African-American slavery made by the application of the tools of cliometrics. As used here "cliometrics" is defined as a method of scientific analysis marked by the explicit use of economic theory and quantitative methods. American slavery of the late antebellum period (1840–1860) was one of the earliest topics that cliometricians focused on and, arguably, the topic upon which they made the largest impact.

Introduction

No historical topic has been more central to the rise, influence, and refinement of the cliometric approach than African-American slavery. The first self-conscious cliometric contribution to American history was a 1957 conference paper, "The Economics of Slavery in the Antebellum South" by Alfred Conrad and John Meyer, which subsequently became an article in the *Journal of Political Economy* (1958). Many of the academic economists associated with the pioneering decades of the cliometric revolution, including myself, examined slavery equipped with the tools of economic theory and quantitative methodology: Douglass North (1961), Richard Sutch (1965), Peter Temin (1967), William Parker (1970b), Robert Gallman (1970), Gavin Wright (1970), and Robert Fogel and Stanley Engerman (1971b). We were not alone. *The Bibliography of Historical Economics to 1980* lists no fewer than 96 individual contributors to the examination of the history of slavery (McCloskey and Hersh 1990).

In the midst of this flood of publications, an ambitious and contentious book on the topic, provocatively titled *Time on the Cross*, touched off a scholarly whirlwind about the potential, the limitations, and the misuse of the cliometric method (Fogel and Engerman 1974). The controversy turned into an academic battle on two fronts, the historians against the cliometricians (Herbert Gutman 1975; Kenneth Stampp 1976) and a Civil War among the cliometricians (David et al. 1976). Although the clamor has since died down and the pace of new findings has slowed, the topic continues to fascinate. Cliometric studies periodically feed the appetite for quantitative evidence on the American horror story (recent examples include Wanamaker 2014; Bodenhorn 2015; Olmstead and Rhode 2015; Calomiris and Pritchett 2016; Pritchett and Hayes 2016).

What explains the original excitement and the sustained attention? First, and I think most important, the Cliometric Revolution really was a revolution. It was so viewed at the time (North 1963: 128). It appears so in the statistics of the scholarship (Whaples 1991). Consequentially, the revolution redefined the scope, method, and goals of economic history as a discipline. Economics departments staffed by professors with degrees in economics commandeered the field of economic history, which was subsequently abandoned by history departments and professors with degrees in history. Like with all revolutions, the young were in the frontlines. Assistant professors and graduate students published papers overturning the interpretations of distinguished full professors and scholars who had been held in high repute for several generations. That was empowering and tended to make true believers of those who joined the revolution. As true believers, they persisted for the long haul.

The first efforts that engaged cliometric methods addressed easy questions and there were many. One of the most enthusiastic advocates of econometric history, Robert Fogel, claimed that any random page from a history book contained "either an explicit or implicit quantitative statement that needed to be measured" (Fogel 1990: 28 (350)). The economic theory and statistical expertise required was often elementary. The only difficult work was gathering data from the archives. While tedious, this required no special talents, but the resulting studies achieved great success. They revised the old consensus interpretation of slavery and swept aside the sentimental (and racist) descriptions of the Old South and its "peculiar institution" seemly without protest. As Peter Temin has noted, that impact made the topic and even the tedious data collection "an enormous amount of fun" (Temin 1999: 45 (433)).

The topic of slavery held special relevance at the time because the Conrad and Meyer 1957 conference paper appeared during the Civil Rights Era. That year federal troops were sent to enforce school integration in Little Rock. Martin Luther King gave his "I have a Dream" speech at the 1963 March on Washington. The Civil Rights Act of 1964 prohibited discrimination based on race, color, religion, or national origin. In 1965, President Lyndon Johnson gave his "We Shall Overcome" speech to Congress and the Voting Rights Act was passed. In that context, a "new" view of slavery seemed to be required to accompany the movement for racial equality. Many of the first cliometricians were personally committed to the civil rights movement. For example, Gavin Wright's direct involvement led him to pursue graduate study in economics and to specialize in economic history and the study of slavery (Wright 2013).

Race remains a hot-button topic and any hard look at the history of slavery is controversial; discussions about black slavery are often fraught with emotion. Articles and books on the subject, however dispassionate on their surface and from whatever quarter, still attract close attention and agitated debate (for a recent example, see Murray et al. 2015). My task, however, is not to offer a behind-the-scenes, I-was-there memoir, but to put emphasis on the concrete contribution of cliometrics, quantification, and social science to our knowledge of the history of slavery.

Conrad and Meyer
