> Perhaps the biggest challenge facing economic history is that in its attempt to pursue truth, economic history is at the same time too vast and too small. In a historical sense, we try to accurately compile all the facts relevant to a given topic of study. The smaller the topic, the easier it becomes to gather and arrange all the relevant facts, and the more rigorous the result is likely to be. . . . But for the historian who aims to create general truths, the economic, like any other conventional division of the subject matter of history, is too narrow a conception. (Diebolt and Haupert 2018, 3)

The search for general truths is compounded by the tendency for scholars to stay within the confines of their academic disciplines. Military historians write military history, economic historians worry about problems of economic history and development, and cliometricians stay focused on the use of economic theory and statistical methods to predict the past with ever greater precision. Nowhere is this challenge more evident than in the study of war and economics in the twentieth century.

An Age of Catastrophes

Everyone agrees that the First World War and its aftermath was a major turning point that fundamentally altered the course of world history in the twentieth century. What makes the changes brought about by the war and its aftermath even more dramatic is the suddenness with which these events occurred. In the space of 5 years, the German Empire, the Habsburg Empire, the Russian Empire, and the Ottoman Empire were overthrown and replaced with a collection of new nation states with very different political regimes. “Battle losses of World War I” writes historian

Michael Clodfelter, "were totally unprecedented in human history. Even the greatest battles of the continental wars of the seventeenth and eighteenth centuries in Europe paled beside those of World War I." (Clodfelter 2002, 479). If one adds the deaths resulting from the Russian Civil War and territorial conflicts immediately following the end of the Great War, at least 12 million men lost their lives. The Second World War was even more deadly. "The toll of World War II," according to Michael Clodfelter, "surpasses 30 million – with 40 million a more likely figure and some estimates going as high 55 million" (Clodfelter 2002, 581). These estimates suggest that, if you include the noncombatants – including the seven million victims of the holocaust who died during the war – as many as 80–100 million people may have died as a direct consequence of the two world wars.

The wars were only a part of the story. Military historians tend to view the two decades following the end of the Great War as a lull before the resumption of fighting in 1939. To economic historians, the interwar years were anything but a "lull"; they were a period of intense economic and social turmoil as people struggled to get back into some sort of "normalcy" amid the destruction and confusion surrounding the end of the First World War and were then confronted with a global depression. Among the most visible signs of the economic uncertainty caused by the war were the instability of international financial markets, the collapse of antebellum trading patterns, widespread unemployment throughout the industrial nations, and episodes of hyperinflation that paralyzed several countries immediately after the war. Historian Eric Hobsbawm has characterized the period from the outbreak of the First World War to the end of the Second World War as an *Age of Catastrophes*. "For forty years," he wrote, "[Western civilization] stumbled from one calamity to another. There were times when even intelligent conservatives would not take bets on its survival." (Hobsbawm 1994, 7). Figure 1 presents a quick view of the economic and military events that comprised the Age of Catastrophes. In addition to the "world wars," there were civil wars in Russia, China, and Spain that attracted attention from major powers throughout the world.

The Economics of the Great War

Cliometricians have provided a large body of quantitative research on the economic impact of these changes, including military expenditures and national income of the five major powers during and after the war. Their estimates show that military expenditures, which had totaled just over £468 million in 1913, jumped to £4.1 billion in 1914, and soared to just over £4 trillion in 1915, which was the first full year of fighting. Military personnel which had totaled just over five million men in 1913 had risen to 25.5 million men in 1915. Figure 2 plots the level of military expenditures and personnel from 1910 to 1940. The huge increase in spending during the war was matched by a dramatic demobilization at the end of the war that posed a whole new set of challenges as men returned from the fronts and government spending fell back to the prewar levels.

The need to mobilize resources for the war also had a pronounced effect on the composition of government spending in belligerent countries from 1913 through

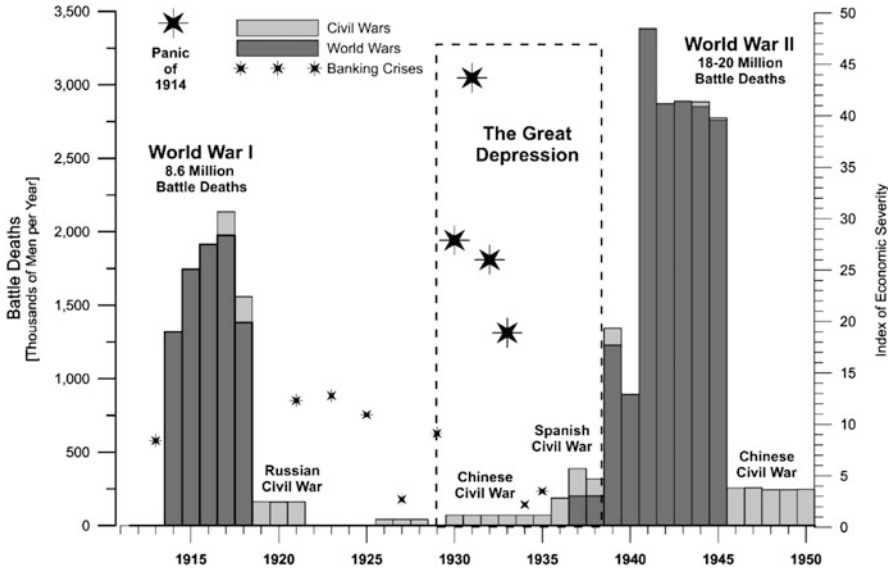

Fig. 1 An Age of Catastrophes, 1914–1945. (Sources: The data on military deaths is from Correlates of War Project (2010) and Clodfelter (2002). The dates and relative severity of banking panics are from Reinhart and Rogoff (2009) and Kindleberger and Aliber (2005). The severity of the crises is measured as the number of countries experiencing banking crises in that year weighted by the share of world GNP for those countries.)

1918. Figure 3 shows the share of national income allocated to military expenses by the five major powers during the war. In 1913, France, Britain, and Germany were all spending about 10% of national income for military expenditures; for France and Germany, military expenditures doubled by the end of 1914 and reached just under 50% by the end of 1915. The share of military expenditures in national income of all three countries remained at or above the 1915 level for the rest of the war. Austria-Hungary also saw a dramatic increase in the share of national income going to military expenditure during the first year and a half of the war. However, unlike the more developed economies of Western Europe, the Austrians were unable to sustain their war effort, and the share of military expenditures in national income actually decreased over the last 3 years of the war. The Russians, who were still recovering from the disastrous losses of their 1905 war with Japan, were already spending a third of their national income on military expenditures in 1913, and the burden of their war effort fell dramatically after the end of 1915. The growing unrest and opposition to the war produced a situation where the defense expenditures decreased as a fraction of income. Both the Austrian and the Russian economies were finding it difficult to finance the war expenditures.

In addition to having to supply the needs of the military, governments had to find a way to pay for the goods and services required by the war. It soon became apparent that the tax systems of peacetime governments would not meet the needs of waging a

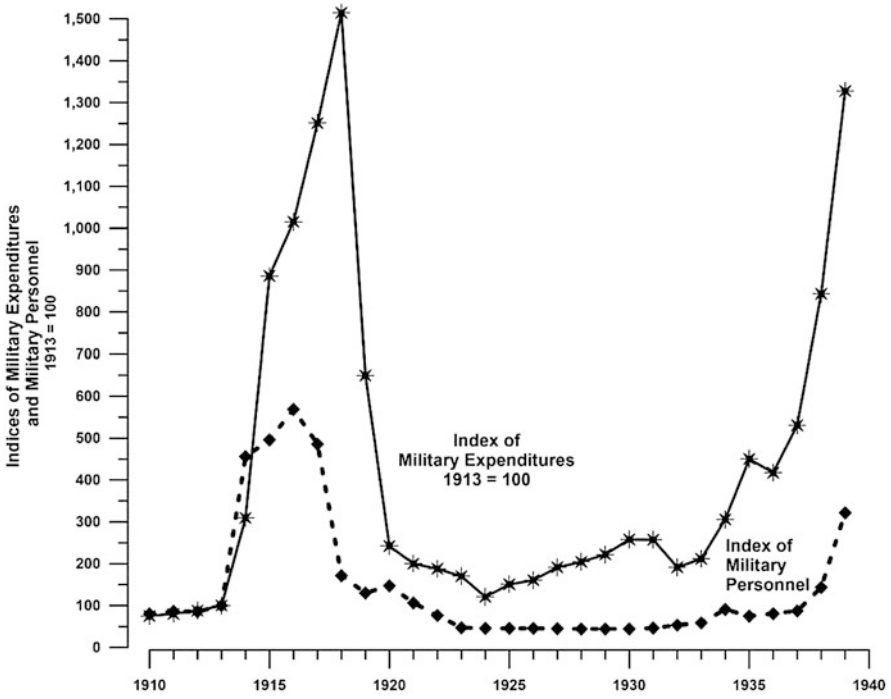

Fig. 2 Indices of military expenditures and military personnel of the major powers, 1900–1939 [1913 = 100]. (Sources: (Correlates of War Project 2010) Data set for military personnel and annual military expenditure in pounds sterling. major war. An obvious alternative to expanding revenues would be issuing government bonds. However, even for countries like Great Britain, which had a well-developed capital market, issuing bonds was not going to cover the costs for the war. In the absence of any other mechanism, governments were forced to simply print money to pay the for the huge budget deficits. The result of this sudden increase in the money supply was that, within months of the outbreak of hostilities, the belligerent countries began to experience significant increases in the level of consumer prices. Figure 4 presents data on consumer prices in Great Britain, Germany, France, Russia, and the Austrian-Hungarian Empire during and immediately following the war.

High rates of inflation, a phenomenon which none of the belligerent countries had experienced during the three decades leading up to the war, persisted for several years in every country. The great advantage of inflation was that it was a tax that nobody could avoid. Consumers paid what amounted to an "inflation tax" in the form of higher prices for the same bundles of goods. The British and French managed to limit the impact of inflation to a doubling of prices over the course of the war, but the other countries were not as successful. In Germany, prices had

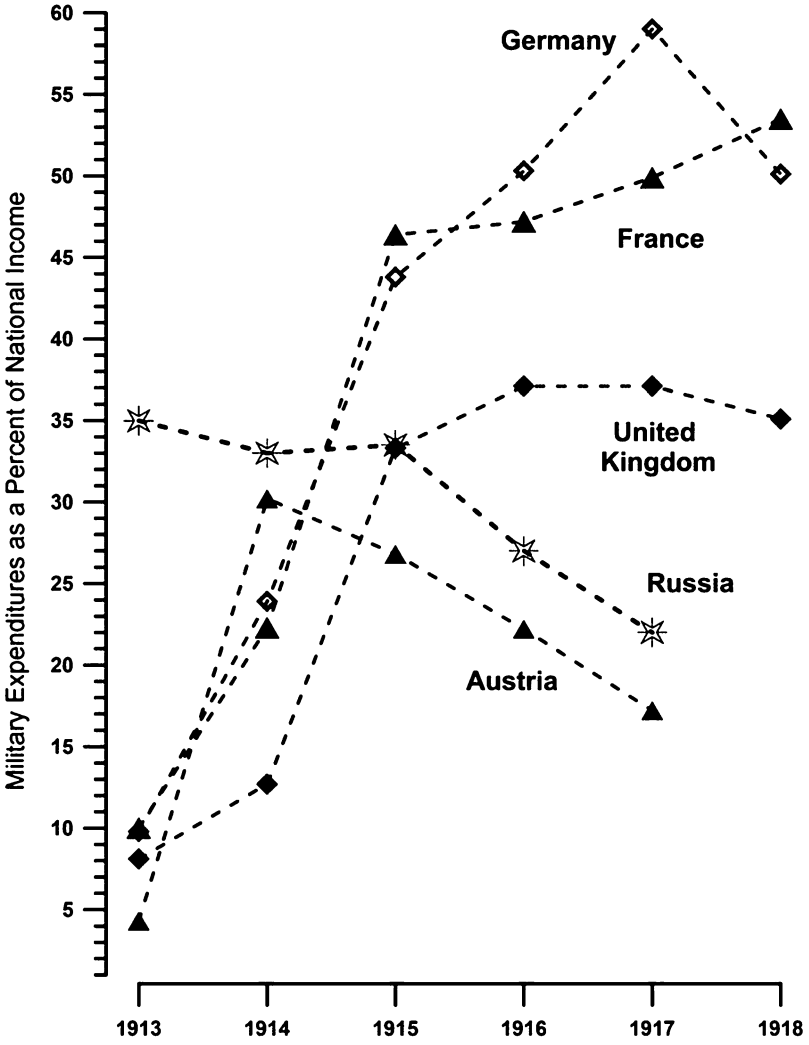

Fig. 3 Military expenditures as a fraction of national income, five European powers, 1913–1918. (Sources: Broadberry and Harrison 2005, 15, Table 1.5.)

quadrupled by the end of the war and the inflation spiral continued to grow out of control. By 1924, the German currency had become worthless. Similar episodes in hyperinflation right after the war were experienced by Russia and Austria-Hungary.

The First World War is often depicted as war where the industrial revolution had produced economies that could provide the weapons, munitions, and skills that armies needed for war in the twentieth century. However, as historian Avner Offer has pointed out, it was shortages of food, not weapons, that ultimately forced Germany and Austria out of the war (Offer 1989, 2000). In both countries,

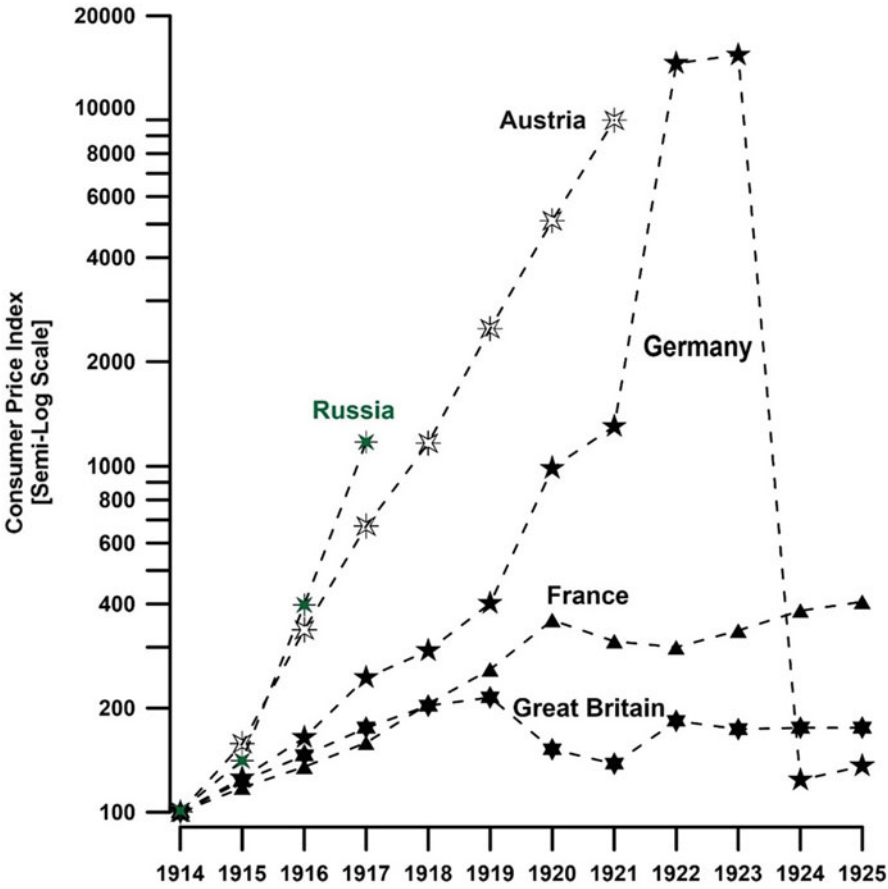

Fig. 4 Consumer price indices for five European powers, 1913–1925. (Sources: (Mitchell 1998, 865–6). All indices have been converted to 1914 = 100)

agriculture was very labor-intensive, and the labor shortage created by men being drafted into the Army placed serious constraints on the production of agricultural output. The shortage of manpower in agriculture was compounded by shortages of imported fertilizers which were no longer available because of the British blockade. The collapse of international trade meant that imported food was no longer available. The result was a constant crisis in the supply of food for the home front throughout the war.

Food was not the only problem posed by the collapse of international trade in 1914. The impact of the war on the international system of trade scrambled the markets for traded goods in the belligerent and neutral countries. The statistics that are most often used to measure international trade are the value of exports and imports. However, the high rates of inflation make it difficult to infer the physical volume of trade from these series. There are, however, enough data for specific

commodities to accept Findlay and O'Rourke's statement that "it is safe to conclude that the volume of trade fell sharply during the conflict, if by an unknown amount. However, such aggregate effects mask a large range of individual country experience." (Findlay and O'Rourke 2007, 435).

The War at Sea

The reliance on trade to supply food and other commodities created an "economic war" in the form of naval blockades to restrict the ability of countries to import or export goods. For the Entente Powers, this involved blocking the western and northern ends of the English Channel. There were however some problems with stopping ships belonging to neutral countries. Historian Mark Frey estimates that Dutch exports to Germany more than doubled between 1914 and 1916, and Dutch foodstuffs amounted to 50% of all German food imports (Frey 2000). For Germany, a blockade of Great Britain involved the use of submarines. In 1915, the Germans announced that any ship entering territory near the British Isles would be subject to attack by German U-boats. The experiment was successful from a military point of view, but the indiscriminate sinking of neutral ships brought forth strong objections from the United States and other neutral countries, and the policy of unrestricted U-boat attacks was rescinded after only a few months. When the Germans reinstated unrestricted submarine warfare in early 1917, U-boats were able to briefly reach a goal of 600,000 tons a month; however, this was not enough to starve the British economy. By the middle of 1918, the allied Navies were able to substantially reduce sinkings through the use of the convoy system to a point where losses from U-Boats no longer threatened food supplies in the United Kingdom.

Was the blockade a major factor in the outcome of the war? Cliometricians Lance Davis and Stanley Engerman presented a cliometric analysis of the German blockade during the First World War and concluded that it "directly accounted for only about a quarter of the decline in German food production. The other three quarters of the fall can be traced to the decline in domestic food production." (Davis and Engerman 2006, 230). The British blockade of Germany was more effective. Historian Albert Ritschl argues that the German reaction to the continuing blockade was an important element in the planning for any future war." (Ritschl 2005, 654–655). Also see, Hardach 1977, 148–150; Davis and Engerman 2006, Chap. 6.

The Chaos of Victory

The treaties that emerged from the Peace Conference in Paris in 1919 paid very little attention to the economic challenges created by the establishment of new national boundaries and governments in Eastern Europe and Russia. The Council of Four had very little interest in a continued involvement with the territories created by the destruction of empires. Britain, France, and the United States substantially reduced the size of their military forces, and they remained at that level until the eve of the

Second World War. The index of military spending also fell dramatically right after the war and did not begin to increase until the mid-1930s.

The British managed to stem the inflationary increase in prices by 1920 and were able to maintain fairly stable prices to 1925. The French elected to pursue a policy that slowed the increase in wartime prices, but they made no attempt to return to the antebellum level of prices. The Austrian and Russian economies eventually collapsed under the weight of hyperinflation by the end of 1917, while the newly created Weimar Republic of Germany inherited a price level four times above the 1913 level and soon found themselves caught up in an explosion of prices that eventually forced the government to revalue the system of currency in 1924. The economic disruption from inflation in every economy after the war, which is depicted in Fig. 4, was a significant factor shaping the political and economic reorganization of the Weimar Republic that emerged in the wake of wartime defeat (Feldman 1997).

Much of the blame for the economic and political problems associated with the economic chaos after the war was initially placed on shortcomings in the Treaty of Versailles. In the summer of 1919, John Maynard Keynes, who had been part of the British delegation to Paris, returned to Britain and wrote a scathing indictment of the treaty and the politicians who framed it. The treaty, according to Keynes, included

> . . . no provisions for the economic rehabilitation of Europe, nothing to make the defeated Central Empires into good neighbors, nothing to stabilize the new States of Europe, nothing to reclaim Russia; nor reached at Paris for restoring the disordered finances of France and Italy, or to adjust the systems of the Old World and the New. (Keynes 1920, 226)

Keynes laid the blame for the shortcomings of the treaty on the narrow attitudes taken by the Council of Four in their deliberations at the Paris Peace Conference. However, the Treaty of Versailles was only the first step in a prolonged process of establishing a peaceful world after 1918. Four additional treaties were signed with the other central powers, and military conflicts involving disputes over borders between the newly formed states of central Europe lasted for another 4 years.[1] Margaret Macmillan points out that the peace makers "could not foresee the future and they certainly could not control it. That was up to their successors. When war came in 1939, it was a result of twenty years of decisions taken or not taken, not of arrangements made in 1919." (MacMillan 2001, 493–494).

By 1925, some semblance of economic stability had returned in the form of stable prices in Germany, France, and Great Britain, but the economic disruptions caused by wartime mobilization had dramatically changed the global marketplace. The antebellum financial stability of world trade had rested on the acceptance of a *gold standard* that was the underlying mechanism for the payment of international credits

[1]The other treaties were: The *Treaty of Saint- Germaine- en- Laye*, signed with Austria on September 10, 1919; The *Treaty of Neuilly- sur Seine* with Bulgaria on November 27, 1919; The *Treaty of Trianon* signed with Hungary on June 4, 1920; and The *Treaty of Sèvres* with the Ottoman Empire on August10, 1920. Also see, Henig 1995; Boemeke et al. 1998; Ransom 2018, Chap. 8).

and debts. Currencies were convertible into gold on demand and linked internationally at fixed rates of exchange. Gold shipments were the ultimate means of balance-of- payments settlement. The demise of the Gold Standard and the resulting instability of exchange rates reflected the loss of confidence and the constant fear of unstable markets. In a world fearful of the unknown, the ties that bound the system of global payments were torn apart.[2] An added element of uncertainty in the international capital markets came from the Allied decision to impose reparation payments upon the defeated Germans. After much deliberation, the amount demanded was set at 132 billion gold marks, which was divided into three "bond issues" over several years. As events played out, the Germans eventually wound up paying only about 20 billion marks. Most economic historians have concluded that that the impact of the reparation payments was more of a political problem than an economic problem (Ferguson 1999; Ritschl 2005; Marks 2013). The reparation payments eventually became a political football that was kicked around the Reichstag and Allied governments until Adolf Hitler repudiated the remaining debt in 1933.

Economic Collapse: The Great Crash

All this economic chaos came to a head with the collapse of stock prices on the New York Stock Exchange on October 29, 1929. Figure 5 presents the monthly index of the closing value of stocks on the New York Stock Exchange from October 1929 to January 1934. The 36-point decline of the stock index on "Black Thursday" 1929 was the beginning of a downward plummet of stock prices that continued for the next 3 years. By July of 1932, the index of stock prices had fallen to only 12.3% of its value in 1929. The decade of the 1930s was a period of falling commodity prices, declining industrial production and gross domestic product, a collapse of world trade, and very high levels of unemployment throughout the world.

The Great Crash had become the Great Depression.

People were still struggling to recover from the chaos of the war when the economic foundations of the global economy crumbled under the pressure of global economic panic. Figure 6 presents four indices that measure the economic performance of the global economy from 1929 to 1938 (Crafts and Fearon 2013b). What is immediately apparent is that all of these indices experienced enormous changes. The index for gross domestic product declined by 15% in 3 years and was only 5% above the 1929 level by the end of the decade. The stagnation of world trade is also evident. The two variables that experienced the greatest fluctuation were the level of employment and the index of consumer prices. After a decade in which the world had

[2]For more on the loss of confidence associated with the problem of exchange rates and the gold standard, see Eichengreen and Temin 1997; Eichengreen 1992; Eichengreen 1991; Ransom 2018; Findlay and O'Rourke 2007, Chap. 3; Wolf 2013.

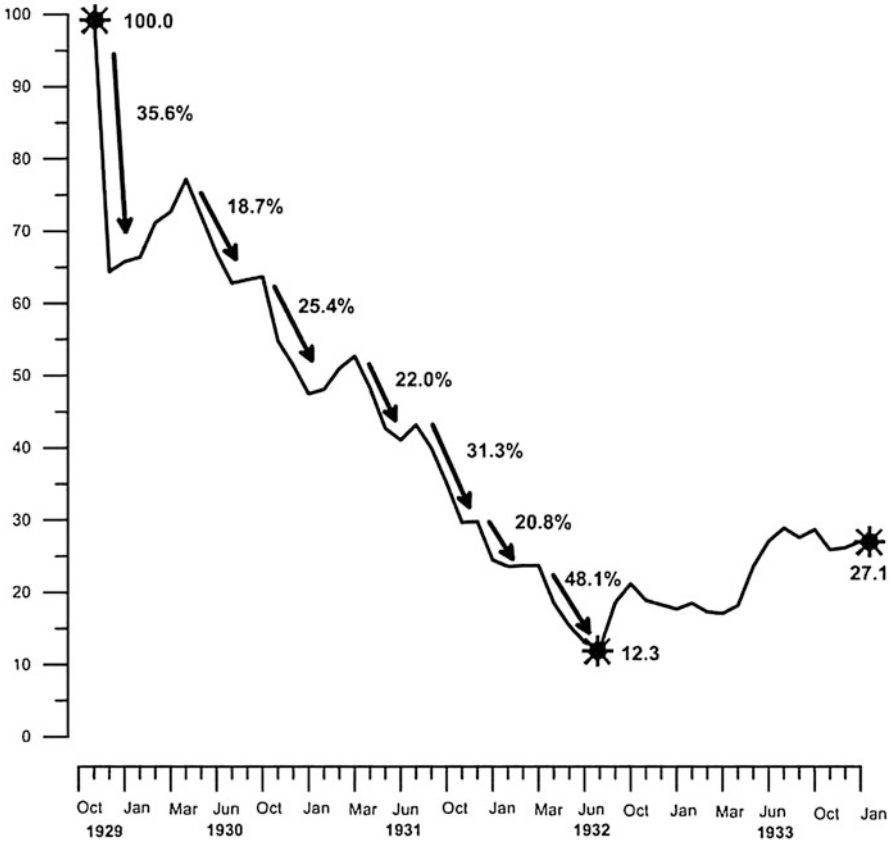

Fig. 5 Average closing value of the New York Times stock index, October 1929–January 1934. (Source: Ransom 1981, 118–19)

experienced runaway inflation, the 1930s saw a 30% decline in prices by 1933. The global index of unemployment reached 30% in 1933 and was still about 15% in 1939.

These phenomena could not be explained by the existing economic theories of how markets were supposed to behave. "Financial instability," economist Hymen Minsky observed, "is a nonevent, something that just cannot happen, insofar as the standard body of today's economic theory is concerned." (Minsky 1982, 13–14). Charles Kindleberger, perhaps the most celebrated chronicler of financial crises, refers to them as "hardy perennials" that are not easily explained. "Econometricians among my friends," he notes, "tell me that rare events such as panics cannot be dealt with by the normal techniques of regression but have to be introduced exogenously as "dummy variables." (Kindleberger 1978, 8).

Faced with a situation where the state of the world did not correspond to the theoretical assumptions of their economic models, economists in the 1930s looked

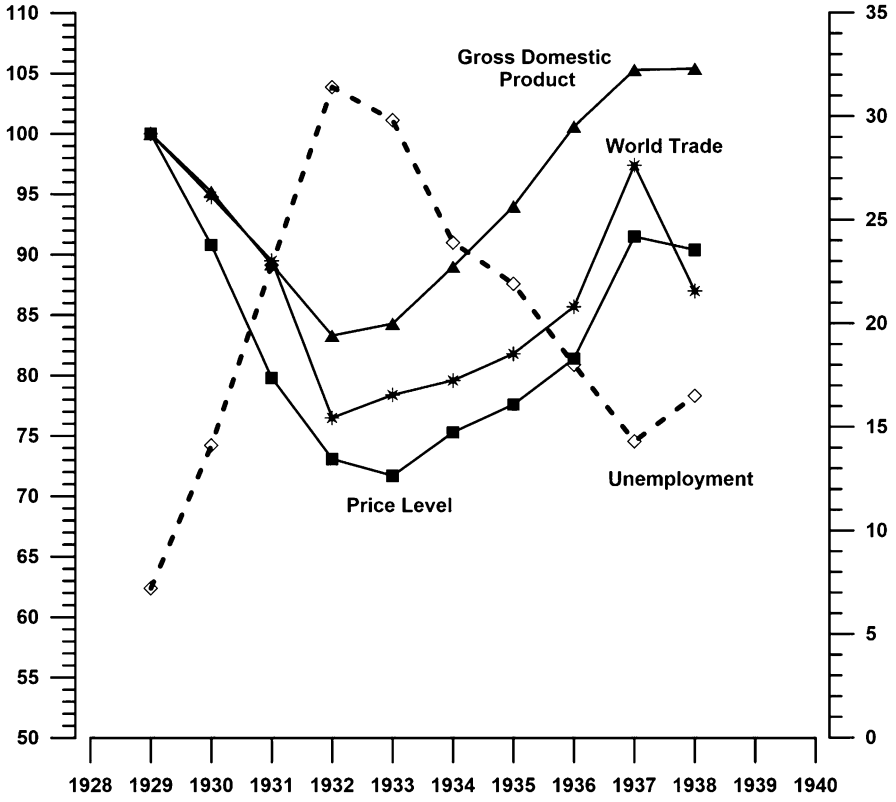

Fig. 6 The Great Depression in Europe, 1929–1939. (Sources: (Crafts and Fearon 2013b, Table 1.1, 1) The authors cite the following sources for each variable: *gross domestic product* (Maddison 2010), Western European and European offshoots; *price level* (Nations 1941) 17 Countries; *unemployment* (Eichengreen and Hatton 1988) 11 countries; and world trade (Maddison 1985) 16 countries.)

for new ways to explain what was happening. In 1936, John Maynard Keynes published *The General Theory of Employment, Interest, and Money* (Keynes 1936). Keynes' macroeconomic approach challenged the existing paradigm of economics markets, which argued that the aggregate level of employment and production would always move towards an equilibrium that guaranteed full employment of resources. Keynes suggested that there would be times when expanding the scope of government spending would be the only effective way of eliminating unemployment.

Keynes's macroeconomic model made it possible to measure the impact that the economic collapse of the 1930s had on the world economy, but by itself, the theoretical framework could not explain the causes of the global economic collapse. Keynes himself admitted as much with his comments at the end of *The General Theory* about the role of "animal spirits" in sparking the boom that led to the Great

Depression. As scholars searched for the key to understanding the Great Depression, they realized that the economic collapse was tied to the political and social changes brought about by the First World War (Crafts and Fearon 2013b; Temin 1981, 1989; Feinstein et al. 2008).

At the root of the problems facing policymakers in the years after 1918 was the inescapable fact that, despite its ferocity, the Great War did little to resolve any of the political issues between the major states of Europe that existed in 1914. The five treaties which emerged from the Peace Conference in Paris in 1920 created a host of new problems in the form of nation states formed from the collapse of German, Austrian, and Russian empires. While there was no resumption of major military conflicts between the larger states of Europe in the interval 1919–1937, there were numerous "border conflicts" and three civil wars, which attracted intervention by third parties at one time or another.

The interwar years were a period when new leaders pursued aggressive policies to maintain or expand their economic and military status in the postwar environment. None of the belligerents were happy with the outcome of the Great War. The British had saved their Empire, but the effort left them with an exhausted economy that would struggle to maintain their economic status as a great power through the next two decades. The French economy was also stretched to the limits of its capacity, and they were fearful that the stipulations of the Versailles Treaty designed to limit Germany's ability to reassert its economic power in central Europe were far too weak. An added element of uncertainty over the next two decades was the frequency with which both Britain and France experienced changes in the government. Italy felt cheated out of their share of the spoils of victory and Italian nationalists claimed this impeded Italy's progress in becoming a "Great Power." In the fractured world of postwar Italian politics, political sentiment moved steadily to the right, culminating with Benito Mussolini's fascist party gaining control of the Italian government in 1925. The Americans showed little interest in European affairs after the war. President Woodrow Wilson was unable to gain support for American participation in the League of Nations and The United States Senate did not approve the Treaty of Versailles. Lacking any previous experience with democratic institutions, and faced with a very uncertain future, postwar governments in the new states moved towards authoritarian rule as the only way to maintain a stable government. By the time the Great Depression had run its course, the only country in central Europe that had managed to maintain democratic institutions was Czechoslovakia.

Russia: The Union of Soviet Socialist Republic

Among the most difficult challenges posed by the chaos after the war were the problems facing the former Russian Empire. In March 1918, the newly formed Bolshevik government had signed the Treaty of Brest-Litovsk with Germany, which ended the fighting between Germany and Russia. The Russians agreed to abandon their claims to Poland, Finland, and the Baltic states, and the Germans continued to occupy part of western Russia that included the Ukraine and Crimea.

The Treaty of Versailles negated this huge transfer of Russian territory to the Germans; however, the territory was not returned to the Russians (Ransom 2018; Herwig 1997; White 1994). The Allied powers did not recognize the Bolshevik government and the Russians were not invited to the Paris Peace Conference in 1919.

Five years of fighting a bitter civil war had produced a command economy in Russia where every aspect of economic activity was tightly controlled by the state. Vladimir Lenin proposed an ambitious set of reforms known as the *New Economic Policy* [NEP]. The strict restrictions on agricultural and industrial prices and production were eased; labor markets were given greater flexibility to accommodate the needs of producers, and individuals could form their own small enterprises. The immediate effect of these changes was a rapid expansion of agricultural output produced on small family farms. However, the industrial sector, which remained largely under the control of the state, experienced only a slight increase in output. The opportunity to form private enterprises created a new group of entrepreneurs – called "NEPmen" – who formed private enterprises in both urban and rural areas (Ball 1987). Lenin regarded the NEP to be a temporary measure that would help shape a Soviet economy that would rely on markets as well as government controls (Fitzpatrick et al. 1991).

On January 21, 1924, the man who masterminded the Bolshevik victory passed away. Vladimir Lenin had been the heart and soul of the Bolshevik victory in the civil war and his death prompted a spirited scramble among the Bolshevik leaders eager to replace him at the head of the Soviet government. The principal contenders were Leon Trotsky, who was the man that Lenin would probably have chosen to be his successor, and Joseph Stalin, who was the general secretary of the Communist Party. Stalin was able to use his political position to eventually emerge as the head of the Soviet government (Kotkin 2014; Service 2006).

Stalin had originally been a strong supporter of Lenin's NEP; however, the two men gradually drifted apart as Stalin become convinced that even the limited role of market capitalism that was embedded in Lenin's NEP was not well suited for the Soviet Union in a world where all of the major powers were likely to be hostile to the Soviet Union. While Lenin had hoped to integrate the Soviet Union in the global economy, Stalin envisioned a centralized command economy characterized by what he called "Socialism in One Country." His primary objective was to provide the economic basis for a military machine to defend the socialist state.

Economic historians have devoted considerable effort to the development of quantitative estimates of economic variables in the Soviet Union in the interwar period. Figure 7 provides data relating to the growth of population and gross national product from 1928 through 1938. There was virtually no growth in either GDP or population before 1932. Stalin's attempt to reorganize agriculture by collectivized farms was an economic disaster that produced a food crisis that reached the level of a famine in many rural areas during the 1930s (Davies 1980; Davies and Wheatcroft 2004). From a global perspective, the main effect of these policies was to isolate the Soviet Union from the economic and political tensions that were sweeping through Western and Central Europe (Davies 1989; Davies

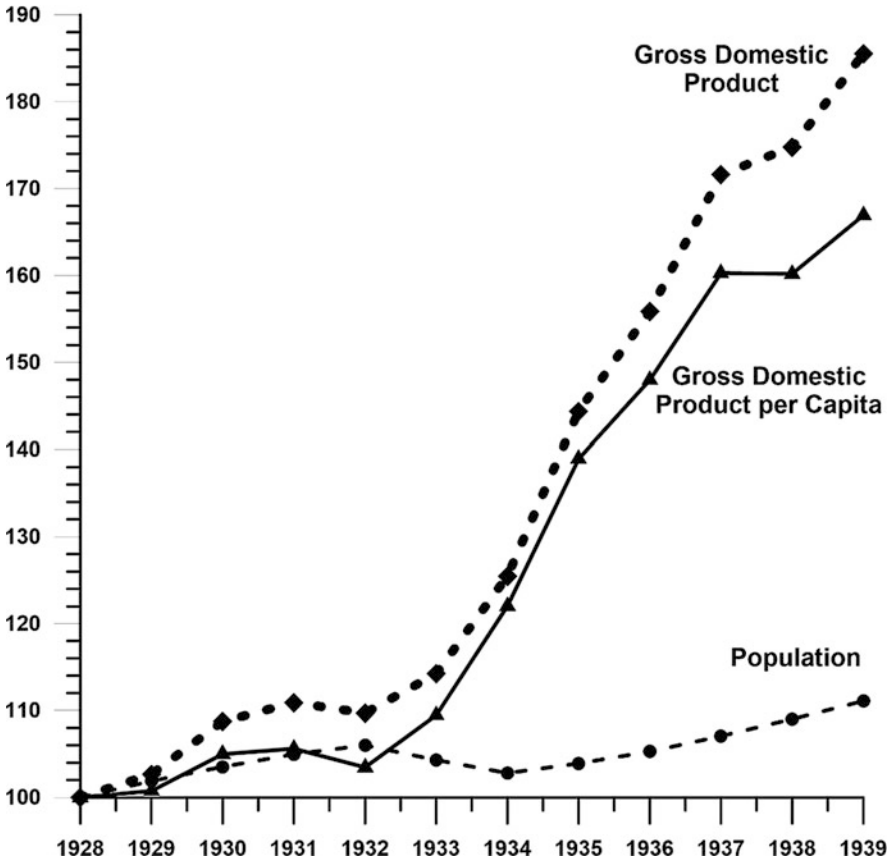

Fig. 7 Gross domestic product and population of the Soviet Union, 1928–1939. (Source: Davies et al. 2018, Table 1, p. 29.)

et al. 2018). For Stalin, all of the other powers were potential enemies by 1937. He was determined that the Soviet Union would be ready wherever the next blow might fall.

Germany: The Rise of the Nazi Party

By 1929, the Weimar Republic had managed to establish some degree of economic stability; however, the political situation remained unsettled. In November 1923, a group of Nationalist Socialist Party members, led by Adolf Hitler, staged an unsuccessful effort in Munich to gain control of the Bavarian government. Hitler and several of his followers were sentenced to 3 years in Landsberg Prison. Hitler made good use of his prison time, spending several hours of each day dictating notes to a

colleague, for a book that was published in 1925 and 1926 (Hitler 1936). In the summer of 1928, Hitler wrote a second manuscript that was apparently intended as a sequel to *Mein Kampf*. The existence of this manuscript, which was not found until 1958, was published in 1961 (Hitler 1961). Hitler's thoughts present a blueprint for the policies which he would implement if he were ever to gain power. At the center of those plans was the need to expand Germany's boundaries to include populations that Hitler regarded as "German." The borders of Bismarck's Reich, according to Hitler, "encompassed only a part of the German nation." The pre-1914 borders, Hitler insisted, "ran straight across German language areas, and even through parts which, at least formerly, had belonged to the German Union, even if in an informal way." (Hitler 1961, 48–49). Hitler intended to see that the German state reclaimed these areas. "No foreign policy aim," he wrote, "could have been more obvious for the strictly formal national state of that time than the annexation of those German areas in Europe which, partly through their former history, had to be an obvious part not only of the German nation but of a German Reich." (Hitler 1961, 56).

The global economic collapse of 1929 had a devastating effect on the German economy. Between 1929 and 1932, gross domestic product fell by 25% and unemployment reached 31% (Crafts and Fearon 2013a, 3). The economic crisis was accompanied by a collapse of the political coalitions in the Reichstag. The Nazi party emerged from the 1932 federal election with 230 seats, which was more than any other party, but not enough to form a government. Paul von Hindenburg defeated Hitler in the presidential elections of 1932, but he was unable to form a government that did not include the Nazis. Eventually, the president realized he had no other choice than to appoint Adolf Hitler as Chancellor of Germany. By the end of July 1933, Hitler had effectively taken control of the German government (Fischer 1995; Abelshauer 1998). As soon as he became Chancellor, Hitler began to expand expenditures of the German government. Figure 8 presents data on German government expenditures between 1932 and 1938. In 1932, government spending was 1.4% of gross domestic product; by 1938, it had grown to 19%. Military expenditures grew from about one-fourth of the total budget to just under three-quarters of all government expenditures.

In January 1935 voters, in the Saar region of Germany, which had been occupied and governed by the United Kingdom and France from 1920 to 1935 under a League of Nations mandate, voted overwhelmingly to return to German control. A year later, German troops marched into the Rhineland without meeting any opposition. Hitler's next target for expansion of the Reich was the German population of Austria. When his initial plan to set up a pro-Nazi government in Austria did not work out, German troops crossed the border into Austria and were warmly greeted by the Austrians. Hitler proclaimed an *Anschluss* which was approved by the Reichstag on March 13 and ratified by a plebiscite on April 10, 1938. There were 3.2 million Germans who lived in the Sudetenland – a region in the western part of Czechoslovakia – which Hitler claimed should be "returned" to Germany. Although the Czech Government was strongly opposed to having them unified into Germany, none of the Western Powers were prepared to challenge Hitler's claim. Benito Mussolini encouraged Hitler to host a Conference just outside Munich on September 30, 1938, to

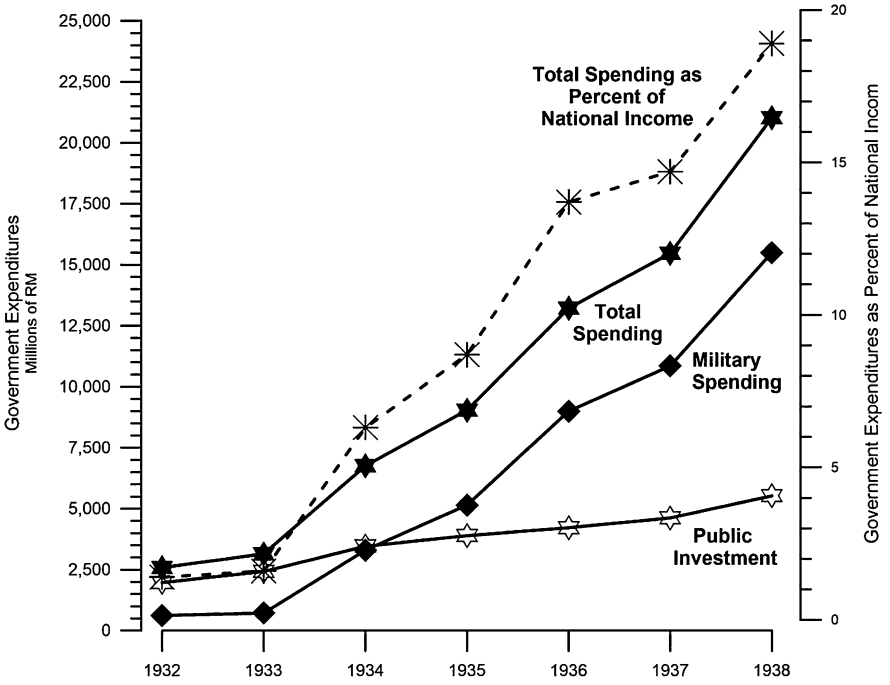

Fig. 8 German government expenditures, 1932–1938. (Source: Abelshauer 1998)

determine the fate of the Sudetenland Germans. The result was an agreement signed by Mussolini, Hitler, Neville Chamberlain of Britain, and Eduoard Daladier of France that the Germans would occupy the Sudetenland. In effect, the agreement allowed Hitler to control all of Czechoslovakia (Weinberg 1995, Chaps. 8 and 9, Ferguson 2006).

Hitler now turned his attention to the Germans living in Poland. Stalin was not likely to quietly watch Germany gobble up all of Poland, so Hitler sent his foreign secretary – Joachim von Ribbentrop – to Moscow to work out a "nonaggression pact" with the Soviets that included a secret agreement to divide Poland. On September 1, 1939, the German troops invaded Poland. This time Britain and France both declared war on Germany.

The Second World War had begun.

Japan: The Empire of the Rising Sun

While the Germans and the Russians were rebuilding their countries after the war, another empire was emerging halfway around the world. The Japanese had been isolated from the rest of the world until the middle of the nineteenth century when a series of visits to Tokyo Bay by the American Admiral Mathew Perry forced them to

open their economy to the world of international trade. In 1868, a group of younger nobles and samurai staged a rebellion that placed a 16-year-old Emperor in charge of the government. Despite their fears of foreign intervention, the leaders of the Meiji Restoration were quickly drawn into the international marketplace. Figure 9 provides data on the Japanese gross domestic product and foreign trade from 1875 to 1940. The index of trade – measured here as the sum of exports and imports – provided a wide range of goods, services, and raw materials. The Japanese economy experienced a steady growth in GDP rate of about 2.5% per year in the years leading up to World War I. International trade was an important part of that growth up to World War I, and then became highly volatile in the two decades after the war.

The Meiji government was willing to use military force to expand their influence in Manchuria, Korea, China, and Taiwan. In 1895, the first Sino Japanese war ended with the Treaty of Shimonoseki. The Chinese were forced to grant the Japanese favorable treaty status similar to that accorded the European powers, and Taiwan became a Japanese province (Paine 2003, 2017). In 1904, Japan declared war against

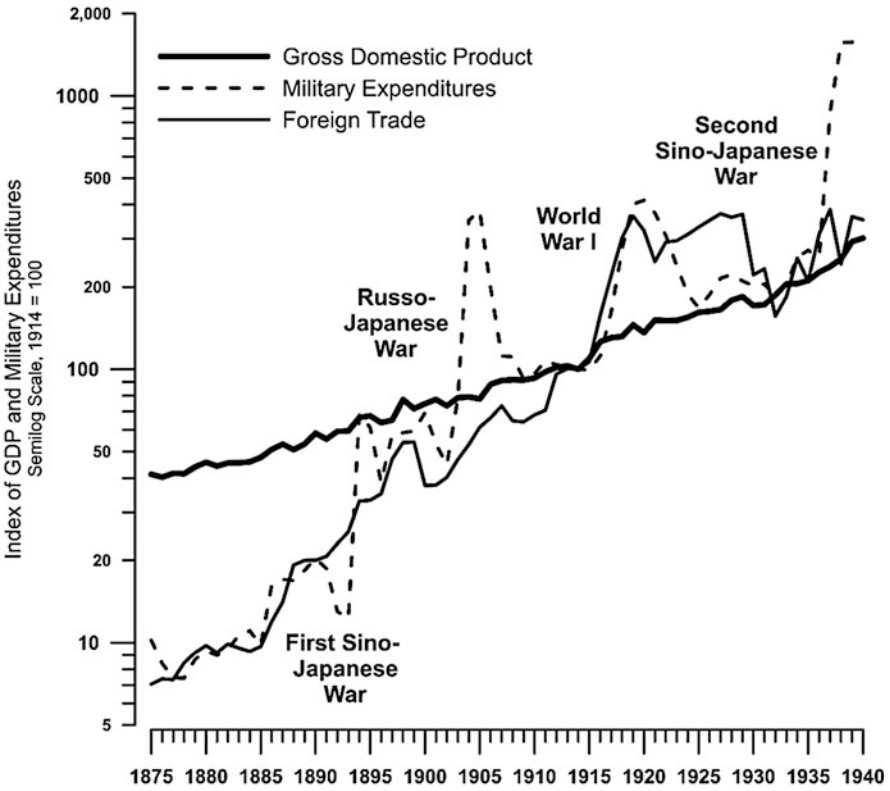

Fig. 9 Japanese gross domestic product, foreign trade, and military expenditures, 1874–1940. (Sources: Gross national product (Maddison 2010); military expenditures (Correlates of War Project 2010).)

Russia to settle a territorial dispute over Manchuria. The war ended in 1905 with a settlement negotiated by American President Teddy Roosevelt (Jukes 2002; Ransom 2018). The Japanese could have stayed neutral in the First World War, but Prime Minister Okuma Shigenobu saw the European war as an opportunity for Japan to further increase its Pacific Empire. Japan declared war on Germany in August of 1914 and proceeded to seize the German naval installation at Tsingtao and the German colonial possessions in the Marshall Islands. By the end of the war, Japan had managed to collect the nucleus of a colonial Empire in Asia. The dramatic impact that each of these wars had on Japanese military expenditures is evident in Fig. 9.

Official Japanese policy throughout the 1920s was to stay out of Chinese affairs; however, they had few qualms about interfering with events in Manchuria. When disagreements between the Kuomintang Party of Chaing Kai-shek and the Communist Party of Mao Zedong erupted into a civil war, the Japanese saw their opportunity to take control of Manchuria. On September 10, 1931, a group of junior army officers staged a minor explosion along the South Manchuria Railway which they blamed on Chinese forces. The "Mukden Incident" served as an excuse for the Japanese Army to occupy the town of Mukden. The generals quickly discovered that the Chinese were not in a position to oppose further Japanese advances, and within several months, the Japanese army occupied all of Manchuria. In February 1932, the Japanese government established Manchukuo as an independent state. By the end of 1937, invading Japanese troops occupied the eastern coast of China (Taylor 2015).

Italy: Too Small to Be a Major Power

Benito Mussolini came to power in 1922 with the promise that he would restore Italy to its former glories. The cornerstone of Mussolini's plan to return Italy to its former glories was the expansion of Italy's colonial foothold in North Africa. In October 1935, the Italians invaded Ethiopia, and they eventually succeeded in subjugating the African nation by the fall of 1936. Adolf Hitler's support for Mussolini's actions in Africa, together with their shared objective of undermining the Treaty of Versailles and expanding their territories provided the basis for what would gradually become a very close military and economic alliance. When Hitler became Chancellor of Germany in 1932, the two countries signed the *Pact of Steel*, an agreement between Fascist Italy and Nazi Germany that eventually led to the creation of the Axis Powers of World War II.

All of this took place in the context of an Italian economy that had been stretched to the limit by their efforts in Ethiopia and Mussolini's support for Francisco Franco's efforts in the Spanish Civil War. Figure 10 presents data on Italian gross domestic product and foreign trade (measured as the sum of imports and exports). GDP was stable through the period 1929 through 1938; however, the index of imports and exports fell dramatically after the great crash and did not recover over the course of the next decade. Vera Zamagni argues that the loss of imports created serious problems in obtaining strategic raw materials – particularly liquid fuels – during the war (Zamagni 1998, 187–88, Table 5.6). Figure 10 also shows that

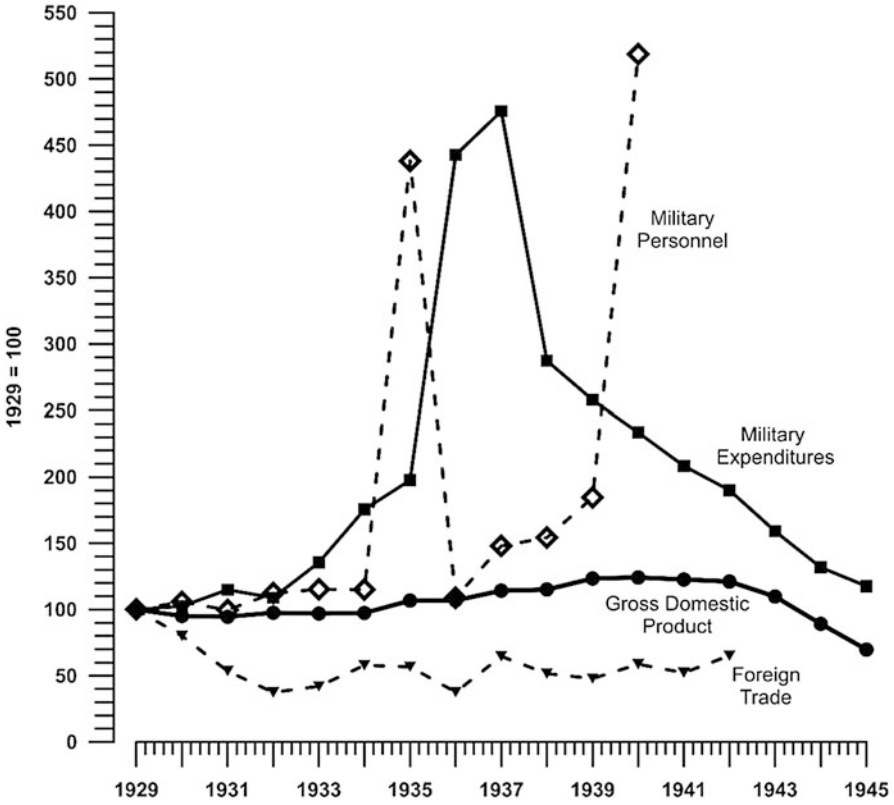

Fig. 10 Indices of gross domestic product, foreign trade, and military personnel and expenditures for Italy, 1929–1945, 1929 = 100. (Sources: Gross domestic product (Maddison 2006); foreign trade, military expenditures, and military personnel (Correlates of War Project 2010).)

military expenditures rose sharply after 1932, and the impact of the Ethiopian and Spanish military adventures is evident in the explosion of military expenditures and personnel in 1935–1937.

Mussolini had one more territorial ambition. Having expanded his colonial holdings in North Africa with the acquisition of Ethiopia, he now shifted his focus on a plan to seize the Suez Canal. In the spring of 1940, Italian troops launched a series of attacks against the British forces in Egypt (Ferris and Mawdsley 2015a; Clodfelter 2002). Looking at the Italian war effort, Vera Zamagni concludes that "If one includes human losses, it is beyond doubt that World War II cost Italy less than World War I, and far less than many other combatants. The Italian economy was unable to engineer any sizable economic expansion during the war." (Zamagni 1998, 212). Simply put, Italy could not afford the Second World War. When the Allied forces successfully invaded Sicily in July 1943, Mussolini's government was overthrown, and a puppet government controlled by Nazis used German troops and continued the fight against the Allied forces in Italy (Moseley 2006).

Blitzkrieg: A New Form of War

In the Spring of 1940, the world was once again on the verge of a World War. The Japanese had already been fighting in China for 2 years. The Germans and the Soviet Union had dealt with the Poland issue, and Hitler was preparing to invade France. It is tempting to say that this was all just a continuation of the Great War of 1914–1918. The same countries were involved in both wars, and at least for Western Europe, the story seems very familiar. But 20 years of political and economic disruption together with new leadership and new technology for fighting wars had produced a very different scenario by 1940. In 1914, the great powers had stumbled into a war they did not want. In 1939, there were three countries – Germany, Japan, and Italy – who were consciously pursuing policies which they knew would eventually escalate into major wars.

The major battles in the First World War had been characterized by prolonged periods of furious fighting that ended without either side being able to claim a victory. Examples include Verdun (1916), the Somme (1916), Passchendaele (1917), and the Ludendorff offensives (1918) on the Western Front; Gallipoli (1915) in the Middle East; and the Brusilov Offensives (1916) on the Eastern Front. All of these battles were titanic struggles involving thousands of casualties, yet none of them created a significant turning point that changed the outcome of the war. World War I was a war of attrition that not only produced horrendous casualties but it also consumed economic resources at a prodigious rate. In the end, it was the economic collapse of the Central Powers, not adverse military outcomes, that forced them to ask for a cease fire (Ransom 2018, Chaps. 7 and 8).

The Second World War, by contrast, was a war of motion and battles whose outcomes fundamentally altered the course of the war. The Blitzkrieg tactics of the German army combined armored vehicles and infantry in Panzer Divisions that historian Karl Heinz Frieser argues "caused a revolution in the image of war in comparison to battles of attrition of the first world war. The principle of physical or not annihilation was replaced by the principle of psychological confusion." (Frieser 2015, 351). In May of 1940, the German Army marched through Belgium and Holland and invaded France. The British BEF was pinned against the English Channel at Dunkirk, where they managed to evacuate over 300,000 men but lost almost all of their equipment and vehicles. The French army collapsed in the face of the German offensive to the South, and on June 22, 1940, an armistice was signed by France and Germany at Compiegne in the same railroad car used for the German surrender to the Allied Powers in 1918. The north and west coasts of France and their hinterlands were occupied by the Germans. What remained of the Third Republic was replaced by a government headed by Philippe Petain, who cooperated with the Nazis. In the space of 6 weeks, Hitler and his generals had managed to accomplish what 5 years of bloody fighting on the Western Front had failed to accomplish 20 years earlier, and they did so at a surprisingly low price.

By the end of 1941, the Third Reich controlled territory from the western coast of occupied France to the Soviet border in Poland. Table 1 summarizes the territorial

gains to the German Reich from the Anschluss with Austria in 1938 to the invasion of Greece and Yugoslavia in April 1941. In addition to the areas occupied by German troops, three countries – Bulgaria, Romania, and Hungary – allied themselves with the Nazi regime. Including the three allies in the Balkans, the Third Reich had increased its territory from 470,000 square miles in 1938 to 2.5 million square miles in 1941, together with a doubling of the population.

Hitler had hoped that Britain would leave the war after the defeat of France. Instead, Winston Churchill stood defiantly in the House of Commons declaring that Britain would fight on. Hitler and his generals had made no plans for an invasion of Great Britain, and it soon became clear that the British Fleet and the Royal Air Force [RAF] made the success of such a venture doubtful at best. Herrmann Goering insisted that the Luftwaffe could force Britain out of the war by air attacks. The "Battle of Britain" commenced in early July, and by August, German air raids were having an effect on the British defenses. However, the *Luftwaffe* could not sustain the level of losses it was incurring, and Hitler and Goering decided to switch the focus of German raids away from the RAF bases to bomber attacks on major cities – particularly London. By the beginning of October, it was apparent that the air attacks could punish the British, but

they were still in the war. Hitler cancelled Operation Sea Lion in September of 1940 (Ferris and Mawdsley 2015b).

In September 1940, Germany, Japan, and Italy signed the *Tripartite Pact,* which was the last in a series of treaties and agreements that formed the Axis Powers.[3] Hitler hoped that linking the military aims of the three countries would facilitate his plans for German expansion. As things turned out, his new partners proved to be a mixed blessing. The Japanese were preoccupied with a major war in China and unable to offer the Germans any immediate assistance against the Soviet Union. Mussolini hoped to drive the British out of Egypt; however, by the end of February, the Italians had been driven west all the way to Tobruk, and Hitler was forced to come to his ally's rescue. In March of 1941, he dispatched Erwin Rommel in command of the *Afrika Corps* to stabilize the situation there. Rommel was able to drive the British back into Egypt by the end of the fall campaign.

While the Germans were taking control of Europe, the Japanese were expanding their Empire in Asia. By the end of 1941, Japanese forces occupied all of the major cities along the eastern coast of China from Manchuria to Indo-China (Van De Ven 2015). The United States and Britain vigorously objected to the Japanese aggression, but there was not much they could do to check the Japanese military advance in China. In August 1940, Japanese Foreign Minister Matsuoka Yosuke announced the creation of the *Greater East Asia Co-Prosperity Sphere* [GEACS]. This was put forward as a coalition of governments in Japan, Manchukuo, and China that would eventually lead to the construction of a new order in Greater East Asia. A major force behind the creation of the GEACS was the need for the Japanese to secure access to natural resources such as oil and raw materials that were an essential part of the Japanese military-industrial complex. The United States had been a major supplier of scrap iron and petroleum products, and American financial institutions controlled the payments for Japanese international trade. On July 25, 1941, President Roosevelt issued an executive order freezing all Japanese assets in the United States and placing an embargo on oil and gasoline exports to Japan. The effect of the President's order was dramatic. The Japanese were gripped by a paranoia, which convinced them that the United States would the able to choke off the resources Japan needed to survive (Miller 2007). The American economic sanctions gave added credence to those in Japan who believed that a war against the United States was the only way for Japan to accomplish its aims for an Empire in Asia. Neither the Americans nor the British military forces were in a position to seriously intervene with the battles in China. The only real threat to the Japanese military aggressions in China or Southeast Asia was the American Navy. Plans were already underway for an IJN strike against Pearl Harbor.

[3]Hungary (November 1940), Bulgaria (March 1941), and Romania (November 1941) subsequently joined the Tripartite Agreement.

Barbarossa: The German Invasion of Russia

On the eve of his greatest gamble, Hitler wrote a letter to Benito Mussolini explaining why the invasion of the Soviet Union was necessary. The elimination of the Russians, he assured Mussolini, would not only provide security in the east for Germany and Italy; it would also represent "a tremendous relief for Japan in East Asia, and thereby the possibility of a much stronger threat to American activities through Japanese intervention." (Hitler 1941).

At 3:00 am on the morning of June 22, 1941, the massed German guns along a 1,800-mile front in western Russia erupted with terrifying fury. Operation Barbarossa, the German invasion of the Soviet Union, was underway. The invasion consisted of three army groups. Army Group North had as its objective the capture of Leningrad. Army Group Center, which was the largest of the three armies, had as its objective the city of Moscow. Army Group South was aimed at the city of Kiev and the oil fields of the Caucasus.

Despite warnings from the British and his own intelligence people that the Germans were planning an attack on the Soviet Union, Stalin was taken completely by surprise. By the end of September, the front lines stretched in a fairly straight line from Lake Ladoga in the North to the top of the Crimean Peninsula in the South. German forces occupied a huge part of the Soviet Union, but they had not yet captured either Leningrad or Moscow. Summer was coming to a halt, and the Red Army, though severely battered, was still in the field (Glantz 2012). In October, the first rains complicated army maneuvers for both sides, and the situation would get worse as fall turned into winter. Operation Typhoon, the final push organized to capture Moscow before the winter weather struck, was launched at the beginning of October. The Germans managed to encircle three Soviet armies within 2 weeks, and the spires of Moscow were in the sights of advance units by the beginning of December. But the Soviet line held fast. The German drive on Moscow had been halted.[4]

Every historian's account of Operation Barbarossa mentions the Russian winter as a significant factor in the German failure to occupy Moscow at the end of 1941. However, the weather affected both sides. The huge Soviet casualties and the rapid advance of the German forces in the summer months tend to overshadow the extent to which the Germans casualty rates were also huge, and Germany was not able to absorb these losses without moving troops from some other front. The Russians, by contrast were able to bring fresh divisions from Siberia along with newly developed rocket launchers and T-34 Tanks (Clodfelter 2002). Stalin's emphasis on developing the Soviet military-industrial complex in the late 1930s was paying huge dividends. In 1941, the Russians were already out-producing the German economy in terms of tanks (Mawdsley 2009).

[4]The account of the German invasion of Russia in 1941 draws on: Nagorski 2007; Weinberg 1995, Chap. 5, 1994, Stone 2015; Citino 1987, Chap. 1, Clodfelter 2002; Glantz 2012.

What all this meant was that the momentum of the battle for Moscow had shifted dramatically in favor of the Soviets. On December 5 and 6, the Russians launched a major counteroffensive that pushed the *Wehrmacht* back to their November positions. For the moment, at least, the Soviet Capital had been saved, and on December 8, Hitler issued a directive ordering his overextended units hold their positions at all costs. Looking ahead to the spring, Hitler and his generals were confronted with a difficult choice. Should they reinforce the troops in front of Moscow to make a final effort to take the city, or should they redirect their efforts towards the successes they had enjoyed in the South.

Either option involved another risky gamble, but they had to do something.

Tora, Tora, Tora: The Japanese Attack on Pearl Harbor

While the Germans were struggling to capture Moscow, the Japanese had their ambitions focused on Southeast Asia. Following the outbreak of the war in China in 1937, relations between the United States and Japan grew steadily worse. Isoroku Yamamoto, the commander in chief of the IJN, was working on a plan to protect the Japanese forces in Southeast Asia from the American intervention. The existing plan was that the IJN would sit behind a screen of islands in the Western Pacific and lure the Americans into a huge defensive battle. Yamamoto argued that this would not protect the forces in Southeast Asia. "The presence of the US fleet in Hawaii," he pointed out, "is a dagger pointed at our throats. Should war be declared the length and breadth of our southern operation would immediately be exposed to serious threat orders point" (Potter 1967, 84). In August 1940, when Yamamoto presented his plan to have the IJN attack the American fleet at Pearl Harbor to the Naval High Command, the idea was not well-received. However, Yamamoto's arguments that the IJN must take the offensive received a boost from the course of diplomatic and economic events. Back in Washington, Secretary of State Cordell Hull and President Roosevelt continued to tighten the embargo against American exports to Japan. Dwindling supplies of gasoline and oil were becoming critical, and in early November, Hideki Tojo presented Yamamoto's plan to the Emperor for the first time. On November 5, before the Emperor had even heard of the plan, Yamamoto was making preparations for the "Combined Fleet" (as the Pearl Harbor task force was called) to rendezvous at Tankan Bay, a remote spot in the Kurile Islands, to refuel and prepare to launch an attack on Hawaii. By the time Hirohito had signed the order authorizing the attack, the IJN carrier force had already set sail for its target (Kuehn 2015; Prange 1981, Part I).

It was an impressive armada: a total of 31 ships in all, including six carriers, two battleships, two heavy cruisers, and nine of the navy's newest destroyers. What the Japanese Navy had created with their combined fleet task force was equivalent to what the Germans had created with their Panzer Corps on land: a naval strike force with offensive power that was unmatched by any fleet in the world. While diplomats on both sides debated with each other in an effort to gain their concessions, the carriers sped through the North Pacific. Only a handful of men in the IJN knew the

full scope of the plan; even Prime Minister Tojo had been briefed on only the most general aspects of the plan. At 6 o'clock on the morning of December 7, 1941, 183 aircraft took off from the Japanese carriers situated 230 miles north of Oahu and headed for Pearl Harbor, guided by the signal of a radio station in Honolulu. In the space of 2 h, Pearl Harbor was turned into a burning inferno. The Japanese lost 55 airmen in the attack; the Americans lost 10 times that number of personnel along with 8 battleships; 3 cruisers, and 3 destroyers either sunk or damaged, and more than half the 231 planes stationed at the base damaged beyond repair.

The Pacific War between the United States and Japan had begun. While it has generally been regarded as a masterpiece of military planning and a skillful tactical blow against the Americans, "Pearl Harbor," as John Keegan noted, "was no Trafalgar" (Keegan 1989, 255). It was certainly a "wake-up" call that brought the Americans into a war they otherwise seemed determined to avoid – and in which Japan was not likely to win once it was started. The most serious shortcoming of the raid was that none of the American aircraft carriers were docked at Pearl Harbor – which meant that the US navy still had the potential to disrupt Japanese plans in Southeast Asia. Yamamoto would have to come up with another plan to destroy the American Fleet (Prange 1981).

The End of the Beginning: Midway and Stalingrad

Yamamoto's Pearl Harbor gamble did pay significant dividends for the Japanese Army's efforts in Southeast Asia. By the end of April 1942, the Japanese had effectively taken over the British, Dutch, and American colonies in Southeast Asia. All of this was accomplished without the loss of a single fleet carrier, battleship, or heavy cruiser. Despite the shortcomings of the Pearl Harbor raid, the attack on Pearl Harbor meant that the American Fleet was not in a position to quickly interfere with Japanese moves in Southeast Asia. Japan's control now extended as far south as Australia, eastward across Northern New Guinea to the Solomon Islands.

The Japanese high command had several options at this point. One possibility would be to return to the original plan put forward by the IJN in 1940 and build a powerful defensive perimeter to the east of the newly conquered areas in Southeast Asia. As they had during the arguments over Pearl Harbor, proponents of this strategy favored letting the American fleet come west so that the Japanese fleet could engage the enemy in home waters. Once again, Yamamoto's challenge was to convince his peers that the IJN could not sit still and wait for the Americans to come after them. Pearl Harbor had seemingly taken America out of picture, and the naval operations in the waters of Southeast Asia and the Indian Ocean had neutralized the fleets of the other imperial powers. The successes of the Japanese Army in February and March of 1942 meant that the land operations in China had reached a point where further advances would not yield major gains. This meant that the Army was looking to the South for its next move – a proposal that the Navy was quite content to go along with, since the area just north of Australia and eastward along the Solomon Islands was at that moment the weakest link in the defensive perimeter.

The plan that eventually emerged from these considerations was a joint naval and army operation whose principal objective was the capture of Port Moresby, New Guinea, and the fortification of strongholds in the Solomons The Americans hoped to block the Japanese threat to Port Moresby. The result of this action was the battle of the Coral Sea, a naval battle in which the ships engaged were never within sight of each other because the attacks were carried out entirely by aircraft. On paper, it would appear that the Japanese had the better of it at the Battle of Coral Sea. They had one fleet carrier damaged and lost an escort carrier. The Americans lost their biggest carrier and had another carrier seriously damaged. Yet most historians have concluded that it was the Americans who gained the greatest strategic advantages from the battle. The Japanese called off the invasion of Port Moresby, which disrupted their plans to reinforce the defenses in the Southern area of their newly created empire.

The Japanese decision to retreat represented the first significant check to the Japanese army in the south pacific. Although the Japanese still maintained the initiative in the Pacific war, the Battle of the Coral Sea was the first small step leading to the Americans taking the initiative. Yamamoto wanted to draw the Americans into a major fleet action where the superiority of the IJN carriers would overwhelm and destroy the American carriers. The IJN assembled a task force, which included four of the six aircraft carriers in the Japanese Navy. Unbeknownst to the Japanese, American code breakers had succeeded in breaking the Japanese naval codes to the point where they could read virtually all the Japanese messages. With the element of surprise on his side, USN admiral Chester Nimitz committed all three of his fleet carriers to attack the Japanese fleet approaching Wake Island, Nimitz' plan was simple; the Americans would position their forces north and slightly east of Midway and wait for the Japanese to arrive. It was Yamamoto and the IJN, not the USN, who were sailing into a trap.

The most significant sea battle of the Second World War began just as the sun rose on the morning of June 5, and it had run its course by the time the sun had set that evening. Both sides were caught up in a desperate combat in which neither side could see what the other was doing – and indeed for most of the battle, they did not even know where their foes were. Each side sent planes to find and destroy the enemy, with limited success. Then in a stroke of luck, two squadrons of dive bombers from *USS Yorktown* found the Japanese fleet in the process of preparing planes for an attack on Midway. In less than 15 min, the American planes managed to destroy one half of the enemy's aircraft carriers together with a large share of its airplanes. By the morning of June 6 the full extent of the carnage was apparent to both sides. The Japanese had lost all four of their fleet carriers together with more than 250 planes. They had lost over 3,000 men – including 250 of the elite *Kidō Butai* pilot corps. The Americans lost 1 fleet carrier, 100 planes, and 300 men killed in action (Parshall and Tully 1962; Thomas 2006).

The Battle of Midway was one of the most decisive victories in naval history. The Japanese lost four aircraft carriers that could not be replaced. Even under the best of circumstances, any new ships would not be ready in time to counter the growing might of the USN. In contrast to this bleak situation facing the IJN, the United States

already had six new Essex-class fleet carriers under construction at the time of the battle of Midway – four of which would be in service by the end of 1942. Until Midway, the Japanese had been able to trade carrier losses with the USN without losing parity in the number of fleet carriers available for action. After Midway, the United States lost only two carriers from enemy action for the rest of the war. There would be more naval battles in the coming months, but the eventual outcome of the naval war in the Pacific was no longer in doubt. The ability of the Americans to continue to expand their fleet while systematically destroying IJN forces led to the eventual defeat of the Japanese forces. The strength of the American economy would determine the outcome of the war.

While the Japanese struggled to hold on to the southern limits of their empire in Asia, the Germans were considering their options in Russia. As they assessed their situation, Hitler decided not to continue the battle around Moscow. A new strategy, *Operation Blue*, had German forces push southward towards the Oilfields at Maikop and Stavropol and then move south along the Donetz Corridor toward Stalingrad. The economic arguments behind Operation Blue made a great deal of sense. Both the German and the Soviet economies needed the oil from the Caucuses. It was, however, a very ambitious plan considering the circumstances confronting German troops in the Soviet Union at the beginning of 1942. The *Wehrmacht* was an understaffed, banged-up army that was only a shell of the finely tuned machine that had raced into Russia the previous summer. Bolstered by more than 50 divisions of Italian, Hungarian, and Romanian units from the Adriatic, the German forces pushed their territorial gains eastward to the Don River and as far south as Stalingrad and the Caucasus Mountains. By the end of summer 1942, the limits of German territory in the Soviet Union ran in an irregular arc from the outskirts of Leningrad southward to a front just west of Moscow, south to Voronozeh, and the west bank of the Don at Stalingrad. It looked as if Hitler might still be able win his great gamble of June 1941. If his armies could anchor the southern end of the eastern from by capturing the city of Stalingrad, Hitler believed he could complete the conquest of the Soviet Union by finishing the attacks on Leningrad and Moscow. (Weinberg 2015).

General Friedrich Von Paulus' sixth army reached the city limits of Stalingrad at the end of August 1942. Slowly but surely the Germans forced themselves further into the city until, on November 11, von Paulus mounted a final assault that actually got to the river. That would be as far as they would get. The Germans were exhausted, and the Russians had finally regrouped enough to mount a massive counterattack. On November 23, the Soviet armies linked up west of the city and more than a quarter of a million German soldiers were trapped in the resulting "pocket." On February 2, 1943, von Paulus surrendered his troops.

Stalingrad was a huge victory for the Soviets. The cost of the battle for both sides totaled more than 750,000 men, including prisoners. In addition to the losses inflicted on the Germans, the surrender of an entire army was a huge psychological blow to the Nazis and had an equally large positive effect on Soviet morale. In addition to relieving the pressure on Stalingrad, the Russian offensive forced the Germans to abandon the Caucuses – which had initially been the main focus of the summer offensives.

The tide of war had inexorably turned against the Axis Powers.

The Economics of the Second World War

If there was one lesson that generals, politicians, and planners learned from the experience of the First World War, it was that waging war was an economic as well as a military challenge. Economic historians have compiled an abundance of economic data documenting the economic performance of the major powers. A cliometric picture of the war closely mirrors the military events outlined above. Figures 11 and 12 present data on gross domestic product and military manpower of the major powers during the war. The data show that for the first 2 years of the war, the military successes enjoyed by the Axis Powers provided economic resources that substantially exceeded those of the Allied Powers. However, when

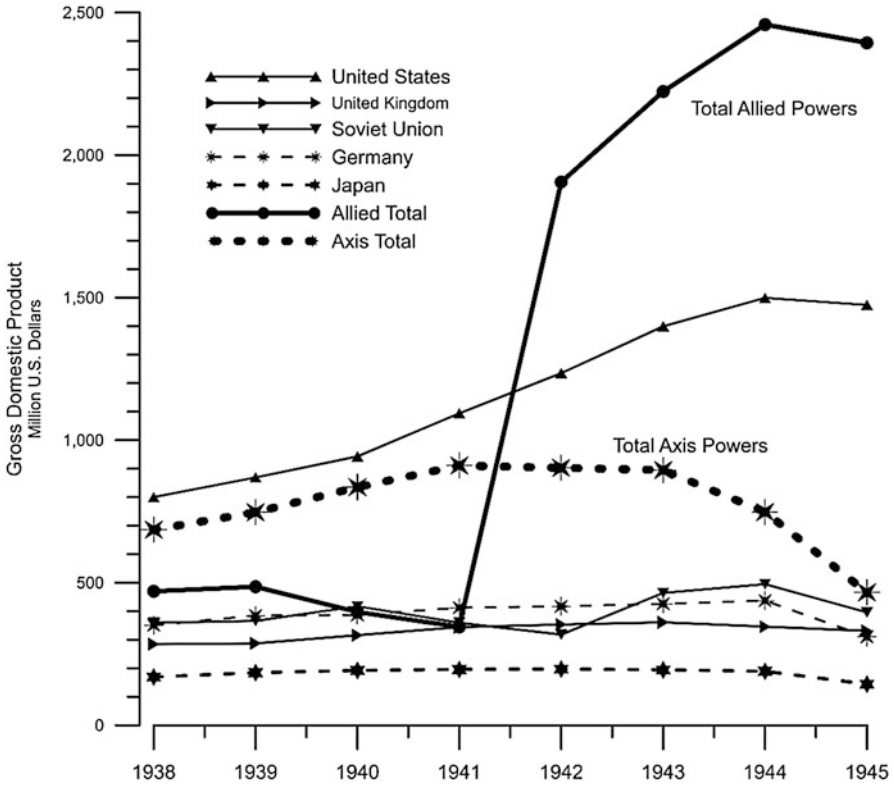

Fig. 11 Gross domestic product of the major powers, 1938–1945. (Sources: USA (Rockoff 1998, 86, Table 3.2); UK (Broadberry and Howlett 1998, 51 Table 2.1); USSR (Harrison 1998b, 278, Table 7.5); Germany (Abelshauer 1998, 135, Table 4.12); and Japan (Hara 1998, 261, Table 6.13))

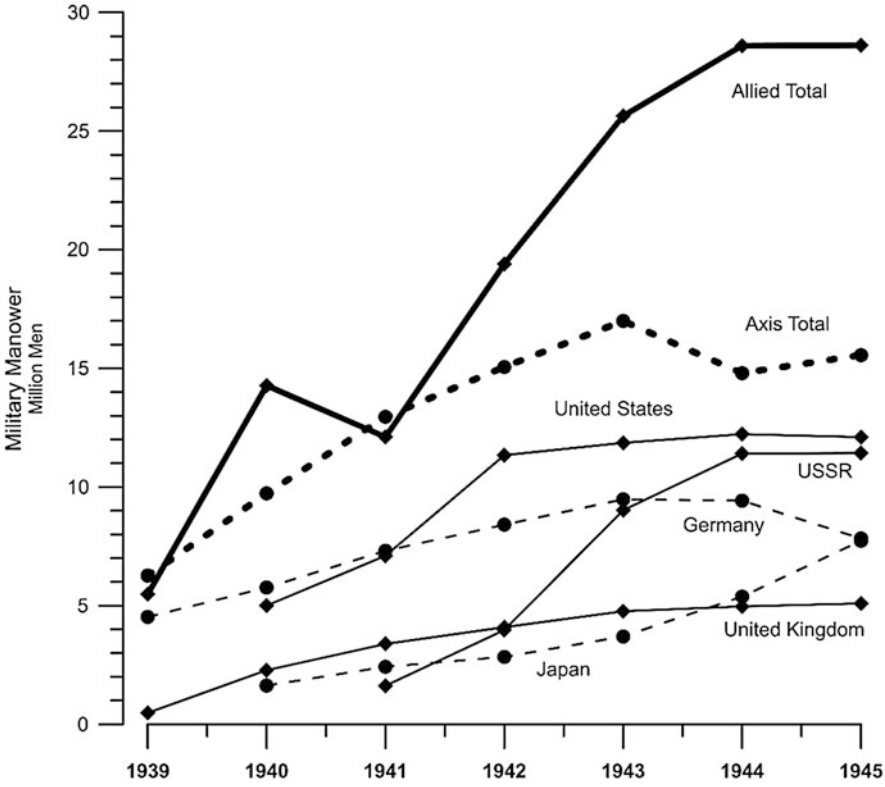

Fig. 12 Military manpower of the major powers, 1939–1945. (Sources: Correlates of War Project 2010)

the United States and the Soviet Union joined the fight in 1942, the economic balance of power shifted dramatically in favor of the Allies.

In 1918, the British were still trying to figure out how to best use their tanks. The British tanks were developed for trench warfare. They were large and unwieldy and easy targets for antitank guns. By 1940, the Germans had developed tanks that were much smaller and mobile. When combined with specially trained infantry units, these tanks comprised the backbone of the Panzer units that were the heart of their blitzkrieg strategy. Airplanes, which were also still in their infancy at the end of the Great War had evolved by 1940 into valuable weapons against both enemy troops and enemy populations. In a war where new weaponry involved thousands of armored vehicles and combat aircraft, the ability to produce these weapons played a significant role in the outcome of battles. Table 2 presents data on the production of these weapons for the United States, Soviet Union, United Kingdom, Germany, and Japan during the war. The figures reinforce the picture provided by the data in Figs. 10 and 11. As might be expected given their preparations for war in the late 1930s, the Germans and the Japanese had more

tanks and aircraft than the Allied forces at the outbreak of hostilities in 1939. However, the ability of the Americans and Russians to produce these weapons soon turned the balance of military power in favor of the allies. Over the course of the war, the United States, the Soviet Union, and the United Kingdom produced almost five times as many tanks and three times as many combat aircraft as Germany and Japan. In 1941, the Russians were already producing as many tanks and combat aircraft as the Germans. Because of the disorganization in the leadership of the Soviet forces after the purges of the 1930s, there was a tendency to assume that the Russians were a much weaker military power than the German invaders. That was clearly not the case. As Victor Davis Hansen points out,

> Germany revolutionized armored warfare, yet Russia built the most and best tanks while the British and Americans deployed the most effective ground-support fighter-bombers. So great were the Allied material advantages in armor and artillery that the superiority of German tank crews and Panzer generals ultimately was for naught. (Hanson 2017, 504)

Perhaps the greatest mistake Hitler and his generals made in 1941 was their failure to recognize the economic might of the Soviet Union.

We have seen how the Germans tried unsuccessfully to "starve" the British into submission through a policy of unrestricted submarine warfare as part of their economic war against the Allies in 1917–1918. In 1939, they once again waged an economic war against Allied ships in an effort to curb imports into the British Isles. Figure 13 presents data on Allied shipping sunk by the Germans from 1939 to 1945. This time they had the advantage of ports along the western French coast which extended the range of protection for the U-boats and allowed air attacks by planes and surface raiders. The results were impressive for the first 3 years. By 1942, losses from submarines reached 6.2 million tons of shipping a year and airplanes accounted for another 700,000. Losses for the duration of the war totaled more than 14 million tons of shipping, which is an impressive total, but it was not enough to seriously threaten the flow of men and materials from the United States to Great Britain. The ability of the United States to build "liberty ships" largely canceled the losses of tonnage sunk by German U-Boats. Davis and Engerman argue that "the Allied navies and air forces had effectively broken the blockade before the end of 1943." (Davis and Engerman 2006, 287).

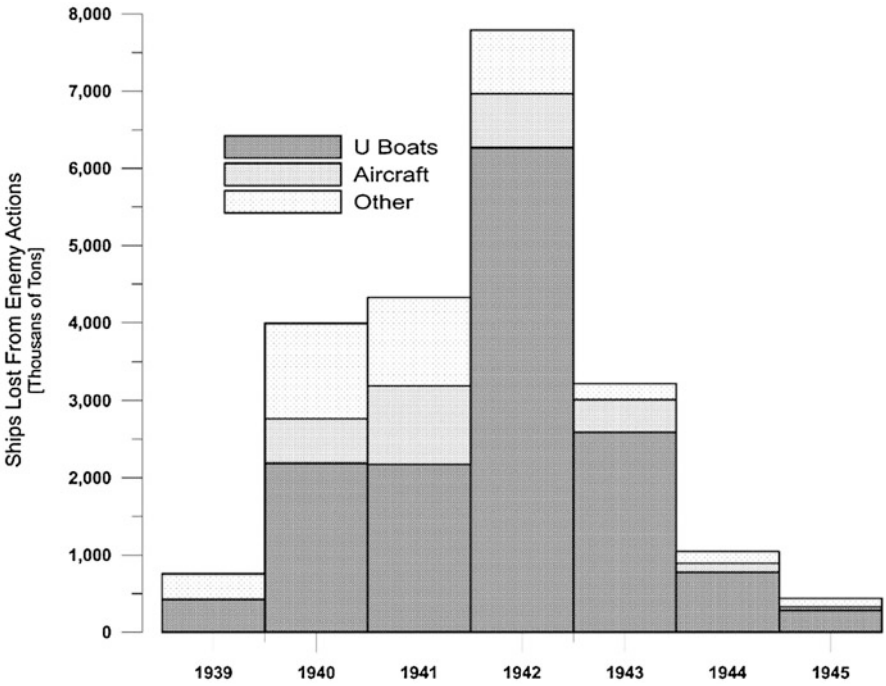

Fig. 13 Allied ships lost to enemy action, 1939–1945. (Sources: (Davis and Engerman 2006, 288, Table 6.3) "Other" includes mines and armed surface vessels acting as raiders and "unknown causes.")

While the German blockade in the Atlantic was ultimately a failure, the American naval blockade and air attacks against the Japanese homeland was a stunning success. "The war against shipping" note Davis and Engerman, "was perhaps the most decisive single factor in the collapse of the Japanese economy and logistic support of military and naval power." The impact of the blockade can be seen in the 50% fall in the consumption of staple goods over the course of the war (Davis and Engerman 2006, 378). The naval blockade was accompanied by massive air attacks made possible by the development of the B-29 bomber. According to Vincent Hanson:

> The bombers may have damaged Japanese industry as much by shutting down its transportation, ports, docks, and factory supplies as by the firebombing of industrial plants. Over 650,000 tons of Japanese merchant shipping was destroyed and another 1.5 million tons rendered useless, given the inaccessibility of ports and Allied control of the air and sea. (Hanson 2017, 114)

These attacks eventually culminated with the decision to drop atomic bombs on Hiroshima and Nagasaki on August 6 and 9, effectively ending the Pacific War with Japan. Whether or not the use of the atomic bomb was necessary, given the damages to Japanese cities already victimized by firebombing, is a matter of some debate. What is clear is that the ability of the American war effort to spend billions of dollars to develop super weapons such as the atomic bomb and the B-29 bomber provides additional support for the argument that the role of economic efforts was a pivotal factor in the outcome of the war.

Going "All In": Gambling on War in an Age of Catastrophe

A basic conclusion to emerge from this essay is that by the beginning of the twentieth century, war and economics were inexorably joined together so that economic strength was as important as military might in determining the outcome of a major war. Victories on the battlefield were a *necessary* condition to winning a major war, but they are not a *sufficient* condition to guarantee victory. In December 1914, Erich von Falkenhayn, the commander-in-chief of the German Army went to the Kaiser and urged him to negotiate a peace treaty with the Entente states following the First Battle of the Marne. The Schlieffen plan, he explained, had come up short of its objective, and there was no way that Germany would be able to win a protracted war of attrition. (Ritschl 2005). Our cliometric narrative supports Falkenhayn's early assessment of the large picture of the war. In the spring of 1918, the German army managed once again to get to within 40 miles of Paris, but the inability of the German economy to support both the troops in the field and the population on the home front meant that the Germans were unable to turn their battlefield successes into a final victory in the First World War. In 1942, Operation Barbarossa brought the *Wehrmacht* within a few miles of Moscow, but that proved to be the high watermark of their offensive capabilities and they were eventually forced to abandon their attack

on the Soviet capital in the face of Soviet counter attacks. The German defeat at Stalingrad ended any hopes the Nazis had of winning the war. In both world wars, the Germans were unable to sustain the level of economic activity necessary to support their military prowess. A similar argument can be made for the Japanese effort against American forces at Pearl Harbor and Wake Island. The military defeat of the IJN at Midway was an economic as well as a military disaster because the losses of men and ships could not be replaced.

While cliometric research provides a guide to the larger picture of why the Allies prevailed in the two world wars, the reasoning behind the decisions by leaders to persistently choose risky gambles on war over other policy options remains something of an enigma. Economists and cliometricians are used to dealing with outcomes based on "rational" thinking on the part of participants. However, in choosing to gamble on war, rational thinking was seemingly trumped by what John Maynard Keynes called "animal spirits" – decisions that were based on an overconfidence on the part of generals that their plans for the conduct of the war would succeed, combined with a fear of losing the war if they did not "do something."[5] Generals, in other words, displayed a strong propensity to gamble on fighting a battle – even if the outcome is very risky – rather than accepting what they viewed as a gamble on a peaceful settlement might have a lower risk of failure. The tendency of countries to choose war over peace was reinforced by the propensity of political leaders to leave the final decisions with regard to military strategy to generals.

Conclusion

Cliometricians have tended to avoid the question of what "causes" wars and follow the example of Ronald Findlay and Kevin O'Rourke, two cliometricians who reluctantly admit that the First World War "appears as somewhat of a *diabolus ex machina*" in their analysis of the causes of the war (Findlay and O'Rourke 2007, xxv).[6] For cliometricians, wars are exogenous events that must be built into the assumptions of the theoretic model. While such models do not explain the causes of wars, they have produced an impressive body of empirical data that allows us to examine the economic consequences of war in an Age of Catastrophes.

[5]Keynes' use of the term "animal spirits" was applied to his analysis of investor speculation during the stock market boom leading to the Great Depression (Keynes 1936, 129). For more on the use of animal spirits to explain decisions involving war and economics, see Ransom 2018, Chap. 1, 2016.

[6]They go on to explain that "There is of course no shortage of authorities who have argued that the way in which the late-nineteenth-century world economy operated helps explain the eruption of World War I, but the causes of this disaster remain controversial." (Findlay and O'Rourke 2007, xxv).

Innovation, Transportation, and Travel

Innovation in Historical Perspective

Stanley L. Engerman and Nathan Rosenberg

Contents

Abstract

It is necessary to study the historical record concerning the economic nature of technological change, the constraints it confronts, and the complementarities with other sectors of the economy in order to fully understand the nature of innovation. Consideration must be given to the market environment, the available production facilities, the existing body of knowledge, and the social and organizational contexts of the innovation, in addition to the series of required changes within other sectors, not just to the limited aspects of a narrowly-defined specific innovation. Since theoretical models cannot deal with the full complexity of the process of invention, innovation, and the utilization of new devices, some historical study is required to develop a full understanding of these processes. Without consideration of past events, it is difficult to understand either the present

or the future. Consideration of these factors will not only increase our historical knowledge but also serve to enrich our theorizing about these questions.

Introduction

In a conversation with Nathan Rosenberg on the topic of innovation, Kenneth Arrow pointed out (to paraphrase) that theoretical models do not provide a complete depiction of the process of innovation, in part because of the impossibility of having "a theory of the unexpected."[1] Such theoretical modeling has tended to be unsuccessful both in providing guides to understanding the past and in pointing to future changes. The implication is that it is necessary to study the historical record concerning the economic nature of technological change, the constraints it confronts, and the complementarities with other sectors of the economy to fully understand the nature of innovation. Consideration must be given to the market environment, the available production facilities, the existing body of knowledge, and the social and organizational contexts of the innovation, in addition to the series of required changes within other sectors, not just to the limited aspects of a narrowly defined specific innovation. These points will be discussed in various sections in this chapter. In short, since theoretical models cannot deal with the full complexity of the process of invention, innovation, and the utilization of new devices, some historical study is required to develop a full understanding of these processes. Also important is the role of the historical background in influencing economic and technological developments, what some refer to as path dependence (or, suggesting a less certain set of outcomes, path influenced), but where "history matters" (Rosenberg 1994, pp. 9–23). Without consideration of past events, it is difficult to understand either the present or the future.

A related set of points about the nature of innovations were made earlier by Simon Kuznets, in two articles published in the 1970s (1973, 1979). Kuznets described several important aspects of the nature of innovations and the difficulties in evaluating their effects. First, there is the great initial uncertainty concerning the complete set of the ultimate effects of any one innovation. Second, there is the great importance of complementary positive adjustments – technologically, ideologically, and organizationally (including social and legal institutions) – before the full effects (positive and negative) of an innovation can be determined. These concerns mean that it will often take a long time before all the invention's impacts can be represented as "a major transformation of their pattern of living" (1973, p. 199), as well as adequate time to adapt to the dislocations affecting productive labor and other resources used in production and the other social difficulties caused by the

[1]Neither Nate nor Stan can find a published source for this claim. Arrow himself is not sure if, and where, it appears in print. The quote is from Arrow (2012, p. 43). It might be noted that this difference between theoretical models and historical complexity applies generally to all theoretical models.

introduction of new innovations (1973, pp. 202–208). Most innovations do present negative effects and cause reductions in welfare. Mokyr (2014), citing Tenner (1996), points to examples of innovations providing positive benefits but with offsetting costs such as DDT, sugar beets, lead for paint and gasoline, and asbestos, while Kuznets (1973, pp. 205–208) points to their impact on the environment and the increase in pollution. Some of these difficulties such as possible deterioration of the natural environment can, once recognized, and with appropriate political and technological developments, be overcome. In some cases, these can be accomplished by appropriate use of price incentives, but in some cases, it may require government-introduced regulatory policy. This, however, can be a lengthy and expensive process and may offset only some part of the difficulties. Kuznets did believe in the long-run net beneficial outcome of the cumulative process of innovation, demonstrated in his brief comparison of what the world of 1960 would have looked like if innovation had actually ceased one century earlier, particularly in regard to consumer goods (1973, pp. 189–190; 1979, pp. 66–69).

The Role of "Learning-by-Using"

This chapter is intended to draw more attention to certain aspects of the historical study of technological change and to the contribution of economic history to its theoretical analysis. It will first give attention to the background to certain innovations and the initial expectations of what benefits they could provide. Then it will discuss a number of reasons for what is often regarded as the relatively slow impact on measured total factor productivity and then describe why innovations often have significantly greater impacts on the economy than just in those sectors in which the innovation occurred. Given his major contributions to the study of these issues, we will draw heavily upon the published works of Nathan Rosenberg, but we shall extend several of his points and arguments.

The difficulties in "predicting and preparing for" specific innovations and preparing for all the effects of any innovation have been well illuminated by Nathan Rosenberg (2010, pp. 153–173), in an essay entitled "Uncertainty and Technological Change," dealing with the differences between the initial expectations of inventors and the ultimate role played by their innovations. The initial expectations often reflected the very particular problem that the invention was trying to solve, and even the innovators were unable to anticipate the subsequent improvements and developments that would take place. Thus, the early development of the steam engine was concerned with providing a means to pump water out of flooded mines (Rosenberg 2010, pp. 164–165). The "first railroads were expected to serve only as feeders into the existing canal system or were to be constructed in places where the terrain had rendered canals inherently impractical" (Rosenberg 2010, pp. 162–164; MacGill 1917, p. 291). Alexander Graham Bell saw the telephone as being mainly "improvements in telegraphy," not as its replacement (Rosenberg 2010, p. 156). Marconi saw the major use of his wireless innovation as being an aid mainly to ships, for either ship-to-ship or ship-to-shore communication (Rosenberg 2010, p. 156). More

recently, some believed that the main function of the transistor was expected to be the development of better hearing aids for the deaf (Rosenberg 2010, p. 157). Obviously more examples of such varieties of incorrect expectations can be given, but it is clear that innovations made in response to particular needs, or for a specific purpose, will often turn out, when improved and more fully developed, to have much different and broader uses, with their contribution to economic change being much larger and often in an unexpected direction than earlier anticipated.

There are several related reasons for the underestimation of the full effect of an innovation. First, we often date the introduction of an innovation quite early in the development process, where it can best be described as "primitive" (Rosenberg 1994, p. 69). With use – what we can describe as "learning by using" (Rosenberg 1982, pp. 120–140) – and with further experimentation, the specific piece of hardware (the innovation proper) will be improved upon its initial state, making it more productive, and also may be seen to have further, often unexpected, uses, which add to the benefits from the initial innovation, benefits not anticipated when the innovation was introduced.

"Learning by using" is to be distinguished from the more familiar concept of "learning by doing" since the latter refers more directly to the gains in productivity in the production process due to repetitions in the process of production. "Learning by using" refers to the emergence of new problems which arise from the process of production of the new innovation which must be solved to permit its utilization, problems which cannot be known until production is begun and are generally unexpected. The importance of "learning by using" is that most innovations, when introduced, are at a rather early stage and therefore require some improvement. Often the ability and need to make improvements can only be known and accomplished after the new technology is introduced. At an early stage, neither theoretical nor empirical approaches to the analysis of the new technology could anticipate many of the problems that will arise in the production process, and it is only by observation of the actual process that the problems are revealed and the basic information needed to make improvements known. Thus there may be a considerable time before the benefits are obtained.

"Learning by using" can account for a large part of overall productivity change. The impact of "learning by using," as well as the lag between the introduction of an innovation and its impact on measured total future production, however, lacks the dramatic appearance that comes from the study of the application of new scientific knowledge or the initial introduction of the new physical machinery. Further, these adjustments may, unlike the basic invention, not be patentable, leaving a less observable record. Yet the improvements made in the process of production are often crucial to making innovations productive and efficient. Given the inability of any model to describe all the possible operating eventualities, more information awaits the actual use of the innovation. "Learning by using" may be regarded as providing a joint product with the good produced, with elements of cost shared between the production of the good and the future benefits derived by the new knowledge, or else as a "free good" resulting from its production, an externality

resulting from the start of production, with all the costs attributed to the production of the good.

Important aspects of the learning process have been studied in several key articles. Jamasb (2007) and Stein (1997) present models that incorporate learning in the innovation process. Stein notes also the spillover of external benefits and costs to other firms, while Breschi et al. (2000) point to the possible differences in the nature and rate of innovation between new and old firms. Jovanovic and Lach (1989) point to the benefits that accrue to later entrants able to take advantage of what has been learned by earlier producers. Rantisi (2002) looks at learning as a function of the clustering of similar firms which provides for sharing of knowledge and practices.

Also important, as described in detail by Kuznets, is that to obtain the full set of benefits and to offset the costs of an innovation may take time, as there are often a variety of complementary adjustments, material and institutional, that must be made (Kuznets 1973, pp. 185–201; Kuznets 1979, pp. 56–99). Two particularly dramatic examples relate to the development of energy sources for the economy. The initial limited effect of the development of electricity upon the measured productivity of the economy was due, in large measure, to the need for technological and institutional changes to permit the widespread use of this innovation. To obtain more benefits in the manufacturing sector, it was necessary to redesign and reshape the factory floor, as well as to take advantage of the locational flexibility that had not previously been permitted to factories. The expanded use of electricity permitted new technologies in other sectors, such as metallurgy and steel production, benefits not immediately apparent when the basic innovation was introduced. Electricity has, of course, had a dramatic impact upon nonindustrial aspects of the economy, including transportation and the lighting of streets and houses, and has been the power source for many consumer goods (Mowery and Rosenberg 1998, pp. 105–109; Hughes 1983). To permit the widespread use of electricity by businesses and consumers required wiring, above and below ground, and this meant the increased ability of the state and/or the private sector to impinge on the property rights of individuals and businesses. While governments had long used the power of eminent domain, electrification required a considerably more extended use of this legal principle, dealing with many more individuals over larger areas, to be successful.

In the early twentieth century, petroleum was to become the important source of energy in the economy. Petroleum was not then a new product; the earliest major US discovery of oil had occurred in Pennsylvania in 1859 (Rosenberg 1982, pp. 185–186). Indeed, so uncertain was oil's future at this time that even as shrewd a businessman as Andrew Carnegie, contemplating the future prospects for oil, tried to corner the market since he expected that the United States would soon run out of oil (Sabin 1999). Fortunately for himself, Carnegie had a diversified investment portfolio. It took several decades before new discoveries of oil increased its supply, and significant increases in the demand for oil for use in various products, before the full impact, was achieved. This required, for example, the innovation and many successful refinements to the automobile with its internal combustion engine as well

as improvements in the airplane, both depending on oil for fuel (Mowery and Rosenberg 1998, pp. 47–70; Mowery and Rosenberg, in Rosenberg 1982, pp. 163–177). Vincenti (1990), is a detailed examination of the role of "learning by using" in airplane invention. To get the full benefits from these transportation developments, extensive expenditures by federal, state, and local governments, as well as by firms in the private sector, were necessary. The public sector assumed responsibility for building highways, roads, and bridges to permit private travel and the business movement of goods. For air travel, governments provided airports and traffic controls as well as safety regulations. For the automobile, the private sector provided the production and sale of automobiles and trucks, in both of which there were relatively rapid technical improvement in production, as well as a network of private stations to service autos and trucks as well as to make gasoline and oil available to needy customers. Various credit arrangements, such as installment credit as earlier pioneered by the Singer Sewing Machine Company, were also introduced to permit individuals and firms to afford the costs of purchasing cars and trucks.

These examples of what is required for all of the effects of an innovation to occur can be repeated for many other cases where developments after the initial introduction of an innovation were important, whether within the same sector as the innovation or elsewhere in the economy and whether they were innovations of hardware or of institutions. This latter point has been raised by Kuznets (1979, pp. 56–66) who states (p. 65), "It is the interplay of technological advance and organizational, economic, and social adjustments that the crucial feature of the innovation, the *application* of new technological element, lies." As Rosenberg (2010, p. 163) notes about the long time before electric power had a large impact on factory production that "such technological innovations commonly require significant organizational changes as well."

General Purpose Technology

A particular type of innovation that has a widespread set of uses and effects in several sectors of an economy has come to be called a general purpose technology (see Rosenberg and Trajtenberg, in Rosenberg 2010, pp. 97–135; Bresnahan and Trajtenberg 1995). These have been described as "a certain type of dramatic innovations" that "has the potential for pervasive use in a wide range of sectors that drastically change their modes of operation" (Helpman 1998, p. 3; see also Lipsey, et al. 2005). While often these were not expected to have such a wide range of uses when initially innovated, the general purpose technology invariably developed many new applications after its first adoption, which was intended for a specific purpose. The key examples discussed are the steam engine in the eighteenth and nineteenth centuries, the electric motor in the late nineteenth and early twentieth century, and the semiconductors, the laser, and the computer in the late twentieth century. To be fully effective as a general purpose technology, there must be a large range of complementary innovations as well as related changes in technology and organization in several different sectors of the economy.

The evolving nature of general purpose technologies is one explanation for the uncertainty of the full impact of new technologies, since the full set of the uses of an innovation often go far beyond its original intent. While the original incentive may be for an improvement aimed at one specific use, as new improvements take place, there are a wider range of different, unexpected uses in other sectors. One implication of this is that subsequent advances may take place in sectors other than the focus of the original innovation, posing issues of coordination among the different sectors. This problem of decentralized decision-making may result in a lower rate of overall technical advancement than if changes were more centralized. The time needed for the development of complementary technologies and other adjustments to take advantage of network externalities to make full use of the general purpose technology means that a long time may be required before marked changes in the measured rate of technological progress can be observed.

Faulty Predictions

Even more faulty have been the predictions, often by eminent scientists, that the stage of development had been reached that no further innovations could occur or at least none that could have substantial impacts in generating high employment or rapid economic growth. Such distinguished nineteenth-century economists as John Stuart Mill and Alfred Marshall presented some similar claims, as did the twentieth-century economist Alvin Hansen, in the Great Depression of the1930s (Mill 1895, II, pp. 334–340; Marshall 1920, pp. 67–68, 242–244; Hansen 1939). For more optimistic expectations by Mill, see Hollander (1985, I, p. 223; II, pp. 881–888). Unlike many others, Mill regarded the stationary state as a desirable outcome. Indeed, most periods of economic decline have provided proponents of such a decline of innovation, as John Taylor has pointed out (Taylor 2014). Most recently, such a claim has been made by economists such as Benjamin Friedman and Robert Gordon, despite the body of past evidence to the contrary (Gordon 2012, 2014; Friedman 2013; see, however, Mokyr 2014).

Competition Between Old and New Technologies

Given the nature of the economy, it is to be expected that new methods and innovations will emerge in competition with older technologies. The persistence of earlier technologies can often be the cause of delays in benefits for the new innovation slowing the rate of introduction of the new methods. Some of this may be due to improvements made to older technology, which keep them competitive with the new for at least a longer period of time. The long-term existence of a capital stock based on the older technology, which no longer needs to cover fixed costs, means that relatively lower prices may lead to some continued use of the older technology. Some of the lag may be due to the investors of the old technology who may, via the use of market forces or government action, work to reduce or exclude

the new. Similarly, laborers who prefer the economic conditions under the old technology may use the market or the government to prevent or delay the introduction of new methods, such as containerization (Levinson 2006). The late nineteenth-century political commentator Henry Sumner Maine (1897), in his argument against democracy, claimed that if workers had been able to vote on the introduction of innovations, the Industrial Revolution could not have taken place. Other delayed impacts may reflect government-chosen policies, at times in response to citizen's wishes. Tariffs (or their absence) have long played a major role in the timing of the introduction of a new technology. The nature of the patent system and its changes, over time, will affect the incentive to innovate as well as their diffusion (Khan 2005).

In the early days of the introduction of railroads in New York State, in competition with the Erie Canal, there were several attempts to reduce the railroad's competitive edge, such as limiting railroad operations to times when the canals were closed, requiring railroads to pay a toll equivalent to that of canals for freight carried, and a requirement that the railroad freight charge be the same as canal charges (MacGill 1917, pp. 291–294, 316–322, 344, 353–356, 368, 389, 398–400, 489, 495, 533–557; Engerman and Sokoloff 2006, pp. 110–112). Other states and nations introduced policies to limit expansion of railroads at the expense of canals. Pennsylvania introduced a tax on the Pennsylvania Railroad in 1846 to "guarantee the states against losses that might be sustained as a result of competition between the new railroads and the public works" (Hartz 1948, pp. 267–271; Dunlavy 1994). Ohio, similarly, had passed legislation to require railroads "to reimburse the state for half the canal tolls lost in all freight that the road carried between cities located on the Ohio Canal," as well as other limiting regulations (Scheiber 1969, pp. 270–317). None of these state legislations lasted very long, but they do indicate the type of problems confronted by innovations in competing with entrenched interests who were able to use governmental power.

Another consideration affecting the timing and magnitude of the introduction of an innovation and its full accomplishments is the cyclical nature of the economy, reflecting expectations of the future path of profitability as well as the availability of capital for investments required (Rosenberg and Frischtak, in Rosenberg 1994, pp. 62–84). The influence of cyclical changes can explain the clustering of innovations, as well as the lag between innovation and introduction into production, a point stressed by Schumpeter (Rosenberg 1982, pp. 5–7).

The Axiom of Indispensability

In determining the benefit-cost ratio of all the expenditures on research and development leading to innovations, it is important to remember that we should not look only at successful innovations and ignore the costs of failed attempts to develop new techniques, often in direct competition with those methods that have been successful. Thus, estimating the return to the antebellum canal network should not stop with the measured benefits from the Erie Canal, but needs to also deal with the losses of the

six other cities that, at roughly the same time, unsuccessfully competed against the Erie Canal (Engerman and Sokoloff 2006, pp. 97–98, 112. See also Rosenberg 2010, pp. 275–279; 1982, pp. 55–62).

An important consideration relating to estimates of the benefits of an innovation is what Robert Fogel called the axiom of indispensability (Fogel 1964, p. 10; cf. Rosenberg 1982, pp. 27–29). Fogel claimed that in the absence of the innovations that made the railroad successful, resources could possibly have been devoted to seeking other means of overland transport, such as the automobile, which might then have been introduced earlier than it was and which, as did the railroad, could improve its efficiency over time. Thus Fogel denies that the railroad was necessarily indispensable for US economic growth. Given some limitation upon the magnitude of resources that society will devote to innovating and improvements, the expenditures on a particular set of innovations and improvements will reduce expenditures on alternatives which, even if not ultimately as effective as the successful innovation was, may have been nearly so successful as was the adopted successful innovation. That such a possibility is not fanciful can be seen in current debates as to whether the pattern of change in the internal combustion engine came at the expense of devoting resources to developing such possible alternatives as the electric car, leaving us far behind in adapting to the current climate crises.

A further issue raised by Fogel's axiom of indispensability is the possibility that alternative innovations could have been made to replace any one specific innovation or several related innovations. This points to a broader set of questions concerning the possibility of alternative innovation in different parts of the world. This has been most frequently discussed in the context of arguing about the differences between East and West and the causes of the economic rise of the West. Most studied have been the nature and also the impact of innovation in China compared to that in Europe. There are several questions. One is the contention made by Needham (1969; see Winchester 2008) about the greater early successes of China in innovations than in Europe, an early lead that over centuries disappeared as economic and other expansions in Europe came to exceed those of China. Second, why, in many cases, did early modern Europe do more to make these innovations practical and useful than did China – whether due to cultural factors or taste differences, the range of usable knowledge, differences in relative factor prices and resource scarcities, or some limits of technological skills (for this discussion, see Allen 2011; Landes 1996; Jones 1981; Rosenberg and Birdsall 1986; and Mokyr 2002) among those discussing this point? Third, suggested most directly by the Axiom of Indispensability, is it possible or probable that East and West pursued different technological and institutional means to achieve the same general aim? Given differences in historical background and resources, were there differences in technological development that emerged before large-scale contact between these societies? In today's world with rapid communication and much day-to-day contact among scientists and inventors, the possibility of major divergences might seem doubtful. Nevertheless, the examination of the existence of such differentials at earlier stages of science and technical development should prove to be of importance and of interest.

Linear vs Chain-Linked Models

Despite his important role for economists and economic historians in pointing to the importance of technological change in accounting for economic growth, Schumpeter's story is in some ways still incomplete (Rosenberg 2000). He distinguishes between the major innovation and the subsequent improvers, whom he describes as "mere imitators." Thus he downplays the importance of those improvements made after the introduction of the innovation. These "imitators" can be heavily involved in enhancing the productivity of an innovation (Rosenberg 2000, pp. 55–78). The "imitator" may not get the glory that goes to the innovator, but it is often the imitators who reap the largest financial rewards. The "first mover" innovator may not be the greatest financial beneficiary of change, a phenomenon true not only for innovators but also for the economic growth of nations, as pointed out in an article by Ames and Rosenberg (1963; also Engerman and Sokoloff 2012).

Schumpeter further argues that the importance of major innovations plays a great role in contributing to the maintenance of the capitalist system (Rosenberg 1994, pp. 47–61). Capitalism creates new structures, new commodities, new technologies, new sources of supply, new markets, and new forms of organization – which drive out existing structures by the process he calls "creative destruction" (Schumpeter 1942, pp. 81–86), the mechanism by which new innovations drive out older systems. To Schumpeter, it is by the major innovations and in big jumps in the innovations, rather than by minor changes, that, he argues, capitalism is able to keep expanding (Rosenberg 1982, pp. 3–33).

One customary view of the innovation process, which has been called the linear model, suggests a rather "smooth, well-behaved linear process" from new developments in science to invention to innovation to production to marketing. This model allows for no feedbacks and no interactions among the various steps and is compatible with a Schumpeterian emphasis on innovation as an exogenous process and with technological change being regarded as discontinuous. Distinctions are made between the current scientific frontier and the past accumulation of scientific knowledge. The reality of the innovation process clear, however, to those who study the historical process of innovation has been better described as a chain-linked model, "complex, variegated, and hard to measure." This can include feedbacks and temporal interactions among accumulated science, innovation, production, and marketing (Kline 1985; Kline and Rosenberg in Rosenberg 2010, pp. 173–202). Developments at each stage influence, and are influenced by, what happens at the other stages, as for example, the contribution of technological improvements to the progress of science. This view is compatible with recent studies of innovation that regard it as being incremental and continuous, with attention given to the importance of small improvements based primarily on experience and "learning by using," with the prototypical case being the aircraft industry (Vincenti 1990; Rosenberg 2010, pp. 153–172, Rosenberg 1982, pp. 120–140; Mowery and Rosenberg, in Rosenberg 1982, pp. 161–177).

The introduction of innovations and improvement do not necessarily begin with new scientific information, but often are based on a preexisting state of knowledge. It

is often that developments in technology, as with the microscope, permit new scientific discoveries. These may result from "learning by using," with the benefits that result from solving problems that arise in the production process.

For these and other reasons, such a chain-linked model is more realistic than the linear model and serves to highlight the difficulties and complexities of the innovation process as it actually takes place. Innovations may not be based only on the newest science but can draw on the accumulations of past scientific development. This linked-chain model has been seen to be quite useful for describing productivity changes in the airplane, as well as the increased importance of electricity in the economy (Vincenti 1990; Kline 1985). In both cases, there were many unanticipated difficulties, necessitating modifications in product design as well as in operating and maintenance procedures. And, as seen in the case of nineteenth-century America and twentieth-century Japan, the technologically advancing nations can benefit from imitating the developments in the scientifically more advanced nations and need not themselves develop new innovations.

Conclusion

This chapter is intended to draw together some aspects of technical change and innovation that have been understated in the recent literature. The studies of the historical process by which innovations are made, introduced, and contribute to economic growth demonstrate the complexity of the process which is masked in some theoretical discussions.

The complexity of the process by which innovations occur and are introduced and diffused throughout the economy has become recognized. Large-scale technological steps have long been the primary focus in the examination of technological change. But more recently, the importance of what seem to be relatively minor adjustments have led to some shift in emphasis in historical and economic studies. This has led to a greater understanding of the great uncertainty in forecasting future technological changes, of the often long-delayed measured achievements of what are regarded as new major technologies, and of the need to bring in the study of institutions into the analysis of technological change. Consideration of these factors will not only increase our historical knowledge but also serve to enrich our theorizing about these questions.

Acknowledgments We wish to thank Philip Hoffman, Zorina Khan, Joel Mokyr, and the editors of this volume for very helpful comments on earlier drafts.

The Cliometric Study of Innovations

Jochen Streb

Contents

Abstract

Per definition, cliometric studies of innovations use statistical methods to analyze large quantities of data. That is why historical patent statistics have become the standard measure for innovation. I first discuss the advantages and shortcomings of patent data and then show that the distribution of patents across countries, regions, or inventors is characterized by two salient features: its skewness and its persistence over time. To explain these features, the influence of various supply-side, demand-side, and institutional factors will be discussed. I will stress the importance of path dependency. This chapter ends with a closer look at technological transfer that came along with patent assignments and foreign patenting.

Keywords

Patent · Patent statistics · Human capital · Skewed distribution · Technological transfer · Path dependency · Innovation · Region · Patent law · Access to market

Introduction

Economic historians agree on the stylized fact that innovations are the main driver of long-run economic growth. For example, Greg Clark (2007, pp. 197–202) estimates, on the basis of a growth accounting exercise, that about three quarters of long-term growth of output per worker in the industrialized world has to be directly attributed to the permanent increase in productivity which, in his opinion, mainly resulted from the myriad of smaller and larger innovations that were developed to improve the efficiency of production processes. An important corollary of this empirical observation is that the unequal geographical distribution of innovations might be the key factor for explaining why some nations became rich and others stayed poor. That is why cliometric studies of innovations usually concentrate on two main tasks. First, they aim for measuring the distribution of innovations across space and time. Second (and based on this measurement), they try to identify those factors that have influenced the innovation of nations, regions, or firms. To perform this task with the method that differentiates cliometric studies of innovations from other research projects in innovation history – advanced statistical analysis –mass data are needed, the collection of which is at the same time one of the major methodological challenges. The epistemic interest of this research program is clearly related to the field of development economics: underdeveloped countries of today might learn from historical experience how to foster their own innovative capabilities and therefore their future economic performance. In the following, I will discuss the problems and results of measuring innovations under the headings "quantifying innovations" and "skewed distribution." The cliometric approaches to elucidate the development and diffusion of innovations are presented under the subtitles "explaining innovations" and "technological transfer."

Quantifying Innovations

In the early twentieth century, Schumpeter (1934, p. 66) provided his famous and still very instructive definition of innovation by distinguishing five different cases: the introduction of a new good or a new quality of a good, the introduction of a new method of production, the opening of a new market, the conquest of a new source of supply of raw materials or half-manufactured goods, and the carrying out of the new organization of any industry. The practical research problem of economic historians who aim at basing their empirical research on Schumpeter's definition is how to collect complete data about these rather different types of innovations in a way that allows consistent comparisons across space and time. Compilations of historical innovations that are usually provided by scholars of the history of technology are by no means comprehensive and frequently show a considerable selection bias because historians tend to prefer both basic innovations to incremental innovations and product innovations to process and organizational innovations. That is why economic historians usually rely on patent statistics as the standard measure to quantify past innovations. This preference is obviously based on the implicit assumption that,

in comparison to the compilations of innovations by historians, patent statistics offer a more complete and less biased overview of the universe of innovations. In general, two types of patent statistics have to be distinguished. Patents applied for are a measure for innovations that were appraised to be new and potentially profitable by the applying inventor. In patent systems, where the patent office is vested with the task to reject patent applications because of lack of novelty, patents granted can be interpreted as a measure for the subset of innovations which were additionally judged to be new by the impartial technical experts of this administration. Both groups of patents can differ considerably. In pre-First World War Germany, for example, only about 40% of patent applications successfully passed the technical examination by the patent office (Burhop and Wolf 2013, p. 76).

Patent statistics have obvious shortcomings too. Griliches (1990, p. 1669) highlights the three most important of them: "Not all inventions are patentable, not all inventions are patents and the inventions that are patented differ greatly in 'quality', in the magnitude of innovative output associated with them." The first part of this statement points out that patent statistics can only contain information about product and process innovations but fully neglect, as most of the compilations of innovations, the last three types of innovations on Schumpeter's list that are in general not patentable. To close this gap of knowledge, survey-based studies in modern innovation economics sometimes explicitly ask for information about organizational innovations in marketing, procurement, or internal organization of a company. In economic history, however, comparable mass data are usually not available. The same is true for input indicators, such as R&D expenditures by private firms or public research organizations, which are also often used in nonhistorical studies of innovations, which concentrate on the development in the last decades.

The second part of Griliches' statement refers to the fact that the propensity to patent varies considerably across industries. Whereas some industries try to appropriate the return of their innovations with the help of patenting activities, others prefer keeping them secret instead. The formula for Coca-Cola, for example, has never been patented because its public disclosure in a patent application would have allowed competitors to imitate this product after the end of the patent protection. Given these differences in industries' patenting activities, it could be misleading to interpret a particular industry's comparatively low number of patents automatically as a sign for its alleged below-average level of innovation. To assess the magnitude of this measurement problem in cliometric studies of innovations, Moser (2012) uses an alternative source to identify them. She looks at the number of British and American exhibits presented at world's fairs between 1851 and 1915. The historical catalogues used to guide the visitors through the exhibition of a particular world's fair comprise information about the exhibitor's name, location, and a description of the innovation. The latter allows Moser to assign every exhibit to exactly one of ten different industries. Because the catalogues also provided information about whether or not the exhibit was patented, she can also calculate the patenting rates of the exhibits. At the Crystal Palace exhibition in London in 1851, for example, about 89% of British exhibits and 85% of the American ones were without patents. In the light of this observation it is hard to maintain the general claim that historical patent

statistics offer a sufficiently precise overview of innovative activities. In addition, Moser identifies considerable differences in industries' propensity to patent. In 1851, industry-specific patenting rates of British exhibits ranged from 30% in manufacturing machinery and 25% in engines to a mere five percent in mining and metallurgy. Moser concludes that patenting rates were especially low in those industries where innovations were difficult to imitate. In the middle of the nineteenth century, this argument also applied to chemicals, because modern methods of chemical analysis that allowed chemical products to be "reengineered" had not yet been developed. Even though patenting rates gradually increased over the course of the second half of the nineteenth century, Moser's analysis clearly shows that patent statistics are by no means a perfect measure for historical innovations. On the other hand, patent statistics are often the only source of mass data available for cliometric studies of innovations. When using this second-best measure, researchers are therefore well advised to control for industry effects in their regression analysis.

The third part of Griliches' statement addresses the problem that patent counts allocate the same weight to every patent, no matter whether it had a high or a low economic value for the patentee or society. This is an additional reason why inferring the level of innovation from the raw number of patents can lead to considerable measurement error. For this particular problem, however, scholars found various ways to deal with it. Ideally, one would like to assign each patent an individual weight that quantifies its technological or economic significance. Townsend (1980), for example, rated historical patents related to coal mining according to their importance, on a scale from 1 to 4. This procedure might be recommendable for specific industry studies, but does not work for large patent populations where the careful evaluation of every single patent would be very time-consuming and would require engineering competence in a wide range of technological fields. In order to address this problem, economic historians use three other methods to identify patents with a high economic value. Figure 1 illustrates these methods. We already know that the set of patents filed in a particular country is only a more or less large subset

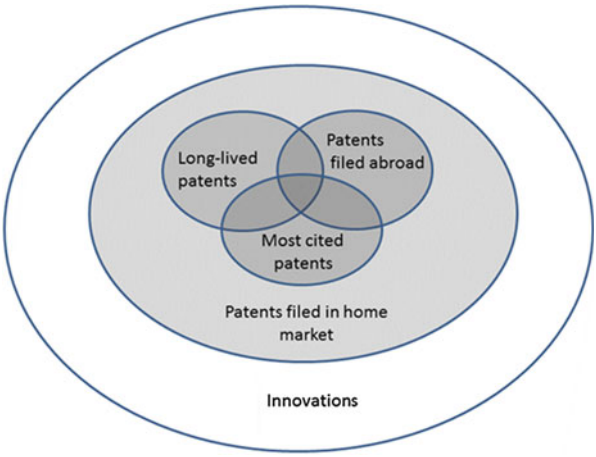

Fig. 1 Identifying valuable patents

of all innovations that have been developed there in a given time period. Among all patents filed in the home market are in turn three non-disjoint subsets that, for different reasons, all might represent valuable patents. These are the subsets of foreign patents, long-lived patents, and most-cited patents.

An inventor can apply for a patent not only in his home market, but also in foreign countries. Getting a foreign patent, however, imposes additional costs in the form of expenses for patent lawyers and translators, fees for filing and renewing, and the longer-term costs of international disclosure of the underlying technology. Future returns on a foreign patent can arise from two major sources. A patentee can use the temporary patent protection to increase his profits either by exporting the innovative good or by licensing foreign producers to manufacture and sell it in their respective home markets. After weighing the costs and benefits of foreign patenting, most inventors decide to file a patent only in their home country. Only the most promising innovations will also be patented abroad. That is why foreign patents might represent an especially valuable part of a country's patent stock. Today, the so-called triadic patents that are simultaneously filed at the European Patent Office (EPO), the United States Patent and Trademark Office (USPTO), and the Japanese Patent Office (JPO) are used to identify a country's best innovations.

Economic historians usually concentrate on foreign patenting in the United States for two reasons. First, early on the United States established a large and developed market in which only excellent foreign innovations could take hold. Second, the USPTO provides comparatively detailed and long-term historical patent statistics. The most comprehensive cliometric analysis is provided by Cantwell (1989) who analyzes the patenting activities in the United States of 17 industrialized countries and 27 sectors for the years 1890–1892, 1910–1912, and 1963–1983. A shortcoming of this kind of identification strategy is that the volume and structure of foreign patents are probably not independent of the characteristics of the foreign country where they are filed. In general, firms will seek patent protection only in those foreign countries where two preconditions hold: first, the potential market for their innovation is large, and second, the probability of imitation is high. What is more, some countries might even discriminate against foreign inventors by delaying or even declining the granting of their patent applications (Kotabe 1992). As a result, the portfolio of a country's foreign, and therefore valuable, patents might look very different depending on whether it has been derived from foreign patenting activities in, for example, Germany, Japan, Spain, or the United States.

In historical patent systems like those of Germany or the United Kingdom, where patent holders had to renew their patents regularly by paying a renewal fee, valuable patents can alternatively be identified by their individual life span (Schankerman and Pakes 1986; Sullivan 1994). Legislators had introduced patent renewal fees in the hope that many patent holders who were not able to profitably exploit their patents would give them up early and thereby make the new knowledge that was documented in the patent file publicly usable long before the maximum possible patent duration would have elapsed. If this mechanism worked as intended, a long life span of a historical patent can be seen as a reliable indicator of its comparatively high private economic value. In the German Empire, for example, a patent holder

had to decide annually whether he wanted to prolong his patent by another year. The renewal fee amounted to 50 Marks at the beginning of the second year and then grew steadily up to 700 Marks at the beginning of the fifteenth and final possible year of patent protection. The resulting cancellation rate was high. About 70% of all German patents that were granted between 1891 and 1907 had already been cancelled after just 5 years. About 10% of all patents were still in force after 10 years and only about 5% reached the maximum age of 15 years. Streb et al. (2006) interpreted those German patents that survived at least 10 years as the valuable patents within the German Empire.

However, the method of identifying valuable patents by their individual life span has three shortcomings. First, it can only be employed if the respective patent law stipulated the obligation to renew patents annually or, as in the British case, after 3 (later on: 4) and 7 years of patent protection, respectively. This was not the case in the often-researched US patent system, where patentees only had to pay a registration fee. Second, in industries with a high rate of technological progress, even patents representing important basic innovations might have been cancelled after just a few years as the technological frontier moved on. Third, in a world with imperfect financial markets, private inventors and smaller firms with limited financial capacity might have been forced by comparatively high renewal fees to give up their patents even though they still represented a high economic value (Macleod et al. 2003). Both types of short-lived but valuable patents will be systematically ignored by the life-span approach.

In academics, the value of a scientific article is often measured by the numbers of citations it received in following publications. A similar measure can be used to identify valuable patents. The idea is that the more often a particular patent is cited in subsequent patent specifications, the higher inventors evaluate its technological and economic significance (Jaffe and Trajtenberg 2002). Unfortunately, before the First World War, it was not common practice to refer to a preceding patent for defining prior state of the art. Even though most citations appear within one decade of patent issue, Nicholas (2011b) found that some British patents of the interwar period were still cited in US patents in the decades after the Second World War. Nuvolari and Tartari (2011) identified another way to make use of the concept of most-cited patents in cliometric studies. Their basic research design is to exploit Bennet Woodcroft's "Reference Index of Patents of Invention" published in 1862. This volume provides a list of references to technical and engineering literature, legal proceedings, and commentaries in which a patent is mentioned for each English patent granted between 1617 and 1841. Nuvolari and Tartari assume that the absolute number of references assigned to a particular patent shows its visibility in the contemporary technical and legal discussions and is therefore a reasonable indicator for its underlying value.

Depending on both data availability and the particular research agenda, a researcher is free to choose the most appropriate among the aforementioned methods for identification of valuable patents. However, to sharpen the definition it might be worthwhile to employ two or more methods simultaneously and concentrate on

those valuable patents which lie in intersections of the three subsets of foreign patents, long-lived patents, and most-cited patents depicted in Fig. 1.

Summing up, due to the scarcity of alternative sources for mass data, the vast majority of cliometric studies of innovations are studies of patenting activities. The main problem with this approach is that patent statistics neglect all innovations that were never patented, either because inventors preferred secrecy to patenting as a means to appropriate the return of their innovations or because the patent law did not provide for patenting particular innovations. Organizational innovations are an example of the latter problem. On the other hand, the use of patent statistics has the important advantage that researchers can choose between different sophisticated methods of identifying the valuable innovations within the set of all patents granted.

Skewed Distribution

A striking (and often neglected) feature of patent statistics is that the distribution of patents across countries, regions or inventors is highly skewed. Figure 2, for example, displays the number of long-lived German patents that were held by firms and private inventors located in the 20 most innovative foreign countries before the First World War. This represents the intersection between each country's long-lived patents and its patents filed in Germany, indicating a subset of particularly valuable patents.

Before the First World War, the United States dominated foreign patenting activities in Germany, with 29% of all long-lived foreign patents. Overall, the respective shares of the three (five) most innovative countries came to 63 (82) percent. This ranking of technological leadership has been persistent over time. On a world scale, the United States, Great Britain, France, and Germany (which, by definition, cannot show up in Fig. 2) have dominated foreign patenting activities for more than 120 years (Cantwell 1989; Hafner 2008). The only country that was able to join this exclusive club of technological leaders was Japan in the second half of the twentieth century. Cantwell suggests that we should explain the inability of most backward countries to achieve a similar level of innovation by the fact that in most industries new knowledge is generated as an incremental, cumulative and path-dependent process. As long-term paths of research and development provide no major shortcuts for latecomers, the technological leaders are in general far ahead of their followers when it comes to the development of major innovations.

Assuming that transaction costs (search and information costs, bargaining costs, monitoring, and enforcement costs) generally increase with distance, so-called gravity models predict that geographical (and cultural) proximity fosters bilateral foreign trade flows. Burhop and Wolf (2013) show that the same was true for international trade in German patents during the pre-First World War period. All other things being equal, the frequency of patent transfers decreased with growing distance between the buyer and the seller of a particular German patent. In addition, similar evidence can be found for the more general case of foreign patenting

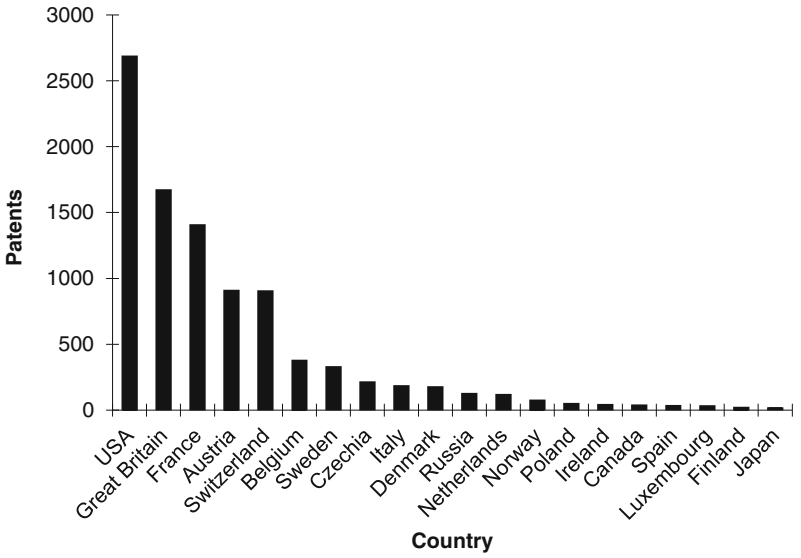

Fig. 2 Long-lived German patents of the 20 most innovative foreign countries before the First World War (Source: Degner and Streb 2013, p. 24)

activities. In particular, the comparatively high number of long-lived German patents that countries such as Austria or the modern-day Czech Republic possessed (see Fig. 2) might have resulted from direct proximity to this large neighboring economy. In contrast, these two countries played no major role in the American patent market, where Canada held a relative high number of patents.

The very uneven distribution of innovation across countries is mirrored within the innovative countries themselves; an observation that is reminiscent of the self-similarity of fractal geometry. In an influential paper that triggered many cliometric studies of innovations, Sokoloff (1988) points out that in the early nineteenth century, the level of patents per capita in southern New England and New York surpassed those of the rest of the United States by a factor of 20. Between 1890 and 1930 most Japanese independent inventors lived in the areas around Tokyo and Osaka (Nicholas 2011b). Streb et al. (2006) reveal that the long-lived German patents granted to domestic patentees before the First World War were also not uniformly distributed across the different German regions but were, as shown in Fig. 3, geographically clustered in the districts along the Rhine as much as in Greater Berlin and Saxony. A particularly high level of innovation, it seems, is a characteristic of regions rather than countries. For that reason, scholars have concentrated recently on the analysis of regional innovation systems (Malmberg and Maskell 2002).

Firm-level data indicate that above-average innovation of regions, in turn, is often based on achievements of just a few very innovative firms. Degner (2009), for example, presents the astonishing result that from 1877 to 1900 two thirds, and

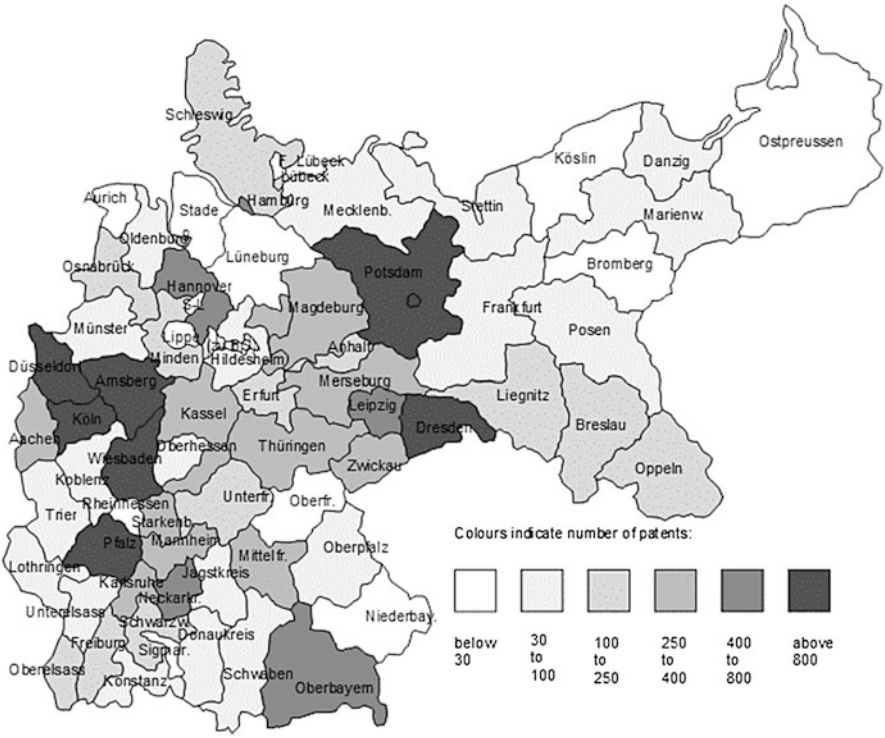

Fig. 3 The geographical distribution of high-value patents in Germany, 1878–1914 (Source: Streb et al. 2006, p. 364)

from 1901 to 1932 between 40% and 55%, of all long-lived German patents granted to domestic firms were held by only the 30 most innovative firms. That this distribution of innovation across firms was extremely skewed is emphasized by the fact that more than 266,000 firms with more than five workers existed in Germany in 1930. Many of the firms on Degner's list, such as Siemens or BASF, are also among the most innovative German firms of the early twenty-first century.

To conclude, many empirical observations lead to the conclusion that innovation, measured by the number of (valuable) patents, is a rare and persistent characteristic both at the macroeconomic and the microeconomic level. Surprisingly, most cliometric studies of innovations do not address these features explicitly.

Explaining Innovations

Traditionally, scholars have argued about whether an observed increase in innovations was primarily evoked by supply-side or demand-side factors. Mokyr (1990), for example, takes the view that demand-side factors might influence the direction of innovative activities but cannot explain the absolute level of technological creativity

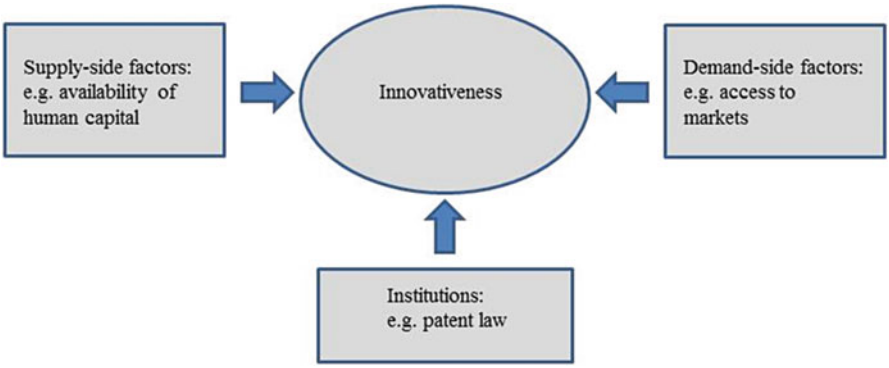

Fig. 4 Determinants of innovation

in a society. In his opinion, the latter was historically determined by various supply-side factors such as geography or the availability of basic technological knowledge. He also believes that demography and its influence on labor costs and popular preferences like the degree of risk aversion or the openness to new (technological) information were important. More recently, researchers also explored how the detailed anatomy of patent legislation influences the volume and structure of innovations. Figure 4 depicts the relationship of these three approaches.

Supporters of the view that it is the supply side of the economy that drives innovation stress the importance of human capital. In general, human capital comprises the stock of all qualifications and skills that increase an individual's productivity in economic activities. It can be acquired by formal education and learning by doing and therefore accumulates over the lifetime of a worker or researcher. Like physical capital, however, human capital can also be devaluated. Such a scenario is likely to occur in the aftermath of technological shocks. Handloom cotton weavers, for example, were highly paid specialists at the end of the eighteenth century, but were quickly replaced by unskilled adults and even children after Edmund Cartwright invented the power loom in 1785. Unfortunately, exact measures for human capital do not exist. Researchers therefore often rely on imperfect proxies like literacy rates, years of schooling, formal degrees, or even the Whipple index, which measures the extent of age heaping in a society (Baten and Crayen 2010).

At least since the Second Industrial Revolution, human capital has become an indispensable input in industrial innovation processes. In the late nineteenth century, chemical and electrical engineering companies invented the new organizational concept of the R&D department. Thus, for the first time in history, scientists and engineers collaborated to search systematically for new goods that could be profitably sold by their employer. In other industries such as mechanical engineering, drawing offices, and experimental departments, which also had to be equipped with well-trained employees, became an increasingly familiar sight. Human capital was now needed even for the purely imitating activities of firms. Reverse engineering, for example, meant in practice that workers had to have the skills to disassemble

complex machinery, to record each component with the help of engineering drawings, and to produce replica parts and fully functional copies. That is why Benhabib and Spiegel (1994) hold the view that human capital is essential for enlarging a country's level of technology by making possible either the imitation of foreign superior technology or the development of its own innovations. In their empirical approach, they measure a country's capability to innovate by its human capital stock, which they estimate by enrollment rates in primary, secondary and higher education. Specifically, a country's potential to imitate is approximated by the gap between the productivity level of the technological leader and its own inferior productivity level. The extent to which this potential can actually be used for catching up depends again on the available human capital stock. Analyzing the reasons for cross-country variation in growth rates of GDP per capita of 79 countries between 1965 and 1985, they confirm that in order to grow economically, emerging countries could rely on adopting foreign technology while industrialized countries had to develop better technology. These different growth strategies might also demand different strategies of human capital formation. Acemoglu et al. (2006) suggest that backward countries that want to catch up by imitating foreign technology should invest primarily in secondary education, whereas countries at the technological frontier should concentrate on increasing the quality and quantity of tertiary education.

Comparing the development of the synthetic dye industry in Great Britain, Germany, and the United States before the First World War, Murmann (2003) identifies the relative abundance of well-trained domestic chemists as one of the key factors that explain why German firms came to dominate the industry, as measured by both innovations and share in worldwide sales. From this observation arises the question whether the availability of an appropriate stock of human capital also influences innovation on a more disaggregated level. To answer this question, Baten et al. (2007) analyze the patenting activities of 2,407 firms located in the 52 districts of the state of Baden, Germany, around 1900. They measure regional human capital formation as the number of students in technical and commercial schools of secondary and tertiary level per 1,000 inhabitants. If the efficiency of a firm's R&D primarily depended on locally available human capital, firms that were located in districts with many students should have displayed more innovations than firms in districts with a below-average number of well-educated people. The econometric results suggest that Baden's small- and medium-sized firms relied on hiring graduates from technical and commercial schools in their geographical neighborhood. By contrast, Baden's large innovative firms were apparently able to cross geographical boundaries and acquire new researchers and engineers from distant German and foreign regions.

Principal-agent theory assumes that a worker's productivity depends not only on his human capital but also on the personal effort he is willing to make on the job. If the employer cannot observe the exact effort level because of asymmetric information and is therefore not able to reward diligence or punish sloth, a worker is not likely to do more than what is necessary to keep his job. This hypothesis might also be true for employees in industrial R&D departments, especially if they receive their pay in the form of a fixed salary. If a researcher does not participate in the company's

additional profits generated by his own innovations, he has no incentives to dedicate himself to the development of new goods and processes with all his heart and mind. Theoretically, an employer can set such incentives by paying a variable salary that increases with a researcher's output. Burhop and Lübbers (2010) explore whether this kind of incentive scheme worked in the R&D departments of German chemical and electrical engineering industries around 1900. They analyzed the contents of individual researchers' working contracts and found that among the three firms Bayer, BASF, and Siemens, only Bayer offered ex-ante contracted bonus payments that depended on the profits resulting from the employed researcher's inventions. In contrast, BASF and Siemens implemented discretionary reward schemes with no clear link between the level of bonus and a researcher's individual achievements. Regression analysis reveals that a high share of bonus payments in total compensation significantly increased the number of long-lived patents granted to a firm. Moreover, individual experience also mattered: total patent output rose with the average tenure of researchers.

If human capital has been the decisive bottleneck of innovating activities in history, its unequal distribution across countries and regions might help to elucidate the even more skewed geographical distribution of patents. Sokoloff and Khan (1990) disagree with this supply-side argument. They assume that during early American industrialization the skills and knowledge that were needed for successful patenting activities were widely spread among the general population. In their view, it was the unequal access to mass markets for innovative goods that explains why some regions became innovative and others did not. This demand-side argument is based on the assumption that the expected profitability of a patent increases with the size of the market in which the patented innovation might be sold. As land transport was prohibitively expensive before the introduction of railways, firms that were either located near highly populated metropolitan areas or able to transport their innovative goods at low costs on navigable waterways to distant markets had arguably much higher incentives to take out patents than did firms in more remote areas. To support this hypothesis, Sokoloff (1988) demonstrates that previously non-innovative northeastern American regions in the neighborhood of canals increased their patenting activities considerably after the completion of these waterways. Analyzing the biographical information on 160 "great American inventors," Khan and Sokoloff (1993) show that men of great technological creativity who did not already live in the traditional centers of innovation in New England and New York tended to move there. Interestingly enough, New England and New York kept their above-average level of innovation even after other American regions had gained similar market access due to the large extension of the railway network. This observation implies the likelihood of path dependency, which we will address below in more detail.

Demand factors not only influence innovation, but also firms' original choice of location. That is why it is necessary to distinguish clearly between a firm's choice of location and its decision to patent. Sokoloff is well aware of this problem and therefore controls for the division of the labor force between agriculture and manufacturing. It turns out that the estimated positive relationship between a

firm's proximity to navigable waterways and the intensity to patent is robust to the inclusion of this variable, which is supposed to measure the level of industrial activity in a region. Hence, in Sokoloff's sample, demand factors seem to influence the geographical distribution of patents independently of the original choice of location. The German case, however, suggests that the aggregated level of industrial activity might not be the adequate variable to distinguish between demand effects on firm location and on the decision to patent, respectively. German industries widely differed in their propensity to patent. The patent classes "electrical engineering," "chemicals including dyes," and "scientific instruments" together comprised more than one quarter of all long-lived patents granted between 1877 and 1918 (Streb et al. 2006). In addition, many valuable patents in the field of mechanical engineering were spread over several patent classes, such as "machine parts" or "steam engines" and less obvious ones like "weaving" or "agriculture" (which included textile machines and agricultural machines, respectively). The uneven propensity of industries to patent matters because of their simultaneous uneven geographical distribution across Germany. Obviously, the broad west-east strip of German regions with an above-average number of high-value patents, depicted in Fig. 3, was also the favored location of those industries in which most of the high-value patents originated. Long before the German patent law of 1877 actually came into force, the original choice of location for these industries might have been influenced by a variety of factors, such as the expected market volume or the availability of raw materials and intermediate products. Large (and later very innovative) chemical firms like BASF or Bayer, for example, preferred to settle on the banks of the Rhine, which was not only an important navigable waterway but was also used as a water source and a way to dispose of effluents. The great majority of chemical firms located themselves along waterways independently of their later decision to patent. Consequently, waterway areas had an above-average density of chemical firms, and because of this industry's high patenting activities, also had a higher number of patents than regions with a similar industrial activity level that were dominated by industries that patented less than the average. The same argument holds for mechanical and electrical engineering. Firms engaged in the field of mechanical engineering were especially concentrated in the geographical neighborhood of iron and steel producers, namely, in the Greater Ruhr area, and near textile firms, namely, in Saxony. Berlin was the center of German electrical engineering. To test the robustness of the relationship between a firm's proximity to metropolitan areas or mass transportation infrastructure and the propensity to patent proposed by Sokoloff, it would therefore be advisable to control not only for the general level of industrial activity in a region but also for the respective activity levels of different industries located in it.

Another point is worth mentioning. Sokoloff and his coauthors concentrate on the period of the First Industrial Revolution in early nineteenth-century America when the comparatively low level of human capital needed to invent a new steam engine or textile machine was widely dispersed among merchants and artisans. That is why, in the early nineteenth century and before, it might have been the access to mass markets for innovative goods that made a potential inventor into an actual one. During the Second Industrial Revolution of the late nineteenth century, however,

when basic innovations occurred in chemicals and electrical engineering, broadly dispersed general technical knowledge and skills might no longer have been sufficient for achieving a major technological breakthrough. This assumption is also supported by the fact that, in this period, the share of independent inventors among all patentees declined steadily while the respective share of researchers in industrial R&D departments increased (Nicholas 2011b, p. 1003). By then, the unequal geographical distribution of patenting has been rather determined by the unequal supply of higher education. It is therefore conceivable that the increasing importance of science and technology for innovation processes over the course of the nineteenth century shifted the main emphasis from demand-side factors to supply-side factors when it comes to explaining innovations.

Yet another argument in favor of the view that innovation is mainly driven by demand-side factors is the observation that upstream manufacturers' search for innovations is often driven by the concrete needs of their downstream customers. Streb et al. (2007) observe a statistically significant bidirectional Granger causality between German net cloth exports and patents in the technological classes "dyes" and "dyeing," which suggests that during the German Empire, the knowledge exchange between chemical and textile firms created an upward cycle of endogenous growth. Specifically, after the invention of many synthetic dyes in the last third of the nineteenth century, German chemical companies soon realized that textile manufacturers were not able to process synthetic dyes with their traditional equipment. That is why the former also engaged in the development of new chemical and mechanical procedures suitable for processing synthetic dyes. In a next step, this new knowledge was communicated to the downstream textile industry. The main channel of this knowledge transfer was the newly invented customer consulting service of the German dye manufacturers, which regularly informed textile firms about both new dyes and new dyeing methods. The German textile firms subsequently increased their international competitiveness to a considerable extent by exporting cloth colored with the innovative dyes. The increasing demand for synthetic dyes by the prospering textile firms in turn encouraged further R&D projects by the innovative chemical firms that led to new patents and again, via customer consulting, to additional economic benefits of the German textile industry. This upward cycle, however, was not infinite. It came to an end when the synthetic dyes technology had matured.

Various cliometric studies of innovations (Burhop and Lübbers 2010; Cantwell 1989; Khan and Sokoloff 1993) imply that the outstanding innovation of certain regions, companies, and independent inventors might have been built up in a path-dependent process. Degner (2012) elaborates on this hypothesis. The starting point of his theoretical considerations is the emergence of a new technology, such as the aforementioned chemical synthesis of dyes in the middle of the nineteenth century. Inspired by the economic opportunities that come along with a new technological field, in a first round of R&D, many newly founded companies with similar innovation capabilities will try to arrive at innovations. Given the high uncertainty of the innovation processes, however, only a few of these companies will succeed. Those firms will possess two advantages in the following second round of R&D.

They can now build on the scientific and economic knowledge their employees have acquired during the first round of R&D. In addition, the sales of the innovations developed in the first round of R&D might have led to the establishment of large financial reserves that will allow the innovative firms to expand their R&D capacities and therefore carry out several innovation processes simultaneously in the second round of R&D. Both advantages taken together considerably increase the probability that the winners of the first round of R&D will also make innovations in the second round – which, in turn, will foster their level of innovation in the third round of R&D even more. In contrast, firms that failed in the first rounds of R&D will soon no longer have a chance to catch up to the growing advantage of the early innovators. In the longer run, a path-dependent process will split initially very similar companies into few very innovative and many non-innovative companies.

To test his theoretical model, Degner analyzes the patenting activities of more than 1,000 German firms between 1877 and 1932. His striking result is that a firm's stock of valuable patents is a robust predictor of future patenting activities, whereas neither firm size, access to capital market, market structure, nor regional human capital endowment have a robust, significant influence on the number of valuable patents. Future research will show whether these empirical observations can be generalized. If this is the case, both the skewness of distribution of innovations across firms and regions (where innovative firms and individuals are clustered) and the persistence of innovation could be explained by the process of path dependency outlined by Degner.

Until now we have interpreted patent statistics as an admittedly imperfect but still objective measure for innovations. This view neglects the possibility that the introduction or change of a particular patent law itself might influence both the level and the direction of innovation activities. From a theoretical perspective, the introduction of formal intellectual property rights promises to foster innovation. The argument is that, in a world without patent protection, many inventors would have to fear economic losses because competitors would imitate innovations quickly and sell them at prices that only cover their own production costs but not the original inventor's R&D costs. Expecting this ruinous competition in advance, many potential inventors might decide to forego R&D projects that would otherwise lead to socially useful innovations. To fight this underinvestment in R&D, governments introduced patent protection, which allow successful inventors to recover their R&D costs by selling their innovations as a temporary monopolist.

This simple textbook explanation of the beneficial effects of formal intellectual property rights might be misleading in a more complex historical setting in which emerging countries struggle to catch up to the technological leaders. Murmann (2003), for example, argues that German chemical companies owed their meteoric rise to world market dominance in the late nineteenth century to a large extent to the absence of a German patent law before 1877, which made it possible to imitate British and French synthetic dye innovations and sell them in the unprotected German market. During this period of ruthless imitation, German imitators learned to master the new technology, build up R&D departments, and develop their own innovations. Perhaps unsurprisingly, after learning by imitation was completed,

German chemical firms began to lobby for the introduction of a domestic patent law because they now judged their newly acquired capability to innovate more profitable than their traditional imitating strategy. Richter and Streb (2011) confirm Murmann's narrative for the case of German machine tool makers who, in the second half of the nineteenth century, used various channels such as reverse engineering, visiting international exhibitions and foreign firms, scrutinizing international patent applications, and hiring foreign craftsmen and engineers to imitate superior American technology. In the early twentieth century, many of these former product pirates became internationally renowned innovators of machine tools.

In the nineteenth century the Spanish government found an elegant solution to have the best of both worlds: a full-fledged national patent system while maintaining the possibility to imitate superior foreign technology for free. So-called patents of introduction could be granted to Spaniards who were the first to introduce a foreign innovation into the Spanish market. For this technological transfer, the authorization by the original foreign inventor was not needed (Sáiz and Pretel 2013).

To conclude, good imitators can become good innovators when unsecure intellectual property rights give them the time they need to adjust to international competition in innovation. There is, however, one important caveat: Degner (2012) has shown that it is in general very difficult to catch up to the accumulated stock of experience innovative firms in industrialized countries have already built up in many historical R&D projects. Nevertheless, developing countries may realize that it does not pay to be an early complier with international rules of law with respect to intellectual property rights. Doing so may not only amplify the dominance of the traditional technological leaders but can also slow down the speed of technological and economic progress in their domestic industries.

Moser (2005) questions the alleged innovation-stimulating effects of patent protection on a more general level. Based on her research on exhibits presented at world's fairs between 1851 and 1915, she shows that countries without domestic patent laws did not display lower levels of innovation than countries with a long-standing tradition of patent protection. Switzerland, for example, which switched towards a fully functioning patent system only in 1907, regularly presented a comparatively high number of high-quality innovations at the world's fairs as measured by the jury prizes they received for exceptional novelty and usefulness. Moser has to admit, however, that patent laws might have influenced the direction of innovation activities. According to her research, countries without domestic patent protection concentrated their R&D activities on industries for which secrecy was a comparatively efficient means to appropriate the return to innovation. Many innovations in food processing, for example, such as milk chocolate, baby foods, and ready-made soups, were developed by Swiss or Dutch inventors in periods when neither country had a patent law. From this perspective, the current leading position of Dutch and Swiss companies in international markets for consumption goods might be a legacy of a long-gone era without patent protection.

Nicholas (2011a) adopts another approach to test for the influence of patent protection on innovation. His starting point is the observation that international patent systems differed considerably with respect to the fees a patentee had to pay to keep a patent in force. At the end of the nineteenth century, the total costs of

maintaining a patent for 15 years came to £265 in Germany, £84 in Belgium (for a 20 year term), £60 in France, and £54 in Italy. The important outlier was the United States where a mere £7 secured a 17-year patent protection, a fact which is believed to have promoted the "democratization" of innovation activities in this country (Sokoloff and Khan 1990). Nicholas does not exploit this cross-country variation, but concentrates on the English case where patent fees were reduced from £175 to £154 in 1883 for a 14 years' term. To be precise, the English fee reduction did not affect the two renewal fees payable by the end of the fourth year (£50) and by the end of the seventh year (£100). Only the initial fee, which was due at the beginning of the patent protection, declined from £25 to £4.

Following the arguments by Macleod et al. (2003) a first payment of £25 might have been prohibitively expensive for many potential English inventors. From this group's perspective, the fee reduction of 1883 represented the first affordable patent protection for their inventions. One would therefore expect an increase in English patenting activities after 1883, something which actually happened. Nicholas, however, wanted to know whether the 1883 reform also fostered innovation as measured by valuable patents, which he identified with the help of both the number of citations they received and their individual life span. Using a difference-in-difference regression to analyze changes in valuable English patents relative to the control group of valuable patents granted to English patentees in the United States, he concluded that the decrease in patent fees did not increase innovation. This finding has an important methodological implication. If the level of patent fees only influenced the number of total patents, but not the number of the valuable ones among them, an international comparison of the latter would be possible even when the variation of national patent fees was considerable.

National patent laws also differed with respect to other features. For example, some countries introduced technical examination or compulsory licensing clauses, while others did not. Moreover, some patent administrations discriminated against foreign inventors, while others did not (Khan 2013; Moser 2013). Because of these various differences, scholars should exercise a degree of caution when comparing patenting activities across different countries.

Technological Transfer

A major merit of patent laws is that they create a reliable legal framework for the diffusion of technology both within countries and between countries. The first channel through which the diffusion of technology can take place is the public disclosure of new knowledge. A patentee is required to provide a detailed technical description of his innovation in the patent specification that is then made available to the general public. Even though others are not allowed to exploit this information for the economic purpose specified in the patent during its period of validity, they can immediately use it as a starting point for related R&D projects. To prove that this diffusion mechanism already worked in the nineteenth century, Moser (2011) shows that innovation activities in the US chemical industry became less geographically

concentrated after this sector's propensity to patent had increased in the late nineteenth century.

To analyze the volume, direction, and impact of international technological transfer empirically, researchers traditionally rely on international data for bilateral trade flows or FDI. However, patent specifications can also serve foreigners as a source of new knowledge, especially when these patents were published in their native language. That is why Eaton and Kortum (1999) measure the direction of technological transfer by patenting activities in foreign markets. They conclude that since the end of the Second World War the world's long-term productivity growth has been mainly driven by the foreign patenting activities of a few leading research economies. The United States has been the dominant source of new knowledge, followed by Japan and Germany. Khan (2013) changes the perspective from countries of origin to the recipient countries. Interestingly enough, the average share of foreign patents in all patents granted varied considerably across countries between 1840 and 1920, for instance, from 78% in Canada, 59% in Spain, 34% in Germany, 22% in the United Kingdom, to only 7% in the United States. Based on this observation, she develops the hypothesis that lower rates of patenting by foreign inventors indicate a higher level of innovation of their domestic competitors. This might be true if inventors of any other country first and foremost engaged in those foreign markets where they did not fear the high technological creativity of the domestic population. Note, however, that Khan's considerations contradict the traditionally held assumption that foreign patenting concentrates in countries where the probability of imitation is high due to a comparatively rich endowment of technical competencies and skills.

According to Khan's statistics, the German patent market was a preferred destination of foreign inventors relative to other third markets. Using the concept of revealed technological advantage, Degner and Streb (2013) analyze the international patterns of technological specialization on the basis of foreign patenting activities of 21 countries from the European core, the European periphery, and overseas between 1877 and 1932 in Germany. It turns out that the countries of the European core revealed technological strength in the old technological fields of the First Industrial Revolution and in the new technological fields of the Second Industrial Revolution. Great Britain, for example, excelled in textiles, machine tools, electrical engineering, chemicals, and mass-consumption technology. In contrast, the Eastern and Southern European countries of the European periphery demonstrated technological strength only in the well-known technological fields of the First Industrial Revolution, such as Spain or Poland in the textile, coal, and steel industries. This difference suggests that a country's technological advantages were significantly influenced by its current stage of economic development. While the economically advanced countries of the European core had already explored the prospects of the more science-based technologies of the Second Industrial Revolution, the less advanced countries were still engaged primarily in the traditional technological fields of the First Industrial Revolution. This finding supports Cantwell's (1989) hypothesis that backward countries were not able to catch up to the superior level of innovation of the leading research economies.

A closer look at the performance of individual countries reveals further insights. The availability of domestic natural resources obviously influenced a country's technological specialization. Most of the countries with their own natural deposits of coal, iron, or other nonferrous metals, especially Belgium, Luxembourg, the modern-day Czech Republic, Poland, Norway, and Spain, displayed strong advantages in the technological field of the coal and steel industry, which included mining technologies for nonferrous metals. France, the Netherlands, and Denmark used their advanced agriculture to concentrate on innovations that fostered the mass consumption of foodstuffs and drinks. It is not surprising that Italy and France displayed great technological strength in the field of motor cars. Canada, however, which is not renowned for manufacturing automobiles, also revealed some technological advantage in this field before the First World War. Therefore, historical patterns of technological specialization might also produce information about abandoned national paths of technological development that would be otherwise forgotten.

The second channel through which patent protection facilitates the diffusion of technology is by decreasing the transaction costs of information exchange. As long as intellectual property rights were insecure, inventors who wanted to sell new ideas always had to fear being cheated out of their financial compensation. After the introduction of patent protection, it became easier and less risky to transfer knowledge via patent assignments, and particularly creative inventors specialized in invention activities. Lamoreaux and Sokoloff (1999, 2001) claim that the particular features of the American patent system, namely, the very low registration fee and the requirement that only the "first and true" inventor was entitled to apply for patent protection, were the key behind the pronounced division of labor in American innovation activities. Specialized inventors concentrated on the creation of technical inventions and then sold their new knowledge via patent assignment to established firms that took over the task of manufacturing and selling the innovation. Patent agents or lawyers often acted as an intermediary between inventors and companies. The relative importance of this type of technological transfer is demonstrated by the fact that around 1900, about one third of American patents was fully or partly assigned after issue. The historical German patent market was less liquid than the American one which can be explained at least partly by insufficient inventor protection (Burhop 2010). The German patent law ruled that the first applicant, not the initial inventor, was entitled to a patent grant. As a result, many innovations that were created in industrial R&D departments were directly granted to the company and not to the employed researcher. This is another example of how the details of a national patent law can significantly influence the outcome of innovation processes and therefore patent statistics.

Future Research

Until now, most cliometric studies of innovations have concentrated on patenting activities in leading research economies such as the United States, the United Kingdom, Germany, or Japan. To learn more about imitating and innovating in less advanced countries, future cliometric research projects should take a closer

look at patenting activities in the European periphery and overseas. The greatest challenge will be to harmonize the different national patent statistics and merge them into one unified data base that would allow for testing for the various determinants of patenting activities on the basis of a broad international panel. Given the obvious shortcomings of patent statistics, researchers should also keep on searching for alternative historical mass data which include information on innovations that have never been patented.

Another desideratum is to get more information about the microeconomics of historical R&D management. Here, the research idea of scrutinizing historical working contracts of employed researchers (Burhop and Lübbers 2010) might be a good starting point for further empirical analysis. Surprisingly enough, cliometric studies in innovations have widely neglected to research the impact of innovations on economic performance. It would be very interesting, however, to learn more about how the skewed (and persistent) distribution of innovations across countries, regions, and inventors affected the respective distributions of economic outcome indicators such as GDP per capita, productivity, or profit.

Arts and Culture

Karol Jan Borowiecki and Diana Seave Greenwald

Contents

Abstract

The economic history of arts and culture includes both "high culture" – like the fine arts, theater, and classical music – and popular culture, such as pop music, movies, and newspapers. This chapter focuses primarily on the high arts but also provides a cursory description of the literature addressing more popular cultural production. The four sections of this chapter correspond to four key areas of inquiry in the economic history of arts and culture: what are relevant data about the arts and how to capture them, how market forces encourage the consumption and supply of culture, how artistic production is linked to geography and clustering, and what drives creative output. This chapter surveys scholars' engagements with these questions across a wide range of art forms and time periods. It

Art · Creativity · Innovation · Art markets · Culture

Introduction

A chapter on arts and culture is a necessary component of a handbook of cliometrics, if only to honor the Greek god for whom the discipline is named. According to Greek mythology, Clio was the muse of history, seated alongside her fellow muses responsible for the inspiration of poetry, music, dance, and other arts. Clio herself is sometimes credited with being the "proclaimer" of all these arts – announcing, preserving, and praising them for history (Graves 2012: 577–781). Like the muses, the economic history of arts and culture is multidisciplinary. Economists, economic historians, sociologists, and art historians have all made significant contributions to the subfield. Therefore, while this chapter will focus primarily on contributions by economic historians, it will necessarily summarize and engage with work originating in other fields.

Although considered a subcategory of cliometrics, the economic history of arts and culture is vast. It includes both "high culture" – like the fine arts, opera, classical music, and ballet – and more popular culture, such as pop music, movies, novels, newspapers, and video games. In just one chapter, it is impossible to summarize all of the work done on these many subjects. Therefore, this chapter focuses primarily on the high arts, the expertise of the co-authors. While we focus on the high arts, it is important to note that these are *cultural* products; they are a consequence of the wealth and tastes of individuals existing in a particular cultural setting. We do our best to also include an at least cursory description of the literature addressing other more popular cultural production, what Ruth Towse describes as "media economics. . .the area of the broadcasting, audiovisual and publishing industries" (Towse 2010: 6). Nonetheless, this chapter should not be viewed as a definitive survey of *all* cliometric work that can be classified as dealing with arts and culture. It is, instead, an introduction to the field, including suggestions for future reading for those interested in pursuing the economic history of arts and culture.

This chapter is divided into four sections, each of which responds to the four key questions in the economic history of arts and culture. The first section, "Problems with Data and Culture," asks what are relevant data about arts and culture and how do we capture them. The research question central to the section "Art Markets and Their Logic," is: if artistic output is a response to market forces, how have these forces changed over time to encourage and form consumption and supply? "Cultural Output and Geography," the third section, examines where artistic consumption and output are located. The market for the arts is *not* a globalized commodities market where interchangeable goods can be traded for a worldwide price. Instead, it is

centered in specific places and often involves a live performance. The final section, "Capturing and Fueling Creativity," summarizes the literature that explores whether it is possible to understand what drives creative output and therefore determine how to encourage it. Understanding what drives creativity is of significant policy interest as economies become service economies. In a service economy, economic growth is driven by highly educated workers who are often employed in positions and industries that demand creativity and innovation. Understanding the economic history of artistic output can help policy makers understand what will encourage creative output in the future.

In the conclusion to this chapter, we will describe the future of the subfield and how we believe it will continue to address these lines of inquiry and which new questions may be on the horizon. We encourage readers considering delving into the economic history of the arts in greater depth to explore the reference list included.

Problems with Data and Culture

To address research topics in the economic history of the arts – such as how and why individuals create high-quality artwork and understanding how art markets function – scholars need good data about historical cultural output. Like in other areas of economic history, it is challenging to find these data. However, locating high-quality historical data takes on a couple of important new dimensions when the study of arts and culture is involved. There are several obstacles that scholars face when determining what is relevant data about arts and culture and how to capture these data.

The first obstacle faced is the ability to translate the aesthetic quality and value of a work of art, music, literature, or performance into a data point. First, scholars need to adjust their usual data-driven methods to measure the unique and often subjective quality of cultural output. For example, should scholars use artists as their level of observation – therefore aggregating professional performance across a career – or should they focus on individual works, which can capture the good and bad works by famous artists and the occasional influential work by an otherwise unsuccessful artist? There is no correct answer to this question, but it is an example of the ways in which economic historians need to adjust to the particularities of studying artistic output.

A second difficulty is related to survivor bias, which is particularly pronounced in the study of the history of arts and culture. Unlike a census or other systematic data collection, the focus of historical artistic data is *not* on average individuals, but rather exceptional ones. Data typically only exist for famous artists, those who "made-it" and are observable in the present, often decades or centuries after their deaths. Third, the market for arts and culture is particularly opaque. Even today, an important proportion of works of art are sold by private dealers for prices that are never made public; the bottom-line of movie or theater producers, if private, are similarly privileged. Therefore, when cliometricians go in search of historical artistic data, they face two problems: locating data from years past and locating data generated by markets that are relatively small and where pricing is frequently private. Because of

the importance of data quality in this subfield, many contributions to the existing literature are significant in part because they provided new arts data that allowed for new insights.

One of the problems that economic historians of art struggle with the most is how to capture the *quality* of artistic output. However, before tackling quality questions, it is surprisingly difficult to even grasp the true *quantity* of art produced and consumed over time. For the visual arts, several sources are available. Auction data can, of course, capture large samples of art produced across several centuries; art from ancient times to the present can be sold at a contemporary auction. Several online databases – such as artnet and Blouin Art Index – provide this data for the past few decades; hard copy works like Gerald Reitlinger's three-volume opus *The Economics of Taste* (1961–1970) lists works sold at auction from 1760 to 1960 (although this data has been critiqued since publication, notably Guerzoni 1995). Other sources of the quantity of output over time include exhibition data like those used in Greenwald (2018a), museums increasingly accessible lists of their permanent collections, and catalogue raisonnés – complete lists of a given artist's production – assembled by art historians. Finally, a number of scholars have located sales data for historical markets. Many recent papers, in addition to making analytical contributions about art markets, have contributed significant new troves of data about historical artistic production. Recent examples of work that contributes exceptional art market data include Federico Etro and Laura Pagani's study of art markets in seventeenth-century Italy (Etro and Pagani 2012); Kim Oosterlinck, Christian Huemer, and Geraldine David's work about the multinational nineteenth-century art dealer Goupil & Cie (David et al. 2014); and Richard Goldthwaite's recent "economic biography" of an early Italian composer (Carter and Goldthwaite 2013).

Of course, scholars are not only interested in charting and understanding greater quantities of artistic output but also in tracking and understanding what drives higher *quality* creative work. Following standard economic theory, many scholars use prices to approximate the value of goods and services, and this includes artistic output. Within visual arts, this can be done rather conveniently with past results from art auctions and under the assumption that market prices reflect the true quality of a painting. First in a landmark article (Galenson and Weinberg 2001) and then in the book *Old Masters and Young Geniuses* (2007), economist David Galenson used auction prices as a proxy for the quality of an artwork. Focusing on nineteenth-century French artists, his arguments depended on auction prices decades after the creation of an artwork as a proxy for intrinsic quality. Other scholars working on the visual arts, notably Christiane Hellmanzik and Douglas Hodgson, have also used auction prices as indicative of quality (e.g., Hellmanzik 2010, or Hodgson 2011). There is, however, some bias in these approaches in so far as prices are affected by certain unobservable trends and fashions – whether contemporary or historical – and it can be difficult to account for these. Take, for example, the significant price increases of modern art since the turn of the twentieth century, especially in comparison with, say, Baroque art over the same time period. This is unlikely a reflection of higher perceived quality and artistic merit of modern art, but rather a shift in fashions (the taste for religious art is on the decline) and market trends (the

expectation of higher returns on modernism attracts further investment). While using auction data is useful for the study of artworks, it has its limitations outside visual arts and cannot be applied easily to music or literature. A composer's hand-written music manuscripts can be auctioned for a non-negligible amount, but here the link between quality and price is less clear. The manuscripts are historical artifacts, not the works of music themselves.

Another way of assessing the quality of an artist's oeuvre is to use contemporaneous expert opinion – namely, opinions formed at the time a cultural work was produced – to judge the quality and importance of a work of art. Helpfully, there are expert opinions published not only about visual arts but also about the performing arts, music, movies, and books. Economists have tried to gauge the ability of neutral experts – like critics and the awards committees – to pick "winners" in arts and culture, both financially and in terms of artistic reputation. In two 2003 articles, Victor Ginsburgh (Ginsburgh and van Ours 2003; Ginsburgh 2003) examines the role of expert opinions in a classical music competition, American movie awards, and international book prizes. He concludes that positive expert opinions or awards given shortly after the production of a work are usually correlated with economic success. However, these pronouncements do not correlate with the long-term survival or acclaim of the work of art or artist. In the visual arts, Kathryn Graddy specifically tested the correlation between quality rankings created by renowned seventeenth-century art critic Roger de Piles for artists active in his own period and the prices attained by those artists on the auction market over the subsequent three centuries. She finds that his highest-ranked artists attain both better financial returns on the market and art historical acclaim (Graddy 2013). It is therefore unclear how reliable contemporaneous expert opinions can be.

Therefore, many scholars choose to engage with *retrospective* expert opinion. In short, they use "best of" lists, comprehensive dictionaries of artists, writers, and musicians (e.g., Grove Art Online, Grove Music Online, and the Encyclopedia Britannica), and other retrospective compendia to gauge the importance of a given cultural producer and his or her output.[1] Using the length of entry about a producer in these compendia is a strategy to measure the significance and quality of a producer's contributions to his or her field. O'Hagan and Kelly (2005)[2] discuss this approach and the relevant literature in depth. They also developed their own selection algorithm using a column-inch method, in which they look at the space devoted to each artist in an art dictionary and gauge the quality of an artist by how much space is allocated to him or her. The underlying assumption that the length of entry correlates with an artist's importance finds support in empirical evidence. However, there are also drawbacks to this approach. First, artists who lived longer have naturally longer

[1]For example, in "The Dictionary of Composers and Their Music" (1979 & 1993), the two musicologists Gilder and Port provide information about who wrote what, and when. The dictionary is a recognized survey of the most influential classical compositions and served often as a source for composer's output (e.g., Borowiecki 2013).

[2]http://www.tandfonline.com/doi/abs/10.3200/HMTS.38.3.118-125

biographies, albeit longevity may also correlate with their fame; these individuals simply had more time to produce potentially famous work. Second, artists in early periods, especially prior to the eighteenth century, typically have shorter biographies because documentation and historical sources from this earlier period are less common and less well-preserved. Third, and perhaps most difficult to deal with, is the existence of biases to the home or target market country of the reference work; this issue persists even in the most prestigious publications. Therefore, building on selections of artists from just one reference work will create a bias that is inevitably directed toward the country of origin of the source and, as a result, one will over-represent artists of a particular nationality or gender and under-represent others – women artists, artists of color, and artists from the global south are chronically underrepresented.

To overcome these issues, one would ideally use a larger number of international dictionaries and pursue various selection algorithms, depending on the objectives of research. An example of this kind of extensive work is *Human Accomplishment* by Charles Murray (2003). In this book, the chapter "Excellence and Its Identification" describes how Murray selected the most prominent people in various fields – including visual arts, music, and literature – and outlines his comprehensive selection methods. His selections are based on numerous international dictionaries and reference works to mitigate the risk of country- or marketing-biases. Murray's lists of famous achievers have been often used to identify samples in other research projects (e.g., in visual arts, Hellmanzik 2010, or in music, Borowiecki 2013). Though not included in Murray's sources, other data sources that can be used to gauge the importance of an artist are the collections of museums and performance programs at operas, symphonies, and theaters, which are all determined through a combination of audience demand and the subjective choice of curators or artistic directors (Alfred Loewenberg's "Annals of Opera" [1978] is a reference work on notable performances, used by, among others, Giorcelli and Moser 2016).

Though applicable to many fields and a practical method for gauging an artist's quality and prominence, using data from encyclopedic lists of the collections of cultural institutions is vulnerable to significant sample bias. To even qualify for inclusion in these publications and institutions, an artist, composer, or author had to have made a meaningful contribution to the relevant arts canon. The sample of creatives presented in these publications is non-random (Gilder and Port 1993; Borowiecki 2013). Hence, one may ask: what about the lives and works of ordinary artists? There is no dictionary of mediocre artists or low-quality artworks. However, recent research has proposed ways to work around this obstacle. One approach is to obtain data from censuses. For example, Borowiecki (2018) pursues this method and collects data on thousands of average artists using the United States census as recorded in the Integrated Public Use Microdata Series database. The comprehensive decennial population census provides information from 1850 on occupational status, which can be used to identify various high art occupations, including artists (visual arts), authors (literary arts), musicians (music), and actors (performing arts). Working at the level of individual works, Greenwald (2018a, b) explores data about historic exhibitions that captures *all* the artists who participated in contemporary

art exhibitions at a series of venues around France and the United States during the nineteenth century. There are also scholars working with online searches for certain artists or artworks, or downloads of certain types of music from streaming platforms, in order to move closer to un-curated demand by art audiences (Borowiecki and O'Hagan 2012; Waldfogel 2014; Aguiar 2017).

As is common in other research areas in economic history, there is no one perfect data source for information about arts and culture. Survivor bias related to works of art and artists – in the visual arts, music, literature, and other areas – is particularly pronounced. Notable, artwork and artists dominate the available data. It is convenient to assert that famous artists have made very significant contributions to the arts and our cultural heritage, and therefore constitute a particularly appealing sample to look at. Famous artists are also the right sample if one is interested in understanding what drives outstanding creative output and genius. Though economic historians of arts and culture have conducted exhaustive archival research and come up with novel methods for capturing creative output, persistent sample bias is a reality that must be acknowledged and addressed in this subfield, perhaps more than in other cliometric disciplines.

Art Markets and Their Logic

Unsurprisingly, many works of economic history dealing with arts and culture address research questions related to *markets* for art and culture. Economic historians generally accept that the output of any good is a response to market forces; therefore, just like for other goods, scholars examine how these forces have changed over time to encourage the consumption and supply of creative output.

Art markets – particularly markets for visual arts – are peculiar in a number of ways. First, "value" in these markets is subjective. Judgment of the relative quality of cultural product depends on the combination of expert opinion and audience reception. Furthermore, judgments of a book, film, or other work of art's value can change significantly over time. Consider the example of Vincent van Gogh, whose work received little recognition during his lifetime. Despite producing approximately two thousand paintings, he sold very few of them while he was alive and died penniless at the age of 37. Today, his paintings are among the most valuable in the world. Largely because of these subjective valuations, there are significant asymmetries in information between suppliers and consumers in cultural markets. This creates ideal conditions for the presence of intermediaries – art dealers, record labels, movie studios, publishers, etc. – to mediate interactions between the cultural producers and their audiences. Later in this section, we will describe the growing literature dedicated to these intermediaries, their development, and their behaviors. This section often focuses on the market for visual arts, because it is a large literature and engages with research questions related to markets for other art forms; however, we also make an effort to discuss studies of markets for other cultural goods.

When studying art markets, scholars' primary research questions generally fall into one of three categories. The first category is the description of a particular

historically significant moment in the history of art, including moments of significant transformation in market structure. The second category is the performance of art as an asset over time, which depends in large part on the structure of the art market. The third category consists of efforts to understand how markets for art and culture have been formed by the broader socioeconomic context in which they exist, and how, in turn, these markets have had long-term effects on communities where they are present. This section describes studies in each of these areas.

There are several major contributions to the economic history of arts and culture that provide specific data and historical detail about significant moments in the history of art markets. A foundational example of this type of work is the literature about art markets in Golden Age Holland. Economist John Michael Montias's examinations of seventeenth-century Dutch painting (Montias 1982, 1989) provided extensive price data about paintings produced during this period and social and economic detail about the communities where art was produced and consumed. His scholarship was the first in a series of economic history works in this area conducted by both art historians and economists, included Filip Vermeylen, Neil De Marchi, and Hans Van Miegroet (e.g., Vermeylen 2003; De Marchi and Van Miegroet 1994). Other scholars have tackled the Italian Renaissance and Baroque periods, like Richard Goldthwaite's work on Renaissance Florence (Goldthwaite 1993) and Federico Etro and Laura Pagani's study of art markets in seventeenth-century Italy (Etro and Pagani 2012; Etro 2018), which presents exceptional data from contracts between artists and patrons. A recent notable example of this kind of work dealing with another period and geography is Kim Oosterlinck, Geraldine David, and Jeroen Euwe's research about the art market in in German-occupied Europe during World War II. Using novel data, they show that demand for art was booming during the war and that this demand is attributable to a wartime need for portable and saleable assets (Oosterlinck 2017; David and Oosterlinck 2015; Euwe 2007). Across this body of work, scholars seek to understand the particularities of supply (who, why, and how people are selling art) and demand (who purchasers were and why they decided to acquire artworks) at clearly defined moments in time. There is research with similar goals in other areas of the arts. For film markets, for example, Pokorny and Sedgwick (2010) chart the development of the US film markets from 1929 to 1999, focusing on a comparison of the 1930s and 1990s. In particular, they show that similar levels of profit variability existed in both decades; however, while in the 1930s the main source of profits was from low- to mid-budget films, in the 1990s the main source of profits was high-budget films.

Other research seeks to understand *transitions* from one art market structure to another. Frederic Scherer, for example, describes the evolution of European music markets from the 18th to the 19th centuries. In particular, he examines how composers transitioned from being employed by their patrons to being entrepreneurs seeking support and income from a variety of sources (Scherer 2004). In the 1960s, William Baumol and William Bowen used a blend of historical and contemporary data to examine how the costs of producing and supplying the performing arts had increased over the twentieth-century. They attributed this increase to large fixed costs – including growing costs of labor – for the performance of an opera, ballet, or

piece of theater and termed the problem a "cost disease." In turn, they argued that this cost pressure influences demand either by making the ticket price for the performing arts out of reach of many potential audience members or demanding that the state or private foundations provide significant subsidies for productions. This phenomenon damages the economic viability of the performing arts (Baumol and Bowen 1965), although this theory has been debated and questioned since its presentation (Cowen 2000).

Baumol and Bowen were interested in an on-going transformation in the market for the performing arts. Other scholars have produced purely retrospective work that focus on past changes. One of the most studied transitions in the structure of art markets took place in France during the nineteenth century. In *Canvases and Careers: Institutional Change in the French Painting World*, sociologist Harrison C. White and art historian Cynthia A. White examine the transition in late nineteenth-century France from a system of centralized state support for the visual arts to what they call the "dealer-critic" system, a decentralized market-based system for the exhibition and sale of contemporary art (White and White 1993). Many works have followed the Whites' lead in exploring and explaining why the market for arts and culture has changed over time. David Galenson and several co-authors have published a number of papers in direct response to *Canvases and Careers.* A paper published with Robert Jensen argues that the fracturing of a centralized state-sponsored exhibition system in nineteenth-century France can be partially attributed to artists' entrepreneurial impulses to exhibit and sell in their own group shows (Galeson and Jensen 2002). In another article, Galenson and Bruce Weinberg describe how the new decentralized market-based system encouraged and rewarded innovation among artists and helped foster the advent of modern art (Galenson and Weinberg 2001).

We describe this literature about nineteenth-century art markets in detail not only because it is much-cited in the field but also because it introduces an important topic in the economic history of the arts: the changing importance of certifiers and intermediaries in art markets over time. Under the decentralized "dealer-critic" system, the number of individuals participating in the market grew. This created a growing role for market intermediaries like art dealers and auction houses, including Christies, Sothebys, and Drouout. Some of the most studied intermediaries are contemporary art dealers. Works including Bystryn (1978) and Fitzgerald (1995) demonstrate that dealers have become essential for the economic success – and perhaps the art historical staying power – of modern artists. The most recent major contribution to this area, Olav Velthuis' *Talking Prices* (2005), presents compelling ethnographic research suggesting how pricing in the primary art market is fluid and depends on the ability of particular dealers to consistently adjust to the immediate conditions of supply and demand.

The role of market intermediaries is the focus of studies of other markets for cultural goods, including books, journalism, and music. In book history, publishers, printers, and booksellers are a particular focus (St Clair 2004; Dittmar 2011; Finkelstein and McCleery 2012). Scholars working on the economic history of the music industry have examined technologically driven challenges posed to traditional

intermediaries like record companies and the musicians they represent. As the contemporary music market changes radically (the initial dominance and then decline of records and CDs, the arrival of legal and illegal downloads, and now the rise of streaming), what counts as the "history" of the changing music market has been accelerated. Debates over intellectual property protection and its effect on the quality, quantity, and format of music produced have been central to the literature about intermediaries in music. Many articles (e.g., Oberholzer-Gee and Strumpf 2007 and Waldfogel 2012) have found that illegal downloading on services like Napster had little to no effect on the observed decline in record sales in the beginning of the twenty-first century and did not lead to deteriorating quality of music produced during the same period. As music piracy becomes less common – particularly in Europe and North America – scholars have instead turned towards assessing the effects of legal digital music streaming (Aguiar and Martens 2016). This literature about the music industry is directly related to another recurring theme in the economic history of the arts: the importance of copyright and protection of intellectual property. We will address this topic in detail in section "Capturing and Fueling Creativity."

As the art market and number of intermediaries grew from the nineteenth-century forward, buyers began to invest in art for financial as well as aesthetic reasons. Art became a valuable and easily saleable asset (Velthuis 2011). There is a large literature dedicated to judging the performance of art as an asset over the long run. In general, these papers find that art performs poorly as an investment. Useful surveys of these findings are conducted by Frey and Eichenberger (1995), Goetzmann et al. (2011) and Renneboog and Spaenjers (2013). The particularities of markets for art – persistent asymmetries of information and the influence of intermediaries like auction houses and art dealers – have a profound effect on art's performance as an asset. David, Oosterlinck, and Szafarz (2013) and a number of papers by Orley Ashenfelter, Kathryn Graddy, and Christophe Spaenjers examine inefficiencies in auctions for art and other luxury goods and how these inefficiencies negatively impact the performance of art as an asset (Graddy and Ashenfelter 2011a, b; Spaenjers et al. 2015).

The third and final group of studies of art markets examines the interaction between art markets and the broader social and economic context in which they exist. The most cited contribution in this part of the literature is from sociology. In *Distinction: A Social Critique of the Judgment of Taste*, famed sociologist Pierre Bourdieu asserts that "there is an economy of cultural goods [with] a specific logic" (Bourdieu 1984: xxv).[3] This logic is determined by the education and upbringing – the *habitus* – of the participants in the cultural economy. Bourdieu writes: "One can say that the capacity to see (*voir*) is a function of the knowledge (*savoir*). . .A work of art has meaning and interest only for someone who possesses the cultural competence, that is the code into which it is encoded. . .A beholder who lacks the specific

[3]Pierre Bourdieu, *Distinction: A Social Critique of the Judgement of Taste*, trans. Richard Nice (Oxford: Routledge, 1984), xxv.

code feels lost in a chaos of sounds and rhythms, colors and lines, without rhyme or reason."[4] Because transacting in this cultural economy demands this encoding, Bourdieu concludes that class may be not only expressed but also defined and transmitted to future generations through the consumption of cultural goods. Finally, he argues that formation of class distinction on the basis of cultural tastes is particularly effective. While upwardly mobile people may be able to accumulate financial capital in one lifetime, cultural understanding is the product of "total, early, imperceptible learning, performed within the family from the earliest days of life and extended by a scholastic learning which presupposes and completes it. . ..[B] ourgeois families hand [this] down to their offspring as if it were an heirloom" (Bourdieu 1984: 59). Since its publication, *Distinction* has established as given the assertion that cultural activities, tastes, and institutions are potent sites of class formation. The effects of this assertion have been far-ranging across fields that deal with the arts, including in cultural economics and the economic history of the arts.

Bourdieu used contemporary survey data and quantitative methods to support his assertions. While cultural economists working on contemporary issues have also used survey data to study connections between artistic consumption and socioeconomic background (e.g., Ateca-Amestoy 2008), economic historians have needed to look for other sources that allow them to study this interaction in the past. Therefore, this area of the economic history literature often focuses on how demand for art is related to and enshrined in bricks-and-mortar cultural institutions. This scholarship asks: how is the particular demand for or supply of art encouraged by and preserved in museums, operas, and symphonies? Furthermore, how do these institutions continue to form art markets after their founding?

In the visual arts, there have been several studies of the relationship between demand for art and the founding of art museums. Though not an economic historian, sociologist Paul Dimaggio has made major contributions to the economic histories of museums and other arts institutions. Building on Bourdieu's work, Dimaggio examines nineteenth-century American patrons' socially motivated founding of new museums, operas, and symphonies. He argues that these institutions changed how cultural output was delivered, and put a solid fence around what was considered "high culture" and what was "popular culture" (Dimaggio 1982). These categories of art and their distribution remain separated from one another today, and an artist's inclusion in a major museum collection (or the performance of a composer's work at a major opera house or symphony) remains an important certifier of an artwork's status as "high culture" and of its quality. Bruno S. Frey and several co-authors have made important contributions that document this phenomenon both in historical settings and today (e.g. Frey 2013).

Currently, the most active area of inquiry into the effects of bricks-and-mortar arts institutions is related to how the founding of an institution can form the supply of, and demands for, art in a given place for centuries *after* the institution was founded.

[4]Ibid.

Readers will note that almost all of the literature described here deals with the arts in a particular time and place. Even financial history papers that aim to measure the returns on art as a globally traded asset must concede to the importance of local and idiosyncratic interventions of intermediaries like those described in Velthuis (2005). Artistic output is not equivalent to a commodity like wheat or coal. Instead, trading in cultural goods is often done face-to-face, depends on personal relationships and takes place in dedicated physical institutions. These geographical factors are explored in greater detail in the next section, "Geography and Art."

Geography and Art

In the economic history of art, scholars often return to the topic of geographic clustering – both of consumers and suppliers of art. They have observed that across historical eras that the most active audiences and the best-known artists tend to be centered in particular cities. This section describes the work demonstrating this phenomenon and explores the effects of clustering on artistic output. It begins with studies of demand for arts and culture, and then transitions to research focusing primarily on supply.

Two recent contributions have discussed the persistence of demand for culture in cities with a long legacy of supporting the arts. In a paper titled "Phantom of the Opera" (Falck et al. 2011), Olivier Falck, Michael Fritsch and Stephan Heblich use the location of Baroque opera houses in Germany as a quasi-natural experiment to test whether or not high human-capital employees are drawn to cities with cultural amenities. They find that the presence of a Baroque opera house increases the current presence of educated workers. This suggests that there is persistence of "cultured" activities – and the reputation of being cultured – in certain cities. There have been several comments and challenges to this paper, but a recent replication study (Bauer et al. 2015) did find the same effect for Baroque opera houses; although there were also positive effects on the share of high-capital workers for historical brothels and breweries. The "Phantom of the Opera" paper did not set out to gauge demand for the arts; instead, it sought to understand why highly skilled workers choose to live in certain places, and how this clustering affects the growth path of a certain city and region. In contrast, Borowiecki (2015b) does set out to understand the persistence of support for the arts and demand for cultural goods in certain cities in Italy. He finds that cities and provinces that had high-levels of cultural activity in the past – measured by the number of active composers in the area – continue to have more concerts and operas performed in the present. Furthermore, residents still spend relatively more money on high-culture activities as compared to other entertainment, like sporting events. Demand for and support of the arts, once established in a given city, appears to persist.

Measuring clusters of demand for the arts is a new and small literature when compared with scholarship that aims to understand the geographic distribution of artists. One of the earliest quantitative studies on this topic dates back to the turn of the twentieth century, when Gustav Michaud explored the spatial spread of artists

and intellectuals in the United States and described his findings in the article "The Brain of the Nation," published by the Century Magazine in 1905 (Michaud 1905). This area of research has received considerable attention, especially in the last 20 years as many countries transition to a service-based economy. Studies of agglomeration economies have established as given that economic activity is concentrated geographically. However, geographic clustering of successful artists is remarkably more concentrated, and it has often been observed that throughout history the global population of prominent artists is located in a handful of cities. For example, Mitchell (2016) documents the extent of geographic clustering of a sample of 370 significant poets and writers in the UK and Ireland born 1700–1925. She identifies the Greater London Area as an unrivalled cluster, with 79 (or 21%) of writers born within this region, and during its peak more than 50% of all authors working there. Dublin, Edinburgh, Oxford, and Cambridge emerge as the only other cities that see minor clustering of authors at any point in the sample. Other major contributions that document this intense clustering include Hall (2006), Murray (2003), and Schich et al. (2014).

At Trinity College Dublin, John O'Hagan, now Professor Emeritus, leads a research group specifically dedicated to the study of creative clustering. This group has produced a series of projects compiling detailed databases that cover the lifetime migration histories of hundreds, or even thousands, of famous artists, ranging from visual arts, to music, to literary arts. Research by this group and by Maximillian Schich show that the clustering of artists is not driven primarily by large numbers of births of artists in given cities, but rather by patterns of migration. Schich et al. (2014) use a database of 150,000 notable people – including artists – to show that the median distance between birth and death place for these people has remained largely constant from the fourteenth to the twenty-first century.

O'Hagan and Hellmanzik (2008) specifically examine famous visual artists' migration and clustering patterns for four periods (based on their date of birth): Renaissance Italy, Europe in the first half of the nineteenth century, and the Western world in general for the periods 1850–1899 and 1900–1949. These data support Schich's conclusions that famous artists clustered at a remarkably high level in all periods. Florence and Rome dominated in Renaissance Italy, with significant clustering because of artists' birthplaces and domestic migration. Paris and London witnessed a marked clustering of artists born in the first half of the nineteenth century. These two cities were the main work locations for 55 of the 72 artists studied. The French capital continued to dominate among artists born in the second half of the nineteenth century, while artists born in the first half of the twentieth century clustered in New York City, with all prominent American artists clustering there. The geographic distribution of music composers is studied by O'Hagan and Borowiecki (2010), who examine annual migration and clustering patterns of 522 important composers of the last 800 years. In line with visual artists, it is shown that Paris has been a major center for composers. The concentration of composers in this one city perhaps reflects the general prominence of Paris as a cultural city. Some composers were born in the French capital, but most migrated to it. Table 1 outlines the broad pattern of migration of prominent composers over the

Table 1 Type of movement of famous music composers by century

	Movement						
	None		Internal		External		All
Century of Birth	Total	Relative	Total	Relative	Total	Relative	Total
12th	2	0.50	2	0.50	0	0.00	4
13th	0	0.00	2	0.50	2	0.50	4
14th	2	0.18	8	0.73	1	0.09	11
15th	0	0.00	31	0.61	20	0.39	51

All	77	0.15	306	0.59	139	0.27	522

Source: O'Hagan and Borowiecki (2010)

centuries. O'Hagan and Borowiecki find that 86% of all prominent composers spent the longest period of their working lives away from their place of birth, 59% migrated to a city within the country of their birth, while the remaining 27% migrated to work in another country.

These studies show a significant rate of migration going back several centuries for artists, musicians, and other creative people. This suggests that creatives existed in an integrated global world many centuries before average people regularly migrated towards urban clusters. Importantly, as the markets for art and culture were not (and are still not) globally integrated, the suppliers of art have had to travel to cultural centers where art markets, institutions, consumers, and other producers are located (Florida 2014).

These migration patterns appear to hold for more than just notable artists. In an effort to address the issue of sample bias in the subfield, Borowiecki (2018) examines differences in the clustering intensity and location choice between famous and average artists in the United States from 1850 to the present. This is done using both census records to cover average artists and data from art dictionaries listing famous artists. He shows that the geographic spread of the census artists (the "average" artists) is greater, which implies a lower clustering intensity – albeit still very noticeable – in comparison with the famous creatives. This reconfirms the previous statements that extraordinary achievers concentrate more than average individuals. It is interesting to observe that for both populations of artists the same dominant clusters emerge: New York City, followed by Boston, Chicago, Los Angeles, and San Francisco. Borowiecki (2018) also shows interesting differences across artistic domains. However, some discipline-specific clusters emerge. New Orleans has a very high concentration of births of musicians, while Seattle constitutes an important work location for literary artists.

Often, businesses that help sell the creative output of artists also cluster, usually near the artists themselves. Several studies of the locations of art dealers over time

show that like artists themselves, they cluster intensively in the same place – even in the same neighborhood in a culturally active city. Examples of this geographic work on art dealers includes art historians Pamela Fletcher and Anne Helmreich's study of the nineteenth-century London art market (Fletcher and Helmreich 2012) and the mapping of the location of Parisian art dealers from 1815 to 1955 created by the Artl@s research group at the École Normale Supériuere (Saint-Raymond et al. 2015). Significant clusters of intermediaries have also emerged in theater and cinema. Broadway in New York City and the West End in London are dense clusters of theater activity. Organizations at the heart of these clusters – and organizations in the same city or metropolitan area but outside the principal cluster – have produced significant innovations in theater. (Castañer and Campos 2002 provides a comprehensive overview of this literature.) Hollywood is a globally dominant cluster in the film industry. Several articles have examined how this cluster emerged and how it continues to propagate its dominance. Research has particularly focused on the large budgets of early Hollywood films and the ability of films made in southern California in the early to mid-twentieth century to penetrate foreign markets (Miskell 2016; Bakker 2008, Sedgwick 2000). Just as art dealers cluster near artists, Hollywood and Broadway are two clusters that unite both the creators of the art themselves – actors, directors, writers, etc. – and the individuals and organizations who provide the funding and distribution necessary to create a movie or theatrical production (Caves 2000; Scott 2004).

Observing geographic clustering is an important contribution to economic history. However, not surprisingly, economists and economic historians are not content with just making this observation. They want to understand why clustering fosters creativity. For policy making in today's service-driven economy, scholars seek to understand how governments and institutions can fuel innovation and creative activity, either by fostering clusters or with other policy interventions. The next section addresses these questions.

Capturing and Fueling Creativity

Is it possible to understand what drives creative output and how to encourage it? While scholarship surveyed in the first three sections of this article certainly touches on this question, this section presents papers that make permutations of this research question their primary focus. Therefore, this section deals more with the work of scholars who are interested in using historical data and case studies to examine how employment and economic production in the "creative industries" – a fluid category including industries ranging from visual arts and fashion to advertising, journalism and software design – have developed over time (Towse 2010).

Importantly, this work aims to understand how creativity and creative industries develop. Creative and arts sectors are seen as a "key ingredient for job creation, innovation and trade" (UNCTAD 2010) and are believed to constitute opportunities for depressed cities and developing countries to participate in high-growth areas of

the world economy. Typically, scholars working from this policy perspective describe their research area as "cultural economics." In this literature, creativity is sometimes modeled as a result of rational decision-making (Frey 2013) or as a function of some objective and quantifiable factors, such as general education or experience (Bryant and Throsby 2006). However, the most recent contributions have looked at how specific extraordinary individuals make their discoveries and produce creative output due to peer effects and emotional drivers, how creativity can be induced by an increased demand for innovation, and how intellectual property protection can foster creativity.

Famous artists have been shown to exhibit remarkable clustering patterns. With these observations in mind, Hellmanzik (2010) provides an important study on the existence of location premiums by exploiting a sample of prominent modern artists born between 1850 and 1945. She combines auction data with records about whether and when an artist worked in Paris or New York, the two main cluster locations of that period. The findings suggest that paintings created in Paris or New York have been valued higher by 11% and 43%, respectively. Furthermore, artists working in one of these two cluster locations are shown to reach a peak in the age–price profile of their work significantly earlier than artists working elsewhere. Similar results are presented by Mitchell (2016) for writers. Mitchell finds that an author becomes more productive by around 11% each year when residing in London.

When teasing out the causal effects of clustering, scholars must ask whether geographic clusters attract the most creative artists, or whether artists who cluster are more productive because of positive externalities associated with cluster locations. In other words, is self-selection driving the empirical evidence on better performance in geographic clusters, or does a clustering benefit exist? This question – and escaping the endogeneity problems one faces in answering it – is of considerable policy importance not only for the arts but also for other sectors (see Rosenthal and Strange 2004). Borowiecki (2013) uses data for a global sample of 116 prominent music composers born between 1750 and 1899 to them to answer this question. A historical approach enables him to exploit the variation in the geographic distance between a composer's birthplace and a geographic cluster as an exogenous source of clustering, and thus to credibly assert that the association between clustering and productivity is a causal relationship rather than simply a correlation. Borowiecki finds that geographic clustering increases creativity: composers were writing around one additional influential work every 3 years they spent in a cluster. Drilling down further into the dynamics of notable artistic clusters provides some clues as to how clusters encourage higher-quality artistic production. Borowiecki (2015a) develops a simple theoretical framework explaining the trade-off between agglomeration economies (peer effects) and diseconomies (peer crowding), which suggests that the productivity gain due to the presence of peers is characterized by an inverted U-shaped relationship and eventually decreases if the peer group size becomes very large. These theoretical predictions are supported by data for music composers: a composer was about 10% more productive when an additional prominent composer was located in the same city. However, the effect is nonlinear and may begin to decrease for very large numbers of peers.

What drives the benefits from clustering with peers? The literature has provided three distinct answers about the internal dynamics of a cluster: knowledge exchange between peers in the same field, interaction between individuals from diverse creative fields, and competition between peers. Geographic proximity facilitates spillover effects between individuals in the same field (Marshall 1890). Therefore, in cities with a particularly high concentration of artists, synergies and spillovers may positively impact the individual's ability to innovate. Porter (1996) suggests that local competition in specialized, geographically concentrated economic activities may constitute a significant stimulus for growth. The competitive working environment experienced by artists when they are concentrated forces innovation. One can find anecdotal evidence for this argument. In 1778, Mozart was in Paris, the most crowded creative market he ever lived in. His productivity peaked in this year, and he wrote 19 influential compositions, which is three times higher than his annual work-life average of around 6.6 compositions.[5]

The literature has suggested further factors external to clusters that can both foster the creation of a creative cluster and innovation more generally. These factors include specific market demand for innovation, differing levels of intellectual property protection, and political competition for creative talent. In their influential study about modern art, Galenson and Weinberg (2001) suggest a significant shift in demand for innovation in art. The authors explore how an artists' quality of artworks, approximated with auction price data, changed over his or her lifetime and show that the peak age occurred much earlier for later cohorts, who were exposed to increased demand for innovation. It was therefore not by chance that Paul Cézanne and Pablo Picasso created their most significant works within 1 year of each other, although they were born more than 40 years apart.

Apart from market conditions in a given time and place, many scholars have discovered that copyright protection over time and across countries and regions has created different creative environments. Ruth Towse has contributed extensively to this literature and has examined the effects of copyright protection on a variety of creative industries and conflicts between artists and intermediaries over ownership of intellectual property (Towse 2001). Her work deals primarily with contemporary policy and economic conditions. More historical in her focus, Petra Moser has researched the effects of copyright and patent protection across a variety of industries, geographies, and eras (e.g., Moser 2011, 2013). Recently, she has worked with artistic data – specifically book publishing in nineteenth-century Britain (Li et al. 2017) and the effect of Napoleonic rule on Italian operas (Giorcelli and Moser 2016) – to examine the effects of copyright on innovation. Giorcelli and Moser exploit variation in the adoption of copyrights due to the timing of Napoleon's military victories in Italy. The authors are therefore able to estimate the causal effects of copyrights on creativity and find that basic levels of copyright protection increased not only the quantity of creative output but also its quality. These creativity gains are

[5]The category of "influential compositions" is recorded by the the musicologists (experts' selection) in Gilder and Port (1993).

explained by the fact that copyrights reward the greater composing effort necessary to produce high-quality work.

Beyond intellectual property rules, other political and policy factors can have an important effect on artistic output. Vaubel (2005) develops the hypothesis that competition among neighboring states may favor cultural innovation. This hypothesis is then backed up with the empirical observations that European instrumental music had its breakthrough during the Baroque era and that the most famous composers came from the two countries characterized by the highest degree of political fragmentation: Italy and Germany. Vaubel then measures the average duration of employment as a proxy for competition on the demand side and shows that famous Italian and German composers of the Baroque period changed their employers significantly more often than their French and British counterparts did. These insights suggest not only that political fragmentation has promoted musical composition and encouraged quality but also stimulated the mobility of composers.

While much of the research about creativity has focused on the effects of clustering and specific policies, there is a growing economic history literature that explores how biological factors drive artistic creativity. Thinkers since Aristotle have theorized that creativity and emotional state are linked. Other disciplines – notably applied psychology literature – have probed this link, along with the apparent correlation between famous creative people and psychiatric disorders like depression and bipolar disorder. Economic historians of the arts have recently engaged with this literature by looking at the letters of famous artists and seeing how their emotional state correlates with their creative output. Borowiecki (2017), for example, uses textual analysis to calculate the extent of positive and negative emotions expressed in a large number of letters written by Wolfgang Amadeus Mozart, Ludwig van Beethoven, and Franz Liszt. This allows him to create well-being indices capturing emotional states throughout each man's lifetime. He then shows that negative emotions have a causal impact that leads to increased creativity, as measured by the number of high-quality compositions written.

While it is clear that clustering drives increased creative output, this greater output may have come at a cost for artists' physical and emotional well-being. Fierce competition between peers anecdotally led to depression and nervous breakdowns, as was the case for Maurice Ravel, who was diagnosed with neurasthenia in 1912 immediately after the failure of his ballet "Daphnis et Chloé." His condition was presumably aggrevated by an exceptional performance of his fellow Frenchman and competitor Claude Debussy's "Prelude to the Afternoon of a Faun," also performed in Paris just 10 days earlier. With anecdotes like this one in mind, Borowiecki and Kavetsos (2015) argue that the concentration of talent is likely to have adverse effects in terms of health and well-being. They attribute these outcomes to the continuous mental strain individuals go through in order to achieve their aspirations, which become more intensified in settings where one's peers thrive. Borowiecki and Kavetsos approximate for peer competition in various ways and suggest that it reduces composers' longevity. For example, all else equal, a 1% increase in the number of composers located in the same area and time reduces composer longevity by about 7.2 weeks. Essentially, clustering leads to greater

quantity and quality of creative output, but this can come at a cost for one's wellbeing. These findings are thought-provoking, especially if one considers that the first fundamental theorem of welfare economics also argues that competition is indispensable in producing Pareto-optimal outcomes.

Conclusion

Economic historians have rarely turned their attention to the arts. Often, when they did decide to study the arts, it was a mid-career decision driven not primarily by a belief in the centrality of arts and culture as topic in economic history but because they had a personal love for art, music, or another cultural good. These later career engagements created *excellent* scholarship – and there are exceptions to the characterization of scholars in this subfield starting midcareer. (In fact, the co-authors of the underlying chapter are just such an exception.) However, the fact remains that studying the economic history of the arts has long been a secondary topic in our field.

Happily, this is now changing. This change has been largely driven by the shifting composition of developed economies. Developed economies are now dominated by services – including the ever-growing category of "arts, entertainment and recreation".[6] The continued growth of the arts sector and other service industries demands creativity and innovation; this innovation often emerges from clusters of creative people, whether it is in Silicon Valley, a major metropolis like Paris, or in smaller clusters around universities and other cultural institutions. Today's economic dynamism therefore shares many common features with artistic output over the course of history. Understanding what fosters and drives creative achievement means understanding what fosters and drives economic success today. For this reason, the economic history of art and culture has become more important in the broader field and is poised to become increasingly important.

Beyond applications to contemporary economics and policy questions, cliometric approaches to the study of the arts are having a growing impact on other humanities fields that have typically resisted quantitative research. The rise of the digital humanities – first in the study of literature and now in art history, musicology, and other fields – has made humanities scholars more receptive to the use of quantitative methods (Jockers 2013; Moretti 2005; Fletcher and Helmreich 2012). However, literary scholars, art historians, and other humanities researchers often do not have the prerequisite statistical and computational training to compile and analyze quantitative evidence. This creates a golden opportunity for cliometricians to contribute to these other fields and use quantitative methods to address long-standing research questions in these areas. Consider the following example: cliometricians have documented the geography of creative clusters and explained how these have evolved over time and across various regions of the world. It could certainly be

[6]These numbers for the United States are available from Federal Reserve Economics Data (FRED). URL: https://fred.stlouisfed.org/series/CES7071000001

argued that art and music historians have been aware that Paris was an important center for the arts. However, there would quite likely be less agreement on how important it has been, the timing of its prime, and how it compared with other major cities. In other words, the extent of the dominance of Paris has not yet been quantified, nor has it been compared across creative domains. In this way, cliometrics provides a representative, objective, and robust measurement of the importance of cities, which can later be used within the humanities in various contexts.

Unfortunately, cliometricians have not yet seized this opportunity for collaboration. Practitioners in the digital humanities have engaged mostly with computer scientists and statisticians to implement tools such as 3-D mapping, algorithmic literary analysis, and linguistic patterns in textual corpora. Economists and economic historians should take this opportunity to have an impact on another field. Early efforts include the "Genius for Sale!" conferences, organized in 2014 at the University of Oxford and 2016 at Brandeis University.[7] These conferences invited scholars working both in the humanities and social sciences to present on topics related to the arts in their broader economic contexts. We need to create more collaborations like these that may, in turn, result in important interdisciplinary publications.

Railroads

Jeremy Atack

Contents

Abstract

From the outset, railroads excited the public's imagination, leading to extravagant claims regarding their contribution to economic growth and development that only grew with time. Skepticism about these claims eventually led to their debunking, most notably by Robert Fogel whose seminal work was also central to the emergence of cliometrics and inspired the first major controversy in the discipline. The flood of work that followed paints a more nuanced picture, generally assigning a larger growth and development role to the railroad than Fogel, but one far short of the hyperbole of past generations. Railroads were important to the economy and transformative in their effect but not decisive. By lowering transport costs – especially after adjusting for quality – they not only

diverted trade but also created new opportunities in part by generating positive externalities that promoted scale and agglomeration economies with network spillovers continent-wide.

Introduction

Over the course of the nineteenth century and into the twentieth, the view that railroads were the dominant force in the economy and in society's progress had become an increasingly common theme (see, for example, Emerson in a speech from 1844 (1903, 364), United States Census Office (1864, clxix), Adams et al. (1871, 335) or Jenks (1944, 3)). Consequently, when W. W. Rostow asserted that "the introduction of the railroad has been historically the most important single initiator of take-offs" into modern self-sustained economic growth (Rostow 1956, 45), few questioned his claim. It would, however, receive increasing pushback as he elaborated that theme (Rostow 1960, 1963). One scholar, in particular, Robert W. Fogel, then a graduate student at the Johns Hopkins University, challenged Rostow's bold claims in what would become his doctoral thesis (Fogel 1962, 1964). In it, Fogel introduced a new concept, social saving – the gain to society from an innovation – to measure the contribution of the railroad to America's growth. In the process, he helped lay the foundations for what we today call "cliometrics" – the subject of these handbooks. Indeed, Fogel's work on railroads was cited as the basis for his winning the Nobel Prize in Economics (jointly with Douglass C. North) in 1993 (https://www.nobelprize.org/nobel_prizes/economic-sciences/laureates/1993/press.html). As a result, this review of the putative role of the railroad in American economic development and growth also casts light upon the evolution of the field of cliometrics.

There is also a parallel body of work, dating from slightly later, regarding railroads in countries elsewhere and on every continent that I will ignore here. That literature was, by and large, motivated by the same issues as the American. Moreover, as tools – both empirical and applied (such as trade theory and geographic information systems (GIS)) – have continued to develop, railroads have remained a focus on interest (e.g., Donaldson and Hornbeck (2016)) around the world including China's latest development initiative, "One Belt, One Road."

Early Railroads

The idea of using rails to provide a smooth track for wheeled vehicles carrying heavy loads, hauled by man or animals and eventually pulled by stationary engines, dates back centuries. Agricola's famous manual on mining, for example, illustrates one

such configuration and subsequent innovation led eventually to such familiar devices flanged wheels to locate the vehicle correctly on the track (Agricola et al. 1912). Rather, the real innovation that made the *railroad* practical as a means of long-distance transportation was the development of a mobile steam engine which was small yet powerful enough to provide the necessary motive power. Such a breakthrough occurred, more or less simultaneously, on both sides of the Atlantic at the start of the nineteenth century (Bathe and Bathe 1935; Dickinson and Titley 1934). Even so and although the idea had been in the air for over decade (See Sellers 1886, p. 13 quoting from an 1812 address by Oliver Evans), it would be more than a generation before steam locomotion itself would become a reality.

The pioneering railroad with steam locomotion was built between Stockton and Darlington in northeast England in 1825 to carry coal from a mine to a coastal port. Despite its intended purpose, the first trip attracted several hundred passengers – far more than the promoters had anticipated – many of whom rode atop the coal. Following this successful "proof of concept" demonstration, the invention was innovated with the Manchester to Liverpool Railway in England and by the Baltimore and Ohio Railroad in the United States, both of which began (some) service in 1830.

Trade and Improved Transportation

Other railroads quickly followed, driven in part by local commercial interests fearful that they might be eclipsed if cheaper or better means of travel and shipping diverted business elsewhere. Indeed, such trade diversion was of explicit concern for east coast US cities like Boston, Philadelphia, and Baltimore which had already seen some of "their" traffic siphoned away by New York once the Erie Canal opened in 1825 (Condit 1980). Faced with this threat, the city fathers in Boston and Baltimore promoted rail alternatives (the Boston and Worcester Railroad and the Baltimore and Ohio Railroad) linking their ports and trading houses to points west, ideally the Great Lakes and Ohio River valley. Philadelphia facing the same decision, however, made the wrong choice and opted instead to promote a canal system that, because of topography, was a much inferior alternative to either railroads or the Erie Canal. The Pennsylvania Mainline Canal would eventually fail, and its lack of competitiveness retarded the growth of Philadelphia (although it did facilitate the development of coal mining, especially anthracite, in the state).

Trade diversion occurs because trade, like electricity or water, flows in the direction of least resistance, where that resistance is caused by trade barriers such as transport costs and other frictions (e.g., handling charges, spoilage and other losses, speed, and timeliness). Wagon transportation was extremely slow, hard on whatever was being carried (passengers or freight) and with limited capacity. It was therefore very expensive, and there was little to no technological progress in the industry to reduce costs. Water transportation, while often slow (where powered by wind, paddle, or animal as by sailboat, canoe, or canal barge), had the virtue of cheapness and relative smoothness (except where transshipment was necessary at breaks in transportation). Where powered by steam, shipping by water could be

relatively speedy and became progressively cheaper as technological change drove down costs. Rail, however, combined directness of travel, speed, gentle handling, and capacity as well as benefiting from sustained advances in technology that reduced operating costs over time, including growing positive externalities (like network effects and agglomeration economies). Trade flows thus increasingly favored rail connections over the alternatives (Swisher 2017).

Improved transportation and communication not only diverted existing trade but also created new trading opportunities, leading to increased regional (and local) specialization in agriculture and manufacturing. For example, an instrumental variable analysis of the expansion of railroads in the Midwest before the Civil War suggests that they were responsible for more than half of the urbanization that occurred in the region in that period and almost two-thirds of the increase in improved acreage (that is, land in agricultural production) (Atack et al. 2010; Atack and Margo 2011). Some of these changes occurred quickly– for example, the decline of agriculture, especially grain production, in New England and the rise of manufacturing in that region (Field 1978). Moreover, these changes had far-reaching consequences such as moving agricultural production into areas better suited or less plagued by pests (Olmstead and Rhode 2008). It also allowed manufacturers to realize scale economies and quality improvements through specialization and skill development and to take advantage of agglomeration economies as well as promoting the development of mineral resources (especially coal and iron ore) in the interior of the country.

By 1840, the US railroad mileage was comparable to that of canals but still only a small fraction of the miles of navigable river, especially those served by canoes, rafts, and other shallow water vessels. However, unlike rivers which went where nature desired, roads, railroads, and canals went where their builders intended – and usually by a more direct route. Moreover, even large teams of horses were limited in the cargo that they could haul given indifferent road surfaces, poor grading, and wheel and wagon designs of the time. Indeed, most of the nation's roads were unpaved and little changed until the twentieth century when the "Good Roads" movement (started by bicyclists but continued by early automobile pioneers) lobbied for increased government spending on roads– including by the federal government. These efforts began to pay off, particularly after World War One, with improvements to the roadbed and surface, drainage, and building of bridges over streams and small rivers. Until then, there was little or no change in road travel times or the costs of road transportation – a.k.a. productivity change. This pattern is in stark contrast to the dramatic productivity gains in water and rail transportation manifest in sharply reduced fares and freight rates, sometimes by as much as 90% that benefitted both producers and consumers and increased the demand for transportation services (Taylor 1951).

Rail Construction and Its Geography

GIS data: Railroads were "big news," and so we know a great deal about railroad construction from contemporary local newspaper reports, annual reports by railroads to their shareholders, trade journals (like the *American Railroad Journal* and

Railway Age), contemporary travel guides (like *Appletons Travel Guide* or *Rand McNally Travel Guide*, some of which were published annually), and histories, especially of individual railroads (e.g., Stover 1975, 1987).

Railroads were also marked on maps (and with ever greater geographic precision over time (Modelski 1987)). Unfortunately, these multiple sources are often inconsistent with one another and may even represent different things. Maps, for example, show rail links between points, but there was a time lag between the map being engraved and its being published. Did the engraver mark only those links that were known (and based upon what source?) when the engraving was made or did they include those railroads that they expected to be operational by the time that the map was published? Cities and towns were points on most maps to or through which railroads "connected," but most railroad companies had their own stations and freight yards that were physically separate and not (easily) connected to those of other companies. Incompatibilities between railroads, especially track gauge (see below), also produced discontinuities in practice. Rivers were also represented by lines on maps, but not all were, in fact, crossed (bridged, anyway) by railroads (also shown as lines on maps). Instead, passengers and freight (and sometimes the wagons complete with their contents and locomotives) were instead ferried across the river. Sometimes two different railroad lines connected the same two points, or a single railroad built two tracks to allow concurrent two-way traffic. Where the rail line was single-track (as most in the United States were), sidings and turnouts had to be provided along the way so that trains traveling in opposite directions might pass one another. Moreover, with regard to construction itself, this took time and might be interrupted at any moment by events both natural (e.g., inclement weather) and man-made (e.g., financial panics or corporate bankruptcy). Some rail once built might be improved (e.g., straightened or regraded); other track might be abandoned. Each of these circumstances presents a challenge for statistical reporting, some of which is apparent in Fig. 3 (compare Carter et al. 2006; Wicker 1960).

Much of the most recent work on railroads relies upon spatial location derived from geographic information systems, especially the databases and shapefiles developed by Atack (2013, 2015), reflecting a growing belief that spatial relationships and location are as importance as miles. There were also important earlier efforts to model this spatial dimension, pre-GIS (Craig et al. 1998; Fogel 1964).

While Atack's GIS data represent spatially accurate locations for rail links (many of which no longer exist), they also strip out important features such as double tracking, sidings, and turnouts because these features do not generally appear on maps or in contemporary accounts and thus cannot be dated. However, even the dating of the main lines is imprecise because it is based on the copyright date for contemporary maps which provided "evidence" of the existence of a railroad connection between points (Atack 2013, 2015, 2018). These maps are georeferenced (using ArcGIS) – a procedure designed to accommodate and adjust for inaccuracies in drafting the maps and to compensate for differences in scale and projection so that they align with known geographic coordinates.

From 1861 onward, the maps selected represent best guesses of the railroad system at approximately 5-year intervals to 1911 based upon map copyright dates. When the interval between maps was reduced, there were many more inconsistencies

between them. When the interval was increased, it was felt that important information on timing was lost. During the 1850s, the data are at approximately 2-year intervals, except in the Midwest where they are annual because good data on construction and railroad operation from contemporary sources exists (Paxson 1914). Before then, I relied upon the database of railroad construction originally assembled by an agricultural economist Milton C. Hallberg (now deceased) from Pennsylvania State University that is available online at http://oldrailhistory.com (Hallberg 2004). This database gives the year when each stretch of line was built before 1850. In each case, the precise location of the railroads (given that these involved major earthworks and structures like bridges and tunnels) was then provided by satellite imagery and US Geological Survey maps (many of which date back to the late nineteenth century and are available online) by digitizing tens of thousands of points along them (Atack 2013, 2018).

Once a GIS database has been constructed, GIS software enables many calculations to be made quickly and easily – such as proximity to a rail link (using, e.g., the ArcGIS "buffer" command) and their geographic density, calculations that Fogel (1964) also made but which took him months without GIS and computers (personal conversation, 2008). However, even with modern technology, the construction of a network like that used by Donaldson and Hornbeck (2016) still requires considerable work (particularly in establishing the rules by which railroads connected to each other and to other modes of transportation – issues on which reasonable people and factual evidence may also still disagree).

Railroad construction: Early railroads were built in both the Northeast (e.g., the Boston and Worcester) and the South (e.g., the Baltimore and Ohio). Indeed, for a brief moment in the 1830s, the South boasted the longest railroad in the world, the Charleston and Hamburg, which enabled shippers to avoid the rapids (and transshipment) on the Savannah River at Augusta, diverting river traffic away from Savannah and toward Charleston.

By the end of 1840, there were around 3000 miles of track in service or under construction (GIS-derived estimates, i.e., rail links between different points) – more than in any other country in the world (Mitchell 2007) – a preeminence that the United States retains to this day. The majority of early railroad track was in the Northeast, but over 42% of the rail links were in the South with the balance in the Midwest, where early railroads, for example, connected Toledo to southern Michigan (the Erie and Kalamazoo). Thereafter, beginning in the late 1840s, much of the push would be focused on the Midwest (and eventually, the West). The first railroad linking Chicago to the East Coast (the Michigan Southern) opened in 1852, and by 1858, the Pittsburgh, Fort Wayne, and Chicago Railroad was providing the first all-rail route to the eastern seaboard from Chicago. This, together with Great Lakes shipping, helped make Chicago the center of the world's wheat trade.

Since the Census regions differ immensely in size, perhaps a better metric for access to rail transportation is square miles of land per mile of track (Table 1) – a measure easily calculated using GIS data. These calculations show that the density of railroads in 1840 in the Northeast was 6 times that in the South and more than 30 times that in the Midwest. In the decades that followed, the density of rail links increased

Table 1 Proximity of land to railroads by Census region, 1840–1900

	Square miles of land per mile of railroad			
Census region	1840	1860	1880	1900
Northeast	105	20	9	6
South	661	124	47	18
Midwest	3434	78	21	10
West		51,559	267	50

Computed using GIS data from (Atack 2015)

everywhere as more railroads were built, but the ratio remained relatively constant between the South and Northeast in 1860. However, between 1840 and 1860, rail density in the Midwest increased sharply relative to elsewhere so that by 1860 it was one-fourth that of the Northeast. If we think of a railroad track bisecting the land, then in 1900, the average section of land (=640 acres = 1 square mile) was within 3 miles of a railroad in the Northeast (i.e., 3 miles either side of the line) and just 5 miles from a railroad in the Midwest. Even in the South, average distance to a railroad had shrunk to just 9 miles. Distances remained large only in the West, and even in that region this was only because of the vast areas of desert and marginal land that lay between about the 100th meridian and the Sierra Nevadas.

Most railroads were built by the private sector in response to market signals whether real or imagined. When they were "best" built was a matter of conjecture. Certainly, if traffic justified their existence from the get-go (like the Erie Canal, where sections of the canal were opened as built and generated immediate profits, years before the entire project was finished), then construction was "too late" from the economy's standpoint. But, were they built ahead of demand? According to an 1860 editorial in the *Picayune* (a New Orleans newspaper), "nine-tenths of our roads when first traversed by steam pass through long ranges of woodlands in which the ax has never resounded, cross prairies whose flowery sod has never been turned by the plow, and penetrate valleys as wild as when the first pioneers followed upon the trail of the savage," suggesting that railroads preceded settlement.

The evidence, however, suggests otherwise. Fishlow (1965), for example, found that most early midwestern railroads were profitable almost immediately, which is unlikely if they were built before trade justified their existence. Moreover, most of the railroads built in the Midwest during the 1850s – a major (and arguably, speculative) construction boom – served established farm regions rather than those parts of the state most recently settled. For example, 60% of the railroad mileage in Illinois by 1853 was built in the leading wheat and corn counties that made up just 25% of the state's area. Similarly, in Wisconsin, seven wheat-producing counties (plus Milwaukee), just 10% of the state's area, had 60% of the track in 1856. Those counties that got railroads in the 1850s were already growing and developing faster before the coming of the railroad. Even so, more recent GIS analysis using IV has also found that the coming of the railroad to these midwestern counties explains more than half of the urbanization – that is, population living in towns larger than 2500 person (Atack et al. 2010) – and perhaps two-thirds of the growth in land under

cultivation (Atack and Margo 2011). Indeed, there is much to suggest that railroads (and other man-made transportation systems) were endogenous to growth (Swisher 2017) and thus that a general equilibrium outcome will differ dramatically from the partial statics solution.

It is argued that the slow expansion of railroads in the South reflected the abundance of rivers in the South connecting to the coast which met area's needs for shipping low value-to-weight and nonperishable freight (e.g., baled cotton) out of the region. These rivers, however, did little to promote intra-regional trade, and what railroads were built had difficulty exchanging traffic and shipping outside the region because of differences in track gauge and the lack of bridges across major rivers – especially the Ohio. These issues would have consequences for the Confederacy in fighting the Civil War.

The mechanism was usually that a group of railroad promoters petitioned the state for a corporate charter to build a railroad between two points – sometimes the request was more specific regarding routing, probably to secure more political support in the legislature pre-adoption of state general incorporation laws. Once the privilege was secured, the promoters sought construction funds locally, nationally, and internationally primarily through the sale of fixed interest debt secured by mortgages on the property, although most New England railroads were equity-financed locally (Chandler 1954). More distant investors appreciated the "guaranteed return" and the liquidity which those investments assured by the hoopla surrounding railroads both general and specific. Local investors were often local landowners, merchants, banks, and city boosters who stood to gain either through increased business or rising land values as the benefits of that trade were capitalized into the fixed factor – an outcome critical to assessing the railroads' contribution (e.g., Donaldson and Hornbeck 2016; Fogel 1964; Swisher 2017). Actual construction would employ hundreds of manual laborers as well as skilled engineers and surveyors, and once opened, the railroad would require a locally resident staff for stations, signaling and traffic control, maintenance, and repair as well as the train crews. Railroads were big business and that business spread everywhere.

By 1860, when there were more than 25,000 miles of rail links (i.e., point-to-point connections by rail) in the United States (and 30,000 miles of track – including double tracking, sidings, etc.), the Midwest's share had grown to 38% of the nation's rail links, while the Northeast's share had shrunk to a third and the South's to 28%. This geographic distribution of railroad links in the United States is shown in Fig. 1 (this figure also shows track gauge, on which more is said below). Two features are notable with respect to the geographic distribution. First, there were large areas of the country devoid of railroads (particularly in the mountainous areas of the Appalachians). Second, there were no rail connections between the Midwest and the South, which surely handicapped interregional trade.

The outbreak of the Civil War brought an abrupt slowdown in new rail construction, although some new track continued to be built in both the Confederacy and the Union. For example, a stretch of railroad was built in Alabama and Mississippi between Selma, Alabama, and Meridian, Mississippi (but split by the Tombigbee River, which was not bridged during the war), while the Union extended the

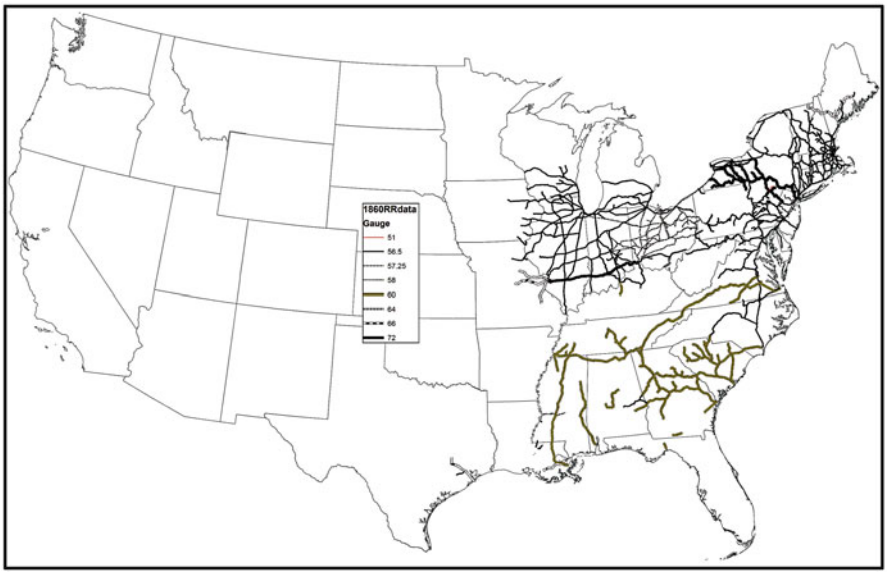

Fig. 1 American railroads in operation in 1860. (Gauge data represent the distance between rails in inches from (Taylor and Neu 1956). Standard gauge is 1435 mm (=4 feet 8 1/2 inches).) (Source: Computed using GIS data from Atack (2015))

Nashville and Northwestern Railroad westward to the Tennessee River after their occupation of Nashville. By far the most significant Civil War railroad project, however, was the authorization for the first transcontinental railroad in the Pacific Railroad Act of July 1862. Construction on this project was begun by the Central Pacific Railroad in early 1863 building eastward through the Sierra Nevada mountains. However, the Union Pacific Railroad building westward from Omaha did not break ground until July 1865, several months after the war's end.

The military on both sides were quick to recognize the importance of railroads in deploying troops to battlefields from Bull Run to Appomattox. As a result, railroads became military targets (as in the burning of Atlanta and Sherman's March), while at the same time increased intensity of use accelerated water and tear on the track. The orientation of southern railroads to southern ports rather than intra-South trade and relative to those in the Northeast and Midwest, however, made them far less useful in the conflict than the Union's railroads, although there is (as yet) no cliometric work on this (Turner 1953).

One consequence of the greater intensity of the use of railroads during the Civil War was that the Pennsylvania Railroad began to experiment with steel instead of iron rails in late 1862 or early 1863, ordering 150 tons of steel rails from British mills. This would have a substantial long-term payoff after the War as steel rails proved capable of withstanding heavier trains running at higher speed for orders of magnitude more years than the iron rails they replaced – all issues related to productivity.

Initially, the higher cost of steel discouraged replacement of iron rails with steel. In 1867, for example, iron rails cost $83.13/ton compared with $166/ton for steel from the first American Bessemer steel producer, the Cambria Iron Works. This cost difference only made steel worthwhile where wear was particularly high, as on curves and at stations. Moreover, worn-out iron rails were readily sold for scrap from which to produce new rails, but no such market for scrap steel then existed. However, as a domestic Bessemer steel industry ramped up, production costs fell (Temin 1964) so that, by 1880, with 24 domestic steel mills in production, the cost of steel had been cut to $67.50/ton while iron cost $48.25/ton. More importantly, after 1883, steel actually costs less than iron. As a result, all new track was probably laid in steel, and by the end of the 1880s, more than 80% of the nation's track was steel. This compares with only 30% at the start of the decade. Moreover, the availability of progressively cheaper steel had spillover effects for other industries (Atack and Brueckner 1982).

The replacement of wartime destruction, deferred maintenance, and pent-up demand for new lines led to a railroad construction boom after the war. This shows up clearly in all statistics regarding rail construction (Fig. 3). Unfortunately, there is no single definitive series for this. A Census of Transportation taken as a part of the federal decennial census in 1880 provides one retrospective series. Other data have been assembled from the trade magazine *Railroad Age*, and there are data on the mileage owned and the mileage operated by railroads. Similar disagreements exist about earlier data (Wicker 1960), and the addition of GIS estimates of railroad links only further muddies the water.

Between 1868 and 1873, track mileage doubled. Indeed, almost 7500 miles of track was built in 1872 – almost as much as had existed in the entire country at the end of 1849. Much of this construction took place in areas already well served – like the Midwest and the Northeast – but it also included the completion of the first transcontinental railroad in May of 1869. After 1873, construction activity varied from year to year but stayed above 1400 miles per year from 1866 through 1914, with several years when more than 5000 miles were built (Carter et al. 2006; Chandler 1965). This was especially so in the 1880s when the boom in construction, concentrated primarily in the Plains states, eclipsed even the post-Civil War construction boom. Moreover, other transcontinental railroads would follow, providing additional trunk lines in the southern and northern plains to which branch lines could connect. These facilitated the growth of mining in Colorado and Utah and of farming communities in the Great Plains states.

As a result of these late booms in construction, the density of rail track increased sharply everywhere (Fig. 2). According to *Historical Statistics*, railroad track operated (net of yards and sidings) plateaued in the 1910s and 1920s at around 300,000 miles before beginning to decline in the 1930s as the Great Depression took hold and railroads disposed of unproductive assets. Thereafter, abandonments of track have generally exceeded new construction so that by 1980 there were about 200,000 miles of track in operation, net of sidings and yards.

Track Gauge: The map of railroad links in the contiguous United States in 1900 (Fig. 2) does not separately identify track gauge because, by then, virtually all the nation's railroads had adopted a single gauge –"standard gauge" of 4 feet 8.5 inches –

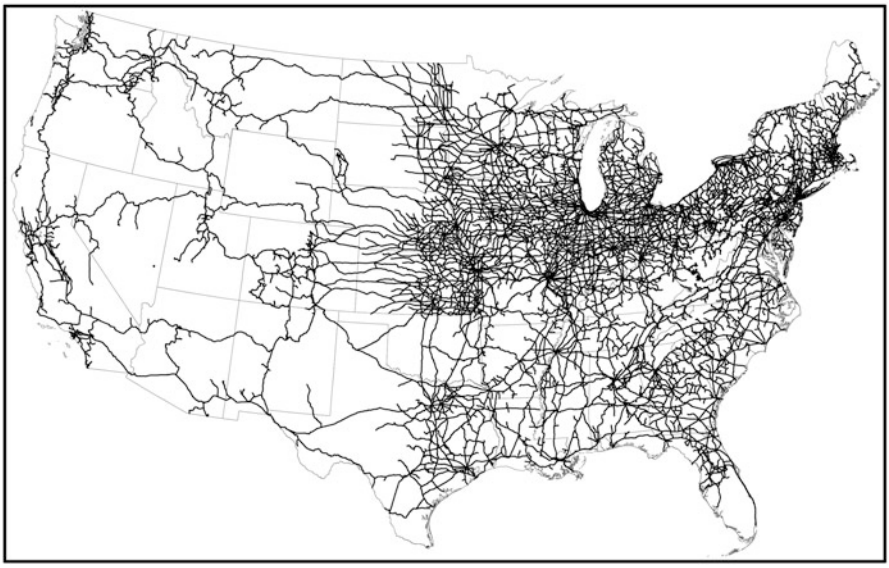

Fig. 2 Railroad links in 1900. (Source: Computed using GIS data from Atack (2015))

and locomotives and rolling stock could (in theory, anyway) be used anywhere. This harmonization of track gauge began in earnest following the Civil War and was finally realized in 1886 when the last of the southern railroads converted (Gross 2016; Puffert 2000).

The earlier multiplicity of track gauges reflected institutional, technical, and economic forces, and, despite harmonization, there would remain isolated pockets, particularly in the higher mountains, where narrow gauge railways still held sway because tight curves could not be negotiated by larger locomotives or wagons (i.e., technical considerations dominated). Absent terrain constraints, technical considerations argued for a broader rather than a narrower gauge to take advantage of the scale economies offered by the larger enclosed volume of wagons and carriages. However, broad gauge wagons not only have difficulty negotiating sharp curves (despite the invention of flexible trucks), but their greater laden weight challenged locomotives with only limited power on steeper grades. Standard gauge was a compromise well suited to most terrain although broader gauges, like the 5′ used in much of the South and the 6′ gauge adopted by the Erie in New York, were preferred where the terrain was relatively flat and the track was straight. Rail wagons operating on 5′ track were also allegedly better suited to transporting the standard cotton bale than those built for standard gauge. Of course, other considerations sometimes intruded like the decision by many of Maine's railroads to use a 5′ 6″ gauge because that was the gauge of the Grand Trunk Railroad in Canada, and Maine hoped to siphon trade from that system to Portland and other ports along their coast. These incompatibilities between gauges "locked in" users (for other examples, see Arthur 1989, but also see Liebowitz and Margolis 1994).

The initial adoption of standard gauge in America traces to the Baltimore and Ohio railroad, America's first steam railroad. As the pioneer railroad, there was no domestic source of locomotives and rolling stock from which to order equipment, so these came from England and were built to the prevailing English gauge. However, since the B&O was starting with a tabula rasa, this was of no consequence, and the B&O had no reason to specify differently – especially because their route to the Ohio River was anything but straight and level.

These explanations, however, do not satisfactorily explain the adoption of a 4′ 10″ gauge by most of the railroads in Ohio, which, not surprisingly, became known as the "Ohio gauge" and was stipulated in many of the Ohio railroad charters. Perhaps the best rationalization of this anomaly is that the first locomotive delivered to the Mad River and Lake Erie Railroad (the first railroad chartered in Ohio and the second to start operations) had been built by Rogers, Ketchum, and Grosvenor in Paterson, New Jersey, for a New Jersey railroad to a 4′ 10″ gauge. But that order was cancelled before delivery, and the locomotive was resold to the Mad River Railroad. The difference between standard gauge and Ohio gauge, however, was of no practical consequence as the earliest Ohio railroads did not connect to any others. Moreover, when they eventually did interconnect, locomotives and rolling stock could use either gauge because of the width of the wheel tread and the bullnose of the rails which kept trains centered on the track. All of this makes track gauge, especially the decades-long persistence of the "Ohio gauge," an excellent historical example of path dependence (Arthur 1994; Puffert 2000, 2009).

In 1860, eight different track gauges (besides narrow gauges of 4′ or less) were in use by American railroads (Fig. 1), although three of these 4′ 8.5″, 4′ 9.25″, and 4′ 10″ were compatible with one another. Indeed, the 4′ 9.25″ gauge was used by just one line, a spur off the Mad River Railroad connecting Corey and Findlay, Ohio. It appears to have been a compromise between standard and Ohio gauge.

Nationwide, standard gauge dominated (Table 2), accounting for at least 60% of the track mileage (net of sidings, double tracking, etc.), and those compatible with standard gauge accounted for 72% of the nation's rail links. However, the dominant gauge in the South was a 5′ gauge, accounting for 18% of the rail links in 1860, and was the last to change (Gross 2016), although many of the railroads built in Virginia and North Carolina adopted standard gauge from the start or had switched to

Table 2 Railroad links by track gauge, 1860 (shading denotes compatible gauges)

Gauge (inches)	Mileage	Share of total links
51	34	0%
56.5	15335	60%
57.25	16	0%
58	3133	12%
60	4486	18%
64	183	1%
66	852	3%
72	1486	6%

Source: GIS calculation from (Atack 2015) following classification by (Taylor and Neu 1956)

standard gauge by 1860. This profusion of track gauges prevented the American rail system from being a network and dissipated the positive network externalities (Puffert 1991, 2000, 2009; Taylor and Neu 1956). A question, however, remains as to how large these externalities could have been, especially earlier on (Arthur 1994; Liebowitz and Margolis 1994, 1995).

These artificial breaks from breaks in gauge were compounded by delays in bridging many rivers (the Mississippi was bridged relatively early at Rock Island in 1856, but no railroad crossed the Ohio until 1871 – partly because of opposition from steamboating interests and constitutional concerns relating to navigability) and the reluctance of railroads connecting to the same cities to build "Union" stations and have common freight yards. For example, Colton's 1856 map of the Boston area held by the Library of Congress shows six distinct railroad depots in Boston proper terminating different railroads from the south, west, and north. Moving freight or passengers between these sometimes involved traversing the entire city and its narrow, congested streets. The first "Union" station was opened in Indianapolis in 1853 and was jointly owned and operated by railroads serving the city. Most, however, date from much later; Chicago's first effort, for example, wasn't until 1881, while Washington DC's Union Station dates from early in the twentieth century.

Such breaks in transportation were the bane of travelers but through traffic a boon to local businesses and workers (laborers, teamsters, etc.) providing transportation between the breaks (but congesting the streets) and lodging and food for weary travelers, many of whom likely missed connections (Bleakley and Lin 2012). Indeed, such local interests underlay the "Erie gauge war" in the early 1850s when the city of Erie, Pennsylvania, fought to maintain a break of gauge in that city between the broad gauge of the Erie Railroad out of New York and standard and Ohio gauge railroads (Kent 1948), providing a concrete example of Frederic Bastiat's economic sophism of the "boon" to be realized from a "negative railroad" (Bastiat and Stirling (trans) 1922, especially Chap. 17).

Eventually the positive network externalities prevailed everywhere, and gauges were harmonized (Puffert 1991, 2009). But this came at a cost. For example, the adoption of standard gauge in the South led to the diversion of southern traffic from a mix of rail and ocean shipping to all-rail shipping and led to the decline of shipping through ports such as Savannah and Charleston (Gross 2016). The changeover, however, was a triumph of planning. Like the earlier conversion of the southern portions of the Illinois Central, the change in gauge was accomplished in a single 24-hour period, by stationing crews along the track ready to move the rails and fix axles and wheels as soon as traffic was shut down – a result of and triumph for meticulous planning and coordination.

Railroad Finance and Construction

One part of Fogel's attack on Rostow's argument was to diminish the importance of railroads as a critical factor in American economic growth, especially during what Rostow termed "the take-off into self-sustained growth" (Rostow 1956, 1960).

During that phase, dated by Rostow to between 1843 and 1860, railroad construction supposedly played a decisive role in the United States (as it did in many other countries) through its demand for iron, wood and coal, transportation equipment, and other inputs. The timing clearly coincides with a pronounced uptick in railroad construction (see Fig. 3).

However, Fogel determined that railroad demand probably played little role in developing these other industries – at least during Rostow's time frame. For example, much of the iron used by railroads (whether for rails or in fabricating parts for locomotives and rolling stock) was imported from England since domestic mills had difficulty producing the requisite quality. Moreover, most locomotives at that time burned wood, not coal, and most railroad ties were split rather than milled. There was thus an impact on lumbering (an agricultural pursuit) but not sawmilling (an industrial activity) (Fogel 1964). True, domestic iron was used for railroad spikes but more was used in shoeing horses, while demand for railroad rolling stock almost certainly reduced the demand for wagon, canal barges, and steamboats – that also used iron.

This is not to deny that railroads had an impact. Railroad demand was absolutely critical to the emergence and the growth of a domestic Bessemer steel industry. It also accounted for a substantial fraction of coal consumption once locomotives

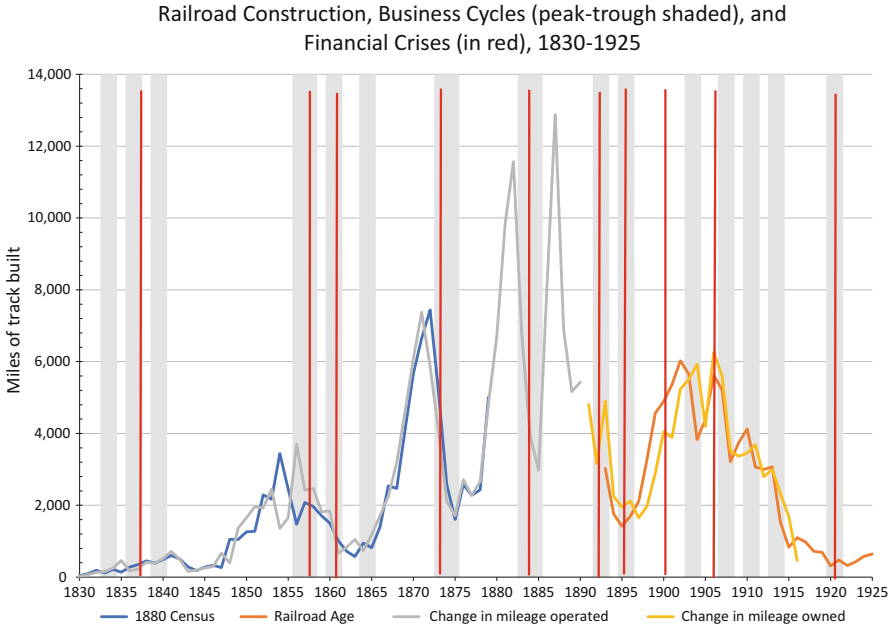

Fig. 3 Railroad construction and economic cycles, 1830–1925. (Source: Railroad construction from (Carter et al. 2006, series Df882–885); business cycle dating from (Davis 2006); financial "crises" are an amalgam of events affecting US banks and financial markets)

switched from burning wood. Initially, most engines were fueled with wood which was available in abundance in the eastern United States. But, as more land entered cultivation and the railroads pushed westward into treeless prairies and deserts, wood became less readily available and more expensive, so coal increasingly became the fuel of choice in the 1850s. Some railroads, such as the B&O, used coal from the start, despite the difficulties of burning anthracite. The growing availability of bituminous (softer and more easily burnt) coal and declining coal prices made the switch easier. By 1880, more than 90% of railroad fuel was coal (White 1968, pp. 83–90), accounting for a significant fraction of coal production. In 1915, for example, US railroads consumed 28% (122 million tons) of bituminous coal production and 7% of anthracite production (Fernald 1918, p. 179).

The pattern of rail construction in Fig. 3 shows a distinct cyclical pattern and correlates closely with the dating of the business cycle (the gray-shaded columns denoting peak to trough in the cycle by calendar year) and also with financial panics and crises (the red vertical lines). Although the dating of business cycles is imprecise (in part because these come from a mix of lagging, coincident, and leading indicators) and none of these data enjoy a broad consensus, they are suggestive. According to Harley (1982), railroad construction cycles played a major role in the Kuznets business cycle. This is not surprising. Each mile of single-track railroad, for example, represented at least 350 tons of iron or steel and employed hundreds during construction, moving earth and ballast to grade the rights-of-way, lay the track, and build refueling stops for water and coal (or wood). Just the Bessemer steel and locomotives account for more than 6% of the Davis index of industrial production (2006). Consequently, railroads figure prominently in the writings of business cycle scholars from Thorp et al. (1926), Schumpeter (1939), and Fels (1959) onward, playing a major role in most cycles of economic activity both long and short, regardless of whether or not their role was decisive (Fogel 1964).

Harley (1982) also argues that the cyclical pattern of post-War railroad construction reflected the periodic breakdown of informal oligopoly agreements among the railroads regarding exclusive construction rights in particular areas. These agreements came about because construction at a particular time in a specific location generally precluded construction later (although there were cases of what today would be called "greenmail" – beginning construction on a new line in the hope and expectation that one will be paid to drop the project – e.g., the New York, West Shore, and Buffalo Railroad, although the ploy did not always work). Later construction, when the economy had grown more, would clearly be more profitable and thus more desirable from the railroad's standpoint than construction today. This provided a strong incentive to delay construction, but only if a railroad could be sure that those higher profits would be reserved exclusively to it.

Thus, railroads had an incentive to collude, but as gains increased with settlement, so too did the incentives to break ranks. Harley's case study of Kansas concluded that once settlement reached about 35% of its potential, these incentives could become irresistible although the optimal cooperative strategy was to delay construction until settlement was 75% complete (Harley 1982). By comparing actual

mileages of new rail construction in the Great Plains with those predicted by these strategies, he concluded that railroads were likely locked in competition during the depression of the 1870s (1873–1878) and after 1883 but cooperated at other times.

Railroads represented major financial investments, costing $25–30,000 per mile early on. This expenditure was comparable to that for canals but substantially more per mile than turnpikes. It was also about 10 times the average investment in a farm and 20 times or more the capital invested in the typical manufacturing firm at the time. For railroads built in mountainous areas (like Appalachia and especially the Rockies and Sierras) that required more cut and fill or in swampy areas (like much of the coastal South) where the ground was too unstable to support ballast, ties and rails cost even more to build per mile. By 1860, perhaps $1 billion had been sunk into railroads – an aggregate investment equivalent to that in all US manufacturing at the time – and would more than quadruple before the end of the century.

The cost of building each railroad was sufficiently large that most had to depend upon pooled investment, secured primarily from capital markets rather than banks, although some early railroad charters also had banking privileges (e.g., the West Feliciana Railroad and Banking Company). The raising of external capital was facilitated by grants of incorporation and limited liability to railroad promoters by the individual states. These assets were publicly traded and represented a major component on many markets. In 1885, for example, railroads accounted for more than 80% of the stocks traded on the New York Stock Exchange and almost two-thirds of those traded on the Philadelphia market (O'Sullivan 2007). Much of the financing for construction (and sometimes more than was actually spent on construction) was raised through the sale of debt, often secured by mortgages on land, rather than equity (except in New England where railroads were shorter and capital needs therefore less (Chandler 1954)). This debt traded on both domestic and especially foreign markets (where it was often denominated in pounds sterling) and quickly eclipsed in volume all other public investments – including US government debt – during most of the nineteenth century. The money raised not only financed construction but also provided a pool of money for fraud, bribery, and corruption (see, e.g., United States. Congress. House 1873).

Much of the construction finance raised by railroads went into grading the right-of-way, drainage, and bridging – investment that was completely immobile and had few other uses (except for roads – which many would become in the twentieth century as railroads abandoned their rights-of-way). It was literally a "sunk cost." Much of the rest went into track and ties, ballast, rolling stock, and the like – a fixed, if not sunk, cost. As a result, railroads had low marginal (and variable) costs relative to total costs. This cost structure is made for volatile shipping rates with changes in demand since roads could minimize losses by just covering variable costs. While low rates during economic downturns benefitted shippers, the shortfall in earnings comprised the ability of railroads to meet interest payments on their debt, making them highly vulnerable to bankruptcy in adverse economic circumstances (e.g., 1857, 1873, and 1894) and (potentially) hostile takeovers and mergers (Adams et al. 1871). Investors soon found this to their cost when the New York and Erie Railroad filed for bankruptcy in 1859 – the first trunk railroad in America to fail – although many

smaller railroads had preceded it and many more, both large and small, would follow in the subsequent decades, for example, in 1873 and more especially in 1893. Indeed, in the 1870s, perhaps a fifth of the railroad mileage in the country belonged to railroads in default. Defaults peaked again in the 1890s when more than 40,000 miles of track was in the hands of receivers and the Pennsylvania Railroad eventually absorbed over 800 other railroads, many of them during the 1890s.

More difficult years would follow in the twentieth century as the nascent trucking industry began to compete with railroad in the shipping of freight, especially beginning in the 1930s (Schiffman 2003). Construction of the interstate highway system accelerated the decline of rail traffic (or at least its share of traffic) as did the switch in home heating and electricity generation away from coal. In the late 1960s and early 1970s, six major rail systems in the Northeast filed for bankruptcy, including the Penn Central Railroad, and freight and passenger rail traffic threatened to collapse, leading to Congressional intervention. This led to the creation of Conrail in 1976, initially a government-owned enterprise, as the principal rail freight shipper in the Northeast and Midwest. Conrail would eventually be sold back to the private sector in 1987. Meantime, Amtrak was created in 1971 with government subsidies to continue to provide rail passenger service although it owns none of the track over which its trains operate, accounting in part for its poor service record.

Government Intervention and Inducements

From the start, governments interfered with railroads – the Baltimore and Ohio Railroad, for example, was the brainchild of Baltimore's city fathers and facilitated by the speedy grants of charters by the states of Maryland and Virginia. Such intervention, however, was neither new nor uncommon (Hughes 1991). The case for railroads was that as durable and sizable investments, they needed the privilege of incorporation to provide for continuity over their long (technical) life and to help raise funds for construction. In return, states often demanded that the railroad be built to a certain standard and track gauge and connect various locations within a specific time frame, sometimes exacting "help" with other matters as well. As part of this mutuality, railroads also got help against extortion by land owners along the right-of-way through recourse to eminent domain and the right to bridge rivers and divert streams. Sometimes, other inducements were given, as in cases where the private returns were viewed as marginal or submarginal. Thus, for example, the federal government in 1850 offered grants of federal land to the Illinois Central Railroad to encourage construction of that railroad from Chicago southward through sparsely settled parts of the state. This policy built upon prior experience encouraging road (e.g., in Ohio) and canal construction (e.g., the Illinois and Michigan Canal). When completed in 1856, the Illinois Central was the longest railroad in the world. It would subsequently extend its reach into Iowa and into the South following the Civil War (although it did not initially have a bridge connection across the Ohio River and the gauge on the other side of the river was the southern 5′ gauge until 1881– that is, several years ahead of the switch by the rest of the South's railroads (Gross 2016)).

As an incentive, grants of land contingent upon construction were seen as a universal success and would be repeated beginning with the Pacific Railway Act of 1862, authorizing the first transcontinental railroad. In aggregate, these land grants to the railroads were huge. Between 1850 and 1871, the federal government gave away 131 million acres – over 203,000 square miles – an area larger than California and New York combined. These land grants potentially provided the railroad with a right-of-way and an asset whose value the railroad's construction would dramatically enhance. Moreover, that land could serve as a security for loans, especially mortgages (whose market was already well developed). However, there are questions as to whether these inducements were really necessary.

A review of the contemporaneous ex ante traffic projections for the first transcontinental railroad (Duran 2013) suggests that such subsidies were not required (although they may have reordered priorities in a capital-constrained world). These estimates are also consistent with retrospective projections of realized returns with and without the land grants (Fleisig 1975; Fogel 1960). Indeed, ex post analysis for the Central and Union Pacific railroads and the Great Northern has concluded that private rates of return exceeded the opportunity cost of capital even in the absence of land grants. For the Santa Fe and the Northern Pacific, the value of land grants may have tipped the balance ex post in favor of construction, while construction of Texas and Pacific Railroad was probably a mistake ex post (Mercer 1974). Even where returns were marginal – as in the early years of the Union Pacific – later returns almost certainly compensated (Fogel 1960). Regardless of the adequacy of private returns, though, there is universal agreement that the social returns were large (i.e., there were externalities that the railroads could not capture and whose value likely far exceeded the opportunity cost of the land ceded to the railroads (Fogel 1960; Mercer 1969)).

Those land grants would, however, also create problems of premature (or abortive) settlement based on putative misrepresentations (certainly, overly optimistic forecasts) (Libecap and Hansen 2002; Raban 1996) to would-be settlers, both those already in the United States and throughout Europe. Moreover, by retaining ownership of much of this land, the railroads could cross-subsidize activities (e.g., in the shipment of coal mined on railroad land) and block competition (e.g., from pipelines) that led to further public intervention.

Governments also interfered with the operation of railroads, in particular, the terms and conditions of service, albeit initially in a roundabout way. As competition between railroads intensified as more lines were interconnected and shippers had choices regarding carriers and routings, the railroads colluded to restrict its effect (Riegel 1931). For example, in 1869, the three dominant railroads shipping between Iowa and Chicago (the Northwestern, the Burlington, and the Rock Island) formed the Iowa Pool by gentlemen's agreement to share 55% of freight revenues and 45% of passenger revenues equally in the hopes of restricting price competition between them. Other regional groupings of carriers would later enter similar agreements, such as the Southern Railway and Steamship Association organized by Albert Fink beginning in 1873.

Such arrangements were not challenged immediately or directly, but governments found the authority to regulate freight rates as a result of an expansive Supreme Court ruling in the case of Munn v Illinois (1876) (Higgs 1987; Hughes 1991). That case originated in a challenge to an 1871 Illinois law, pushed by a recently created fraternal organization known as the National Grange of the Patrons of Husbandry, requiring the licensing of grain elevators and setting maximum rates for the storage and handling of grain, most of which arrived by rail. By then, Chicago was the center of the world's grain trade, supported by trading organizations like the Chicago Board of Trade and with a large infrastructure of grain elevators, many with common ownership, that separated railroads from ships that carried American grain worldwide. Illinois brought suit against the elevator of Ira Munn and George Scott for operating their grain elevator without a license and for charging more than the maximum permitted rate under the Illinois Warehouse Act. After conviction in state court, Munn appealed to the US Supreme Court on the grounds of an illegal taking without due process under the 14th Amendment. In its decision supporting the state of Illinois, the US Supreme Court ruled that common law permitted the regulation of business "affected with the public interest" (which would include railroads as "common carriers"), although Justice Field filed a vigorous dissent against this expansive ruling. The result of the decision, however, was a flood of regulation, much of it covering railroads, from other states, such that, by 1886, 25 of them had passed laws similar to Illinois's.

Another of Illinois's "Granger" laws, this one outlawing freight rates that charged more for a short haul than a long haul "under substantially similar circumstances" was challenged in 1886 by the Wabash, St. Louis, and Pacific Railroad. In their decision on this case, however, the Supreme Court ruled in favor of the railroad since the shipment in question involved the regulation of interstate commerce by the state. Within a year of that ruling, though, Congress passed essentially the same legislation regulating freight rates at the federal level and establishing the Interstate Commerce Commission (ICC) to oversee implementation. This ushered in an era of increasing federal interference in railroad operation such as the Elkins Act of 1903 outlawing rebates and the Hepburn Act of 1906 which gave the ICC the authority to set just and reasonable rates, prescribe accounting practices, and prohibit railroads from carrying any commodity which they or a subsidiary produced. The effect of these laws was profound and long-lasting (MacAvoy 1965; Martin 1971; Ulen 1980). Indeed, the federal government itself would even briefly assume total control over the nation's railroads between 1917 and 1920 as part of the World War One emergency. The rise of trucking, and especially tractor-trailers in combination with interstate highways, private cars, and the airlines, siphoned off much of the railroad's traffic after World War Two. This led to a reorganization and reorientation of the railroading industry by the creation of Amtrak in 1971 and Conrail in 1976, while the passage of the Railroad Revitalization and Regulatory Reform Act of 1976 and the Staggers Rail Act of 1980 dramatically reduced the authority of the ICC over the nation's railroads until the agency was abolished at the end of 1995.

Innovation and Productivity Change in American Railroads

According to estimates by Fishlow, between 1839 and 1909, railroad services grew at an average annual rate of 11.6% – about three times faster than income and commodity output at the time. No other single major sector of the economy grew as rapidly (Fishlow 1966). Part of this growth, of course, reflected the dramatic expansion in the miles of track and the spread of railroads from a few isolated areas on the East Coast to covering the contiguous lower 48 states discussed above and shown in Figs. 1 and 2. However, even after taking into account the increased inputs of land, labor, capital, and fuel used by the railroads, it remains clear that output per unit of input – total factor productivity (TFP) – also increased markedly. Indeed, Fishlow's preferred estimates of TFP show annual average growth rate of 3.5% over the entire period from 1839 to 1909 – a very respectable rate – albeit a dramatic slowdown from the productivity growth experienced in the 1840s of almost 10% per year (Table 3). Rates of productivity growth generally slowed, decade by decade, but most notably in the first decade of the twentieth century. Although Fishlow reports no later data in any detail, he does include a chart showing productivity growth through 1953 which suggests that this slowdown in the rate of productivity growth continued through at least the first half of the century (Fishlow 1966, Chart 1, p. 627). This pattern is consistent with estimates reported by others (Caves et al. 1981).

The productivity growth in supplying railroad services was partially reflected in declines in passenger fares and freight rates. In 1839, passengers paid about 5 cents per mile (a substantial price at a time when the daily wage was a dollar or less for a 10–12 hour day), and freight was paid for an average of 7.05 cents per ton-mile, a price that restricted carriage to relatively high value-to-weight items like manufactures (Fishlow 1965, 1966), meaning that there was plenty of space for other carriers, especially water. Eighty years later, passenger fares had been cut by more than 60% and freight rates by more than 90%. Freight rates for water carriage declined similarly, but the mix of freight was shifting in favor of higher value-to-weight items which favored rail shipment. Road carriage, however, experienced no real change in

Table 3 Average annual rate of growth in total factor productivity in American railroads by period, 1839–1909

	Ending year						
Starting year	1849	1859	1869	1879	1889	1899	1909
1839	9.8%	5.7%	5.5%	4.6%	4.2%	3.9%	3.5%
1849		1.8%	3.4%	3.0%	2.8%	2.8%	2.5%
1859			5.1%	3.6%	3.1%	3.0%	2.7%
1869				2.1%	2.2%	2.3%	2.1%
1879					2.3%	2.5%	2.1%
1889						2.7%	2.1%
1899							1.4%

productivity during the nineteenth century and so lost out whenever there was an alternative means of shipping. Moreover, the price changes in rail understate the real magnitude of the decline in rates as quality, measured in dimensions such as comfort, speed, and the certainty of timely delivery, also accompanied these falling prices.

Fishlow did not allocate railroad productivity growth between specific sources because of the lack of detailed information regarding the timing and extent of use of productivity enhancing devices and techniques, although particularly detailed information is available earlier on in the writings of a Czech engineer Franz Gerstner (Gerstner and Gamst 1997) acting on a commission from Czar Nicholas I of Russia. Fishlow does, however, suggest broad determinants. Consider intensity of use – more freight and passengers per track-mile. Demand for travel and shipping services eventually catches up with the capabilities of the rail system – the country grows into the transportation system that it has. Fishlow's data show intensity of use increased dramatically during the Civil War thanks to the needs of war, while track mileage itself increased only modestly. This probably accounts for a good portion of the much faster rate of productivity during the War decade relative to most other periods. On the other hand, productivity growth in the 1850s was much slower – a period when track mileage was increased sharply especially in areas that were less densely settled than others, like the Midwest.

Fishlow suggests a couple of relatively simple, if blunt, ways to capture the effects of this increased intensity of use. One of these is to recompute productivity assuming that the capital-labor ratio throughout was at its 1909 level. The other assumes that the capital-labor ratio actually increased (as it did in the economy in general) by holding the capital-output ratio constant. In the former case, annual productivity growth over the entire period is reduced from 3.5% to 2.9% – that is, by about 18%. In the latter case, the effect is about twice as large.

This greater intensity of use was also facilitated by various innovations in railroading. For example, the use of the telegraph to control and coordinate train movements (DuBoff 1980; Field 1992), block signaling to control specific stretches of track, and the construction of more sidings and bypasses made it possible to put more trains on each mile of America's predominantly single-track rail system. Moreover, the replacement of iron rails with steel enabled heavier trains to run at higher speeds for years longer before rails needed to be replaced.

These heavier trains and higher speeds were in turn made possible by the development of more powerful locomotives, burning more energy dense fuel (coal) and equipped with flexible trucks that helped guide them around tighter curves without jumping the track. Higher speeds and heavier trains, however, also called for improvements in braking. This was provided by adopting the Westinghouse air brakes which also eliminated the need to have individual brakemen positioned along the train. Getting trains moving and keeping the power applied to all the driving wheels efficiently while dealing with uneven track both front to back (as on a slope) and side to side (as a result of imperfect grading) was accomplished (from an early date) by equalizing levers which transferred loads from side to side and front to back. Fishlow suggests that these and other innovations like automatic couplers (which also drastically reduced mortality among railroad yard workers) collectively

accounted for perhaps half of the measured productivity growth, but without further subdivision and allocation.

So long as American railroads relied upon steam, however, there were some inherent limitations that could not entirely be overcome. Engines burned fuel – initially wood, then coal, and eventually even some oil – to boil water for steam. That steam provided the actual driving force but was exhausted upon use, and eventually the water that it represented had to be replaced. Indeed, locomotives needed more water than fuel, taking on wood or coal only every other stop – which might be as frequent as every 5–10 miles. Efforts to even out the consumption of these two vital components led to experiments with water troughs fed by streams built into the track that scooped water up to replenish the train's supply without it having to stop. By hauling larger water tenders and fuel bunkers (the two often combined with the water tank like an upturned saddle cradling the fuel), this range could be extended 10–20-fold but only by reducing the number of passengers or weight of goods being hauled.

The need for trains to carry their own fuel could be eliminated entirely by electrification. Indeed, this solution was adopted for urban and interurban electric transit systems but was prohibitively expensive for the vast US rail system. There were about 2100 miles of interurban electric track in operation by 1900, and construction boomed up through World War One, by which time there were 15,500 miles of track, principally in seven states, making possible extensive suburbanization around cities such as New York and Chicago as well as smaller cities, such as Indianapolis and Cleveland (Bogart 1906; Hilton and Due 1960). Thereafter, the interurban electric declined in popularity as access to private automobiles increased. For the longer distances involved on trunk line rails, the solution lays in the adoption of the diesel-electric locomotive, where the power to move the train comes from electric motors supplied with energy from diesel-powered generators. These first proved themselves in passenger service in the 1930s but eventually gained acceptance as freight engines (Lytle 1968; Mansfield 1963; Stover 1970). The adoption of electric power in railroading dramatically reduced labor requirements and spurred labor productivity growth in the industry – for example, multiple engines can be controlled from a single location with no need for firemen.

The Social Savings of Railroads

The success of early railroads spelled the beginning of the end for canals. Whereas canals added only about 400 miles during the 1840s, rail mileage grew by over 5000 miles (Carter et al. 2006), and during the 1850s, more miles of canal would be abandoned than were built, but railroad mileage tripled. Railroads simply proved to be superior in the eyes of consumers – whether as a means of shipping or of travel. The question is how big was this superiority? Fogel proposed to determine this by measuring the loss to the economy if the nation had been forced to rely on preexisting means of transportation – canals, steamboats, and wagon – by comparing the actual world with that from a counterfactual state of affairs (Fogel 1964, 1967).

In practice, however, he focused on just canals and wagons, devising a metric that he called "social saving." It was this work that the Nobel Committee cited in its award of the (joint) Nobel Prize in Economics to Fogel in 1993.

Fogel measured this social savings as the consumer surplus associated with switching from shipping by rail to the next best alternative means of shipping while assuming that the supply of shipping services (whatever the sources) was perfectly elastic at the prevailing rates and that the demand for shipping services was completely inelastic. The resulting consumer surplus is the area of a rectangle defined by the difference in the cost of shipping between the best and the next best means of shipping and the quantity shipped and is an upper bound on the actual consumer surplus. Any price elasticity in the demand for shipping would reduce this consumer surplus.

Of course, "the devil is in the details," such as what was shipped and how far. To make the problem more tractable, Fogel restricted his analysis to agricultural commodities – still the dominant sector of the economy until the very end of the nineteenth century in terms of value of output, employment, and movement of goods. He also divided his analysis between long-distance trade – specifically interregional trade – and that closer to home, intra-regional trade. Because good data were available from various government agencies, including the ICC, the Census, and the USDA, Fogel referenced his estimates to 1890, a date by which the railroad was firmly established as the premier mode of transportation (but the picture was not yet clouded by the advent of the internal combustion engine) and its impact should therefore be "large."

The expectation was that interregional trade would dominate. After all, the railroad was most famous for its transcontinental scope and routes like the Illinois Central connecting Chicago with the Gulf Coast. Moreover, resources – and thus trading opportunities – differ more at a distance than close to home. As it worked out, however, the social savings of the railroad in interregional trade were initially calculated as negative – that is, using the railroad imposed a net cost upon the economy rather than a benefit. The reason was simple: the low-cost alternative to rail transportation in long-distance trade was the canal. These offered lower shipping costs than the railroad, and some – like the Erie Canal – were still very much in business in 1890 even if other canals like the Wabash and Erie had been abandoned, hence the negative estimate of the consumer surplus, initially put at -$38 million (Fogel 1964, p. 47, fn. 57). However, this estimate ignored a wide variety of other costs associated with reliance upon water including cargo losses from spoilage and water damage, additional transshipping costs and the costs of shipping from farms to more distant canals, and added inventory costs due to slower shipping and the effects of spring flooding, summer drought, and winter freeze (these issues receive additional critical scrutiny in David 1969). Collectively, Fogel estimated that the net effect of these was to tip the social savings on interregional trade to a positive $73 million.

On the other hand, Fogel determined that the social savings in intra-regional trade were positive just based upon a comparison of the published freight rates without even considering those other factors that made shipping by rail "better." This was

because the next best alternative to rail in intra-regional trade was high-cost, slow wagon transportation – a mode of travel essentially unchanged from the eighteenth century to the early twentieth century. A combination of more expensive and extensive wagon shipping in combination with some limited water shipment would have raised the costs of intra-regional transportation of agricultural commodities by $337 million. This might have been reduced to a social savings of "just" $248 million through a modest, yet feasible, expansion of the canal system that would have brought more of the nation's agricultural land within 40 miles of a water route (Fogel 1964, p. 92, Table 3.10).

By having access to the railroad rather than being forced to rely upon just wagon and canal transportation for the shipment of agricultural commodities in 1890, the United States saved a total of $321 million (=$73 million on interregional trade + $248 million on intra-regional trade). This amounted to about 2.7% of 1890 GNP, a sum that Fogel considered relatively small (certainly in light of all the hyperbole accorded railroads from their inception). More recent estimates of the social saving on agricultural commodities by Donaldson and Hornbeck (2016) revise this figure upward, albeit only modestly to 3.22% of 1890 GNP. The real thrust of Donaldson and Hornbeck's analysis, however, is to estimate the impact that the coming of the railroad (or its loss) had upon agricultural land values (a calculation that Fogel also made). To make this calculation, they rely upon the trade model of Eaton and Kortum (2002) to develop a measure of the railroad's impact upon "market access," based upon least-cost shipping between markets and the importance of those markets (like population), a metric that has found increasingly widespread use. Based upon the change in market access, they conclude that the elimination of railroads in 1890 would have decreased land values in the United States by 60% – a large amount. Indeed, they call the railroads "critical" to the agricultural sector in 1890. Moreover, in contrast to Fogel's arguments, they do not believe that these losses could have been offset in any substantial way by extending the country's network of waterways.

Donaldson and Hornbeck's estimates, like those by Fogel, suffer from the limitation that they are designed to reflect the gain to agriculture from access to railroads rather than all goods, although as producers of relatively low value-to-weight items, agriculture would bear the heaviest burden of higher transport costs. Moreover, they ignore the impact of the railroad upon passenger traffic, which was an important source of revenue for the railroads and gain to the economy before motor vehicle traffic siphoned off that trade. Boyd and Walton (1972) estimate passenger losses at about $344 million in 1890 – more than doubling the loss estimated by Fogel. Thus, these losses combined with Fogel's own rough estimate of aggregate freight traffic savings would raise the total social savings to over $900 million or about 7.3% of GNP.

Such losses begin to look "large." Indeed, in their work, Donaldson and Hornbeck conclude that in the absence of the railroad, declines in population and worker utility would have generated substantial losses in GNP and aggregate welfare, even without considering the effects upon agglomeration and other externalities. Contemporaneous estimates to Fogel's made by Fishlow for 1860 concluded that the social savings

amounted to perhaps $155 million on (all) freight and $70 million on passengers. This loss would have been about 5% of 1860 GNP – and likely would have been much larger by 1890 – perhaps as much as 15% of GNP (Fishlow 1965).

The uncertainties and margins of error surrounding social savings estimates arise from both practical and theoretical issues. Among the practical concerns are the role of externalities such as speed, comfort, and safety (Lebergott 1966), the impact of inclement weather on city food supplies – and the ability of large cities to survive – in a world without railroads, and whether various biases cancel each other out (David 1969). Perhaps the most serious concerns are theoretical and concern the general equilibrium effects, not captured in the comparative statics approach of the counterfactual, of eliminating the railroad. Efforts to model these (e.g., by Williamson 1974, 1975) result in larger estimates than made by Fogel – as one might expect. Calibration is key, and other general equilibrium approaches (Donaldson and Hornbeck 2016; Kahn 1988) have resulted in estimates that lie somewhere between those by Fogel and Williamson.

Whether the railroads were "decisive" in terms of American growth and development seems unlikely, that they were important and their contribution large, however, seems more certain. Much of Fogel's critique was rhetorical, aimed at destroying a straw man that he termed the "axiom of indispensability" and moderating the most extreme hyperbolic claims of both contemporaries like Ralph Waldo Emerson (1903 364), who called the railroad "a magician's rod in its power to evoke the sleeping energies of land and water," and earlier generations of historians (up to and including Rostow) who described the railroad as "essential to the development of capitalism" and "responsible for much of the territorial division of labor" (Bolino 1961, 175).

Concluding Remarks

Although not decisive or critical to American growth and development in the way that generations of observers had claimed prior to Fogel's analysis and critique, railroads were important – arguably more important than Fogel's rhetoric would lead one to believe. Not only did they shape – or rather reshape – trade flows within and from the country for more than a century, but they played a major role in inter- and intra-regional specialization. This promoted economies of scale and agglomeration economies among other externalities by improving the means of transportation and communication. They would also have other, more diverse, and less obvious impacts, especially in areas of business that have not been a focus of cliometrics – for example, management (e.g., the emergence of the multidivisional business), accounting (both cost accounting for internal control and broader financial reporting for investors), and labor relations (e.g., labor unions like the United Brotherhood of Sleeping Car Porters and tracking and monitoring the performance of a geographically dispersed labor force). These aspects receive fuller but still largely qualitative treatment, in the writing of business historians, especially Alfred Chandler (Chandler 1965, 1977, 1979; John 2008) although some aspects of business organization are beginning to attract cliometricans (see, e.g., Guinnane et al. 2007; but especially Hilt 2008).

Clio on Speed

A Survey of Economic History Research on Transport

Dan Bogart

Contents

Abstract

Cliometrics has made major advances in the historical analysis of transportation through better measurement, economic modelling, and estimation. This essay surveys several topics and recent research. First, the revolutionary changes in transport over the last 300 years are reviewed, including analysis on the rate and sources of productivity growth. It is argued that macro-inventions, like steam power, were important but many incremental innovations mattered too. Second, the effects of transport improvements on market integration, trade, urbanization, and aggregate income are examined. Much research focuses on questions of magnitude. In other words, how big are the effects of transport improvements like railroads? Perhaps surprisingly, there is still disagreement about the relative importance of transport even with the applications of new tools and Geographic Information Software. Two novel areas of research concern mortality and

C. Diebolt, M. Haupert (eds.), *Handbook of Cliometrics*,
https://doi.org/10.1007/978-3-030-00181-0_67

persistence. Studies show that transport improvements contributed to higher mortality and influenced population density long after transport technologies became obsolete. These studies yield new perspectives on the effects of transport. Third, this essay examines why transport services were more efficient in some economies with a focus on the role of institutions as a fundamental factor. Evidence suggests institutions influenced investment in transport networks and the degree of public and private ownership. Ownership mattered for transport efficiency, and government involvement sometimes improved outcomes. Overall, cliometrics research on transport offers many insights on a historically important sector.

Keywords
Transport · History · Market integration · Urbanization · Institutions · Agglomeration · Shipping · Railways

Introduction

Transportation has undergone dramatic changes through the ages. Scholars from a wide range of fields have sought to understand the implications and explain those changes. Cliometrics has made key contributions to this broader literature through innovations in measurement, economic modelling, and estimation. This essay reviews the contributions of cliometrics to seven key topics. The first topic concerns the so-called transport revolution. There is much research tracking transport costs and travel speeds over time, making it possible to quantify the rate of change. This research shows that transport has undergone dramatic productivity improvements over the last 300 years. What caused these changes? Were macro-inventions, like steam power, the primary driver? The literature generally supports the importance of macro-inventions, but at the same time many studies show that productivity changes were incremental and contextual. Several examples are given below.

The second section examines transport, market integration, and trade. The trends in market integration are reviewed. Next the effects of transport improvements are examined. Perhaps surprisingly, some research has found that transport improvements were not the most important driver of market integration. But other research finds the opposite. Moreover, in one study, poorly designed transport regulation is argued to be a main driver of market disintegration. The connection between integration and transport is not fully settled.

The third section focuses on the contribution of transport improvements to aggregate incomes. The main question is the following: how much economic growth was attributable to transport improvements? The traditional cliometric methodology calculates the social savings. Recently, cliometrics has developed new data and econometric methods. As will be discussed below, the new research sometimes yields different estimates of transport's contribution. But in some cases, it appears that the social savings provide a reasonable approximation to the aggregate incomes gains from transport.

The fourth section examines the external effects of transport. Greater urbanization is one key example. Due to lower transport costs, individuals may change their location and affect their neighbors' productivity. Several works analyzing the effects of railroads on city population are reviewed. All find that cities with better railroad access increased their population relative to cities with poor access. An outstanding issue concerns possible reorganization effects, where transport causes population loss in areas with worse transport access. The effects of highways on central city population provide a good example of reorganization.

Higher mortality is another external effect of transport improvement. Pollution-related health problems are a major concern in the twenty-first century. This section also discusses how transportation-related pollution was an issue in the nineteenth century.

The fifth section examines the connection between transport and the persistence of economic activity across space. Populations tend to settle where there are natural advantages, like a navigable river. Transport improvements can create new locational advantages, which encourage population resettlement. As time goes on some transport technologies become obsolete and one might think that population would resettle elsewhere. However, the literature shows migration from obsolete transport hubs does not necessarily happen.

The sixth section examines how institutions affect transport. Institutions have long been highlighted in economic history as a fundamental cause of development. In the transport sector, institutions have been linked with the extent and quality of infrastructure networks. Several works are discussed which show that political institutions had a large effect on network development. This suggests that transport is a key channel through which institutions affected development in the past and today.

The seventh and final section discusses public and private ownership in transport. There are theoretical arguments in favor of both forms of ownership. Studies on the impacts of ownership and cost efficiency are discussed. Also, the role of institutions in determining railroad nationalizations in the nineteenth and early twentieth centuries are analyzed. This ties with current debates about when government is more effective in delivering transport services.

The Transport Revolution

The transport revolution is one of the most significant developments in human history and equals the industrial revolution in significance. According to historians (e.g., Taylor 2015; Bagwell 2002), the transport revolution involved dramatic reductions in the time and costs of moving goods and people and in the cost of communication. Britain's transport revolution provides an example of these significant changes. The real freight rate by rail in 1870 was 5% of the real freight rate by road in 1700. The speed of road travel in 1700 was only 8% of the speed by train in 1870 (Bogart 2014). Dispatch times for letters in 1860 were 33% of what they had been in 1820 (Kaukiainen 2001). For comparison, one can look at the falling price of high-valued manufactured goods, which were impacted by mechanization during the British industrial revolution. In 1840, the real price of fine printed cloth, known as calicoes,

was 25% of their price in 1770, implying a 2% annual rate of decline (Harley 1998). The overland freight rates mentioned above declined at an annual rate of 1.7% and dispatch times declined at an annual rate of 2.7%. These and other examples reveal that the transport sector was revolutionized to the same extent as manufacturing.

Much attention has focused on dating the transport revolution in various countries and for inland versus coastal and ocean shipping. In some cases, it is hard to identify the timing of significant change due to the gradual process of improvements. For example, there is evidence that shipping freight rates started to decline in the European trades during the early 1600s (Menard 1991). There is also evidence for greater productivity and lower sailing times in the transatlantic and East Indian trades during the late 1700s (Rönnbäck 2012; Solar 2013). The big changes in shipping productivity and freight rates arguably occurred in the mid-1800s with the introduction of steam power. Steamships were a global technology and brought lower freight rates to much of the world's trade, including India and China. Real shipping freight rates continued to decline between the late nineteenth and early twentieth century. The peak for productivity in pre-World War I ocean shipping was 1913 (Mohammed and Williamson 2004). For the next 50 years, shipping freight rates fluctuated significantly, mainly due to wars and policy decisions. More recently, that is in the last 50 years (1960–2010), freight rates declined once again as ships got larger and accommodated containers. The downward trend in freight rates in the last 50 years looks like the 1870–1913 era.

Inland transport costs also evolved over time. As an illustration, Walton and Rockoff (2013) summarize freight rates in the USA up to 1900. Around 1800 there were two main forms of inland transport: wagon and river. Wagon freight rates were 34 cents a ton mile, while river transport was between 2 and 10 cents a ton mile depending on whether boats travelled upstream or downstream. Significant changes occurred starting in the 1820s. The upstream river rate dropped to 1 cent a ton mile with the arrival of the steamboat. Building canals brought cheap water transport to areas without navigable rivers (around 5 cents a ton). Wagon rates fall to 15 cents a ton mile due to better roads. The introduction of railroads around 1840 was the next phase. It brought low freight rates and greater speed to areas that did have canals because of geography. Freight rates by rail started at 6 cents a ton mile and declined to less than 1 cent a ton mile by 1900. Note that freight rates continued to fall on railroads and canals after they were introduced. These technologies unleashed a period of exceptionally high productivity growth in the USA.

These patterns of lower inland freight rates and travel times were not seen worldwide, however. In a few economies, mostly northwestern Europe and the USA, there were improvements in inland transport starting in the 1700s (De Vries 1981; Bogart 2005; Gerhold 2014). But in other economies, including India, China, and Japan, it was only with the railway that inland freight rates and travel times fell (see Huenemann 1984; Ericson 1996; Kerr 2007). One explanation is that these economies did not improve their roads and waterway networks to the same degree as northwestern Europe and the USA in the late eighteenth and early nineteenth centuries.

The twentieth century has witnessed another transport revolution associated with the automobile and airplane. Their economic impact has been large since the

1950s. Air travel is the most recent example. It led to dramatic declines in the cost of passenger travel and improvements in communication. The average speed of air passenger travel went from 180 mph in 1950 to 408 mph in 1990 (Carter et al. 2006). That is, speeds increased by 2.25 times in 40 years. One effect in the USA has been the concentration of employment near cities with airports (Brueckner 2003).

Over the longer term, consider the following facts. In 1700, most wealthy individuals travelled on coaches at speeds less than 3 mph. In 2000, the wealthy travel in airplanes at more than 500 miles an hour. That implies long distance travel speeds are 166 times faster today than 300 years ago for the rich! In 1700, the poor did not usually travel, but when they did it was generally by foot, moving at 2–2.5 mph. In 2000, the poor often travel at speeds ranging between 20 and 60 miles an hour depending on congestion, roads, and vehicle types. Therefore, travel speeds for the poor are 10–24 times faster than 300 years ago. In the long-run perspective, it is evident that transportation has radically changed, but the rich have enjoyed more gains than the poor. Transport improvements are *not* neutral in their distributional effects.

This brief review should raise questions about the causal factors behind the transport revolution. One issue concerns the importance of large-scale technological changes (i.e., macro-inventions) versus incremental changes (i.e., micro-inventions). The thrust of much research in cliometrics points to the importance of incremental changes without minimizing macro-changes like steam power, the ship container, and the internal combustion engine.

Shipping provides a good example of this research. One narrative is that the productivity of sailing ships changed little over the centuries in comparison to advances associated with steamships. Harley (1988) made this argument starkly in the case of British shipping. Using a real freight rate series, Harley argued that little changed from 1740 to 1830, but after 1830, when steamships became more common, there was a precipitous decline in real freight rates (see Fig. 1). Harley's series challenged those of previous scholars like North (1958) who suggested that transatlantic freight rates declined as much in the age of sail as the age of steam. Harley used a different freight rate series and price deflator. As is often the case in cliometrics, measurement matters.

While steam was clearly important, subsequent research has shown that Harley over-states stagnation in the age of sail. From the 1780s, copper-sheathing protected wooden hulls from ship worm, significantly prolonging ships' lives and incidentally making ships faster and more maneuverable. This new technology reduced freight costs by about a third in the trade between Europe and Asia and led to a significant fall in mortality in the slave trade in the late eighteenth century (Solar 2013; Solar and Rönnbäck 2015). Menard (1991) and Shepherd and Walton (1972) show that freight rates in the transatlantic trade declined in real terms in the seventeenth and eighteenth centuries. In the case of the Chesapeake to London tobacco trade, real freight rates declined at an annual rate of 2.1% up to 1774. These authors attribute over 80% of the decline in freight rates to lower port times and specifically better packaging.

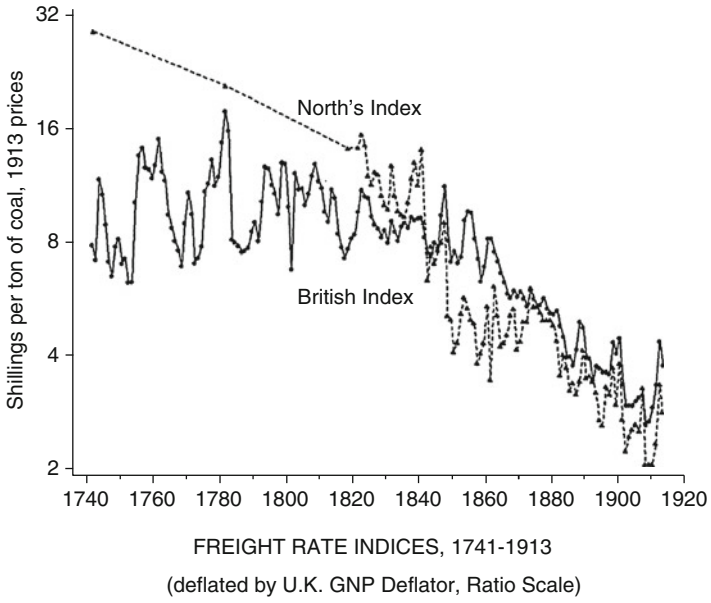

Fig. 1 Two shipping Freight rate indices. (Source: Harley 1988)

It is striking that something seemingly simple, like packaging, could make a key contribution to the transport revolution. The emphasis on packaging relates to an important point about transport costs: the product being shipped matters. Tobacco, cotton, and sugar were amendable to packaging improvements in the pre-industrial world. Other products like coal were not. The combination of products was also important. In another article, Harley (2008) shows that nineteenth century freight rates on grain became very low between New York and Liverpool in part because grain was used as ballast on ships transporting live cattle. Ballast is necessary because it gives stability to the ship. Usually ballast is transported for free or at very low freight rates, because they enable the more valuable good to be shipped. The implication is that absent the live meat trade, and the need for ballast, freight rates on grain would have been much higher.

Overall, the case of shipping suggests that large-scale technological changes were moments of discontinuous productivity advances, but they were often equaled by many incremental changes. Arguably a similar statement applies to productivity growth more generally. In that sense, transport is not different from manufacturing and some services.

Transport Improvements, Market Integration, and Trade

Greater market integration is one consequence of the transport revolution. Market integration relates to the co-movement of prices in different markets as defined in the law of one price. The law states that the price difference for a commodity in two

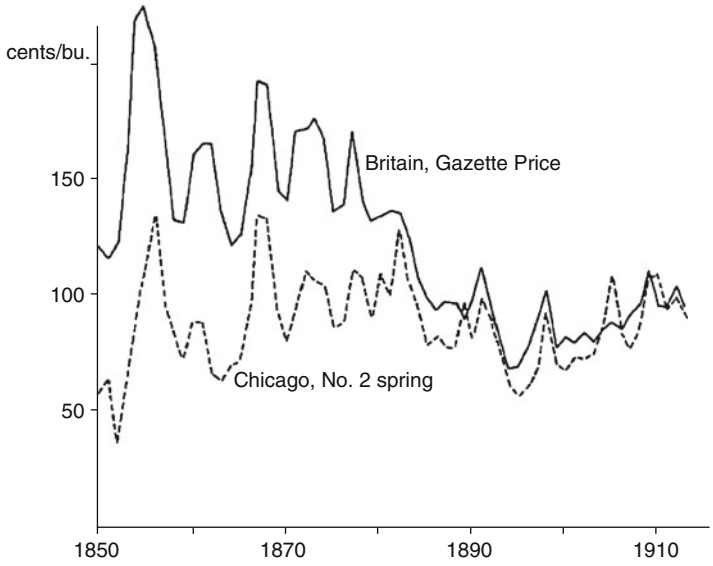

Fig. 2 Wheat prices in Britain and Chicago, 1850–1913. (Source: Harley 1980)

markets should be smaller or equal to transport and transaction costs, the so-called no-arbitrage gap. If the price difference is greater than the gap, trade will occur (commodities will move from the low to the high price market) and the price differences will shrink to the gap. The so-called "speed of adjustment" is the rate at which prices converge to the gap (Federico and Persson 2006).

Perhaps the most striking evidence of integration is the nineteenth-century transatlantic wheat market. As an illustration, Harley (1980) documents the difference in wheat prices between Britain and Chicago between 1850 and 1913 (see Fig. 2). The wheat price difference was high in the 1850s and 1860s (around 50 cents a bushel). By the 1890s and through the early 1910s, the price difference was negligible (around 5 cents a bushel). There was a large growth in trade between the USA and Britain accompanying the greater integration of wheat markets. In fact, global trade grew so much that historians have dubbed the late nineteenth century the first "era of globalization." Based on the wide diffusion of railroads and steam ships in the late nineteenth century, it would appear they were the main drivers of this market integration and international trade.

But in cliometrics reasonable theories are not always supported by the data. Jacks (2006) provides evidence that railroads and canals were not the main drivers of integration. This important paper aims to quantify the contribution of various factors to market integration. It proposes an empirical model to explain integration in wheat markets. The model has variables for technological factors, like railroads and canals, and institutional variables, like tariffs and common monetary regimes. The main specification is the following:

$$\text{Market integration}_{ijt} = \alpha \cdot \text{technology}_{ijt} + \beta \cdot \text{institutions}_{ijt} + \eta \cdot x_{ij} + \delta_t + \varepsilon_{ijt}$$

where market integration$_{ijt}$ is the estimated transaction costs or speed of adjustment between city pair i and j in year t, technology$_{ijt}$ and institutions$_{ijt}$ include the key explanatory variables. The remaining variables are controls including year fixed effects, distance, and common borders. Jacks finds a striking conclusion: institutional factors were more important in explaining the decline in price gaps. For example, having a railroad connection reduced the transaction cost by 0.02 standard deviations, while shared adherence to the gold standard reduced the transaction cost by 0.22 standard deviations. In short, institutional variables were the key driver of market integration during the late nineteenth century according to this model.

This essay will return to the topic of institutions later, but it is worth noting that other studies continue to argue that transport was an important driver of market integration and trade. For example, Pascali (2017) argues that the steamship had a major impact on global trade from 1850 to 1900. The introduction of the steamship led to an asymmetric change in trade costs among countries. Before this invention, trade costs depended on wind patterns, and some countries were favorably located. But wind patterns mattered much less after the steamship was introduced. Pascali uses this fact to identify large effects of steamships on trade. Donaldson (2018) reaches a similar conclusion for railways in colonial India using different data and a different identification strategy.

There is another study which also shows the importance of transport policies, but the effects are towards market disintegration. There is evidence for disintegration of markets in the inter-war period between 1920 and 1940. For example, Federico and Sharp (2013) show there was considerable disintegration of agricultural markets in the USA. They argue that disintegration was largely due to an increase in railroad freight rates. Why did that happen? According to Federico and Sharp, freight rates rose because of the 1920 Transportation Act and legislation that followed. There was a shift from a generally pro-competitive policy among US regulators to one in which railroad companies were subsidized through high regulated rates and were protected from competition by the emerging trucking sector. Matters were exacerbated by the price deflation occurring in the 1930s and the failure of regulators to lower rail rates as input prices fell. Arguably, it was the lobbying pressure of the railroad companies that kept the rates high. This case provides an excellent illustration of regulatory capture in transport. More generally, this study and the previous ones suggest that more research is needed to understand the complex relationship between transport, market integration, and trade.

Transport Improvements and Income Gains

Dramatic reductions in transport costs have potentially large implications for incomes and living standards. Many historians in the early twentieth century assumed transport improvements, like railroads, were indispensable to the growth in incomes during the nineteenth century. Several decades later, some of the most

famous cliometricians questioned whether this was true. Fogel (1964) and Fishlow (1965) approached this issue using the "social savings" methodology. The social savings are approximated by the formula: $(P_w - P_r)*Q_r$, where P_w is the price of transport using the old technology, P_r is the price of transport with railroads, and Q_r is the quantity or ton-miles shipped by railroads. The social savings are meant to approximate the consumer surplus created by railroads at some benchmark date (see Fig. 3). The price P_r is the marginal cost of delivering railroad services and P_w is the marginal cost of some alternative technology like wagons. The marginal costs equal the prices charged under the assumption of perfect competition in transport markets. The shaded region is the social savings, which is $(P_w - P_r)*Q_r$ after a correction for the elasticity of demand. Notice that a more elastic demand (i.e., a smaller slope for curve D) implies a lower social savings. A similar methodology has been used to calculate time savings from transport. Leunig (2006) provides one example for British railways.

The social savings from railroads are often compared with national income to assess the quantitative significance. Fogel and Fishlow estimated that national income in the USA would have been only 3–4% lower in 1860 or 1890 without railroads. In other words, railroads accounted for only a small portion of the income gains between 1840 and later decades. Many cliometricians have followed in their footsteps. For example, Summerhill (2005) and Herranz-Loncán (2014) provide a summary of social savings estimates for railways in Latin America. The savings equal about 25% of total GDP in Argentina, Mexico, and Brazil by 1910–1913. These are huge effects, and much larger than the USA. However, Herranz-Loncán (2014) finds that the social savings were less than 5% in Uruguay, Peru, and Columbia. In the case of Peru and Columbia, their railway networks were small, and their services were poor in quality.

The social savings methodology has some virtues. Ease of calculation is one. All that is needed are aggregate traffic volumes and estimates of average freight rates or speeds. For railroads, the social savings can be estimated in most economies by 1913 because national statistics are usually available by that date. This allows for cross-

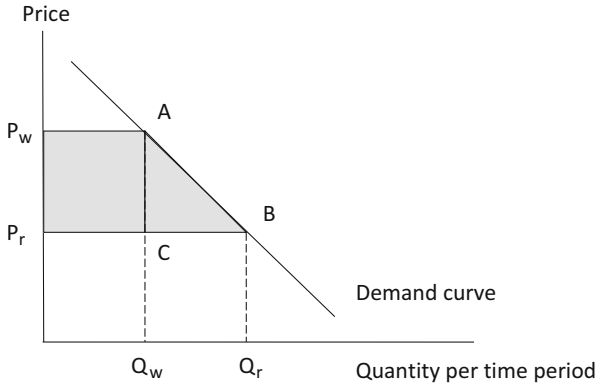

Fig. 3 The social savings of railroads depicted as a measure of consumer surplus. (Source: Author's design)

county comparisons of the gains from railroads and investigation of the factors that led to different impacts.

Nevertheless, the social savings methodology is controversial. Critics point to several problems (see McClelland 1972). First, it is not clear what the price of the alternative transport would have been in the absence of railways (P_w in the formula $(P_w - P_r)^* Q_r$). Congestion would have likely increased on wagon roads and canals if it had to handle the traffic volume associated with railways. The cost of using alternative transport modes is arguably underestimated as a result. Second, the social savings calculation omits backward and forward linkages. Railways increased demand for iron and steel as inputs and thus they fostered the development of these important industries. There are also changes in economic geography to consider. Lower transport costs can lead to agglomeration, which has positive effects on productivity.

Recently, cliometrics has used new data and methods to analyze the contribution of transport improvements to income. One good example is Atack and Margo (2011), who study the link between railroads and land values in the USA. Land values are informative because most externalities, like agglomeration, should be reflected in land income as it is the fixed factor of production. Atack and Margo's railroad data is derived from digitized nineteenth century maps and census materials revealing farm outcomes like land area, land which has been improved, and values in dollars. They cleverly employ Geographic Information Software (GIS) to generate spatial variables of interest. Similar GIS data are also employed to study European railways (see Martí-Henneberg 2013).

Atack and Margo use a difference-in-differences estimator (DID) to measure the impact of the railroad. In this case, DID compares the change in farm outcomes between 1850 and 1860 in a treatment group of counties – identified as those getting railroads during the period – versus a control group that did not. Their estimating equation is similar to the following:

$$\text{Log land improved}_{it} = \alpha \cdot \text{Railroad}_{it} + \eta_i + \delta_t + \varepsilon_{it}$$

where the dependent variable is the natural log of acres of improved farmland in county i, η_i is a fixed effect for the county, δ_t is a fixed effect for the census year (1860), railroad_{it} is an indicator equal to 1 if county i has a railroad in year t, and ε_{it} is the error term. Through the county fixed effects, this specification controls for unobservable factors that are specific to a county across time, and through the 1860 fixed effect it controls for factors specific to all counties in that decade relative to 1850. There is an issue, however, in that railroads were anticipated some years in advance. Farmers in counties that would get railroads may have started to improve their lands prior to railroad arrival. More generally, counties that would get railroads are likely to be different from other counties. For example, they could have a more skilled population and be more likely to develop even if railroads did not arrive. Thus, the assumption that the railroad indicator variable is "as good as random" conditional on the fixed effects is questionable.

Atack and Margo address endogeneity using an instrumental variables (IV) strategy. The idea is to find a variable that predicts railroad access but

does not affect land values in any way except through railroad access. Railroad plans from the early 1820s and 1830s are used to identify likely starting and endpoints for future railroads. The starting and end points are often places of economic or military significance. Atack and Margo then use GIS to create straight lines connecting the start and end points. Counties on this line have no special characteristics except that they are located on a favorable route for building a railroad between places of significance. They estimate a much larger effect of railroads on improved land using their IV strategy compared to ordinary least squares (OLS). They argue that railways were anticipated, leading to a downward bias in the estimated treatment effect. The upshot is that Atack and Margo create a new estimate for railroads' impact on agricultural improvement. Their estimates imply that in the 1850s, there was a 13.8% increase in improved farmland due to gains in rail access, which is nearly all the increase in improved farmland during that decade. Atack and Margo's findings imply that Fishlow's social savings estimate under-states the contribution of railroads. Fishlow argued that railroads could account for only a small portion of total economic growth between 1840 and 1860.

The DID approach to measuring the effects of transport improvements has received some criticism. Recall that DID compares the change in outcomes in a treatment group of counties – identified as those getting transport access – versus a control group that did not. But one might argue that a rail "yes or no" classification does not incorporate network effects. Spatial general equilibrium trade models suggest that a railroad linking a farmer to a major market should have a greater effect than a railroad linking a farmer to a minor market. In the former case, the farmer will get cheaper or better manufactured goods because the major market has more competition and variety. Also, the farmer will get more land rent because it can more easily sell in a market with high demand and hence high agricultural prices. In the language of trade models, a railroad linking a farmer to a major market will provide greater "market access."

The baseline formulation of market access is the following: $MA_i = \sum_{j=1,\neq i} pop_j / tc_{ij}$, where MA_i is the market access of location i, pop_j is the population of any other location j, and tc_{ij} is the transport cost from i to j, and $\sum_{j=1,\neq i}$ is the sum over all other locations j except i. Notice that market access is high when there are low transport costs to more populous locations (i.e., tc_{ij} is low and pop_j is high). This implies that getting close to a railroad line will have different effects depending on its connections. If the railroad creates lower transport costs to large centers, then market access will increase more than if the railroad creates lower transport costs to small or medium centers. It also implies that railroads can have effects on locations very far away through the network structure.

There are several works in the historical literature estimating market access. One of the most well-known is Donaldson and Hornbeck (2016). It is worth examining their approach because it reassesses the effects of railroads on American agricultural development. They build their analysis from a trade model. They derive an expression for equilibrium land rental rates, which are log-linear in one endogenous economic variable, market access, and several exogenous variables like fixed land productivity. This implies that with panel data one can estimate the equation:

$$\text{Log land value}_{it} = \alpha \cdot \text{MA}_{it} + \eta_i + \delta_t + \varepsilon_{it}$$

where MA_{it} is market access of county i in year t, η_i and δ_t are fixed effects for the county and census year. Notice the similarity with Atack and Margo's model. The key difference is that Donaldson and Hornbeck use market access rather than the indicator variable for the county having any railroad. As they point out, one can include both variables in the same specification and compare their effects. Another feature worth noting is that endogeneity is less of a concern for market access variables compared to an indicator variable for having a railroad in a county. Market access is largely determined by network structure, which in many contexts is driven by decisions beyond the county under consideration.

The measurement of market access is another innovation of Donaldson and Hornbeck's study. They calculate the lowest county-to-county freight rate for all combinations of county pairs (tc_{ij} in the market access formula). The calculation relies on three components. Each is worth commenting on. The first uses transportation cost parameters that apply to a given unit length of each transportation mode (railroad, waterway, and wagon). The transport cost parameters consist of freight rates per mile. These are often reported in the literature, but one might wonder about their accuracy. Stated freight rates could be based on a small number of observations or locations. Practically speaking, freight rates could be mis-measured, leading to biases in the estimates.

The second step in calculating market access uses a transportation network GIS database that maps where freight could move along each transportation mode. The GIS data are highly detailed and offer tremendous potential. However, there is an issue in geo-rectifying railroad and waterway maps, which are the under-lying data. As Atack (2013) shows the sources are not always consistent, and researcher choices need to be made. The third step involves the computation of lowest-cost freight routes along the network for given cost parameters. The computation comes from network analysis software. Computation time can be a problem if there are large numbers of counties and many transport modes, although this problem is quickly diminishing with better computing power.

In their analysis, Donaldson and Hornbeck find large effects of railroads on market access and on agricultural land values. Their counterfactual estimates imply that in the absence of railroads, agricultural land values would have decreased by 60% in 1890. In terms of income lost, their estimates imply that Gross National Product (GNP) would be 3.22% lower in 1890. Donaldson and Hornbeck's estimated impact is larger than Fogel (1964), who argued that without railroads the loss in agricultural land values would total 2.7% of GNP in 1890. While this may sound like a small difference, consider that the loss of *all* agricultural land income could at most lower US GNP by 5.35% in 1890. Therefore, the impact of railroads is capped at 5.35% of GNP in the approach focusing on agricultural land. Future research may shed light on the urban land values or capital and labor income. Perhaps the main lesson is that the "market-access" approach offers new insights and is a useful tool for evaluating the effects of transport improvements on income.

Transport Improvements and External Effects

There is a large historical literature examining what can be termed "external" effects of transport improvements. It considers the effects of using new transportation services on changing residence from a rural to urban area, on participating in new trade, or exposure to pollution to name a few. Several interesting papers examine external effects and are worth discussing in some detail.

Greater urbanization was a feature of many advanced economies in the nineteenth and twentieth century. Urbanization was associated with increased consumption opportunities and is considered a good measure of living standards. Urbanization also had effects on productivity through agglomeration. In theory, as more people locate and work in urban areas, the productivity of the average worker increases, leading to higher incomes. There are compelling reasons to think that transport improvements increased the concentration of economic activity for most economies up to the mid-twentieth century. In economic geography models with increasing returns, agglomeration forces are stronger when transport costs change from high to intermediate (Krugman and Venables 1995). In the intermediate range, food is shipped more cheaply, consumers spend more on manufactured goods, which are more productively made in a single location, and workers tend to locate in a single location. The implication is that with better transport innovations, like the railroad, urbanization should have increased.

Several papers examine the effects of transport improvements on urbanization. One example is Hornung (2015), who studies railroads and urbanization in Prussia. In Prussia, urbanization increased significantly between 1841 and 1871. This was quite early by international standards. The other cases of early urbanization were Great Britain and the Netherlands. Prussia was also an early adopter of railroads. Most up to 1850 were built between large cities. This feature was likely due to most early railroad projects being privately owned, financed, and operated. After 1850, the Prussia government began to subsidize railroad construction and the network extended. The reasons for Prussian government involvement are complex. National defense was one key factor.

What were the effects of railroads on Prussian urbanization? Hornung studies many cities and employs various specifications to answer this question. One specification involves a panel regression of log city-population on an indicator for having railroad access. Endogeneity is addressed using straight lines which connect important cities through the railroad network. Hornung's instrument is very similar to the one used by Atack and Margo (2011). The rationale is that lines were mostly built linearly due to high construction costs. Consequently, ordinary cities located on a direct line between important cities gained access to the railroad more by chance. In contrast, cities whose location deviated from the straight line could gain access only for reasons potentially endogenous to the city's growth. Hornung's conclusion is that gaining railroad access increased a Prussian city's population by approximately 15% after 15 years.

Did railroads have a similar effect on urbanization elsewhere? Berger and Enflo (2017) study a similar issue in nineteenth century Sweden. They found that early

railroad access increased city population by 25–30% over several decades. Interestingly, the specifications and data in these two studies on Prussia and Sweden are quite similar, yet the estimated effects of railroads are different. As one reads through several papers of this kind, it becomes clear that the effects of railroads generally differ. A better understanding of heterogeneity is a subject that deserves greater attention in future research.

Another outstanding issue in this area concerns "reorganization" effects, where transport improvements increase population in one area at the expense of lowering it elsewhere. The suburbanization process in the USA during the mid-twentieth century provides a good example of reorganization. Baum-Snow (2007) shows that the aggregate population of US central cities declined by 17% between 1950 and 1990, despite population growth of 72% in metropolitan areas as a whole. Why did this happen? At this time, the US Federal Government funded a massive highway expansion, known as the inter-state highway program. The 1956 Interstate Highway Act committed the federal government to pay 90% of the cost of construction for the 41,000-mile highway system. The rest was financed by state and local governments. National defense is one of the main reasons the US Federal Government increased its contribution. Many interstate highways passed through the central business districts (CBDs) of major cities. In 1956, the CBDs were densely populated in part due to the construction of railroads a century earlier. As highways passed through the CBD, they made it easier for households to live at the edge of the city and to commute to the CBD for work. Baum-Snow estimates that one new highway passing through a central city area reduced its population by 18%. A counterfactual estimate implies that central city population would have grown by about 8% had the interstate highway system not been built. These estimates imply large effects of highways on population reorganization. Similar impacts have been found in Europe. For example, Garcia-López et al. (2015) find that each highway caused an 8–9% decline in central city population between 1960 and 2011.

The Baum-Snow analysis takes other factors into account, namely, the effects of income levels and inequality on suburbanization. The estimates suggest that greater income reduces central city population, which makes sense because households want to buy more housing space with higher income and space is cheaper in the suburbs. Baum-Snow also finds that greater income inequality reduced central city population. This would make sense if rich households wanted to isolate themselves from poor households leading to large differences in schooling and other amenities.

Building on these results, one might wonder how reorganizing the population in space affects welfare. On the one hand, if transport innovations led to more racial segregation, as in the US case, there might be negative welfare consequences. It could also lead to dispersion in production, reducing agglomeration benefits. On the other hand, moving population to suburban areas allowed more housing consumption which is clearly desired by many families. Not surprisingly, the welfare effects are quite complicated and depend on a range of pecuniary and non-pecuniary externalities.

There is a growing interest in the negative externalities associated with transport. Pollution is one of the largest concerns in the twenty-first century and many of

the emissions come from transportation vehicles (Winston 2013). The historical literature has begun to examine this issue. Britain was perhaps the most polluted economy before World War I. Significant amounts of coal were burned for home, industrial, and transportation activities. Were the amounts significant enough to cause poor health? This is a difficult question to answer because air pollutants were not measured before the twentieth century. However, innovative research by Beach and Hanlon (forthcoming) infers pollution using local industrial structure and coal usage by industry in Britain during the nineteenth century. They estimate that a one standard deviation increase in coal use raised infant mortality by 6–8%. As it turns out, transport was not the main consumer of coal in mid-nineteenth-century Britain. It was the home and manufacturing sectors. This would suggest that railroads were not a direct driver of pollution related health problems in this setting.

This conclusion may not hold elsewhere however. Tang (2017) focuses directly on the negative health effects of railroads in the late nineteenth century. An example provides an illustration. In 1886, a cholera epidemic swept through Japan and killed 108,405 people, accounting for 1 out of 9 deaths that year. Strikingly, prefectures with railroad access in 1886 had a higher incidence of mortality, 336 deaths per 100,000, compared to the 245 deaths in prefectures without rail access. Many factors could potentially explain the railroad-mortality connection, but Tang is able to isolate the effects of railroads using matching and DID regression models. The specification has similarities to studies examining the effects of railroads on land values:

$$\text{Mortality rate}_{it} = \alpha \cdot \text{Railroad}_{it} + \eta_i + \delta_t + \varepsilon_{it}$$

where the dependent variable is deaths per 100,000 people in prefecture i in year t, Railroad_{it} is an indicator for prefecture i having a rail connection in year t, and the remaining variables are fixed effects. Tang estimates that rail access accounts for a 5.5% increase in mortality between 1884 and 1893. Moreover, rail-associated mortality represents about 66% of the total increase in mortality pre and post adoption of railroads. Tang also uses official causes of death to show that 75% of rail-associated deaths were due to communicable diseases, like tuberculosis and influenza. The implications of this finding are large. One of the benefits of transport improvements is to increase urbanization and productivity. In fact, in another paper (2014), Tang demonstrates that railroads contributed to industrialization in Japan. But as Tang (2017) shows, in some circumstances greater communication can also lead to disease transmission and higher mortality. The field of cliometrics needs more research on the negative health consequences of transport, as they loom large in the twenty-first century.

Persistence and Long-Run Impacts of Transport

Most of the analysis thus far has focused on the short-run effects of transport improvements. For example, the contribution of railways to increasing land values and urbanization in the nineteenth century. But there are theoretical reasons to argue

that the impact of railroads and other transport innovations matter over the long-run. The channel is through persistence of locational choices. If a population settles in an area because of some natural or human-made advantage in the past, then the population may become "locked-in" for the future. Lock-in could persist even as the original natural or human advantage which determined the settlement becomes largely irrelevant.

Transportation advantages are one of the main factors identified in the persistence literature. Bleakley and Lin (2012) provide one of the classic studies on persistence and the role of transport in creating lock-in. They focus on portage sites in the USA during the early 1800s. Much overland transport went by lakes and rivers at this time. There were some sections of rivers that were not navigable, which meant that traders had to stop and carry their products and canoes along the river until navigation could resume. At portage sites commercial services were provided. Thus, population density tended to be higher at portage sites. Transportation options in the US clearly changed during the nineteenth and twentieth centuries making river transportation far less important. One might imagine that early portage sites would gradually lose population to locations which had other advantages. Bleakley and Lin show this did not happen. They analyze the following model

$$\text{Log}(\text{population in } 2000_i) = \alpha \cdot \text{portage site}_i + \beta \cdot x_i + \varepsilon_i$$

where $\text{Log}(\text{population in } 2000_i)$ is the log of 2000 population in a geographic unit like a county or census tract, portage site_i is an indicator for whether the unit was a portage site in the early nineteenth century, and x_i is a set of city-level controls. Note that portage is defined as a fall line or river intersection. The use of the geographic variables to identify portage makes this specification akin to a reduced form regression, in which endogeneity is not a concern. Bleakley and Lin estimate that portage units have 90 logs points higher population density in 2000. That is equivalent to 145% increase in population density. One might think that portage sites were about 145% larger in the nineteenth century when portage was most valuable. However, this is not true. Nearly half of the population advantage of portage sites emerged between 1900 and 2000, which is long after canoes became a hobby vessel.

There are other papers which document persistence in outcomes associated with early transport investment. Jedwab and Moradi (2016) study colonial Ghana, where the British built railroads linking the coast to sparsely populated mining areas and the hinterland. Using a data set on cities, they look at the effects railroads had on the distribution of population from 1891 to 2000. Jedwab and Moradi first establish the importance of railways for initial urban location. They estimate the following model:

$$\text{Urban population in } 1931_i = \alpha \cdot \text{Railroad in } 1918_i + \beta \cdot x_i + \varepsilon_i$$

where 1931 urban population in a location is regressed on indicators for having rail access in 1918 plus controls x_i. Instruments are introduced to address endogeneity for railroads and are ignored for the present discussion. Jedwab and Moradi estimate that the urban population in 1931 was significantly higher if the location

had a railroad in 1918. They argue that the decrease in internal trade costs encouraged the local cultivation of cocoa, which became a leading export in Ghana. Rural populations increased along the lines as cocoa cultivation required more labor in cocoa-producing villages. Urban populations then increased because villages used the towns as trading stations.

After the 1970s, rail transport in Ghana was far less important. Railroad tracks were not maintained, and road transport increased. Did this mean that areas close to railroads lost population? The answer is no. Jedwab and Moradi estimate a second set of regressions.

$$\text{Urban population in } 2000_i = \alpha \cdot \text{Railroad in } 1918_i + \beta \cdot x_i + \varepsilon_i$$

$$\text{Urban population in } 2000_i = \alpha \cdot \text{Railroad in } 1918_i + \eta \cdot \text{Urban population in } 1931_i + \beta \cdot x_i + \varepsilon_i$$

The first regression identifies whether railroads in 1918 affected urban population in 2000. This would represent a persistent effect because railroads had lost their original significance in transport. The second equation examines whether railroads' effect runs through the urban population in 1931, a lagged dependent variable. Jedwab and Moradi show that railroads in 1918 had a strong effect on 2000 population, but the coefficient on the rail indicator is small once the urban population in 1931 is included in the specification. In other words, the spatial equilibrium became stable after railroads were built. Subsequent transportation technologies (i.e., trucks) did not relocate population from near railroads. The Ghanan case is quite striking because the end of colonialism represented a large economic and political change, but it was not sufficient to wipe out the persistent effects of railroads.

How are these persistence patterns understood? Bleakley and Lin (2012) propose a simple model where an individual's utility is a function of the population density at their location. Two factors affect the utility according to density. One is the strength of congestion. Congestion increases with density and lowers the utility of the individual. The second is the strength of agglomeration. Agglomeration increases with density and raises the utility through greater productivity. Natural advantages, like portage sites, are another factor in the model. They increase the utility of locating in one place versus another. Thus, natural advantages can be crucial at some point in time, leading to a density in one location. If the natural advantage disappears, say because of general technological progress, then an individual might leave a location because it is congested. However, when the agglomeration forces are strong, it may be optimal to stay. Is the strength of agglomeration sufficiently powerful to lock-in locations? While compelling, there are cases like post-war Japan where cities were wiped out by bombs and yet they came back to their original size (Davis and Weinstein 2002). If agglomeration was strong, then these cities should not have remerged. No doubt, the issue of lock-in is far from settled.

Institutions and Transport Development

Much of the existing literature on transport analyzes its effects on income and development. But there is a broader question one could ask. What makes some societies effective in delivering transport services? This is closely related to the broader question of what makes some societies rich and others poor. One popular view is that institutions are a fundamental cause of economic development. Institutions are the humanly devised constraints that structure political, economic, and social interaction. In their formal sense, institutions are constitutions and legal systems, but less formally they include norms and beliefs. As originally emphasized by North (1991), institutions matter because they affect transaction costs and hence incentives to invest and innovate. Extending this logic to transport, one might imagine that institutions affect transport infrastructure investment. Here there are large fixed costs, raising the risk of expropriations or misallocation.

In the literature, there is some evidence that transport infrastructure became more developed in countries with stronger democratic institutions and with greater state capacity. A comparison of England and France in the eighteenth century provides one illustration. In England, road infrastructure was provided through a mixture of local initiative and parliamentary oversight. Local groups submitted petitions requesting the right to form a "turnpike-trust" and improve a stretch of road in their area. Parliament usually granted these requests and named the petitioners as trustees with the authority to levy tolls and improve the road. Parliament set the maximum tolls and gave local officials powers to settle disputes between property owners and trustees. Turnpikes were established on all highways linking London with major provincial cities (Bogart 2005). France had a different approach to their highways. The crown designated some highways as primary roads (royal routes) and others as secondary roads. The primary roads received some funding from the central government in Paris and were constructed and maintained by the Ponts-et-Chaussees, an elite engineering school. Secondary roads were maintained by French communes, generally through the use of corvee labor.

How did these different paths affect the size and efficiency of road networks in England and France? The data suggest that England had more km of paved roads per capita than France. England also had faster travel speeds (Szostak 1991). One reason is that English political institutions placed significant limits on the ability of parliament or the crown to arbitrarily change tolls or to substantially reduce the rights of turnpike trusts. This high degree of regulatory commitment encouraged trustees and private groups to make investments in the road because they expected that parliament would uphold their rights (Bogart 2011). It is unlikely the French crown could make such commitments, and thus private investors would have hesitated in making such investments. A second reason is that the English parliament devised mechanisms for compensating landowners when their land was taken. Parliament empowered juries who had local knowledge. They also gave county Justices of the Peace powers to oversee juries in case they were too generous to landowners. Thus, local knowledge was combined with checks and balances. France had no such

system before the French Revolution and it struggled to overcome local resistance (Rosenthal 2009).

France further developed its road network after the French Revolution. The central government increased its funding of national routes. There was also substantial change in the funding and organization of secondary roads. A French law of 1836 gave communes the right to levy 5% surtax from the four main direct taxes in their jurisdiction. It also allowed departmental councils to impose financial contributions on communes located along roads of regional importance (Price 2017). The changes following the French Revolution provide further testimony to the importance of institutions.

The financing of railways also illustrates the importance of institutions. Railway construction often required financial support from governments. However, many relied on tax revenues collected from trade, which often depended on railways. Bignon et al. (2015) argue there was a two-way feedback between government revenues and railways, with a potential for multiple equilibria. In other words, countries could end up in a "poverty-trap" with few railways and little revenue.

Bignon et al. develop their argument for Latin America. They document that railway and fiscal development were low in some Latin American countries, like Columbia and Ecuador, and high in others, like Argentina and Uruguay. They propose a system of equations to account for the co-evolution between railways and tax revenues. A discussion of their model is useful because it speaks to dynamic effects. The first system models government revenues as a function of trade.

$$\text{Government revenues}_{it} = \alpha \cdot \text{trade}_{it} + \beta \cdot x_{it} + \eta_i + d_t + \varepsilon_{it}$$

where government revenues$_{it}$ is the log of tax revenue of country i in year t, trade$_{it}$ is the log value of trade, x_{it} is a vector of controls, and the rest are country and year fixed effects. The variable trade$_{it}$ is endogenous and Bignon et al. use railways to instrument for trade. The effect of railways on trade is plausible, but do railways affect government revenues in other ways? The authors argue they do not because no taxes were directly levied on railways. There could be indirect effects of railroads, which violates the exclusion restriction for an instrumental variable. Nevertheless, some assumption is needed to identify the effect of trade and railways are a plausible instrument.

The second equation in their model specifies the target size of the rail network measured in the natural log of rail track miles. The equation is:

$$\text{rail}^*_{it} = b \cdot \text{government revenues}_{it} + c \cdot x_{it} + \eta_i + d_t + \mu_{it}$$

where rail*$_{it}$, the target network size, is a function of government revenue, control variables specific to the country, and fixed effects. Bignon et al. argue for a dynamic equation to describe rail development because the target is never achieved in any period. The growth of the rail network from t-1 to t is the difference between the target and the reality in the previous period.

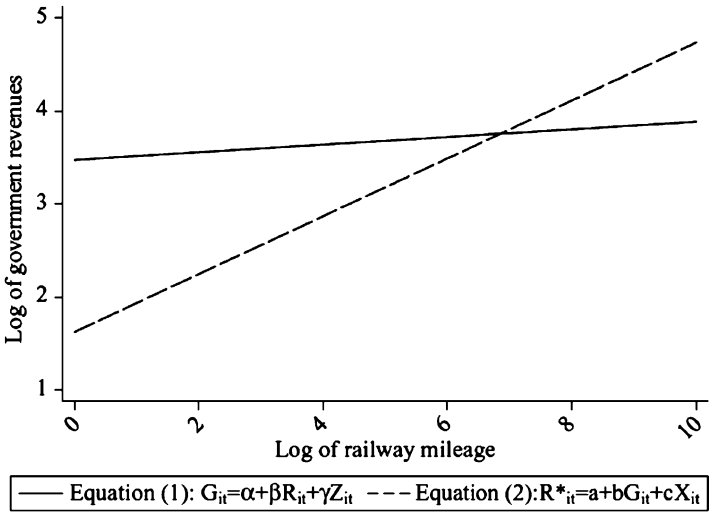

Fig. 4 Estimated relationship between tax revenues and railway miles in Latin America. (Source Bignon et al. 2015)

$$(\text{rail}_{it} - \text{rail}_{it-1}) = \delta(\text{rail}^{*}_{it-1} - \text{rail}_{it-1})$$

In the last step, they substitute the target rail network rail^{*}_{it} into the dynamic equation to get the following specification.

$$(\text{rail}_{it} - \text{rail}_{it-1}) = \delta \cdot \text{rail}_{it-1} + \delta \cdot b \cdot \text{govt.revenues}_{it-1} + \delta \cdot c \cdot x_{it-1} + \delta \cdot \eta_i + \delta \cdot d_{t-1} + \delta \cdot \mu_{it-1}$$

Their aim in this equation is to estimate the effect of government revenue and lagged rail network size on the growth of rail networks. With these two estimates, they can recover the structural parameter b. Importantly, government revenue is endogenous according to their framework. They instrument for revenues with each country's total level of diplomatic representation abroad and an index of legislative effectiveness. Here the authors feature the role of institutions explicitly. Legislative effectiveness is a measure of institutional quality, which arguably leads to more taxation. This assumption is supported by much research on state capacity (e.g., Dincecco 2015).

Bignon et al.'s estimation yields insightful results (Fig. 4). They find evidence for a two-way feedback between railways and government revenues. Their estimates are shown in the following graph for the average Latin American country. More railway mileage is estimated to increase government revenue (the solid line). Also more tax revenues are estimated to increase railway mileage (the dotted line). The equilibrium is reached where these two lines intersect. Notably for history, the equilibrium can change if there is an exogenous shock to either railways or tax revenues. For example, suppose legislative effectiveness improves due to political changes in a

country. This would lead to more revenues and more rail infrastructure (imagine the solid line shifting up). More generally, this analysis illustrates how better institutions can help countries escape a poverty trap through more transport infrastructure.

Public and Private Sector Involvement

Historically both the public and private sectors have been deeply involved in the transport sector. Various scholars have tried to explain the duality (see Newberry 2002; Milward 2005). One view sees some level of public provision as necessary because the private sector would fail to provide the efficient quantity of transport services. One reason is the natural monopoly features of transport. Very large fixed costs, like building a port or railroad, imply that total costs are minimized if there is one supplier in the market. But the one supplier can charge monopoly prices, which is inefficient. A government owner of transport would not necessarily charge the monopoly price however, because governments generally consider more than just profits when making decisions. There is an alternative view that private provision is generally preferred because of government "failure." Interest groups are a potent source of such failure because they can appeal to various layers of government to support socially undesirable infrastructure projects or to kill desirable policy reforms (Winston 2013). Ultimately it is an empirical question whether public or private provision has been beneficial or not.

Railway history provides insights on where the boundary between public and private was drawn. Interestingly, most railways built between 1830 and 1880 were owned by private companies. Afterwards there was a trend to more government ownership. In some cases, governments started to build railways and in other cases nationalizations placed large railway assets in public hands.

There are various reasons why railway nationalizations occurred in some countries and not others before 1913. For the sake of brevity and continuity with the previous section, this essay focuses on political and legal factors. In theory, limited government, embodied by strong constraints on the executive, should work against nationalizations. Constraints made it harder for the government to expropriate private property like railroad tracks and rolling stock. Common law legal systems had a similar effect in theory (see La Porta et al. 2008). In common law countries, courts have traditionally required that expropriations satisfy a "public use" and that owners receive "just compensation." The public use requirement might have made it difficult for public officials to nationalize railroads because they had to explain why government ownership satisfied a public benefit. Moreover, the just compensation clause might have prevented governments from imposing a low price on companies. In civil law countries, railroad companies could also appeal to courts, but they may not have been as effective if governments could intervene and ensure that decisions went in their favor.

Bogart (2009) provides evidence on the role of institutional factors in explaining the likelihood or extent of nationalizations across countries between 1870 and 1913. The author creates panel data on the incidence and extent of nationalizations across

more than 1200 country-year pairs. This is combined with other cross-country data, including constraints on the executive branch of government, the degree of democracy, legal origin, and a host of other variables. Cross-country estimates for 1910 reveal that the incidence of nationalizations (i.e., exceeding a minimum threshold of nationalized rail mileage) was more likely in countries with French and German civil law legal systems compared to common law legal systems and Scandinavian civil law legal systems. Nationalization was also more likely in countries with weak constraints on the executive branch or with less democracy.

The Swiss case provides some insights on why legal systems mattered for railway nationalizations (see Bogart 2009). Up to 1890, most of the railways in Switzerland were built and owned by French companies. The original concessions created a special board of arbitrators, who would settle disagreements between the French companies and the Swiss Federal government in the event of a proposed nationalization. The arbitrators were separate from the Swiss federal court system, and they presumably provided some assurance to French companies that government policy decisions would be made without political interference. By the 1890s, foreign ownership of railways became generally unpopular in Switzerland. But there were public concerns that a government takeover of railways would be quite costly to the Swiss taxpayer because French investors would demand high compensation. In 1896, one year before a major Swiss railway nationalization law was passed, the Federal Council and Assembly passed a law nullifying the authority of arbitrators and requiring that disputes over railways be settled in federal courts. The close timing of the arbitrator law and nationalization suggests they were connected. This example illustrates how government intervention and legal systems interact.

What impact did nationalizations have on the railway sector? Bogart (2010) examines the efficiency of railway operation. In other words, the money an economy spent supplying x ton miles and y passenger miles given wage and fuel prices and stocks of railway capital. The cross-country evidence suggests that the average nationalization lowered the cost efficiency of railway systems. However, there are also some economies where railway nationalizations increased cost efficiency. Colonial India is one interesting example. The initial construction and management of the Indian rail network was done by private British companies operating with a public guarantee. If net earnings (i.e., gross earnings minus working expenses) as a proportion of capital outlay yielded less than the guaranteed return of 5% in any year, the colonial government in India compensated the company with the difference. The guarantees proved costly to the colonial government. Years later it decided to nationalize all formerly private railway lines and become the majority owner. By 1910 the government had nationalized all the private railway companies that built the main trunk lines up to 1880.

Importantly, railway companies in India were nationalized on the 25th or 50th year of their original contract. This fact is useful because the timing of nationalization was determined by the date of the original concession contract and other exogenous events many decades earlier. Bogart and Chaudhary (2012) exploit this fact when they analyze the effects of Indian railway nationalizations on working

expenses (i.e., variable costs). They construct a panel dataset on inputs, outputs and costs for the primary standard and metre gauge railway systems between 1874 and 1912. Regression analysis shows that working expenses were 13% lower on average following a change to colonial government ownership. The cost declines are not driven by firms anticipating takeovers, poor quality, changes in reporting standards, or long-run trends. Rather, the evidence suggests the government reduced operational costs by cutting labor costs. These results are surprising given that nationalizations generally raise costs. Bogart and Chaudhary suggest that the colonial government in India had unique incentives to operate railways well. It had weak fiscal capacity and railways were one of the few industries it could tax effectively, provided it had majority ownership. This case points to the value of detailed studies on institutions, which are often missed in the cross-country analysis.

Conclusion

In summary, cliometrics has made major advances in the historical analysis of transportation through better measurement, economic modelling, and estimation. This essay surveys several topics and innovative research studies. There are several general conclusions. First, there were revolutionary changes in transport over the last 300 years generating high rates of productivity growth. Macro-inventions, like steam power, were important but many incremental innovations mattered too. Second, there is evidence that transport improvements contributed to greater market integration, urbanization, and aggregate income. There is also evidence that transport improvements influenced population density long after their original function became obsolete. But there is still disagreement in the literature about the relative importance of transport and there are also some studies which argue that transport improvements contributed to higher mortality. Teasing out the positive and negative effects of transport improvements on welfare is likely to remain an important area of research. Third, institutions were a fundamental factor in determining why transport services were more efficient in some economies. There is evidence that institutions influenced investment in transport networks and the degree of public and private ownership. There is also evidence that ownership mattered for transport efficiency, and in some cases, government ownership improved outcomes. Overall, cliometric research on transport offers many insights on this historically important sector.

Travel and Tourism

Thomas Weiss and Brandon Dupont

Contents

Abstract

Travel and tourism, once activities that were open only to the elite, have become increasingly accessible to many more people. As a result, tourism is now an important economic activity worldwide. In this chapter, we discuss the

conceptual issues in defining and measuring travel and tourism, efforts to econometrically estimate the demand for travel, and the possible links between tourism and economic growth. We also describe the rise and decline of seaside resorts in England and the cliometric history of tourism in the United States, particularly emphasizing the historical forces that shaped tourism in Hawaii. And while economic historians have largely neglected the topic, we identify issues on which the tools of cliometrics might be brought to bear.

Introduction

Before the widespread use of steam engines in ocean shipping in the last half of the nineteenth century, transoceanic travel was expensive and unpredictable. An Atlantic crossing by sailing vessel in the year 1800 would have taken roughly the same amount of time as the 35-day crossing by Christopher Columbus in 1492 (Fowler 2017). The unpredictable duration and the risks associated with trans-Atlantic voyages clearly limited European-North American commercial traffic, migration, and tourism. There were no more than 2000 Americans who traveled to Europe in any year during the late eighteenth and early nineteenth centuries, but the number increased as steamships replaced sailing ships by the mid-nineteenth century. While the number of Americans who traveled abroad was still small during the nineteenth century, their increase exceeded overall population growth by a healthy margin. Not all of these travelers were tourists, but many of them were.

Tourism has been an increasingly important part of the economy in most countries. According to the World Tourism Organization (WTO 2018a, b), "International tourism is the world's largest export earner and an important factor in the balance of payments of most nations."[1] In 1950, global international tourist arrivals represented only about 1% of the world's population; today, that figure is about 16% (UNWTO 2017). It is one of the world's most important sources of employment, and it is the largest industry in many countries. According to the United Nations Conference on Trade and Development (UNCTAD), tourism today generates an estimated 10% of the world's GDP and 30% of world trade in services. Among OECD countries, tourism accounts for 4% of GDP, 6% of total employment, and 21% of service exports. And there is increasing recognition that tourism might play an important

[1]The World Tourism Organization is an umbrella organization for world tourism that was started in 1925 as the International Congress of Official Tourist Traffic Associations and became the WTO in 1975.

role in economic growth as demonstrated by a recent United Nations report on "Tourism for Transformative and Inclusive Growth" in Africa (UNCTAD 2017).

Tourism is particularly important for some smaller developing economies, especially island economies and others with natural amenities like extensive coastlines. Consider, for example, that tourism represents 62% of GDP in Seychelles, 43% in Cabo Verde, and 27% in Mauritius; it is, however, also important – and increasingly so – for large developed economics. According to the World Tourism and Travel Council (WTTC), tourism accounts for nearly 10% of GDP in the United Kingdom, 9% in Germany, and 8% in the United States.[2]

Tourism's increased importance prompted the UNWTO to lead an international effort in the mid-1990s to produce a consistent metric for travel and tourism across countries. This effort, along with a 1995 Conference on Travel and Tourism at the White House, led to the construction of the Travel and Tourism Satellite Accounts, which complies with the UNWTO standards (Platzer 2014). Numerous countries now produce similar statistics, making cross-country comparisons feasible.

Defining and Measuring Tourism

One of the key conceptual issues is whether tourists should be distinguished from those traveling for other reasons and whether it is even possible to make such a distinction in practice. Even if everyone agreed that tourists traveled for pleasure and make up a subset of all visitors, it is not easy to determine the purpose of each trip. Travel for pleasure can be thought of as a type of final demand while travel for business purposes can be viewed as a derived demand for services that are necessary inputs into the production of some other good or service. But in practical terms, both types of travelers purchase a "composite product involving transport, accommodation, catering, natural resources, entertainment, and other facilities and services, such as shops and banks, travel agents, and tour operators" (Sinclair and Stabler 1997, p. 58). So, while the distinction between final and intermediate demand is important in determining tourism's contribution to GDP, more commonly tourism scholars, governments, and other organizations adhere to a broad definition. Tourism is travel away from home lasting longer than a day for any reason, most commonly for recreation or business, but includes other purposes such as visiting family or seeking health care.

Measuring tourism is no easier than trying to define it. Nevertheless, while it has been referred to as "statistically invisible," researchers have measured what tourists consume: tourists must travel so they can be counted through airline passenger miles or international border crossings, and their spending can be measured by bookings of hotel rooms or other accommodations. Surveys of travelers have also been

[2]This includes direct and indirect contributions according to the World Travel & Tourism Council: https://www.wttc.org/. The Bureau of Economic Analysis shows a slightly smaller share for the US economy.

conducted to obtain more direct information about spending and about their main purpose for traveling.[3] Because they are difficult to separate out, and because they sometimes overlap, business travelers are often included in statistics on tourism collected by most government agencies. The Bureau of Economic Analysis (BEA), for example, specifies that a tourist is someone who "either travels outside of his or her usual environment for a period of less than 1 year or who stays overnight in a hotel or motel."[4] The "usual environment" is the place of normal residence, leisure, study, and work, but in any case is defined by the area within some specified minimum distance of home.[5]

Research on the Economic History of Tourism

Although tourism has been around for a very long time, the earliest travelers were not thought of as tourists. Harold Vogel (2016, p. 235) characterized them as "nomads, warriors, pilgrims, and the elite" whose trips were not primarily for leisure purposes. Some traveled on pilgrimages for religious reasons, while others journeyed for medical care, or were commercial travelers. There were some, however, who as long ago as Greek and Roman times (i.e., around 500 B.C.) fit the mold of what today we think of as a tourist (Casson 1974; Towner 1966).

However inchoate that ancient travel might have been, tourism in Europe began in earnest in the seventeenth century. Initially this meant for the most part, British tourists trekking to the continent, especially to France and Italy, on the Grand Tour in the seventeenth and eighteenth centuries. While we do not know precisely how many people went on the Grand Tour, it was large enough to have been seen as something that upper class young men were expected to do by the mid-eighteenth century (Burk 2005).[6] Beyond its role in the rise of mass tourism, the Grand Tour may have also played an important role as a mechanism by which ideas spread during the European Enlightenment.

The numbers of travelers on the Grand Tour were small at the start. Scholars have estimated around 20,000 such travelers in the eighteenth century, perhaps as high as

[3]The purpose of traveling has been measured by the *Survey of International Air Travelers*, administered by the U.S. Department of Commerce, which asks travelers about the main purpose of their trip. This survey has been administered to a random sample of international air travelers to or from the US (excluding Canadians) on a monthly basis since 1983.

[4]Okubo and Planting (1998, p. 11). The BEA prefers the term visitor to tourist because it is more descriptive of the travel activities included in the satellite accounts (Ibid, p. 8).

[5]For the United States, the BEA defines this area as 50–100 miles of home, whereas the Consumer Expenditures Survey of the Bureau of Labor Statistics uses 75 miles, while the American Travel Survey of the Bureau of Transportation Statistics uses 100 miles, and private surveys use 50–100 miles (Ibid, p. 11). In any case, the distance would be determined by the existing technology and costs of transportation, so would surely vary over time.

[6]Early travel guides were developed as the Grand Tour became more widespread (Burk 2005).

40,000 near the end of the century, and 50,000 in the 1830s (Towner 1985). By that time, a parallel development in domestic travel was proceeding apace. Spas and seaside resorts, which had been the province of the elite in the eighteenth century, were becoming more accessible to the middle classes, increasingly so once the first travel agencies were established in the mid-nineteenth century. By the last quarter of the nineteenth century, tourism was well-established in Europe especially among the English.

The number of tourists arriving in Europe swelled considerably with the advent of steam powered ocean liners in the latter half of the century, as well as continual increases in the speed and quality of the ships, and increases in carrying capacity, driven largely by immigrant traffic. Arrivals from the US alone tripled from 40,000 around 1870 to 120,000 in 1900, doubling again before World War I. After that war, travel resumed where it had left off, with arrivals from the US increasing by about 50% before a substantial downturn occurred during the Great Depression, and a more serious interruption during World War II and the years leading up to it. Travel recovered quickly after the war; by 1950, the number of tourist arrivals in Europe ran around 25 million, and had increased 20-fold by 1990 or thereabouts (Shaw and Williams 1997).

Despite that long history, the study of tourism by historians is a more recent development. According to Towner and Wall (1991, p. 73), before 1990 there was "very little mainstream historical research" on tourism. And work by economic historians was even scarcer. Since then, there has been a vast outpouring of work on tourism originating from a variety of disciplinary perspectives. While most of this work has been done by sociologists, geographers, and those in cultural studies, there is also a large body of scholarship on the economics of tourism and the history of tourism. Many of the economics articles are practical and business oriented, with titles such as "Preventing tourists from canceling in times of crises" (Annals of Tourism Research, 2016), but there are quite a few studies that focus on change and growth. Most are not economic history per se, as they cover recent and relatively short time periods, and are typically policy-oriented, but they are empirical investigations on topics similar to those studied in cliometrics. Although they do not all use the analytical tools of cliometricians, they do make use of pertinent economic statistics.

It would be impossible to summarize all the work that might be related to cliometric type investigations, so we have narrowed down our survey in two ways. We first look at work on two topics – the demand for tourism and tourism's impact on economic growth – regardless of country. We then review the economic history of tourism in two specific cases. In one instance, we focus on the history of seaside tourism as it developed in Britain and Spain. The combined story in essence covers the history of seaside resorts from their origin as exclusive spaces for the wealthy to their present day status as mass tourism. The other story is that of Hawaii, one of the few states in the US in which tourism is of relatively greater importance than it is for the nation as a whole. In both of these histories, scholars have used economic statistics and reasoning, even though they did not make use of counterfactual analysis or more sophisticated economic analysis.

An Overview of the Economic History of Tourism

The conventional wisdom about the economic history of tourism is that tourism has an income elasticity greater than one, so increases in income that took place throughout the industrializing world in the nineteenth and twentieth centuries, and even earlier in England, stimulated the demand for travel. Of course, tourism depends on other things as well, in particular factors that affect the price and supply of tourist services, perhaps especially changes in transportation. Improvements in transportation that reduced the price and speed of travel, and improved the regularity and quality of travel as well, led to increased numbers of tourists which eventually made it possible for firms, including hotels, to take advantage of economies of scale.

One of the key supply-side developments was the packaged tour industry, which is usually thought to have begun with Thomas Cook's temperance tour from Leicester to Loughborough in 1841. He and subsequent packaged tour companies took advantage of the benefits of scale economies and increased transport capacity to offer lower-cost travel opportunities, thereby opening tourism to an even larger segment of society. Competition among tour operators served to further reduce prices and fuel the rise in the number of travelers. The second consequence was the emergence of a "tourist industry." Hotels came into greater use, replacing the private homes that had been the mainstay of the earlier and much wealthier tourists; and restaurants increased in number to serve these hotel patrons. With increased speed of travel by rail, hotels would locate at major railroad terminuses, replacing the more numerous smaller inns scattered along the way to more distant destinations that comprised the Grand Tour. As a result, new tourist destinations beyond the handful that had attracted travelers to the Grand Tour emerged as well. The third consequence was the emergence of "mass tourism," which revolutionized the nature of travel from the small, select, individually arranged trips of the seventeenth, eighteenth, and early nineteenth centuries.

However plausible this summary might sound, there has not been a great deal of evidence put forth to confirm the precise timing of the rise of mass tourism, the mechanism behind it, or the relative importance of the components of that mechanism. As described below, these sorts of questions have been addressed to some extent in quantitative fashion, but not as fully as cliometricians might like. Moreover, the analyses typically focus on the details of the growth process as it played out at the individual country, regional, or local level, not for an entire continent.

The Demand for Tourism

Tourists make a wide range of economic choices, including how much to budget for a trip, the amount of time to spend on it, and how to get there, economic decisions that are to some extent amenable to formal empirical analysis. Following developments in econometrics, scholars have used a variety of methods to estimate the demand for tourism, primarily for the purposes of generating income and price elasticities or to forecast demand for tourist destinations. While this work is

empirical in nature, it is not generally cliometric, primarily because history is not a prominent component of the analysis, and institutional factors impacting tourism are often neglected. Moreover, the research on demand estimation is often policy oriented, focused primarily on very recent trends.

Methodological Approaches

The earliest papers in which scholars estimated demand functions for travel date to the early 1960s, although there was relatively little empirical evidence on the extent to which travel responded to changes in income or other factors until fairly recently. As late as 1997, Shaw and Williams (p. 19), writing about tourism in Western Europe, stated that "there is little quantitative evidence on the elasticity of demand."

There are, however, a number of studies that use various econometric methods to estimate the demand for tourism, typically either to generate estimates of various elasticities or to produce forecasts of demand. While there are a wide range of variables included in these models, most of them regress tourism arrivals or expenditures on some combination of: the average cost of travel between countries; exchange rates; per capita income in the origin country; some measure of relative prices between countries; and in some cases dummy variables to control for various country-specific factors. Eighty-four of the 100 published studies reviewed by Lim (1997) included income as an explanatory variable, 73 used some measure of relative prices, 55 used transportation costs between the countries, and 25 used an exchange rate variable.[7] The particular specification used depends on the nature of the underlying data and the objective of the study, but the traditional tourism models transform all variables into natural logs, and then use OLS to estimate the elasticity values.[8]

Almost Ideal Demand System (AIDS) models, originally developed by Deaton and Muelbauer (1980), have also been used in some empirical work on tourism (for applications in the tourism literature, see Fujii et al. 1985; O'Hagan and Harrison 1984; Syriopoulos and Sinclair 1993).[9] The AIDS models are built on the theory of consumer choice and allow us to consider a multilevel budgeting process whereby travelers allocate spending to various travel-related "goods" (these could be country-destinations or specific travel-related expenditures within a given destination).

[7]Note that exchange rates are part of relative price measures when used, as described by Lim (1997). Also, as Lim (1999) and Song et al. (2010) point out, transportation costs and income are typically highly correlated, so many studies include only income.

[8]Lim (1997) found that 56 of the 100 papers she reviewed used only log-linear models while 14 others used both log-linear and linear models.

[9]One could use other models like the Linear Expenditure System (LES) developed by Stone (1953), the Rotterdam Model (Thiel 1965), or the translog model (Christensen et al. 1975), but most scholars in the tourism literature have used the AIDS models, which do not impose a priori restrictions on the elasticities as do the LES models. See Deaton and Muelbauer (1980) for a discussion of how the AIDS models compare to the Rotterdam model.

The AIDS model can be expressed as follows, where the consumer's budget share w_i for each good i = 1, 2, …, n is expressed as a function of price (p) and total expenditure (x):

$$w_i = \alpha_i + \sum_j \gamma_{ij} \log p_j + \beta_i \log\left(\frac{x}{P}\right)$$

Deaton and Muelbauer (1980) developed a nonlinear price index that is difficult to estimate in practice, so most empirical estimates use a simpler linear price index developed originally by Stone (1953).

The AIDS models are appealing in part because they are derived explicitly from, and thus conform to, the axioms of consumer choice, but also because they yield expenditure elasticities that are of interest in understanding income generated by various tourism-related activities.

A variety of time series specifications have also been used in the tourism literature (especially for forecasting demand), starting with the autoregressive integrated moving average (ARIMA) developed by Box and Jenkins (1970). Variations on the ARIMA models have been used in more recent research as well – Song and Li's (2008) review of 121 articles published between 2000 and 2007 shows that over two-thirds of them used some version of an ARIMA model. As Song and Li (2008) point out, inconsistencies in the forecast performance of ARIMA models has pushed scholars to explore a variety of alternative time series approaches including generalized autoregressive conditional heteroskedastic (GARCH) models (see Chan et al. 2005). Other approaches have used error correction (Song et al. 2000; Lim and McAleer 2001), vector autoregressive models (Wong et al. 2006), autoregressive distributed lag (ARDL) models, or time varying parameter models (Song and Wong 2003). The time varying parameter models are potentially quite important, given the evidence that elasticity estimates vary, perhaps substantially, over time (see Peng et al. 2015).

Gravity models, originally developed by Jan Tinbergen in the 1960s international trade literature, have also recently been used in modeling tourism demand (Keum 2010; Morley et al. 2014; Culiuc 2014).[10] As applied to tourism, the standard gravity model suggests that tourism flows depend on: the size of the origin and destination countries, typically measured with GDP per capita; the geographical distance between the origin and destination as a proxy for transportation costs; and in many cases a variety of country-specific policy measures or dummy variables.

In practice, these models are typically estimated using OLS in the following form:

$$\ln T_{ij} = \alpha_0 + \alpha_1 \ln M_i + \alpha_2 \ln M_j + \alpha_3 \ln D_{ij} + \varepsilon_{ij}$$

where $\alpha_1, \alpha_2 > 0$ and $\alpha_3 < 0$.

[10] See also Kimura and Lee (2006) who found that trade in services is better predicted by the gravity model than is trade in goods.

M_i and M_j represent "economic mass," typically measured by GDP per capita in countries i and j, respectively, and D_{ij} is a measure of distance between countries i and j. The assumption is that travel between two countries depends positively on their GDP and is inversely related to the distance between them (or some other measure of trade costs including common language or currency, for example).

Panel data methods have also been used in more recent scholarship as panel datasets have become more widely available. For recent applications in the tourism literature, see Yazdi and Khanalizadeh (2016) and Culiuc (2014).

Elasticity Estimates

Income elasticity estimates vary considerably across studies, and obviously depend on the model specification, the variables included, and the countries/regions in question, but nearly all of them indicate that overseas travel is a luxury good with income elasticity values higher than one.[11] Based on a meta-analysis of 80 studies of international tourism demand, Crouch (1995) concluded that most income elasticity estimates were between 1 and 2, similar to other studies by Song et al. (2010) and Peng et al. (2015).

There is evidence of considerable variation in income elasticity across origin-destination pairs. Crouch (1995) found income elasticity values ranging from 0.3 for Latin America to 4.4 for the developed Asian economies (apparently mostly driven by income elasticity in Japan, as that is the focus of most of the Asian studies). Peng et al. (2015) find that income elasticity is particularly high among Europeans and Americans destined for Africa (the average income elasticity values are 3.25 and 5.84, respectively), but even for the more common European visits by Americans, the average income elasticity of 1.81 is fairly high.

There is also some evidence that income elasticity has fallen over time. Song et al. (2000) showed that the income elasticity of American and UK tourists destined for South Korea fell from 8.0 and 5.0, respectively, in the 1970s to 2.5 and 2.0, respectively, in the 1990s. Other studies examining different origin-destination pairs similarly show that income elasticity has declined over time. Gunter and Smeral (2016) explore the reasons for falling income elasticities between 1977 and 2013, arguing that structural macroeconomic changes have led to increased precautionary savings and liquidity constraints that limited spending on luxuries (and may have shifted traveler preferences away from international and toward domestic trips).

The length of the trip is another source of variation in income elasticity. Since international tourist travel is a luxury good, particularly for longer trips abroad, tourists may be more likely to cut back during periods of economic stress by taking

[11]Whether one uses per capita income, total income, or some other measure will depend on the purpose of the study; these differences can account for some of the variation in the income elasticity measures. Peng et al. (2015, Table 4) also found that there is some variation in income and price elasticity estimates depending on the general type of model used and the frequency of the underlying data.

shorter trips. But it is possible that long-haul tourists are simply a fundamentally different category of traveler altogether as Anastasopoulos (1984) suggests. If long-haul tourists are high-income, it is conceivable that long-haul income elasticities are lower than that for short-haul travelers. Crouch (1994) proposes that since long-haul travel is no longer accessible only to the wealthy, the income elasticity of demand for long-haul travel likely exceeds that for short-haul trips. His meta-analysis of 80 empirical studies of international tourism suggests that income elasticity does in fact depend in part on the length of the trip, and that while both long- and short-haul trips have income elasticity values higher than 1, travelers on long-haul trips are more sensitive to changes in income. In the studies he reviewed, the average income elasticity for long-haul trips was 2.99 compared to 1.98 for short-haul trips.

As with income elasticities, price elasticity estimates vary across studies because of differences in methods of estimating them, the time periods under consideration, and different origin-destination pairs. Nevertheless, there are some general findings that emerge from this literature. Peng et al. (2015) analyze 195 different studies published between 1961 and 2011 and find an average price elasticity of −1.28. As we would expect, there is a considerable variation in these values across regions. According to Crouch (1995), price elasticity values range from −0.4 in Northern Europe to −0.8 in Latin America.[12] Gatt and Falzon (2014) found that the own-price elasticities derived from an AIDS model for British tourists to Mediterranean countries varied from −0.76 for Turkey to −3.44 for Cyprus. Peng et al. (2015) found that American and European tourists are most price sensitive with respect to Africa as a destination (the average price elasticity is −3.08 for Americans and − 2.19 for Europeans) and least price sensitive with respect to Oceania (the average price elasticity is −0.675 for Americans and − 0.449 for Europeans).

As was the case with income elasticity, Crouch (1994) showed that price elasticity also depends partly on the length of the trip: price elasticity is somewhat higher for short-haul trips (average of −0.6) as compared to long-haul trips (average of −0.48). These differences may partly reflect that tourists are less aware of foreign prices in more distant destinations or it may simply be that tourists see more distant destinations as more irresistibly appealing, and thus less sensitive to changes in price for those destinations.

Most of the empirical studies focus on income and/or price elasticities, but there is some evidence on traveler responsiveness to other factors as well. There is less variation in exchange rate elasticity across regions and studies, with the average elasticity reported by Crouch (1994) of about −1.0 (the exchange rate is expressed as the ratio of units of origin country currency per unit of destination country currency). There is evidence that travelers going to Northern Europe are significantly less sensitive to exchange rates as compared to those going to Southern Europe and the Mediterranean. North American tourists and those from Oceania are the most sensitive to transportation costs according to Crouch (1994), with average elasticities

[12]The regions referred to here are for the region of origin. Crouch (1995, p. 112) also reports results for region of destination.

of −1.52 and − 1.46, respectively. Tourists from Northern Europe and the developed Asian economies appear to be least sensitive to transportation costs, presumably because many of the international trips taken by Northern Europeans are relatively short distance (although the reasons for the low transportation cost elasticities for Japanese and other developed Asian economy tourists are less clear). Costa (1997) found that recreational expenditure elasticities for Americans, which were about 2.0 at the start of the twentieth century, were cut in half by the end of the century. She attributes this change to the falling price of recreation, investment in public recreational goods, and rising income levels.

The Impact of Tourism on Economic Growth

Whether tourism has stimulated economic growth, either nationally or locally, is the sort of question that should interest economic historians. It is certainly of interest to many developing countries and some developed ones as well. Has tourism been a source of economic growth? Have revenues from tourism exports stimulated economic growth in the same way that exports of manufactured goods or some agricultural commodities are thought to have done? Has tourism played as important a role in shaping the economy of some countries or regions as say cotton exports did for the United States before 1840 as described in Douglass North's (1961) analysis? Scholars of tourism have studied some of these issues, although the research is typically policy-oriented and focused on recent time periods in developing countries. The analyses tend to ignore how the tourist industries came to their current state, and do not consider what other paths toward faster growth might have been taken.

There have been more than 100 studies that have addressed the question of whether tourism leads to economic growth, and Brida et al. (2016) have surveyed 95 of them. A few of the studies, mostly those that examined groups of countries, used cross-sectional or panel data analysis, but most were time series analysis using primarily VAR and VECM methods to test for Granger causality. The consensus of these studies is that in the long run, the tourism-led growth hypothesis was validated in many different countries and regions. Only in 19 cases was economic growth found to have led tourism, or there was no Granger causality at all. Tourism-led growth was found in 7 out of 10 cases in Africa and the Middle East; 13 out of 13 cases in the Americas (mostly the Caribbean, South and Central American countries)[13]; 25 out of 32 Asian and Pacific destinations; and in 18 out of 22 European destinations. In the 16 studies of groups of countries, the tourism led hypothesis fared very well. Only one study, which covered 140 developing countries, found no support for the hypothesis. In 11 of the other cases, tourism was found to lead economic growth in all countries in the group, and in four studies, tourism led economic growth in at least some of the countries in the group.

[13]The single US case (Tang and Jang 2009) gave only a short run result, which showed that economic growth led tourism development.

These Granger causality tests make a prima facie case that tourism, especially international tourism, might have fostered economic growth. Strictly speaking, the results demonstrate that tourism is more likely to have caused economic growth than that economic growth caused the growth of tourism exports; or that growth of tourism receipts preceded the growth of income, rather than the growth of a nation's income preceding the arrival of tourism receipts. But it is not clear what to make of all this.

Although these studies present the results as bearing on long-term economic growth, the length of the time periods covered are almost all shorter than 50 years, the length of time that Simon Kuznets thought it would take to demonstrate that a country had achieved modern economic growth. The mode is 27 years, and there are only 11 unduplicated cases covering 40 or more years. Moreover, many of these studies have looked at countries where tourism is one of the more important sectors of the national economy.[14] As Brida et al. point out (2016, p. 424) ". . . there appears a sample bias since the countries, for which the TLGH is tested, are destinations characterised by a high tourism propensity and thus the weight of the tourism sector in such economies is sufficiently prominent to exert a positive impact on economic growth."

More substantively, few studies go beyond testing for the likely direction of causation. An oft-cited study, by Balaguer and Cantavella-Jordà (2002), used quarterly data for Spain for the period 1975–1997 in a regression of real gross domestic product on real foreign exchange earnings from tourism and the real effective exchange rate (a proxy for external competitiveness). They found that tourism had a strong positive impact on the growth of the economy, via a multiplier effect of foreign exchange earnings. They estimate that "a 5% sustained growth rate in foreign exchange earnings from tourism would imply an estimated increase of almost 1.5% in domestic real income in the long run" (p. 881). Policymakers would likely salivate over such prospects, but some skepticism is in order. As the authors point out, in the period before their study, tourism never represented more than 5% of overall Spanish income, which makes it unlikely that it could have such a large impact. Moreover, they also found that external competition was essential. It is the combination of the three variables – real GDP, tourism earnings, and the real exchange rate – that yields a reliable long-run relationship. If the real exchange rate is dropped, they find no cointegrating vector between economic growth and tourism, which seems to suggest that international competition may have been a more important force for economic growth.

In a study of tourism in Nicaragua, Vanegas and Croes (2007) found that tourism exports had a larger impact on economic growth from 1980 to 2005 than did exports of coffee (the main agricultural crop) and manufactured products: a 5% increase in tourism exports produces about a 3% increase in economic growth compared to a 2.5% impact on growth from coffee exports and a 1.6% impact from manufactured

[14]Oh (2005) claims that when tourism is a small share of GDP, we are more likely to see the "causality" run from GDP to tourism.

goods exports. On the other hand, Sinclair (1998) found that tourism had a rather limited multiplier effect, at least for developing countries; income multipliers ranged from 0.78 for the Bahamas to 1.59 in Sri Lanka, and only 3 of the 8 countries in her study had multipliers that exceed 1.0. This appears to be largely because tourism dollars are "channeled to developing countries via tour operators, located and owned in industrialised countries. . ." (Sinclair 1998, p. 29).[15] For more developed economies, income multiplier estimates are generally higher; for instance, Sinclair points to an estimate of 1.7 for the UK (based on Richards 1972).

A more fundamental question is how tourism exports stimulate economic growth? What is the transmission mechanism? Although receipts from international tourists are invisible exports, they can have the same effects as visible exports of agricultural or manufactured goods, by generating foreign exchange that allows a country to import more, especially capital goods, than would otherwise be the case (see Balaguer and Cantavella-Jordà 2002).[16] Local firms that supply tourist services might become more efficient because of competition with other tourist destinations. And the tourist trade might provide the opportunity for local firms to take advantage of economies of scale (see McKinnon 1964, Krueger 1980, and Bhagwati 1988). Other effects, perhaps less widely accepted, are that tourism might stimulate investments in new infrastructure, such as airports, roads, and hotels, and in human capital, increasing knowledge and professional services (Sakai 2009; Blake et al. 2006). And as Marrocu and Paci (2011) pointed out, tourism can enhance regional total factor productivity because it is one way for information to flow across borders.

A study by Capo et al. (2007) used a Solow growth model to estimate the sources of growth in the Balearic and Canary Islands, both of which are major tourist destinations in Spain. Both destinations grew more rapidly than the country as a whole between 1965 and 2000 – the Canaries grew a full percentage point faster while the Balearics grew faster by about ¾ of a percentage point – suggesting tourism contributed to growth for the entire country. But their results show that the chief source of output growth over the 35 years was the growth of capital, which accounted for 41% of the growth in the Balearics and 57% in the Canaries, and productivity (i.e., the Solow residual), accounted for 25% in the Balearics and 18% in the Canaries. More notably, the contribution of productivity advance was greater at the start of the period than at the end; in the last 5 years, productivity advance was negative in the Balearics and zero in the Canaries. They attribute this to the islands' failure to invest in long-term determinants of growth.[17] The tourism industry on these islands did not, and perhaps did not need to, invest in productivity-enhancing

[15]She also points out that tourism often carries substantial costs on infrastructure or other tourism-promoting activities.

[16]The Marshall Plan recognized this possibility as a way to help war-torn countries recover after World War II.

[17]This result is reminiscent of North's (1961) story about US economic growth. The export proceeds entered the US income stream in the South, but the proceeds were used to demand food from the West and manufactured goods and services from the North, thereby stimulating economic growth and development in the rest of the country, but not in the exporting region.

innovation or human capital, with the consequence that their growth slowed down over time relative to those regions that did invest in these sorts of things.

Another question is what impact did tourism's growth have on other industries? Did the growth of tourism crowd out investment and growth in other industries? This has been addressed in computable general equilibrium models that are increasingly being used in tourism studies. Their most frequent use is in economic impact studies, such as the effect of a terrorist attack or a special event such as the Olympic games (see Dwyer 2015), but they have also been used to assess the net impact of a change in tourist demand on a nation's economy. Examples include Australia, Fiji, and Singapore (Adams and Parmenter 1995; Narayan 2004; and Meng 2014). The general result is that the gains from the growth of the tourist-related industries were offset by losses in other industries, such as nontourist exports, because of an appreciation of the country's currency due to the increased tourist demand. As Dwyer concludes, "Unless there is significant excess capacity in tourism-related industries, the primary effect of an economy-wide expansion in inbound tourism is to alter the industrial structure of the economy rather than to generate a large increase in aggregate economic activity" (Dwyer 2015, p. 115). This would suggest that tourism may not be as much of a key to economic development as has been suggested by the Granger causality or input-output models.

And tourism can be on the other side of this process. Forsyth et al. (2014) used a Computable General Equilibrium assessment (CGE) to examine the impact of a boom in mining exports from 2004 to 2011 on the Australian tourist industry. They found that the upsurge in mining exports resulted in Australia suffering from "Dutch disease" manifested by the slowing of growth in the tourist sector. The mining boom resulted in an appreciation of the Australian dollar, which led to a slowing down of tourist arrivals, as well as an increase in outbound tourism, both of which contributed to slowing growth of the domestic tourism sector, an effect which was not completely offset by the income effect of the mining boom.

The Economic History of Seaside Resorts

Tourism may have begun with the Grand Tour, or even earlier with pilgrimages or the travels of Greeks and Romans, but it was not until the eighteenth century that the sort of travel we now consider tourism became well established, even if not yet commonplace. It took the guise of taking the waters at spas and going to the seashore. Travel to spas took place in many locations in the eighteenth century – even in colonial America – but going to the seaside was especially important in Britain. It was the preeminent example of this type of tourism, and a harbinger of things to come at seasides elsewhere. Despite the emergence of competing seaside resorts – first in France and the low countries in the late eighteenth century; then elsewhere in France, northern Germany, Scandinavia, and the Atlantic coast of Spain in the early nineteenth century; and later in the nineteenth century in a few locations in Italy – the British resorts as a whole thrived for roughly two centuries, and indeed are still functioning. Today, however, the seaside resorts in the Mediterranean are

more popular, and not only because tourists have come to prefer warmer climates. That success stems in part from transportation improvements, from the nature or types of seaside resorts that arose in England centuries ago, and from the response of British resorts to the competition of large-scale tourism that emerged in the Mediterranean.

The history of that transformation from the traditional British seaside resorts to the mass tourist resorts in Spain and elsewhere provides a fertile area for cliometric research on matters that are common to the development of other industries. To date, scholars have evaluated the appropriate measures of tourism, assessed the available data, and compiled pertinent statistics. While these are important advances in our understanding of this major shift in the resort industry, there is still much that cliometricians could do. Quantitatively assessing the relative importance of the various factors that shaped the growth and distribution of the seaside resort industry is one such example. Further examination of how the historical and institutional characteristics of various seaside resorts influenced the response to changes in income, transport costs, and hotel prices seems called for as well.

There are elements of path dependence in the development of this particular tourism industry that may not be fully explained by data on prices and tourism flows. Certain decisions made by economic agents and local governments in these various resort areas appear to have had a more profound impact than might be expected. And this is surely not the only tourist industry to have been shaped by path dependence. A better understanding of the broader context in which this particular industry developed will facilitate analysis of the history of other tourist industries. And, at the same time, this sort of analysis is a useful complement to the more technical, statistical approaches described earlier in the chapter.

The earliest British seaside resorts, those in the South of England at Brighton, Margate and Weymouth, as well as Whitby and Scarborough in the North, began in the eighteenth century by attracting an aristocratic clientele. In the early nineteenth century, upper middle class resorts, such as Torquay and Bournemouth, were established, and in the late nineteenth century there was more rapid growth in the number of both resorts and tourists, fed by the extension of the railway system and designed to serve the working class and day trippers. Blackpool and Hastings may be the most well-known, but by the early twentieth century, resorts had sprung up on almost every coastal region in England and Wales. The industry continued to grow rapidly through the early 1970s, save for interruptions by World War I, the Depression, and World War II, although not all seaside resorts fared well (Walton 1997, p. 24).

The seaside resort still provided the most popular form of domestic holiday up through 1974, which marked the zenith of Britons taking domestic holidays (40.5 million holidays of 4 nights or more) of all types, not only seaside holidays (Demetriadi 1997). Only sometime in the 1970s did international competition from seaside resorts outside the UK and competition from other types of tourism, both domestically and abroad, bring about a decline in British seaside holidays. From there on, the shift of the seaside resort industry from the UK to other locations, most notably the Mediterranean, may be as remarkable an economic

change as the relocation of the textile industry from New England to the Southern United States in the late nineteenth century.

UK tourists were drawn to other European destinations in large numbers beginning in the 1960s, first to the Mediterranean seaside, especially Spain, and then to Alpine winter resorts as both became packaged and produced for mass consumption.[18] In the 1980s, some traveled farther to Florida, Australia, Thailand, and Gambia, but Europe remained the most popular international destination for UK residents. This international travel posed problems for British seaside resorts because foreign tourists to the UK, while increasing in number (four million in 1967 vs. 16.6 million in 1992), came for traditional landscape and heritage tourism, and especially for urban tourism in London where 54% of all foreign tourists went in 1992 (Williams and Shaw 1997).

As plausible a story the above seems to be, it has not been fully documented by statistics and analysis. The reason for this is the same shortcoming faced by historical research on tourism everywhere – an absence of appropriate data, even for the most basic variables, such as the number of tourists.

The data problems and efforts to deal with them are described in *The Rise and Fall of British Coastal Resorts* (Shaw and Williams 1997). Because of the lack of data as well as dissatisfaction with some of the existing data, tourism in the British resorts is measured differently over time in this volume. It is variously measured by the resident population of the seaside towns for the period 1900–1950, by the number of holidays of 4 or more nights for the period 1950–1974, and the decline after 1974 is charted by the number of holiday nights spent in seaside resorts. On the Mediterranean side of the story, the editors of *Europe at the Seaside* (Segreto et al. 2009) argue that there had been no study of tourism for the Mediterranean region as a whole primarily because of a lack of statistics. "The aim of this book is to fill this gap," which they do with some success (p. 2).

John Walton (1997), writing about British seaside tourism in the period 1900–1950, argues that there is no plausible evidence on visitor numbers, and obtaining them would require much research into local sources that would not likely be very reliable. Walton is skeptical of the estimates produced by individual resorts in the 1930s and uses census figures on the permanent population of the resort towns, rather than numbers of visitors, even though he recognizes the problems with the census data.

Data on resident population show that the British seaside resort industry was well established by the beginning of the twentieth century. Between the census dates 1881 and 1911, the off-season (permanent) population of the seaside resorts increased by around 60% and accounted for 4.5% of the population of England and Wales, and the share rose to 5% in 1931 and 5.7% in 1951 (Shaw and Williams 1997; see Walton 1983 for further detail). Walton's analysis focuses on population change in a sample of 116 of the most prominent resorts based on reputation and advertising visibility . . . "rather than on more demanding 'scientific' criteria" – and excludes those that

[18]The internationalization of British tourism began in the previous decade with the first air package holiday to Corsica (Williams and Shaw 1997, p. 3).

posed a serious problem of boundary change. He examines their performance in two ways: the absolute increase in numbers of people and the percentage increase in the population.

Based on numbers of people, the large, established resorts, such as Brighton, Bournemouth, and Blackpool, experienced large increases in numbers and retained their preeminence. The notable exceptions were Great Yarmouth, Dover, and Hastings, which recorded declines or only a small increase. Based on growth of population, the fastest growing resorts were those that were small at the start of the period, and were boosted by the development of holiday home sites and holiday camps. These attracted vacationers from East London, who could not have afforded holidays in the more established resorts, as well as Bohemian and artistic middle classes, and a growing number of year-round, elderly residents.

In the end, Walton recognizes that population growth cannot be the measure of success for all seaside resorts. Census data indicated that by 1951 a number of smaller places, such as Grange-over-Sands and Lyme Regis, that had been successful resorts due to their climatic advantages chose to remain small; local authorities and landowners restricted development and discouraged amusements. Others grew slowly but retained their architectural amenities and gardens, and succeeded in other dimensions; Eastbourne, for example, had the fifth highest figure for retail spending per head in 1950. And yet others like Torquay grew impressively but went down-market in the process. Such divergence among the objective function of individual resorts poses a problem for analyzing the causes of tourism growth and its consequences in any country.

Walton argues that regardless of which measure of tourism growth is used, the causes of that growth were to a large extent the same. It was important to have the right conditions for growth, which included "a welcoming attitude to the expanding popular market, as suggested by openness to plotland and holiday camp incursions" (p. 38). Resorts that sought to safeguard a high "social tone" did not grow because they could not, or did not, move down market, at the same time that their traditional, upper class visitors were lured abroad. Accessibility to transport was important to attract visitors as well as enable growth of the resident population; seaside commuting and retirement were important in the interwar years. Whatever the sources of growth, the seaside industry by 1951 had recovered from World War II.

The period from 1950 to 1974 has been labeled the golden years for seaside resorts, although the term might be better reserved for only the decade of the 1950s. That decade had full employment, there was little or no competition domestically or abroad for seaside resorts, and the 1950s was the first decade to experience the full impact of Holidays with Pay Act (Demetriadi 1997). It was still an age of railway travel, not private autos, so the existing resorts remained as accessible and preferred as they had been.[19] Domestic tourism continued its post-World War II rise up to

[19]As car ownership increased and roads improved, tourists were no longer captive to the resort near the railway terminal.

1974, part of which was an increase in second and third holidays; a phenomenon which in the longer run did not bode well for longer term stays at seaside resorts (Demetriadi 1997).

The Shift from British to Spanish Seaside Resorts

Even while the numbers of domestic holidays taken by British residents were rising in the 1960s and early 1970s, the British seaside resort industry struggled with both its own problems and with the emergence of newer and more fashionable seaside resorts elsewhere, especially in the Mediterranean region that drew large numbers of British tourists. By 1969, Spain was the leading destination by far for British overseas travelers, attracting 32% of them (Demetriadi 1997). And the shift continued, with British travelers going to Spain growing at 4.5% per year from 1970 to 1993.

There is a long list of factors that contributed to the decline in domestic seaside holidays. Cooper (1997) identified 20 threats facing British resorts after the Second World War, and he did not include basic economic variables, such as changes in exchange rates, that cliometricians would tend to favor.[20] So what did cause the shift to overseas destinations of seaside vacationers? Did it reflect a failure of domestic entrepreneurs in the seaside resort industry or the foresight, skill and judgment of the entrepreneurs in the Mediterranean? Was it the consequence of improved air transportation, which suddenly made the Mediterranean more accessible, or at least relatively more accessible compared with local transport to the seaside? Or, as many assert, was it due to the introduction of all-inclusive package tours, which took advantage of the improvements in air transportation, especially the introduction of jet airplanes, which made travel not only faster but also cheaper (Lyth 2009)?

Independent airlines were established after World War II to fly routes not served by scheduled airlines and to provide other airline service. They blossomed because they could easily acquire aircraft from the supply left after the War, and because for much of the 1950s, they were subsidized by government contracts to fly troops to war zones, especially to Korea. In 1965, a change in airline regulations gave independent airlines more freedom to compete with scheduled airlines, and they took advantage of the situation (Lyth 2009). Independent airlines in the UK realized before the nationalized airlines did that the demand for air travel was price-elastic, and that on faster flights travelers would not care much about the luxuriousness of the accommodations, and for lower prices would be willing to depart from lesser known airports. Travel agencies embraced these independent airlines and their low fares, and struck deals with hotels and resorts that enabled

[20] Absent to a large extent from discussions of this shift from seaside resorts in the UK to resorts in Spain is the impact of changes in taste. See Urry (1997) for a discussion of the impact of cultural changes.

them to offer all-inclusive package tours that could provide holidays in Spain cheaper than those that could be had in the UK.[21]

But there remain some questions as to the importance of tour packages and the timing of their impact on the transformation of the British seaside resorts. According to Demetriadi (1997), declines in seaside tourism in Britain before the mid-1970s were not due to the growth of overseas tour packages. Although they had begun to play a role in shaping the world market for tourist travel, they were not affordable to a broad segment of the population until after 1972. Overseas package tours did not cut into domestic resorts as evidenced by the small increase (0.75 million) in overseas travel between 1965 and 1970, but a much larger increase of 4.5 million in domestic trips. On the other hand, Cooper (1997) suggests that all-inclusive tours may have been of greater importance before 1974 than Demetriadi claimed, but in any case were among the key factors contributing to the decline after 1974.

The evidence on the prices of tour packages (Lyth 2009) lends some support to Cooper's notion that package tours may have been more important before 1974, but at the same time raises questions about their impact after 1974 or 1975. The nominal prices of tour packages rose by about 10% from 1966 to 1972, but when adjusted for inflation, real fares fell by about 5% between 1966 and 1970, and then fell considerably more from 1971 to 1972. From 1973 to 1977, however, package tour prices rose: more than doubling in nominal prices and rising by 27% in real terms. So, all other things being equal, tour package prices should have had more of an impact on increasing travel before 1974 than after.

Price was not the only consideration. There were other variables – such as changes in exchange rates, rising incomes, and increased holidays – that would have increased demand for tourism of all sorts; domestic as well as overseas, and seaside tourism as well as urban and heritage tourism. And there were also supply-side factors that came into play, in particular the availability and quality of tourist accommodations. Was the Spanish tourism industry better prepared to respond to an upsurge in tourist arrivals? Had they built ahead of demand and travel agents took advantage of that oversupply to construct all-inclusive tours? Why were the British seaside resorts unable – or unwilling – to respond in the same way to the rise of mass tourism?

The growth of tourism in Spain was due in part to changes on the supply side: "to the interaction of multiple actors, such as entrepreneurs, hotel groups, international travel agencies, specialized and non-specialized workers, local, regional and national governments" (Manera et al. 2009, p. 6). The nature and style of this assortment of economic agents varied across nations, particularly as regards Spain (and some other Mediterranean countries) vis-à-vis the UK (and other European countries). In the UK, as well as France and Germany, large, managerial enterprises with large bureaucratic and strong financial structures were more prominent, whereas medium- and large-sized groups of economic agents were more common in Spain (Manera

[21]Package deals also were a way to get around restrictions on the amount of currency that could be taken out of the country.

et al. 2009). Manera et al. argue those differences conditioned the response. In Spain, those business groups or associations responded by adapting the supply-side of tourism, changing the infrastructure, and constructing hotels and resorts geared toward mass tourism. In the UK, on the other hand, the suppliers of seaside tourism tried to cope with the increased demand by duplicating the same small-scale operations that had been so appealing and successful in the past. This reflects the baggage they were dealing with when the Mediterranean competition emerged.

Even when the UK's seaside resorts were thriving in the 1960s, there was a lack of quality accommodations. The older Victorian hotels were no longer fashionable, and remodeling and upgrading, as well as heating and lighting, were more expensive in the larger older hotels. This contributed to a gradual decline in the number of upper and middle income tourists (with some resorts being notable exceptions) who increasingly opted for overseas travel, which in turn led to some of the large hotels being sold or converted to blocks of flats.[22] The number of large-scale seaside hotels declined by 40% between 1961 and 1970. Moreover, the Second World War had opened up other jobs for women, so hotels had less cheap labor available, and the Catering Wages Act in the early1950s boosted wages. Seaside tourism was facing increased competition domestically from heritage sites and urban areas, especially London.

Cooper sees the British response in largely the same terms as Manera et al., but with a somewhat different perspective. The domestic resorts in the UK did little to upgrade their facilities because they had lots of older fixed capital and owners were unable or unwilling to adapt to the changes that affected the industry in the 1970s, in part due to the seasonality of the business. With a shorter season in the UK, resort hotels there did not appear as attractive an investment as urban hotels, or as attractive as hotels in the Mediterranean for that matter. Moreover, the existing capital stock was largely small scale, comprised mostly of independently owned hotels that could not afford to finance expansion.

The Spanish seaside resorts stood to benefit in either case; whether the response by the British resorts was an expansion based on replicating the same small-scale hotels and resorts, or by a lack of response for whatever reason. But Cooper argues further that the British-outbound tourism sector (airlines and travel agents) responded better to meet the increased demand arising from increased real incomes. And this response meant taking advantage of the advances in air travel and working with the newer and more fashionable Spanish hotels and resorts, many of which were established to attract large numbers of middle and lower income tourists (Lyth 2009), those that had become the mainstay of many of the British seaside resorts.

For whatever reason, the failed response in the UK stands in sharp contrast to the behavior of the hotel industry in Spain, perhaps because they were ready for mass

[22]See Demetriadi (1997). Seaside resorts were harmed as well by the rise of second and third vacations, which became more common and were shorter in duration. Travelers increasingly took their one long vacation overseas, and spent their shorter vacations and weekend breaks domestically and increasingly in locations that were more readily accessible than the seaside (Cooper 1997).

tourism, thanks to an earlier history of some seaside tourism. Alicante (Costa Blanca), Malaga (Costa del Sol), and Palma de Mallorca were famous resorts by the turn of the nineteenth century, with Alicante being known as the "Playa de Madrid," thanks to a direct rail link established in 1858 (Valenzuela 1998, p. 55). In any case, the existing hotel owners, especially on Majorca, responded much more adroitly than did their counterparts in Britain. Not only did they expand to accommodate more tourists on Majorca, they invested in hotels in other seaside locations, and continued from there to become some of the leading hotel companies in the world (Serra 2009).

Although this history indicates there was a massive shift in seaside tourism from Britain to Spain, and there is a widely held view in Britain that the domestic seaside resorts have been struggling ever since, the reality is not quite that dismal. Beatty and Fothergill (2003) found that between 1971 and 2001, employment and population in Britain's seaside towns grew slightly faster than the national average, a finding that harkens back to Walton's idea that, for some seaside cities, tourism was a means to attract more permanent residents. Beatty and Fothergill (2003) could not sort out employment in the tourist industries from all other employment, but a later study by Beatty et al. (2010) did so, and found that far from entering a spiral of decline caused by the loss of tourism business, the economy of Britain's seaside towns proved remarkably resilient over this period.[23] The study looked at employment, rather than numbers of visitors or resident population, and found that from 1999 to 2007, employment increased by a little more than 1% per year. Tourism in 2007 was still a major source of employment, equal in size to the telecommunications sector and bigger than the motor industry, aerospace, pharmaceuticals, or steel.[24] They conclude that "far from being in terminal decline as a result of the rise of foreign holidays, a substantial British seaside tourist industry remains alive and well" (Beatty et al. 2010, 10).

Economic History of Tourism in the United States

Tourism in the United States is not as quantitatively important as it is in Europe, or in most individual nations in Europe or elsewhere, but it is not a negligible part of the US economy. Value added by tourism in 2015 comprised 2.7 of GDP, larger than the share accounted for by utilities and mining (Osborne and Markowitz 2017, p. 4).[25] Tourism has accounted for 3.5–4.0% of the nation's employment

[23]They say it should be possible to apply their estimation techniques to earlier years in order to get a longer time series.

[24]Its output is low in relation to employment, which reflects the prevalence of low-wage and part-time employment in much of the industry (Beatty et al. 2010, p. 10).

[25]For those who ascribe to Douglass North's idea that American growth was propelled by the growth of cotton exports, it is worth noting that the income from those exports never exceeded 6% of GNP.

since the early 1990s.[26] Consumer demand for tourism output was equal to 90% of consumer spending on financial services and insurance, and nearly twice the size of spending on motor vehicles and parts.[27] Americans' demand for tourism consumption within the United States dwarfed their spending on outbound tourism and widely exceeded the demand by international travelers to the United States (OECD 2016, Tables 1 and 3).

The rise to its current importance took a long time. The history of tourism in America, as well as travel overseas by Americans, is similar to that for Europe. It was initially confined to the elite, but as incomes rose and transportation costs declined over time, travel became increasingly popular, but early on was still seen as extraordinary behavior. Eventually, so many could afford to travel, and did so, that tourism became a product – advertised widely and produced on a large scale. The absence of a reliable quantitative record of tourism's history, however, has resulted in an assortment of claims as to when American tourism, whether domestic or international, became so important or so large in scale that it could be deemed "mass tourism," and its services could be commodified. Although domestic tourism is larger than overseas travel by a wide margin, the latter is better documented and its long-term trends measured more reliably.

In the late nineteenth century, only around 100,000 Americans traveled overseas, and all of them did so by steamship. Today, there are in excess of 30 million overseas travelers, almost all of whom travel by air.[28] This long-term rise in overseas travel was not smooth and uninterrupted – it was punctuated with significant declines during periods of warfare and economic downturns and significant surges as in the 1950–1970 period – but it rose at an impressive average annual rate of about 5% between 1820 and 2000 (Dupont and Weiss 2013). There were essentially two phases to this long-term growth: prior to World War I when the increase in overseas travel was primarily driven by population growth, and the share of Americans traveling rose very little; and the post-World War II period when travel was driven by improvements in transportation technology and economic factors, such as rising incomes, and tourism rose noticeably faster than the population.[29]

The pace and timing of international overseas travel to the US were similar to those for Americans traveling overseas in the long run, but there were some noticeable differences in shorter time periods. And the volumes were different: the

[26]U.S. Bureau of Economic Analysis (2017) "Travel and Tourism Satellite Account" Sept. 2017, and "National Income and Product Accounts: GDP and Personal Income, Section 6". The earliest estimates cover 1992, 1996, and 1997 (Kass and Okubo 2000, Table 1, and an earlier and preliminary estimate for 1992 in Okubo and Planting 1998). The share rose to 4.3% in 1998–2000.

[27]U.S. Bureau of Economic Analysis (2017) "Travel and Tourism Satellite Account" Sept. 2017, and "National Income and Product Accounts: Gross Domestic Product Third Quarter 2017. Consumer demand for tourism is reported as Direct Tourism Output in the Satellite Accounts.

[28]See OECD (2016), Country Profiles-United States. There are also around 40 million who travel over land to Canada and Mexico.

[29]This statistical record covers only Americans traveling overseas, and does not include travel to places reached over land, mostly Canada and Mexico (Carter et al. 2006, series Dh324).

number of tourist arrivals was below the number of Americans traveling overseas, especially before World War II (see Fig. 1a), but even after the War when the former was less than half of the latter up to 1973. Not until the 1990s did the number of foreign travelers to the US equal or exceed the number of Americans traveling overseas (see Fig. 1b).

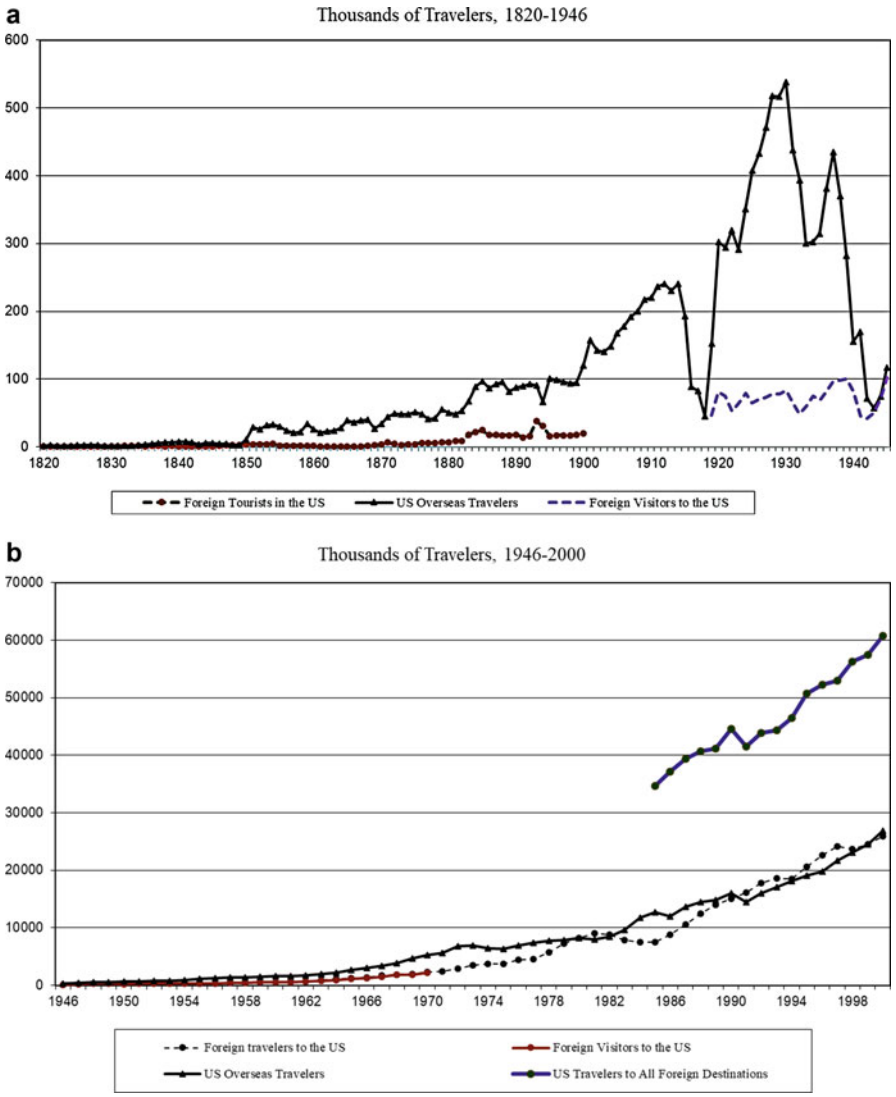

Fig. 1 (**a**) US overseas travelers: Dupont and Weiss 2013; Foreign tourists in the US and foreign visitors: Carter et al. 2006, Dh320 and Dh326. (**b**) US overseas travelers: Dupont and Weiss 2013; US travelers to all destinations, Carter et al. 2006, Dh324; Foreign travelers and visitors: Carter et al. 2006, Dh325–26

One of the biggest changes in overseas travel resulted from the considerable cost reductions that came with improved transport technology. These improvements meant that travel abroad, once available only to the wealthy elite, became increasingly open to middle-class Americans and foreign travelers as well. The most important technological shifts came first with the mid-nineteenth century transition from sailing to steam-powered vessels and then, roughly a century later, the transition from propeller to jet-propelled aircraft. The first transition to steam-powered vessels resulted in shorter passage times and more reliably predictable schedules, both of which reduced costs for passengers. Pan American initiated the mid-twentieth century transition in 1958, advertising "6 ½ magic hours to Europe." This transition reduced travel times further as the average speed of international aircraft increased from 224 mph to 482 mph between 1950 and 1970, although the time savings was much more modest than that generated by the shift from sail to steam. And it still takes 6 ½ hours to reach Europe!

Two papers (Dupont et al. 2011; Dupont and Weiss 2013) have attempted to sort out the relative importance of several factors as explanations of the long-term rise in overseas travel. Population growth alone would have led to an increase of about 1.9% annually from 1820 to 2000, accounting for about 46% of the growth in the number of overseas travelers prior to World War I, but only about 23% in the period from World War I to the year 2000. The remaining growth, due to the rising share of the population traveling abroad, was a small fraction of a percent in the early nineteenth century (between 0.01% and 0.02%), rose more than ten-fold by the early twentieth century, fell during the world wars and the Great Depression, but has risen steadily since the end of World War II. By the end of the twentieth century, the share of the US population traveling overseas was about 9%, some 30 times higher than it was at the end of World War II (Dupont et al. 2011, Table 1). By 2015, 74 million US citizens, about 23% of the population, traveled to international destinations.

The main reasons for the rising share of the population traveling overseas were rising incomes, changes in exchange rates, changes in passenger fares, and technological improvements, such as the shift from sailing to steam-powered vessels in the last half of the nineteenth century and the shift to jet-powered aircraft a century later. The empirical evidence indicates that Americans traveling to Europe responded to some degree to all of these factors, but were most sensitive to changes in per capita income and the price of travel (Dupont et al. 2011). Other factors mattered as well: improvements in hotels and restaurants, the publication of travel guide books, developments in package tours, and growth of official tourism offices abroad, but these are not easily quantified.

In contrast to the statistical evidence available about international travel, the history of domestic tourism in the US still rests largely on anecdote, at least up to the post-World War II era, and to some extent up until the BEA Satellite Accounts produced the first estimates for 1992. Even when scholars have written thoughtful histories about particular places, they have used only a handful of illustrative statistics. Based on that sort of evidence, it has been claimed that mass tourism arrived in the late nineteenth century (Brown 1995), between the world wars (Dulles 1965; Jakle 1985), or not until after World War II (Cocks 2001). Weiss (2004) compiled a crude time series up to World War II that suggests by 1930 tourism had

grown to include many middle-income Americans, but had not yet become mass tourism, which was postponed by two decades due to the disruptions of the Great Depression and World War II.

Clearly, we lack a statistically-based explanation of tourism's rise in the US. There are plausible explanations and identification of the factors that mattered, but no quantitative assessment of which factors were the more important. Cliometricians have not yet studied the growth of American tourism to the same extent as they have examined other industries, such as agriculture or finance, that are not as large or not much larger than tourism, or other components of consumer behavior and spending, such as the durables revolution. If cliometrics is thought of as having two components – the construction of new data series and the use of statistics instead of anecdote and narrative description, and the use of economic models to analyze the data – then so far cliometric research on American tourism has been focused more on the first of these.

Weiss's (2004) survey of tourism before World War II is an example of the first prong, an attempt to measure the rise in the numbers of tourists. Although his evidence has its shortcomings, is limited to a few benchmark dates, and does not extend beyond World War II, it offers a plausible depiction of the long-term trend for the nation and of the relative importance of several different types of tourism and of some specific tourist sites before 1950. Moreover, the derivation of the national totals is clearly specified, so others can replicate the results and revise them as new information comes to light.

For the period after World War II, there are some time series data available from federal and state sources. Estimates of expenditures by travelers have been made at the federal and state level for many years since 1960, but these figures have never been assessed by scholars outside the agencies that created them, nor have they been used in any long-term study of tourism. The consistency among the different sets of estimates has not been determined. Nevertheless, these various data sets could be assessed for consistency with one another and, with appropriate adjustments, combined to form a very useful time series for the post-World War II period.

Data Sets Available

In 1963, 1967, 1972, 1977, and 1982, the Bureau of the Census conducted a National Travel Survey as part of the Census of Transportation. Among the information collected was the number of trips, mileage traveled, and number of days away from home. The Federal Highway Administration conducted the National Household Travel Surveys beginning in 1969, but most of those covered only daily travel, not long distance travel.[30] Two of those surveys, however, the *American Travel Survey* conducted in 1995 and the *National Household Transportation Survey* taken

[30]Surveys were taken in 1969, 1977, 1983, 1990, 1995, and 2001. In the second survey, taken in 1977, long-distance travel was included but was confined to trips of 75 miles-or-more taken during the 14-day period preceding the survey.

in 2001, covered long-distance trips. The former included trips of 100 miles or more taken in 1995, while the latter included trips of 50 miles or more taken in 2001. None of these travel surveys, however, included travel expenditures, but some of the data collected were used by the United States Travel Data Center to reconstruct expenditures.

The US Travel Data Center[31] developed a Travel Economic Impact Model that enabled them to use the travel activity data collected by the Bureau of the Census and average costs of each unit of travel activity (e.g., cost per night by type of accommodation) obtained from other sources, such as the Census of Retail Trade, to estimate tourists' expenditures.[32] The first year for which the Travel Data Center made an estimate was 1974, but it was not until 1983 that the estimates were made readily available with publication in the *Statistical Abstract of the United States*. From 1983 to 2001, the figures were published annually, except in 5 years: 1988, 1991, 1992, 1997, and 2002.

Before 1982, agencies in various states collected data on travel, including travel spending, in their respective states. Some of these studies were conducted under the auspices of the Department of Transportation. The Business Research Division at the University of Colorado periodically gathered data from various state sources covering the period 1960–1982, and published compilations every 2 or 3 years from 1969 to 1984. While data are reported for most states in one or more years, there are some missing observations because not all states collected data in all years. The data for California, for example, are missing in about half the years in the period 1960–1982. Moreover, the consistency of the data across states and even over time within the same state appears questionable in some instances. For example, expenditures in New Jersey were reported as only $778 million in 1972, but $3.5 billion 2 years later.

Implications of These Data

If we use these series in their raw form – that is to say, we ignore any inconsistencies within the state-based series, and take those data as being comparable with those for the period after 1983 – they show several points worth noting. Growth in the aggregate for the nation was substantial in nominal terms, but much less so in constant prices. Between 1960 and 2003, travel expenditures rose at an average annual rate of 8.2% per year, but only 3.7% per year in constant prices of 1982–1984. Almost all the growth in real expenditures per capita for the nation took place before 1983 (see Table 1).[33] Over the entire period from 1960 to 2003, per

[31]The Travel Data Center was established in 1973 and is now called the U.S. Travel Association. https://www.ustravel.org/.

[32]Their model specified 15 different expenditure categories, such as commercial lodging and variable auto/truck costs, and related SIC business types (Frechtling 1976).

[33]The national totals for this period vary in terms of the states covered from year to year, but even if we made generous allowances for the states that were missing in these years, the increase in spending during this period would be greater than in the post-1983 period.

Table 1 Travel spending in the United States. (Million of dollars, except per capita figures)

	Nominal	Real	Real spending per capita
1960	$16,580	$56,015	$314
1967	$25,747	$77,088	$395
1983	$197,597	$198,393	$855
2003	$490,870	$266,777	$917
Average annual rates of change (%)			
1960–1983	11.38	5.65	4.45
1960–1967	6.49	4.67	3.33
1967–1983	13.58	6.09	4.94
1983–2003	4.65	1.49	0.35
1960–2003	8.20	3.70	2.52

Spending per capita is for the resident population, not the number of tourists. Real expenditures are in prices of 1982–1984. For sources, see the text.

capita expenditures in constant prices (1982–1984 = 100) rose by $603, or at an annual average rate of 2.5%. Between 1983 and 2003, the period for which the Travel Center's estimates are readily available, per capita spending increased by only $62. Between 1983 and 2003, there were ups and downs in travel spending, but only a sluggish rate of increase of 0.35% per year.

Along with the increases, there was a noticeable redistribution in the importance of tourism spending among states. For example, California, which today ranks at the top of the list, was only in 7th place in the 1960s, whereas Florida, which was number one in the 1960s, had slipped behind California by 1983. Also of note is that Hawaii, often seen as the premier tourist destination, has never made the top ten list. In fact, while it rose in importance between the 1960s and 1983, going from 34th to 27th place, it subsequently fell back in the rankings.[34]

Explaining the Rise of Domestic Tourism

Perhaps it is not surprising that there has been no cliometric work done to explain the rise of tourism in the United States as a whole. Tourism accounts for only 3–4% of GDP, and it is not an industry known for technological breakthroughs that might have spillover effects on productivity in other industries. Nevertheless, the issues are of greater interest in those states and cities where tourism is relatively more important. This would include states, such as Florida and Hawaii; cities, such as Orlando and Las Vegas; and specific sites, such as Niagara Falls and the Grand Canyon. Even at this level, the historical analyses have not been cliometric in nature, even though there are any number of instances in which counterfactual analysis would have been very appropriate and informative. The history of tourism in Hawaii offers an excellent case study of what we might call near-cliometric analysis.

[34]Space limitations preclude the inclusion of a fuller table showing the state rankings over time.

History of Tourism in Hawaii

Hawaii is one of the mostly highly rated tourist destinations in the world. As attractive as Hawaii now seems, tourism could not have reached its current heights without transportation innovations, especially jet planes, and might not have succeeded as much or as easily without the infrastructure that had been built to serve agricultural markets. Some of its early success in attracting and accommodating travelers, which laid a foundation for subsequent tourist growth, was due to its location on major shipping routes from North America to Asia and Australia. The private sector may have played the dominant role, but government took an active role in shaping the direction in which the economy should go, the extent to which tourism should be managed, and was concerned with "sustainable tourism" as early as 1976, well before that concept was defined in 1992 (Mak 2008).

Perhaps because the government was involved early on in the development of tourism in Hawaii, or because it was an island economy that could more easily monitor and measure some of its economic activity, it is a place for which one can find pertinent historical statistics on tourism. Data collection began around 1911, carried out by the Hawaii Promotion Committee, an organization founded by the Honolulu Chamber of Commerce in 1903 to promote tourism to Hawaii. Its successor organizations, the Hawaii Tourist Bureau (1919), the Hawaii Visitors Bureau (1945), and finally the Hawaii Visitors and Convention Bureau (1997), continued that work producing what were considered "the best tourism statistics in the world"[35] (Mak 2008, p. 111). And, in 1977, Robert Schmitt compiled the *Historical Statistics of Hawaii* to be a counterpart to the *Historical Statistics of the United States* covering the same demographic, economic, and social topics. The tables are complemented by discussion of the development of the statistics in each topical category, and by provision of pertinent definitions, notes, and qualifications, as well as reference to appropriate published sources. One can find estimates of population back to 1778–1779, annually from 1832 to 1976; income from the major export industries (sugar, pineapple, defense, and tourism) annually from 1910 to 1975; gross state product annually from 1939 to 1975; and visitor arrivals annually from 1922 to 1975. Moreover, many of these data, as well as other time series, and more recent statistics, can be accessed on the state government's website (Hawaii http://dbedt.hawaii.gov/).

These data reveal several notable points. Hawaii has always been heavily dependent on exports (see Fig. 2). Just prior to World War II, the value of Hawaii's four major exports – pineapple, sugar, military spending, and visitor spending – equaled 50–60% of the state's gross product, a dependence that suggests there would likely be a continual search for goods and services that could generate export revenues. Although visitor spending was the smallest of the four at that time – about 5% of gross product – the conditions were conducive to its expansion. And not long after

[35]In 1998, the research function of the Visitor and Convention Bureau was turned over to the state's Department of Business, Economic Development and Tourism (Mak 2008).

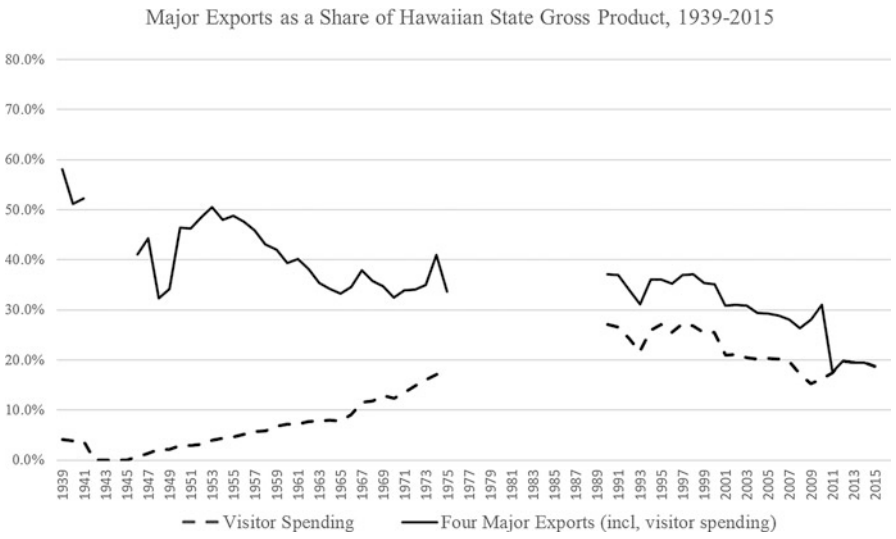

Fig. 2 The major exports are sugar, pineapple, defense spending, and visitor spending. Visitor spending includes spending by travelers from the continental US, so the total is not the value that would appear in the international accounts. (Mak 2015, Table 1, http://dbedt.hawaii.gov/economic/databook/db2016/)

World War II, the expansion began. Growth of visitor arrivals was quite rapid up through the 1980s, languished through the 1990s and the beginning of the twentieth century, and since 2010 has experienced another growth spurt (see Fig. 3). The value of visitor spending, which had fallen to zero during the War, rose to equal about 30% of state gross product and is the only one of the four major pre-War exports of any importance today (see Fig. 2).

These historical data have been used by economic historians to explain the rise of tourism, its leveling off for nearly two decades, the role of government, and tourism's impact on the local economy and population. Although these analyses are not full-blown cliometric studies, the authors rely heavily on statistics and use economic models, at least implicitly, to explain the major patterns in the state's tourism history.

According to James Mak (2008), tourism in Hawaii is essentially a post-World War II phenomenon. Early travelers to the islands were predominantly sailors with few visitors, most of whom were only passing through. What might be seen as a tourist trade can be said to have begun in 1867 when regular steamship travel commenced between Hawaii and the US mainland. Limited growth continued until the end of the century as steamship service improved; it was more frequent, more comfortable, and faster, although still involved traveling on cargo ships. Not until 1927 did the first passenger ship, the *Malolo* with a capacity of 650, make its maiden voyage. Pan Am Clipper airline service began in 1936, but carried only seven passengers at a fare of $356. Despite regular airline service, most visitors

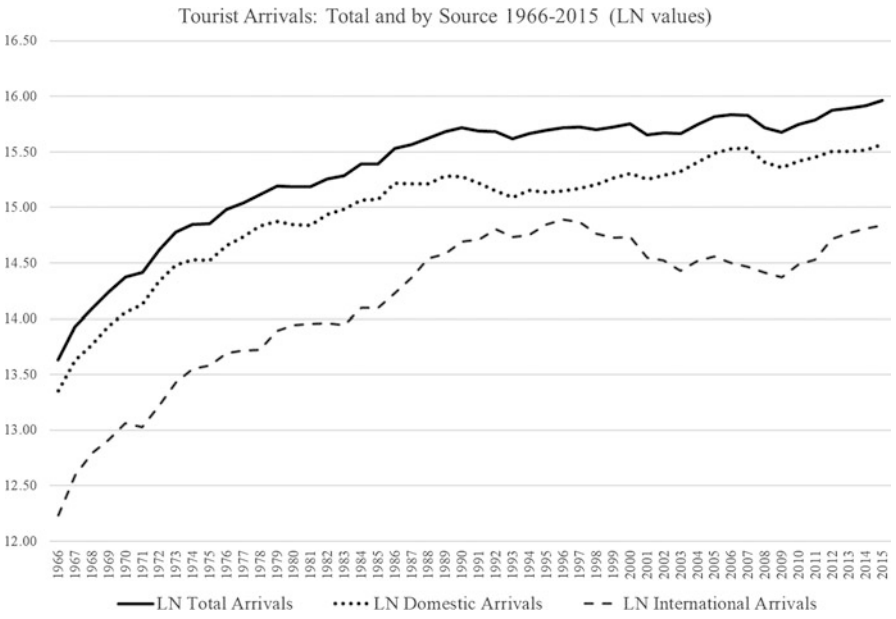

Fig. 3 Domestic arrivals are those from the mainland US. International arrivals are largely from Japan. (Mak 2015, Table 1 and Schmitt 1977, Table 11.7)

arrived by ship until well after World War II. The War shut down the tourist trade, and it took more than a year after the war to return to normal. Then, in 1947, United introduced DC-4 s, which were faster and cheaper ($225 fares) than the Clippers, and in 1948 Northwest initiated flights from Seattle and Portland.

All these events were only a prelude to the tourist boom that was to come and laid a foundation for the mass tourism that came after statehood was achieved in 1959. For example, when private capital was not interested in investing in a first-class hotel after the tourist trade began in the late 1860s, the Hawaiian monarchy did, building the Hawaiian Hotel in downtown Honolulu. The hotel was completed in 1872 and shortly thereafter a small annex in the Waikiki area was built and enlarged in 1894, making it the first major beach hotel in the islands (Mak 2008). Accommodations do not appear to have been a constraint on the growth of tourism before statehood. The number of tourists rose from about 2000 in the 1880s to around 9676 in 1922 (Schmitt 1977, Table 11.7). While that growth may not have propelled the Hawaiian economy, it showed that the state could play a role in developing tourism.

With statehood in 1959 came “a huge surge in tourist travel to Hawaii from the US mainland” (Mak 2008, p. 16) due primarily to increases in airline capacity and reduced airfares. In 1959, Pan Am began jet clipper service and by the mid-1960s almost all propeller airplanes had been replaced by jets, which cut travel time from days in the case of ships to around 5 h. In the1960s, fares set by the CAB fell 46%, most of it during the 1960–1965 period. Yet, with all these favorable conditions, it is

a little surprising to see that the rate of growth of tourist arrivals was about the same in the 10 years before statehood as the 10 years after.[36] What then was the impact of the decline in airfares, the increase in airline capacity, and increases in real income in the US after 1959? Why did tourism growth not accelerate in the 1960s instead of continuing along the same trend? Was tourism growth held back by other forces, such as supply constraints on the islands? These seem like questions ripe for counterfactual analysis, but economic historians have not addressed them.

Transport improvements continued to foster tourism. In 1969, the Civil Aeronautics Board allowed five more passenger airlines to fly from the US mainland to Hawaii, which meant more cities had easier access to Hawaii either directly or via connections. In 1970, Pan Am introduced the 747 jumbo jet, which still took 5 h, but carried many more passengers. And in the late 1970s, the airline industry was deregulated, which resulted in further declines in air fares, especially on long-haul routes and for recreational travel.

The rise in the annual volume of tourists from 242,000 in 1959 to 6.7 million in 1990 was due in part to a large increase in Japanese tourists that began in the late 1960s. That upsurge was due to a relaxation of Japanese prohibition on outbound tourism until 1964, and easing of restrictions on the number of dollars that could be spent overseas (Mak 2008). Once restrictions were lifted, conditions were favorable. Jumbo jets had already been introduced in 1970 and packaged tours arose to take advantage of that airline capacity. With Japan running surpluses in their balance of trade, the yen increased in value and made travel that much less expensive.

Japanese arrivals continued to rise until 1997, except for a dip in 1993–1994. Nevertheless, the Hawaiian tourism industry struggled throughout 1990s. As Grandy (2002, p. 40) put it, beginning in 1991 "the bottom had fallen out of westbound arrivals," i.e., arrivals from the US mainland (see also Fig. 12, p. 22). And just as US arrivals started to rise again near the end of the decade, Japanese arrivals declined between 1997 and 2003, a phenomenon Mak (2008, p. 23) describes as "somewhat of a mystery." Overall, the 1990s were a troubled period, due to a series of events, beginning in 1991 with the first Gulf War, the collapse of the Japanese bubble, and a US recession, especially in California. Then in 1992, Hurricane Iniki hit in September, and a fare war among airlines for travel within the US mainland made flights to Hawaii relatively more expensive. Finally, the Asian Financial crisis of 1997–1998 dampened demand.

There may have been other reasons as well: Waikiki was shabby and in need of renovation, while other destinations – Japan, Australia, New Zealand, and Canada – had become more competitive and were reducing Hawaii's share of the tourist market. The new century did not fare any better at the start with the terrorist attack on the World Trade Center in 2001 and SARS epidemic in Asia in 2003. But after the

[36]See Mak (2008). The rate in the 10 years before statehood was 22% per year from 1949 to 1959 and for the 10 years after it was 20% from 1959 to 1969 (calculated from data in Schmitt (1977, pp. 273–74, Table 11.7).

initial shock of 9/11, Hawaii may have benefited from Americans' fear of traveling abroad and showed a recovery after 2003 (Mak 2008).

The high rates of growth of tourists in the 1950s and 1960s appear to have fostered economic growth at that time. In 1959, income per person in Hawaii was 20% below the national average; by 1970, it equaled the average and, according to Mak (2008, p. 30) ". . .this convergence was largely due to the extraordinary growth of tourism in Hawaii."[37] At the beginning of the period, tourism accounted for 16% of the four major exports, but it had increased to 38% by 1970. Over this period, visitor spending rose by 400%; if one adheres to an export-driven model of economic growth, one would surmise that tourism's impact must have been substantial.

The rapid growth of tourism in the 1960s led some residents and politicians to question whether unchecked tourism growth was good for the state. Even on Maui, which had only just begun to experience tourism growth, there was concern that it could "'spoil the charm and beauty of Maui'" (Blackford 2001, p. 24). Further resentment arose in the 1970s even though tourist arrivals increased at only 8.8% per year. The "Babbie Report" prepared by a public interest group tried to show that the growth of tourism and its induced growth of the resident population resulted in declines in the quality of life (Babbie 1972). It argued further that the quality of life could be stabilized only by halting in-migration, which meant halting growth of jobs, which meant halting growth of tourism (Mak 2008). Others argued as well that too much growth would erode the Aloha spirit, which would significantly reduce tourism to the islands.

By the 1980s, there were further concerns that the state's economy had become too dependent on tourism. There were a variety of responses, including the creation of the Maui Economic Development Board, which was charged with trying to create a more diversified economy by attracting high-tech companies to the area, and develop a more diversified agriculture (Blackford 2001). Neither of those plans worked out very well, at least not by the end of the century, despite having invested nearly $50 million on high-tech ventures. Another effort came when the Office of State Planning established a policy requiring developers to create one nontourism-related job for each hotel room the developer wanted to build, but Mak says the policy did not have much of an impact on the development of tourism.[38] And as described above, it may have been a moot issue as other events slowed the growth of tourism.

Despite these efforts to diversify the economy and a continued slowing of tourist arrivals in the 1990s, tourism remained the dominant export at the end of the decade; at nearly $10 billion, it was 2.5 times the size of the other three major exports and equal to 35% of the state's gross domestic product. Given tourism's greater importance to the economy, its slowing down and stagnation were a more serious concern.

[37]The comparison used current price output values, implicitly assuming that prices rose in Hawaii at the same rates as for the US.

[38]On principle, the developer had the alternative of paying the equivalent of a nontourist job in cash ($25,000); in practice, the requirement could be met in a number of other ways as well.

As the economy continued to struggle in the 1990s, the state attempted to revitalize the tourism industry.[39] Its chief effort was to create the Hawaii Tourism Authority, which would be funded by a hotel tax (Mak 2008). The authority's first plan put forth in 1999 was to promote tourist arrivals, diversify the tourist product, and increase visitor spending per person per day. The latter meant offering higher quality tourism products and services, especially hotels and resorts. Some evidence on average spending for lodging and in total indicates that different islands took different paths, with Maui choosing the high end of the market (Mak 2008). Other evidence, notably the efforts to attract more Chinese tourists, suggests that maximizing tourist arrivals was still a higher priority than attracting higher-spending tourists.

The state and local governments took other actions as well, including the construction of a conference center in Honolulu, increasing funding for marketing, and adopting tax incentives to encourage hotel renovations and build a world-class aquarium (Grandy 2002). Each of these efforts appears to be an event or policy ripe for cliometric examination. Interestingly, Mak provides a narrative of what a counterfactual analysis would have to consider in order to assess one aspect of this government effort to revitalize tourism. He asks if the fairly large increase in spending on the promotion of tourism in 1999 was the reason for the rise in tourism that occurred afterward. But he then begs off answering the question, arguing that it is difficult to determine because there were too many factors that came into play. These included economic conditions in the US and Japan, the yen/dollar exchange rate, lingering effects of the Asian financial crisis, and crises yet to come, such as the September 11 terrorist attack in 2001 (Mak 2008).

Overall, Mak downplays the role of government plans and policies, in part because the government did not impose tight controls over tourism development. Land use laws were the chief means by which the government could control development, and that was not very inhibiting.[40] So, why was the private sector able to be so successful in an industry with substantial external benefits and costs? There seem to be two general reasons. Tourism planning brought all the stakeholders together, helped to inform residents about the role and value of tourism, and helped to form a shared vision for the state's tourism product. Perhaps more important and tangible is that some major private tourist developments in Hawaii have taken into account what we normally think of as externalities, such as preserving or enhancing scenic beauty. The internalization of these benefits was accomplished because of the high concentration of land ownership. Only 72 private owners controlled 46% of all the land in Hawaii. At the extreme, one company owned 98% of all the land on the island of Lanai; an island that was once a major producer of pineapples could, with little government involvement or regulation, be converted into one of the world's most exclusive resort destinations. The owners had incentive to do so because they could capture all the external benefits (Mak 2008).

[39]See Grandy (2002) for a discussion of these efforts.

[40]See Blackford (2001, esp. ch.3) for a discussion of land tax issues as well as Native Hawaiian land issues.

Conclusion

In the cocktail scene from *The Graduate*, a 1967 movie starring Dustin Hoffman, a friend of the family pulls the new graduate aside to give him advice about his future and says, "I want to say one word to you. Just one word. . ..plastics. . .there's a great future in plastics." Today, if they remade the movie, or at least that scene, the friend offering advice would more likely say – tourism! While not identified as an industry in standard industrial classifications, tourism today is an important economic activity in every country, and especially so in some. Although its importance is largely a post-World War II phenomenon, it has been around for centuries, so it has a long economic history. And yet, economic historians and cliometricians have not done much research in the area.

There is great potential for cliometric research in the field. For the period after the Second World War, data are becoming increasingly abundant as tourism's importance increases, so there is plenty of raw material to work with. There is a scarcity of data for the period before the War, but this is the sort of problem cliometricians love to tackle, both to expand the statistical database and to apply imaginative techniques to the sparse data.

Other economists have engaged in tourism research on topics of general interest, such as estimation of price and income elasticities and testing the validity of the hypothesis that tourism growth can generate broader economic growth. Although that work is not economic history, it has identified pertinent time series and data sources, and highlighted current issues that would benefit from a longer term historical perspective.

We also tried to demonstrate that there are interesting long-term studies to be done. We focused on the history of seaside tourism, which began with the rise of British seaside resorts and the subsequent shift of much of that market to the mass tourist resorts in Spain and elsewhere; and on the rise of tourism in Hawaii and its impact on the state's economy. In both cases, scholars have evaluated the appropriate measures of tourism, assessed the available data, and compiled pertinent statistics. Nevertheless, there is much that cliometricians could do. Quantitatively assessing the relative importance of the various factors that shaped the growth and distribution of the seaside resort industry is just one such example. There are also opportunities to conduct counterfactual analyses of tourism. Would Hawaii have prospered more if it had not shifted so heavily to tourism? Which British seaside resorts, if any, might have been better off without having entered the resort business?

There are many other topics in tourism history that we have not addressed, but which should appeal to cliometricians. What have been the consequences for labor productivity and wages of an economy's shift to tourism? What has been the impact on female labor force participation? Has a shift to tourism reduced or increased the likelihood of environmental damage? Can tourism growth be sustained indefinitely, or does it inevitably stagnate because of its impact on the resident population? In all its aspects, creating new databases, applying the latest statistical techniques to their analysis, and using economic theory, cliometrics is well poised to contribute to our knowledge of the tourism industry.

Technique and Measurement

Statistical Inference

Thomas Rahlf

Contents

Abstract

Statistical and, subsequently, econometric inferences have not undergone a cumulative, progressive process. We have seen instead the emergence of a number of different views, which have often been confused with each other in textbook literature on the subject. It therefore makes sense to approach the issue from a historical-scientific angle rather than a systematic one. We intend, using the extraordinarily complex development as a basis, to give a historical overview of the emergence of concepts that are of particular importance from the point of view of cliometrics. We shall start by describing the beginnings of modern probability theory, along with its connection with other statistical approaches.

C. Diebolt, M. Haupert (eds.), *Handbook of Cliometrics*,
https://doi.org/10.1007/978-3-030-00181-0_16

The following overview covers the basic principles of the current concepts of inference developed by R. A. Fisher on one hand and by J. Neyman and E. S. Pearson on the other. Neo-Bayesian approaches have meanwhile been developed in parallel, although they were not taken into account during the initial founding phase of econometrics. A "classic" approach was instead adopted in this respect, albeit with an additional difficulty: the taking into account of time. Cliometrics initially followed a Bayesian approach, but this did not finally prevail. Following on from econometrics, a correspondingly classic, inference-based position was adopted. This chapter concludes with a reference to a fundamental critique of the classic position by Rudolf Kalman, which we also find very promising as an inference-related concept for cliometrics. We often quote authors directly, in an effort to portray developments more vividly.

Introduction

Statistical inference possesses an ambivalence that is present in virtually no other field of science. Current doctrine is built up consistently on one hand (an impression furthermore reinforced an interdisciplinary examination of the relevant literature) across all disciplinary boundaries and along the same strictly schematic lines. The impression given is that it is a logically structured, self-contained edifice possessing universal validity. While the significance of individual methods can differ from subject to subject, their inherent statistical inference-related principles (with particular reference to the method of testing hypotheses and, more generally, assessment of the "evidence" supplied by statistical data) appear to be universally valid.

This was the objection expressed by Gerd Gigerenzer et al. (1989, p. 105f) regarding contradictory and illogical "hybridization":

> . . .scientific researchers in many fields learned to apply statistical tests in a quasi-mechanical way, without giving adequate attention to what questions these numerical procedures really answer.

A look "inside" the statistics gives a variegated impression. Certain quotations from the literature on statistics serve to illustrate the controversies within this area of science. Examples include R. A. Fisher (1956, p. 9), who stated, "The theory of inverse probability is founded upon an error, and must be wholly rejected." Von Mises (1951, p. 188) admitted, with reference to Fisher's "likelihood approach": "The many fine words that Fisher and his followers use to justify the likelihood theory are incomprehensible to me. The main argument [. . .] has nothing to say to me." A. Birnbaum, who brought up the likelihood concept in a widely read contribution to the likelihood principle as a fundamental basis of statistical inference, rejected the confidence principle developed by J. Neyman and Pearson on the grounds of its opposition to the likelihood principle (Birnbaum 1962; Neyman and

Pearson 1928a, b, 1933). He went on to reject the likelihood principle a few years later, however, precisely because of its opposition to the confidence principle.[1] Stegmüller (1973, p. 2) refers to Neyman, who had claimed that the test methods developed by Fisher "[. . .] were, *in a mathematically-definable sense*, 'worse than useless' [. . .]."[2] B. de Finetti (1981), one of the main representatives of a subjectivist theory of probability, was convinced that Fisher "[. . .] showed his feel for the necessity of a conclusion in Bayesian form (with the illusion of being able to express them with an indefinable 'fiducial probability'), with a desire to present the problem in a way that was opposed to the Bayesian approach (like Neyman, essentially)." L. J. Savage (1954), another important defender of a subjectivist approach, who wanted to incorporate into his influential book, *The Foundations of Statistics*, the conventional statistical inference methods developed by him as part of an axiomatic system of a subjectivist doctrine, wrote in the book's second edition: "Freud alone could explain how the rash and unfulfilled promise (made early in the first edition, to show how frequentist ideas can be justified by means of personalistic probabilities) went unamended through so many revisions of the manuscript."[3] O. Kempthorne (1971) finally characterized the various concepts of inference in a way that caused J. W. Pratt (1971 commentary, p. 496) to summarize Kempthorne's theses as follows: "Fiducial and structural methods are nonsense. Jeffrey's Bayesian and subjective Bayesian methods are nonsense. Likelihood methods are nonsense. He doesn't say directly that orthodox methods are nonsense, but he says it implicitly by his remarks [. . .]. In short, he says all methods are nonsense, therefore use orthodox methods." This list could easily be extended, but the impressions given should suffice.

Probability and Inference in Statistics

We would like to start by giving a broad-brush description of how the central concepts have developed.[4] The following milestones mark the most important steps along the way:

Historical milestones in the field of statistical inference

1700–1730	The first systematic definitions of the terms "probability" and "chance" (G. W. Leibniz, J. Bernoulli) and the attempt to arrive at statistical inference (as a conclusion) from probability theory (J. Bernoulli)
1750–1775	Inversion of the probability concept in connection with the error function of Laplace
	Inversion of the probability concept in connection with Bayesian binomial distribution

(*continued*)

[1] Cf. Birnbaum (1962, 1968, 1977).

[2] Original author's italics.

[3] Quoted from DuMouchel (1992, S. 527). The first edition was published in 1954. Cf. Savage (1954).

[4] A detailed treatment of the topic of this chapter can be found at Rahlf (1998) and Gigerenzer/Swijtink/Porter/Daston/Beatty/Krüger (1989).

Around 1810	Synthesis of error function and probability by P. S. Laplace and C. F. Gauss
1820–1840	The further development of statistical inference concepts (law of errors, law of large numbers) and their incorporation into the "social physics" of A. Quetelet
1870–1885	The incorporation of Quetelet's concepts into biology by F. Galton and the conceptual foundation of correlation and regression
1840–1870	Philosophical investigations into the concept of probability (as a parallel development)
1880–1895	The systematization and formalizing of statistical inference concepts by F. Y. Edgeworth and K. Pearson
1895–1900	The application of these systematized concepts of statistical inference to social science data and development into multiple regression by G. U. Yule
	Attempts by K. Pearson and G. U. Yule to clarify the concepts of correlation, spurious correlation, and causality
Around 1900	The concept of the significance test is developed by K. Pearson
1929/1930	The criteria of "good" valuations postulated by R. A. Fisher, a quantitative assessment of the quality of these valuations using the fiducial principle also developed by Fisher
1933	"Classic" test theory and confidence inference according to J. Neyman and E. S. Pearson
1926–1954	Subjectivist Bayesian approaches, such as those of F. P. Ramsey, B. de Finetti, H. Jeffreys, or L. J. Savage
1955	Objectivist Bayesian approaches, such as those of H. Robbins
1949/1962	The likelihood principle developed by Fisher and expanded by G. Barnard and A. Birnbaum

The theory of probability was regarded as something of a "brainteaser" until the middle of the seventeenth century, in the sense of pure combinatorics. The chance of rolling a certain dice number, of a tossed coin falling on one face or the other, or of drawing a particular card from the pack could be indicated without any profound philosophical consideration of the nature of probability. The probability of, for example, tossing a coin ten times and having it come up "heads" four times and "tails" six was to be determined by a combination of purely mathematical considerations, as a coin-tossing "experiment" could be based on a fully specified theoretical model: The events are mutually independent, thus making their sum binomial, the parameter being $\pi = 0.5$.

The questions that arose in a socioeconomic context at this time were, however, only apparently of the same nature. Even variables such as overall gender ratio, life expectancy, infant mortality rates, the proportion of the population available for military service, etc., were considered legitimate in this respect. But how was one to assess the *reliability* of the results obtained?

It was decisive that studies like those carried out by J. Graunt (1662 [1939]) of the register of deaths in London or by E. Halley (1693) of births and deaths in Breslau (present-day Wroclaw) attracted the attention of mathematicians such as G. W. Leibniz, J. Bernoulli, or A. de Moivre, thereby obliging those concerned to

consider the problem of inference. The proportion of people possessing a certain characteristic was unknown, as long as the characteristic concerned could not be computed for a given (sub)population. A possible entitlement to apply the binomial model existed, but there was definitely no theory capable of postulating a value for the parameter that was to be verified. Furthermore, this value could only be determined on the basis of the data and a measure indicated – by means of an interval – for the accuracy of the "estimate." An *inversion* of probability was therefore necessary, although neither Bernoulli nor de Moivre was able to complete this step. We follow S. Stigler at this point while assuming that the conceptual difficulties could be overcome only via the detour of the error function, ultimately by T. Bayes and P. S. Laplace. This "Copernican Revolution" in the development of theoretical statistics[5] was connected with the intention of Bernoulli. It is somewhat curious that this concept is nowadays associated with Bayes rather than Laplace. Bayes had a groundbreaking idea that was nevertheless developed at the same time and, presumably independently, by Laplace. However, Laplace had also constructed a systematic theory of probability that went on to form the basis for a number of applications over many years. The key statisticians (Gauss, Galton, and Edgeworth) subsequently followed a mainly Bayesian line of argument. The most probable parameter value for Gauss, for example, was the maximum of the likelihood function, since it emanated, as it also did for Laplace, from the principle of insufficient reason and thus from an a priori uniform distribution. K. Pearson meanwhile followed a (mostly) sampling-based approach however, and G. U. Yule worked within the same framework, albeit without attributing much importance, in general, to the question of inference.[6]

K. Pearson and G. U. Yule

The works of K. Pearson were of great significance for the further development of statistical inference. Pearson's first independent contribution to the field of statistics, which formed the basis of his subsequent fame, consisted of a system of frequency distributions included in two extensive papers published in the *Philosophical Transactions of the Royal Society* under the title *Contributions to the mathematical theory of evolution* (1894, 1895), which led to him being elected a fellow of the society. The question regarding the form of frequency distributions had been a fundamental issue since the end of the eighteenth century. There was a prevailing general belief that individual phenomena, which were homogeneous in the sense of many individually insignificant influencing factors, had to follow a normal distribution. Not everyone regarded normal distribution as being universally valid however, and collections of data that accumulated over the years implied a series of "skewed" distributions. Pearson above all regarded this fact as a challenge, and he eventually developed a

[5] Stigler (1986, p. 122).

[6] See, for example, Yule (1895, 1896a, b) and Pearson (1898).

"family" of curves, each based on four parameters, by which data could be assigned to different types of curve using their first four moments.

Pearson supplied not only the formulae but also a wealth of practical examples (distribution of air pressure, heights of schoolchildren, and sizes of crustaceans; statistics on poverty and divorce rates; etc.) and showed that these variables could be reconciled to a large extent by using his system. He went even further than Quetelet in this respect. It was not only data with a normal distribution that followed a uniform distribution law, without a need to isolate groups or major factors, but also many others whose distribution was in fact skewed but no less legitimate in this respect. If this were the case, the search for causative factors, as introduced by Galton as part of biology, was invalid:

> The law of frequency is based on the assumption of perfect ignorance of causes, but we rarely *are* perfectly ignorant, and where we have any knowledge it ought of course to be taken into account.[7]

The further application of Pearson to areas that are not necessarily closely subject to a law of constant distribution has been criticized[8]:

> [. . .] I see that there are many cases of 'skew' variation: but all cases which he has given, of variation with an unmistakably skew frequency, are taken from phenomena which are changing with a rapidity much greater than that of any organs in crabs, or such creatures. Pauperism, divorces, and the like, have only been invented, in their present form, for a short time, and as he himself shows, the maximum frequency changes its position at least in ten years.[9]

But the most important counterargument was that the numerous forms that could be adapted using Pearson's frequency curves lacked a theoretical foundation, as they were purely empirical constructs. If a frequency distribution did not lend itself to being represented by a normal distribution, the concept of causation based on a large number of random causes could not be effective. It is precisely this last point that was however, according to Stigler (1986, p. 339), likewise not the intention of Pearson, who was seen to represent a philosophy of science that had been guided by Kantian nominalism. On this basis, Pearson regarded frequency curves only as mental constructs that summarize empirical evidence, without providing any statements on possible causes. Pearson nevertheless also searched in this respect for a formal criterion for assessing deviation in the empirical distributions of his frequency curves and finally found one in the form of his chi-squared (χ^2) test, which he made public in 1900.

[7] F. Galton in a letter to K. Pearson of 18 Nov 1893, quoted by Stigler (1986, p. 336). Original author's italics.

[8] Despite criticism, Pearson's frequency curves soon became part of the standard repertoire of statistics.

[9] W. F. R. Weldon in a letter to F. Galton of 27 Jan 1895, quoted by Stigler (1986, p. 337).

Pearson made another important contribution to modern statistics in the field of correlation. He considered two variables with a normal bivariate distribution, deduced the correlation coefficient and a posteriori distribution[10] (on the basis of empirical standard deviations), and systematized the findings obtained to date. The theoretical derivation was followed by a series of applied examples, which he took from Galton. He did not admit any major possibilities regarding the application to social phenomena:

> Personally I ought to say that there is, in my own opinion, considerable danger in allying the methods of exact science to problems in descriptive science, whether they be problems of heredity or of political economy; the grace and logical accuracy of the mathematical process are apt to fascinate the descriptive scientist that he seeks for sociological hypotheses which fit his mathematical reasoning and this without first ascertaining whether the basis of his hypotheses is as broad as that human life to which the theory is to be applied.[11]

This move was finally made by Pearson's student G. U. Yule in a series of studies of Poor Law legislation. One important question in this respect was the extent to which the proportion of poor people in a given district was connected with its structure of care provision. Yule (1895, 1896b) found a "significant" link, which he nevertheless described as "suggestive," as the distributions of both variables were clearly shown to be skewed. In a subsequent step, he established a "regression line" between the two variables by minimizing the distances between this straight line and the data concerned. He perceived that this approach was easy to extend to higher dimensions, thereby leading to the "normal" system of equations that had been introduced by Gauss several decades earlier in the field of astronomy. From here, it was merely a technical matter, no longer requiring any conceptual step, to extend the approach to more than two variables.

Irrespective of the different views held by K. Pearson and Yule in this context regarding the concepts of correlation and causality, the general question surrounding all these considerations was the following: Did inference refer to a *population* or to *laws*? This was clear in Pearson's case and also, subsequently, in that of Fisher. The aim of studying biological data was to investigate conformity to natural laws. The situation was more difficult when it came to the investigations of socioeconomic data carried out by Yule or studies, such as those of Gosset, of the correlations between

[10]K. Pearson explicitly rejected the concept of inverse probability, although E. S. Pearson was of the view that he implicitly followed this approach on at least one occasion. Cf. Pearson (1898). "The basic of the approach used here is a little obscure and there seems to be implicit in it the classical concept of inverse probability" (Pearson 1967, p. 347), quoted by Dale (1991, p. 379). Pearson expressed himself most extensively on this issue in his paper *The fundamental problem of practical statistics* (1920), which has provoked different interpretations up to the present day. While Fisher (1922, p. 311), for example, believed he recognized a proof of Bayes' theorem in it, Dale (1991, p. 388) considered this as a "totally inaccurate observation." For further interpretations, cf. ibid., pp. 377-391. According to Stigler (1986, p. 345), Pearson worked on multiple occasions "[. . .] (implicitly) in a Bayesian framework."

[11]Pearson (1898, p. 1f), quoted by Stigler (1986, p. 304).

cancer rates and apple consumption, which included at least one exploratory element.[12] The interpretation of a correlation coefficient could only be hypothetical according to Yule, as it was normally possible to give a variety of alternative explanations whose distinction could not be provided by statistics. This problem would prove to be fundamental for statistical inference-based interpretations in the field of social science.

R. A. Fisher

The further development of statistical methodology in the field of biology has been characterized, since at least the time of Karl Pearson and R. A. Fisher, by the possibility of its application to the natural sciences. Fisher (1955, 1956, 1959) attempted to solve, by means of his *Design of Experiments*, the problems of inference-based conclusions in biology caused by their dependence on the conditions that prevail when taking samples.

Fisher's concept of inference was initially characterized by its explicit rejection, directed against Pearson in particular (in 1922), of inverse probability. This view was mainly due, in his opinion, to the confusing of theoretical parameters and estimates:

> It is this last confusion, in the writer's opinion, more than any other which has led to the survival of the present day of the fundamental paradox of inverse probability, which like an impenetrable jungle arrests progress towards precision of statistical concepts.[13]

He nevertheless developed a certain understanding at the same time:

> The criticisms (. . .) have done something towards banishing the method, at least from the elementary text-books of Algebra; but though we may agree wholly (. . .) that inverse probability is a mistake (perhaps the only mistake to which the mathematical world has so deeply committed itself), there yet remains the feeling that such a mistake would not have captivated the minds of Laplace and Poisson if there had been nothing in it but error.[14]

Although Fisher's concept of probability was frequentist, he vehemently rejected a definition of probability as a limit value applying to relative frequency in an unlimited number of repeated attempts (i.e., the von Mises definition subscribed to

[12]Cf. ibid., p. 373.

[13]Fisher (1922 [1992], p. 13), similar also to Fisher (1959, p. 34). There is in the case of Fisher (1956, p. 9) a (more or less) clear rejection of the Bayesian approach. He emphasized that he was "personally convinced" that "the theory of inverse probability is founded upon an error, and must be wholly rejected."

[14]Fisher (1922 [1992], p. 13). Ambiguities such as these are characteristic of Fisher's work. According to Geisser (1992, p. 4), Fisher subscribed – until at least 1912 – to approaches based on Bayesian logic. He then (p. 26f) explicitly rejected the validity of Bayes' theorem. Cf. Barnard (1988) regarding this question.

by most frequentists)[15]: "For Fisher, a probability is the fraction of a set, having no distinguishable subsets, that satisfies a given condition [. . .]."[16]

Fisher postulated that statistical inference should refer to theoretical, and thus fixed, parameters of hypothetically infinite populations, thereby determining the direction of research in the field of theoretical statistics for the following 50 years.[17] Otherwise, his concept of a statistical or "scientific" inference could not prevail. He used the term "inductive logic," not at least in order to set himself apart from the approach of his intellectual rival J. Neyman, who spoke of "inductive behavior."[18] It was possible, in cases where there was an indisputable a priori distribution, to speak of the probability of events, which were to be described as fiducial probabilities.[19] Intervals that express the uncertainty of an estimate were always to be construed as fiducial intervals.

The problem of the "significance test" is closely connected to the problem of using intervals to indicate the accuracy of an estimate. What we now understand as the logic of the significance test became increasingly important during the first two decades of the twentieth century.[20] It can largely be traced back to Fisher and has remained in force alongside the concept of the hypothesis test developed by Neyman and Pearson (see below). For Fisher, the level of significance of a test is a *measure of evidence*, which should neither be defined a priori nor regarded as unalterable, nor established as a guiding principle:

> A man who 'rejects' a hypothesis provisionally, as a matter of habitual practice, when the significance is at the 1% level or higher, will certainly be mistaken in not more than 1% of such decisions. For when the hypothesis is correct he will be mistaken in just 1% of these cases, and when it is incorrect he will never be mistaken in rejection. This inequality statement can therefore be made. However the calculation is absurdly academic, for in fact no scientific worker has a fixed level of significance at which from year to year, and in all

[15]See supporting evidence in Savage (1976, p. 461). In Fisher (1959, p. 32), he emphasized, for example, that no probability of individual events could be established with such a definition.

[16]Savage (1976, p. 461) with corresponding supporting evidence. Savage observes in this respect: "Such a notion is hard to formulate mathematically, and indeed Fisher's concept of probability remained very unclear, which must have contributed to his isolation from many other statistical theorists" (p. 462).

[17]Cf. Geisser (1992). Partly ambiguous terms such as "mean," "standard deviation," or "correlation coefficient" have remained in use to this day to indicate, in various contexts, either theoretical variables or estimators for these theoretical variables.

[18]Cf. Savage (1976, S. 462) with supporting evidence.

[19]Ibid., p. 466: "Nobody knows just what they mean [. . .]. In a word, Fisher hopes by means of some process – the fiducial argument – to arrive at the equivalent of posterior distributions in a Bayesian argument without the introduction of prior distributions [. . .]." We would like to join in with this criticism. As observed by Menges (1972, p. 275): "The fiducial concept considers the results of an observation as indisputable fact in this respect, and as the basis on which to build inference. *It can thus do justice, in principle, to the historical character of social phenomena*" (original author's italics), although this also applies to Bayesian logic in our opinion.

[20]Such as Pearson's chi-squared goodness-of-fit test of 1900, Student's *t*-test, developed in 1908 and formalized by Fisher, or the *F*-test applied to the analysis of variance by Fisher.

> circumstances, he rejects hypotheses; he rather gives his mind to each particular case in the light of his evidence and his ideas.[21]

This criticism was directed against a concept that had been propagated by J. Neyman and E. S. Pearson since the 1930s and which had quickly become the dominant view.

J. Neyman and E. S. Pearson

The works of J. Neyman and E. S. Pearson are likewise unanimously considered to be milestones in the history of theoretical statistics. While Fisher wished to allow, in relation to the testing of hypotheses, only the alternatives "rejection" and "no statement possible," Neyman and Pearson developed a closed test theory which introduced differentiated levels of rejection and acceptance, along with concepts such as the "power" of a test, Type I and Type II errors, and "uniformly most powerful test." Until the end of the nineteenth century, the testing of hypotheses was based on distributions of test statistics which were (1) best suited for use with large samples and (2) employed for intuitive reasons. The introduction of the *t*-distribution by W. S. Gosset (1908) and the contributions of R. A. Fisher, who differentiated the exact distributions of t, χ^2, F, and certain correlation coefficients in normal distributions, meant that at least problem (1) could be overcome. With this problem solved, the question then posed was that of a formally satisfactory test *theory*. E. S. Pearson stated in a review that the idea for this theory came to him via an observation made by Gosset:

> I had been trying to discover some principle beyond that of practical expediency which would justify the use of "Student's" ratio $z = (-m)/s$ in testing the hypothesis that the mean of the sample population was at m. Gosset's reply (to the letter in which Pearson [...] had raised the question) had a tremendous influence on the direction of my subsequent work, for the first paragraph contains the germ of that idea which has formed the basis of all the later joint researches of Neyman and myself. It is the simple suggestion that the only valid reason for rejecting a statistical hypothesis is that some alternative hypothesis explains the observed events with a greater degree of probability.[22]

Gosset argued in this letter that not even a probability value as small as 0.0001 could lead per se to rejection of a hypothesis for a random sample. Only comparison with an *alternative* hypothesis, "which will explain the occurrence of the sample with a more reasonable probability, say 0.05 (such as that it belongs to a different

[21] Fisher (1959, p. 41f). Fisher's failure to include tables of *p*-values in his famous textbook *Statistical Methods for Research Workers* (rather than the tables of significance values that he *did* include) arose from the fact that K. Pearson held the copyright to the former. Cf. Watson (1983, p. 714).

[22] Pearson in a paper from 1939 quoted from Lehmann's comments (1992, p. 68) on Neyman/Pearson (1933) (our italics).

population or that the sample wasn't random or whatever will do the trick) you will be very much more inclined to consider that the original hypothesis is not true."[23]

This idea was then jointly developed by Neyman and Pearson (1928a, b) in an extensive two-part paper, published in *Biometrika*, on the concept of the likelihood ratio test. While Pearson now saw in this the uniform method for which they had been seeking, Neyman was clearly still not satisfied:

> It seemed to him that the likelihood ratio principle itself was somewhat ad hoc and was lacking a fully logical basis. His search for a firmer foundation, which constitutes the third of the three steps, eventually led him to a new formulation: The most desirable test would be obtained by maximizing the power of the test, subject to the condition that under the hypothesis, the rejection probability has a preassigned value, the level of a test.[24]

The result was Neyman and Pearson (1933), which also includes the famous Neyman-Pearson lemma. This states that in the class of all tests with probability α, the criterion function of the likelihood ratio test dominates the criterion function of any other test (i.e., every other test has a greater probability of including a Type II error). Neyman and Pearson used a series of examples to demonstrate the application of this principle and thus laid the foundation for a widely recognized general test theory which today continues to be regarded as "classic," along with the "confidence interval" likewise formulated by Neyman (1937). The method based on Neyman-Pearson logic can be described, after Lehmann, in terms of four steps[25]:

1. Specification of a model using a parametric family of distributions which has produced the data
2. Specification of a hypothesis with regard to a parameter of interest, H_0: $\theta = \theta_0$, and one simple or one class of alternatives H_1, e.g., $\theta \leq \theta_0$
3. Specification of a level of significance α, indicating the maximum allowable probability of a Type I error
4. Selection of the optimum method for testing H_0 against H_1 by minimizing the ß-error[26]

Lehmann finally added a – quite fundamental – fifth item, but this is more of a prerequisite than a procedure:

1. All (four) steps must be completed "before any observations have been seen."

[23]Ibid.

[24]Lehmann (1992, p. 68). This highly important aspect of the Neyman-Pearson theory is often not taken into account. As Borovcnik (1992, p. 92) rightly points out, "[. . .] a frequency interpretation places too much emphasis on the α-error during testing, while the real trick with this method is to minimise the ß-error."

[25]According to Lehmann (1992, p. 69f).

[26]We do not intend to go into the corresponding techniques here but refer instead to textbook literature on the subject.

The approach postulated by Neyman and Pearson actually amounted only to a set of *guidelines*. The two authors expressed, as follows, the conviction that lay behind their theory:

> Without hoping to know whether each separate hypothesis is true or false, we may search for rules to govern our behaviour with regard to them, in following which we insure that, in the long run of experience, we shall not be too often wrong.[27]

Inference statements are therefore hypothetical-deductive and only possible *before* events occur. They therefore do not refer to specific hypotheses but to future *actions* in the long term. This approach was consequently extended by A. Wald (1950) to form a pure decision theory, with Neyman repeatedly emphasizing this behavior theory aspect in his later work.

There was however vehement criticism from no less a person than R. A. Fisher, who might have wished to recognize the Neyman-Pearson theory for situations where permanent decisions had to be taken but was in no way willing to accept statistical inference-based assessments in a *scientific* sense. A further argument concerned the claim of "repeated sampling *from the same population*." Fisher pointed out, following on from J. Venn, that a given sample could always have resulted from a variety of conceivable populations: "so [. . .] the phrase 'repeated sampling from the same population' does not enable us to determine which population is to be used to define the probability level, for no one of them has objective reality, all being products of the statistician's imagination."[28]

These approaches were met with further reservations: On one hand, models would mostly be chosen *in practice* on the basis of data while often examining not just one but several hypotheses using the same data. In many situations, the eventual reduction of inference to a yes/no decision was not appropriate.

It has furthermore been demonstrated that optimum (i.e., uniformly most powerful) tests exist only for limited situations or are so complex (when maximizing their minimum power) that their application presents considerable problems. It should however be emphasized that these reservations are the exception and that an overwhelming majority has, particularly in the field of applied statistics, unconditionally accepted the Neyman-Pearson approach, which has become something of a paradigm, even though today's statisticians continue to argue about where the precise differences between this approach and Fisher's test concept lie.[29]

If we compare this approach to that of Fisher, point 5 (see above) becomes particularly decisive. The method according to Neyman and Pearson is therefore strictly deductive, while Fisher's approach is (also, at least) inductive, with assessment taking place only after obtaining evidence based on data and above all without

[27]Neyman/Pearson (1933 [1992], p. 74). Kyburg (1985, p. 119) sums up their intention in the observation: "That says nothing about the case before us, but it may make us feel better."

[28]Fisher (1955, S. 71).

[29]Cf. Lehmann (1993), for example.

considering an alternative hypothesis. Neyman and Pearson surely did not intend to promote a universal and constant level of significance but rather only in this sense: Even if they allow for different levels in different situations, these must be determined *before* the experiment and/or *before* obtaining any knowledge of the data evidence. The second fundamental difference lies in the *direction* of the inference. Fisher's test concept – and, in this respect, K. Pearson's logically equivalent significance test concept – applies to a state that exists or which, strictly speaking, may already have passed. The inference of Neyman and Pearson, on the other hand, applies to the future: If we act in one way or another in the future on the basis of the test, how often are we then likely to commit an error? The current practice is in fact to apply a blending of both concepts.[30]

Statistical inference was now reduced to the creation of guidelines for conduct in the long term. No contentious epistemological issues were settled using the Neyman-Pearson theory; it related only to a clear statement. Its success can perhaps also be explained by the fact that other positions (K. Pearson, Fisher) lacked such clarity.

The dominant approach since then has in any case been a supposedly objective, frequency-theory, and inference-based position, although a modern, Bayesian, statistical inference has continued to develop in parallel. It is remarkable that modern, subjectivist probability theory was not established by social scientists, who regarded as problematic its individual prerequisites or implications with regard to long-term experimental inference, but – without exception – by mathematicians (Ramsey, de Finetti, Savage) or geophysicists (Jeffreys) who saw problems of logic in the predominant frequency theory-based approaches.

This development took place in three stages: the reestablishing, by F. P. Ramsey, B. de Finetti, H. Jeffreys, and L. J. Savage, of Bayesian probability theories; the expanding, by G. A. Barnard and especially A. Birnbaum, of various likelihood-based approaches to form a likelihood *principle*; and finally the combining of these two components to create a modern Bayesian inference, which has come to exist in numerous forms. The following section considers at first the development of subjectivist probability theories.

Bayesian Probability

These are based on the following three basic assumptions, according to Howson (1995, p. 2):

[30]Johnstone (1986, p. 6) aptly describes the prevailing approach: "In general, tests of significance in practice follow Neyman formally, but Fisher philosophically. Formally, there is mention of 'alternative' hypotheses, errors 'of the second kind', and the 'power' of the test, which are terms due to Neyman (and his colleague Pearson). But philosophically, the result in a test, e.g. the result that the level of significance P equals 0.049, or that P is less than or equal to 5%, is interpreted as a measure of evidence, which is the interpretation following Fisher, and denied repeatedly by Neyman."

1. A hypothesis A is, in extreme cases, certainly true or certainly false. Intermediate degrees of belief in A are permitted.
2. These degrees of belief can be expressed numerically.
3. If they are rational and measured against the closed unit interval, they satisfy the finite additivity axioms.

The subjectivist Bayesian concepts of F. P. Ramsey, B. de Finetti, H. Jeffreys, and L. J. Savage were developed successively but independently of each other. We will now deal with them briefly in chronological order.

The first "modern" subjectivist probability theory was established by F. P. Ramsey in papers written in 1926 and 1928 but published posthumously in 1931.[31] As we have seen, the epistemological conception of probability from Bernoulli to Laplace was subjective as well as in the case of Gauss, Galton, and Edgeworth: "Probability" was interpreted by C. Huygens in terms of betting odds, with chance defined as ignorance. The principle of insufficient reason implied an a priori uniform distribution, which was linked, via Bayes' theorem, to the evidence from data in form of an a posteriori probability for a given parameter value.

Ramsey argued along similar lines, albeit combined with a critique of the logical and frequency theory-based interpretation. His starting point was John Maynard Keynes' *Treatise on Probability* (1921). For Keynes, probability meant a logical relationship between two different sets of propositions that are interconnected via a "degree of belief":

> Let our premises consist of any set of propositions h and our conclusion consist of any set of propositions a, then if a knowledge of h justifies a rational degree of belief in a of degree A, we may say that there is a probability-relation of degree A between a and h.[32]

Keynes did not however require all degrees of belief to be numerically measurable or comparable, thereby avoiding major difficulties. Ramsey postulated instead that probabilities should be expressed as betting odds, which must be rational (i.e., consistent and coherent). Ramsey's observations were of a purely philosophical nature and did not constitute a concept of *inference*. This was supplied in a famous paper by Bruno de Finetti (1937). It was totally clear to Finetti that the basis of all probability was subjective in nature.[33] Bayes' theorem was of central importance in this respect: Subjective assessments/probabilities must be revised constantly in the light of Bayes' theorem on the basis of data and knowledge obtained. This meant that subjectivist probabilities converge to relative frequencies as evidence accumulates. De Finetti did not criticize classical statistics for false results but for its false foundations:

[31] Ramsey (1931a, b).

[32] Keynes (1921, S. 4), quoted by Kyburg/Smokler (1964, p. 9).

[33] Cf. de Finetti (1937).

> The overwhelming majority of modern statistics are in practice completely normal, but their foundations are false. Intuition has however prevented statisticians from making mistakes. My thesis is that the Bayesian method justifies what they have always done, and that they are developing new methods which are missing in the orthodox approach.[34]

Harold Jeffreys (1939) argued along similar lines. He combined a probability theory with a theory of induction. Jeffreys stressed (like de Finetti) that a fundamental problem of science lay in learning from experience:

> Knowledge obtained in this way is partly merely description of what we have already observed, but partly consists of making inferences from past experience to predict future experience. This part may be called generalization or induction. It is the most important part; events that are merely described and have no apparent relation to others may as well be forgotten, and in fact usually are.[35]

It therefore follows that probability is not a frequency but a "reasonable degree of belief, which satisfies certain rules of consistency and can in consequence of these rules be formally expressed by numbers."[36] If an explanation is given for an observed event, a researcher might determine that it is "probably true." It is thus implied that he has a high degree of confidence in a hypothesis, which is in turn (1) quantifiable and (2) based on experience and information.[37] A rule now states how the cognitive process should operate: This is none other than Bayes' theorem. In every probability to which we assign a hypothesis, that hypothesis is conditioned by the information available to us. If this changes (increasingly), the probability associated with the hypothesis must be revised accordingly. This approach is what constitutes the basis of learning from experience, which is formalized using Bayes' theorem: A posteriori probabilities result from the evaluation of a priori probability with the data evidence, using the likelihood function.

L. J. Savage was another important forerunner of modern Bayesian probability theory. Savage, who was influenced mainly by Milton Friedman and John von Neumann, formulated his concept of probability in the late 1940s/early 1950s, on the basis of a utility theory. The year 1954 saw the publication of his seminal work *The Foundations of Statistics*, in which he tried to arrange within a unified framework the (in his view) rather loosely connected set of techniques developed by R. A. Fisher and J. Neyman/E. S. Pearson, intended to be based on a theory of decision-making under uncertainty. However, an examination of the details showed that the venture was doomed to failure. H. E. Robbins (1955) took a different path. He postulated probabilities that were "objective" and a priori rather than epistemic. He started with the question as to whether one could apply the Bayesian approach even if the a priori probability of a parameter is unknown but nevertheless "exists." This

[35] Jeffreys (1939, p. 8).

[36] Ibid., p. 401.

[37] Although the hypothesis can still be false in terms of rule 4.

supposition of an objectively existing a priori probability is not shared by most Bayesians however nor is it, in a positive sense, required.

Bayesian Inference

We have, in the case of the Bayesian works cited above, placed the issue of probability in the foreground. But there is a second Bayesian inference: the likelihood element. Approaches to likelihood initially emerged independently of Bayesian concepts. The likelihood ideas created by Fisher were further developed mainly by G. A. Barnard.[38] These ideas were given a basic theoretical foundation by the pioneering work of A. Birnbaum, who developed them into a likelihood *principle* (LP).[39] By this time, the field of statistics was already being dominated by the Neyman-Pearson approach and its decision theory-based further development by A. Wald (1950).

The likelihood principle had radical consequences. It stated that all the evidence from data was contained in the likelihood function. This made the sample space irrelevant, *after* the data had been obtained. It means that measures of evidence referring to the space of all possible data (i.e., the probability or parameter space), such as p-values or the confidence level, are irrelevant to inference *after* a given piece of data has been created. This was otherwise a rejection of the frequentist position, without having to resort to Bayesian arguments.

Let us now turn to the linking of a priori probabilities and likelihood inference to Bayesian inference. The Bayesian breakthrough eventually succeeded, in practical terms, with a paper by W. Edwards, H. Lindman, and L. J. Savage (1963), which finally made the corresponding approaches available to a wider public.[40]

Edwards, Lindman, and Savage dealt with the main reservations affecting the Bayesian approach, such as how scientific objectivity could be possible if different scientists held different a priori views, thereby creating different a priori probabilities (and probability distributions).[41] They did not bring in the argument proposed by Laplace and Edgeworth[42] (whereby an increase in the range of data causes the influence of a priori distribution to diminish progressively, before eventually disappearing altogether) but opted rather for the question as to whether an a priori distribution can be assumed to be uniform or whether the exact form of the a priori distribution is of no great importance to a posteriori distribution. They showed that "it suffices that your actual prior density change gently in the region favored by the

[38]Barnard (1947, 1949). For historical development, see Berger/Wolpert (1988, p. 22ff).

[39]Birnbaum (1962). Cf. also Bjornstad (1992) on the following. A "standard" work on the subject is that of Berger/Wolpert (1988).

[40]Edwards/Lindman/Savage (1963 [1992]). Our intention from here on is to deal only with certain ideas without going into technical detail.

[41]Ibid., pp. 534–540.

[42]For example, Laplace (1812) and Edgeworth (1884).

data and not itself too strongly favor some other region."[43] These vague indications were then given a mathematical form, thereby showing that such an approach is indeed justified under somewhat weak assumptions.[44]

The authors did however acknowledge, on the other hand, that there are also situations where the exact characteristics of a priori distribution are decisive.[45]

The following includes a section on "Bayesian hypothesis testing." If an alternative to the prevailing classical statistics was to be provided (and this was their claim), this would also have to include such a central aspect as the testing of scientific hypotheses.[46] They started by clarifying the terms "odds" and "likelihood ratios." Using the example of checking to see if a dice is "fair," the application of likelihood ratios in a Bayesian sense was then compared to the classic approach of Neyman/Pearson (see above). They paid particular attention to clarifying the problem whereby classical statistics favored a consideration of Type I and Type II errors on the basis of this test variable:

> The interesting point is made that a Bayesian hypothesis test can add extensive support to the null hypothesis whenever the likelihood ratio is large. The classical test can only reject hypotheses, and it is not clear just what sort of evidence classical statistics would regard as a strong confirmation of a null hypothesis.[47]

We would like to avoid going into the – mostly highly technical – details in this respect. Solutions have meanwhile been found for numerous individual problems and fundamental questions, such as the Bayesian interpretation of frequency theory-based points of view, purely empirical Bayesian approaches, or even a theory of Bayesian data analysis.

One important issue in this context is the assessment of significance tests and confidence intervals.[48] The use of significance tests in their frequency theory-based sense enjoys wide support from a number of Bayesians for use as a heuristic tool, while others reject this approach. If a priori information is lacking, the confidence intervals of classical statistics and the Bayesian probability intervals may be almost numerically identical. They should, however, be interpreted in totally different ways.[49] In the classic, frequentist interpretation, a confidence interval of 95% means that, with the indicated (identical) sample ranges n for $m \to \infty$ (where m is the number of samples), 95% of intervals cover the true, unknown, fixed parameter

[43]Ibid., p. 541. This is referred to as "stable estimation."

[44]DuMouchel (1992, p. 521) points out that this approach is closely related to the "reference priors" subsequently proposed by other Bayesians for use in situations where little a priori information is available, which are also acceptable to classical statisticians.

[45]Edwards/Lindman/Savage (1963 [1992], p. 546).

[46]Bayesian literature does not adopt a uniform position regarding the need for a test theory.

[47]DuMouchel (1992, p. 523). Cf. example no. 3 in appendix A3 and also example no. 2 in appendix A4.

[48]General reference is made to Hodges (1990) in this respect.

[49]The following according to Iversen (1984, p. 31).

and 5% do not. We do not know however (and can only hope) whether the specific interval concerned covers the parameter or not. A Bayesian analysis assumes, in contrast, that the unknown parameter has an (usually subjective) a priori distribution. There is still uncertainty after the data have been obtained, but less so than in the previous case. This uncertainty is still expressed in probabilities but with a wholly different interpretation: The parameter θ lies, with a probability of 95%, between the two values c_u and c_o. Such an interpretation is not possible in terms of classical statistical inference,[50] although misleading interpretations of this Bayesian epistemology can still be found to this day in classic literature on the subject.

The alternative definition of the concept of probability is fundamental, regardless of individual formulations. In order to highlight better the contrast with the classic approach, we should first turn to the classic concept of probability and its weaknesses.

W. Stegmüller counts eight objections, put forward in literature on the subject, to the frequency theory arising from von Mises' definition,[51] regarding at least the last of them as "deadly": He confuses practical certainty with logical necessity.[52] A particular weakness of this concept of probability was seen to lie in its rejection of individual probabilities. According to von Mises' definition, it was impossible, for example, to indicate the probability of a certain throw of a particular dice at a particular location.

K. R. Popper (1990), for example, one of the most vehement opponents of subjectivism, used this problem to develop his own concept of probability (mainly related to the problems of physics) which evolved over the years into a so-called propensity theory.

No agreement has been reached up to the present day (nor is such a clarification likely to be achieved in the near future) about the final definition of probability, as, for example, C. Howson established:

> It would be foolhardy to predict that philosophical probability has entered a final stable phase; surveys of the field tend to have useful lifetimes of a decade or so, at most two. It would also probably be incorrect to pretend that there is likely in the near future to be any settled consensus as to which interpretations of probability make viable and useful theories, and which are dead ends.[53]

Bayesian concepts of inference are however not limited to a subjective element that formalizes a priori probability but link it, by means of Bayes' theorem, with the "evidence of the data," which is in turn formalized in the likelihood function. The likelihood function already played an important role for Bernoulli, Laplace, and Gauss. Its importance as a central element of statistical inference was emphasized by

[50]Ibid: "This is the way many users of confidence intervals want to interpret a confidence interval, but in classical statistical inference such an interpretation is not possible."

[51]See above, p. 86f.

[52]Cf. Stegmüller (1973, p. 32ff, particularly p. 37).

[53]Howson (1995, p. 27).

A. Birnbaum in particular, who introduced the concept of the likelihood principle in this context.[54] The main difference between the likelihood principle and the frequency principle can be formulated as a question: Is it possible to obtain evidence about a parameter on the basis of a specific piece of data (i.e., a "sample")? Adherents of the frequency concept (particularly J. Neyman) emphasize that we can only assess the performance of a procedure if it is carried out repeatedly and measured on the basis of long-term averages.

However, if it is not possible to conduct experiments, and conclusions can only be drawn using existing, repeatable data that have not been scrutinized (e.g., as is the case in cliometrics), the relevance of such a concept must be seriously questioned. If repeatability is purely hypothetical, it should also be explicitly defined as a (subjective) conviction and not as an objective possibility. We therefore find it more reasonable, for such situations, to define probability as a degree of belief, which is then assigned to a parameter value. The evaluation and revision of this conviction with the evidence of existing, non-hypothetical data obtained by applying the likelihood function are also logically consistent in our opinion, especially as it does not depend on asymptotic generalizations. We would like to subscribe to the opinion of D. Lindley in this respect:

> The present position in statistical inference is historically interesting. The bulk of practitioners use well-established methods like least squares, analysis of variance, maximum likelihood and significance tests: all broadly within the Fisherian school and chosen for their proven usefulness rather than their logical coherence. If asked about their rigorous justification most of these people would refer to ideas of the NPW [Neyman-Pearson-Wald, T. R.] type; least-square estimates are best, linear unbiased; F-tests have high power and maximum likelihood values are asymptotically optimal. Yet these justifications are far from satisfactory: the only logically coherent system is the Bayesian one which disagrees with the NPW notions, largely because of their violation of the likelihood principle.[55]

Inference in Econometrics

Let us now turn to inference in econometrics. Two phases can be distinguished in economic statistics and econometrics: an initial phase, in which the description and exploration of economic series or processes predominated, and a second phase of inference and modeling.

The first phase can be characterized by its adoption of correlation concepts developed by Galton (1888) and Pearson. There was, however, a crucial difference: A body of theory did in fact exist in economics, but it was neither uniform nor

[54] See above, p. 99.

[55] Lindley (1991, p. 493).

sufficiently established to make it accessible for direct empirical application.[56] An explorative character was therefore dominant from the beginning in this respect. Phenomena such as "trade cycles" were not physical variables that only had to be measured, nor were they biological variables with distribution that could be determined with arbitrary precision and influencing factors that could be analyzed by experiment. On the contrary, the data were (1) passive in nature and not immediately suitable for reproducing, they had to be (2) precisely defined, and they were not (3) subject to universally stable distribution.

The use of the correlation calculation was theoretically based in the case of Galton. As the observed data came, for example, from a bivariate normal distribution, their relationship to each other could be expressed in a coefficient. But this theoretical reasoning was already abandoned by Yule upon its first application in the context of social science.[57] The functional relationships were considered linear for computational processing reasons, while the parameters were determined, on the same grounds, by means of the method of least squares. Yule's authority (he was one of the leading statisticians of his day) justified the application of biometric techniques, even though the theoretical justification for this approach was doubtful.

Two aspects are of particular significance in this context: Firstly, no in-depth statistical knowledge was needed in order to recognize that the structure of socio-economic phenomena was different to the structure used to determine the growth of plants or relationships between organism body sizes. Secondly, this was made all the more clear as attention turned to the analysis of data that represented *time series*.

The Time Dimension

The analysis of economic events in terms of their processuality did not find, in economic theory, any concrete statements regarding duration, form, or relationships of trade cycles to each other. The pioneers of empirical studies thus went their own ways, with H. L. Moore and W. S. Jevons seeking replacement in the field of astronomy. Not only astronomical phenomena, such as the periodically varying number of sunspots or the strictly periodic path of Venus (an 8-year cycle between the Sun and Earth), were used to provide explanations; the mechanics of astronomy, in the form of periodogram analysis, were also employed. A method such as this had the advantage of being able to make "hidden" periodicities visible. However, the initial euphoria created by the use of the periodogram analysis soon gave way to the sobering realization that the application lacked an important prerequisite: the stability of the object being examined. Trade cycles were not like the planets, with their constant movements of a duration that could be computed with fixed margins of

[56]Economic theories, from L. Walras to A. Marshall, started out from states of equilibrium, which were adapted, independently of historical context, by the same perpetual motives of human action. The economic laws contained in these theories were timeless.

[57]See above, p. 76 f.

error, but were instead phenomena whose length and intensity varied both with time and the intensity of their disturbance factors.

And even this was not enough, as economic data generally tended to be subject to trends. Their long-term development was therefore not distributed on the basis of stable averages. In these cases, there were no timeless states of equilibrium from which (at the most) transient deviations were possible. There was instead an irreversible development.

The solution to this problem did not however lie in using this irreversibility as an opportunity to adopt a fundamentally different view. Instead, two alternatives were taken up: one postulated, even for this long-term development, either a functional, measurement-error-conditioned context in the form of a polynomial or some other trend function (if the long-term curve had a reasonably smooth appearance). The method of least squares was used to determine this trend. This had already developed a life of its own, and its progress was barely stoppable. Either that or one could decide completely against a long-term development model and exclude it by observing the deviations from a moving average. In both cases however, the goal was not a comprehensive analysis of (historical) development, but rather an "exclusion" of whatever could not be incorporated into the scheme of identical timeless structures.[58]

It is to this extent obvious that a component-based concept dominated further research. Mutually independent explanatory factors therefore determined the long-, medium-, and short-term curves by which the trend component was found to be just as disruptive as its short-term "residual" counterpart. It was difficult in this context to respond to the question of correlation. The study of trends and cycles on one hand and of correlations on the other was not a separate epistemic interest but an interrelated factor. According to the statisticians, the trend first had to be excluded to allow the examination of correlations, while the goal of correlation analysis was to examine the conformity of medium-term (i.e., cyclic) curves.

On the other hand, one must however not overlook the fact that it was in this formulation phase that the issue of historical change in economic structures became highly problematic. If there was a long-term trend "component," why should the mutual links between economic variables not then also be made subject to long-term changes? The attempts by Hall (1925), Kuznets (1928a, b), Ezekiel (1928), or Frisch (1931) to extend existing concepts to include time-dependent models, or at least to point out the inadequacy of conventional formalizations, were therefore the obvious thing to do.

We can only speculate as to why this path was not pursued further. One possible explanation might be that the technical difficulties with regard to modeling were too great. However, as these papers were in any case barely implicated in statistical inference, another explanation seems plausible to us: the surprisingly great similarity between an economic index on the trade cycle and a series of computed random

[58]One of the few exceptions, who assigned independent significance to the trend, was S. Kuznets. See Kuznets (1930a, b) in particular.

variables, contained above all in a paper by Slutzky (1937) and presented shortly afterward to the English-speaking world by Kuznets (1929). Did this similarity mean that even trade cycles depended solely on random variables?

Research by Yule and Slutzky went on to form the conceptual basis of the modern theory of stochastic processes. Although both of them described different types of models – autoregressive processes in the case of Yule (1927) and so-called "moving average" processes in the case of Slutzky (1937) – their structures nevertheless had crucial factors in common. They regarded a time series as a realization of a stochastic differential equation. While Yule started with a trigonometric function that could be represented as a differential equation (albeit one in which the error term had a completely different effect to that of the functional form), Slutzky constructed various – at first glance rather arbitrary – sums of random variables. A deeper justification for the chosen type of model (e.g., regarding why a certain number of random variables was provided with different weightings and added up once or several times) was of less importance in this respect than the alarming fact that random variables could create cyclical phenomena.

It is highly surprising that there were apparently, in the case of this conceptualization, bigger problems regarding the acceptance of the idea of a random, yet legitimate, process than there were for cross-sectional regression analysis. Time series were therefore regarded either deterministically, in terms of their essential components (the component model), or as purely coincidental, with cycles which then had no significance. The key point was overlooked: It was not the random variables that were responsible for (pseudo-)cyclical character but the mechanism, i.e., the model.

This inner logic of these models remained hidden to Kuznets, just as it subsequently did to G. Tintner, J. Schumpeter, and John Maynard Keynes.[59] It is therefore not surprising that scientists with less of a mathematical background were no longer willing or able to follow the conceptual idea associated with such models.

R. Frisch (1933) on the other hand, an econometrician with physical background, had clearly recognized the inner logic of these models and had even included a corresponding economic justification of it in his famous article on propagation. In a dynamic model of an economy, certain parameter values not affected by disturbance factors could give rise to damped oscillations. The action of "shocks" could, on the other hand, produce the irregular cycles first referred to by Yule.[60]

[59]Even Tinbergen came to recognize that he "did not understand the role of the shocks as well as Frisch did" (Tinbergen in Magnus/Morgan (1987, p. 125)).

[60]The separation between the role of the mechanism and that of the shock was of great importance for the development of econometrics, even though Tinbergen regarded it critically in retrospect: "[. . .] I think that what interested economics most was not the shocks but the mechanism generating endogenous cycles, and it might very well be that we have overestimated the role of the mechanism. Maybe the shocks were really much more important. This problem was never solved, because the War came along and after the War we were not interested in business cycles anymore" (Tinbergen in Magnus/Morgan (1987, p. 125)).

With the reception of these models into economics, the ways divide. Kuznets' (1934) *Time Series* contribution to the *Encyclopedia of the Social Sciences* described only the component model, without any stochastic implications. No mention was made of models with variable parameters or of the fundamental significance of the models of Yule and Slutzky.[61] Papers by Schumpeter, and also by Burns and Mitchell (1946), took a similar line. Schumpeter did in fact write the opening article of the first issue of *Econometrica*, which was published in 1933, but played no further part in the development of econometrics.

It was of crucial importance to further development that the scientific orientation of econometrics was largely determined by individuals with an educational background in physics, such as Jan Tinbergen, Ragnar Frisch, Tjalling Koopmans, Charles Roos, or Harold T. Davis.[62] These thinkers possessed a different picture of economics to that of "traditional" empirical researchers. They brought a mechanistic, rigorously mathematical model of thinking to empirical research. One example of this development is an account by Koopmans of his career:

> Why did I leave physics at the end of 1933? In the depth of the worldwide economic depression, I felt that the physical sciences were far ahead of the social and economic sciences. What had held me back was the completely different, most verbal, and to me almost indigestible style of writing in the social sciences. Then I learned from a friend that there was a field called mathematical economics, and that Jan Tinbergen, a former student of Paul Ehrenfest, had left physics to devote himself to economics. Tinbergen received me cordially and guided me into the field in his own inimitable way. I moved to Amsterdam, which had a faculty of economics. The transition was not easy. I found that I benefited more from sitting in and listening to discussions of problems of economic policy than from reading the tomes. Also, because of my reading block, I chose problems that, by their nature, or because of the mathematical tools required, have similarity to physics.[63]

It was possible to have in this environment (1) modeling of the economic world in the form of differential equations and (2) a rigid stochastic process. It nevertheless appears strange, at first glance, that Koopmans should develop his approach using the theory of R. A. Fisher and did not see, as Frisch had, measurement errors, in physical analogy, as a justification for a stochastic approach but started out instead, in a biological analogy, from hypothetically infinite populations from which, with constant probabilities, the existing data would have stemmed. The basic stochastic concept was probably not of so much importance in this instance but rather the facts

[61] Cf. Kuznets (1934).

[62] See Epstein (1987, p. 75 note 39), Mirowski (1989, p. 234), and above all Boumans (1993). Even the statistician G. U. Yule, who was particularly involved in research in the field of time series analysis and its potential applications in economics, began his academic career in the study of electrical waves.

[63] Quoted from Mirowski (1991, p. 152). Frisch and Koopmans applied matrix calculus, which was being widely disseminated in physics in the mid-1920s, in the context of multiple regression analysis, to the field of econometrics, thereby making it more difficult for economists to comprehend the texts concerned. Cf. Mirowski (1989, p. 231).

that Fisher had developed a comprehensive statistical estimation theory and that he was regarded as a leading statistician.

Univariate time series analysis turned into a sideshow issue in this context, with thinking in terms of "complete" models coming to dominate instead.[64] These models did not however fully or consistently match, from the beginning, the theoretical economic models, although their consideration was the initial objective of econometrics. Tinbergen had already found himself forced into a series of compromises, as the existing economic theories of his day had not been specified to an extent that permitted direct empirical testing.

The uninhibited, iterative approach of Tinbergen infringed the rules of the stochastic concept of statistics that had just been adopted by Frisch and Koopmans. Some criticism of Keynes or Friedman was to this extent justified. The chosen way was nevertheless followed further and given a certain manifesto-like air by T. Haavelmo, a student of R. Frisch.

"Clarification": Trygve Haavelmo

Haavelmo's line of argument, which set the trend for further development, called – like Koopmans' – for a rigorously stochastic approach. Unlike Koopmans however, Haavelmo did not rely on Fisher's theory but on those of Neyman and Pearson. If we examine the foundations of this theory, its application to (macro)economic developments inevitably appears problematic.

We have seen that acceptance of the Neyman-Pearson approach brings with it a concept directed at rules of conduct. Even the application of Fisher's notion of hypothetically infinite populations, from which random samples are drawn, may appear strange. However, this is even more problematic for the Neyman-Pearson concept of "repeated sampling from the same population." When applying such a notion to macroeconomic time series, the question to ask is the following: "[. . .]how often is the question that an econometrician has to answer a decision problem in the context of repeated sampling?"[65]

Why did Haavelmo use precisely this approach as a basis?[66] One possible explanation could be that the rivalry of the early 1940s between the approaches of Fisher and Neyman/Pearson resulted in the latter emerging as the victor, thereby already representing a "paradigm" in the Kuhnian sense. There is also a personal reason: Haavelmo himself reported that he had for various months enjoyed the privilege of studying under the "world's famous statistician" J. Neyman. This may

[64]Research nevertheless still continued to take place in the "old" tradition, as econometrics began to develop. See, for example, Hotelling (1934), Schultz (1934), Greenstein (1935), and Regan (1936). Even the method of moving averages was still being recommended by Sasuly (1936) in this context.

[65]Keuzenkamp/Magnus (1995, p. 18).

[66]Heckman (1992, p. 881) also poses the question in this context, in criticism addressed to Morgan (1990): "Why was the Neyman-Pearson theory adopted as the paradigm of statistical inference in econometrics, and why were rival theories by Ronald Fisher and Harold Jeffreys less successful?".

have shown him, as someone who was then "young and naïve," "ways [. . .] to approach the problem of econometric methodology that were more promising than those that had previously resulted in so much difficulty and disappointment."[67]

Haavelmo certainly saw the problems that lay in a simple application of the Neyman-Pearson concept and therefore argued from an instrumentalist stance. His writings repeatedly contain remarks such as "it has been found fruitful" and similar. In addition, large parts of his explanations are based solely on "hopes":

> [. . .] we might hope to find elements of invariance in economic life, upon which to establish permanent laws [. . .]. Our hope in economic theory and research is that it may be possible to establish constant and relatively simple relations [. . .]. Our hope for simple laws in economics rests upon the assumption that we may proceed as if such natural limitations of the number of relevant factors exist.[68]

Is it justified, with a stance such as this, in starting out from objective inference? Even if we rule out the problematic underpinnings, there is a series of questions that the Neyman-Pearson approach fails to answer. As Heckman correctly notes, Haavelmo did not, for example, take into account the important aspect of model structure and selection:

> These claims have never been rigorously established, even for analyses conducted on large samples. There is no 'correct' way to pick an empirical model and the problems of induction, inference, and model selection are very much open. [. . .] The Neyman-Pearson theory espoused by Haavelmo and the Cowles group takes a narrow view of science. By its rules, hypotheses are constructed in advance of knowledge of the data and the role of empirical work is to test the hypotheses. This rigid separation of model construction and model verification was a cornerstone of classical statistics circa 1944. Even then, influential scholars, primarily Bayesians such as Harold Jeffreys quarreled with this view of empirical science. Since that time, the monopoly of classical statistics has broken.[69]

Haavelmo's application of the Neyman-Pearson paradigm nevertheless formed the basis in econometric research for several decades. Even Koopmans stopped citing Fisher and defended Haavelmo's approach with respect to R. Vining. The physical world view was thus cemented into place. Koopmans drew comparisons between the "complete" systems of structural equations and the explanatory power of Newton's theory of gravitation, while J. Marshak (1950), Chairman of the Cowles Commission, went so far as to regard the issue explicitly as "social engineering." But does this not ominously remind us of the "social physics" – vehemently rejected in its day – of Quetelet?

[67] Haavelmo (1994, p. 75).

[68] Haavelmo (1944, pp. 13, 22f, 24).

[69] Heckman (1992, p. 882). He gives reasons for Morgan's overestimation of Haavelmo's approach – rightly in our opinion – with the view, which can be traced back to the influence of Hendry, that these problems are generally solvable in the context of the Neyman-Pearson approach. This overestimation is also picked up by Malinvaud (1991, p. 635) and Zellner (1992, p. 220).

Alternatives

There have been increasing attempts, ever since the 1970s, to seek out alternative ways. C. Sims[70] proposed vector autoregressive time series models as a counter to traditional systems based on simultaneous equations. These models initially provided nothing more than a description of the delayed correlation structure present in existing time series. One could, in principle, regard vector autoregressive models as the ideal form for cliometrics. They are, however, associated with the same problem as univariate ARIMA models,[71] in that the "right" model must first be found on the basis of the data, which infringes in turn the assumptions of classical inference. It is moreover not possible, given the high degree of complexity of these models, to use the tools developed by Box and Jenkins for use in univariate time series analysis. Sims therefore proposed restricting the high number of parameters that result from such models, thereby ultimately advocating a Bayesian approach.

Bayesian approaches, which marked the beginnings of structural equation models in the econometrics of the 1960s, were still subject, in technical terms, to greater difficulties than classical statistical inference. These technical difficulties should not, however, obscure the fact that the Bayesian standpoint is considered by its representatives to be, from a conceptual point of view, a single approach:

> That there is a unified and operational approach to problems of inference in econometrics and other areas of science is a fundamental point that should be appreciated. Whether we analyze, for example, time series, regression, or 'simultaneous equation' models, the approach and principles will be the same. This stands in contrast to other approaches to inference that involve special techniques and principles for different problems.[72]

E. Leamer developed the most consistent Bayesian econometric methodology.[73] The main criticism of Leamer appears to us to be the part concerning modeling problems. Leamer rightly pointed out that the classical theory, in which the model is regarded as a given, required an almost "Orwellian" approach to econometrics:

> In such a fanciful world, personal uncertainties and public disagreements concerning how to interpret data would be completely resolved in advance. New data sets would not be distributed to humans at all, but instead would be delivered with elaborate security measures to a centralized warehouse where preprogrammed computers would pore over the numbers and pass the conclusions to the public. Once analyzed, the data would be entirely destroyed, to prevent the urge to try something else from becoming an unwanted reality.[74]

[70] See, for example, Sims (1980).

[71] They were also subject to the same statistical limitations, such as stationarity and linearity.

[72] Zellner (1971, p. 11).

[73] See references in Rahlf (1998).

[74] Leamer (1994, p. ix).

The nonexperimental nature of econometrics prohibits such a notion. Data relating to such factors as the development of a country's gross national product are available only once but are evaluated repeatedly. If there is uncertainty regarding the model and – with respect to the selection of relevant variables – (1) the data are not neutral and (2) the personal conviction of the scientist plays a role (e.g., selection of the determinants of criminality by conservative or liberal researchers, selection of the determinants of inflation by monetarists or Keynesians), then a Bayesian point of view is, in our opinion, the only one that can be justified. The indication of the effect of different assumptions and selected variables, or "sensitivity analysis," appears to offer a promising approach in this respect, although its future reliability would have to be underpinned by a larger number of applications.

D. Hendry (2001) has developed a third methodology. Hendry, unlike Leamer, is convinced that a model structure based on the intensive analysis of a data set can be justified by the methods of classical inference. One revealing example of his approach comes from the reanalysis of a selected model based on comprehensive research carried out by M. Friedman and A. Schwartz of monetary trends in Britain and the United States, although the individual steps of the modeling process involved remain partly obscure. The possibility of validation, using classical "testing" based on the theory of Neyman and Pearson, has therefore been questioned in literature on the subject.[75]

Milton Friedman, by his own account, put no trust in formal statistical criteria. He had already rightly pointed out, in his criticism of Tinbergen's consideration of economic theories, that the traditional testing of significance or of hypotheses becomes less meaningful when it is applied after the analysis of the same data. His own t-tests are therefore also more likely to be understood as pragmatic.

If we consider these methodologies and approaches as a whole, a natural science world view dominated econometric research. Most approaches are based above all on constant, time-invariant parameters. Although the consideration of parameter constancy is part of Hendry's testing batteries, seldom alternatives – other than dummy variables – are modeled. Friedman and Schwartz (1991) do in fact point out the significance of analyzing historically uniform periods, but they subject these periods, in turn, to rigid constraints. Complexity is as a rule reduced to a parameter matrix that reflects the time-invariant structure, regardless of whether it concerns short- or long-term relationships.

Inference for Cliometrics

The question regarding the importance of empirical research to economic history and economics was again picked up in 1949, by A. P. Usher. Usher offered numerous philosophical, psychological, and scientific approaches that should justify a modern

[75]Keuzenkamp (1995, p. 243) therefore uses, for Hendry's approach, the more apposite term "diagnostic *checks*" rather than "diagnostic *tests*."

take on empiricism while highlighting its relevance to economic history. However, his references regarding approaches to philosophical probability theory stand in isolation.[76] Seen as a whole, the discipline of economic history in the first half of the twentieth century was, even in the United States, geared more toward a qualitative approach, with a tendency to reject the quantitative.[77]

The Bayesian Origins of Cliometric Inference

What is the current position regarding the concept of inference in cliometrics? If we define cliometrics generally by (1) the application of explicitly theory-driven, neoclassically oriented economic history research along with (2) the intensive use of mass data and of formal methods for verifying the theories based on those data, the question immediately arises of what difference there is, if any, with respect to the intrinsic concept of econometrics. The headword entry for "cliometrics" in the *New Palgrave* defines the approach as an "amalgam of methods,[78] born of the marriage contracted between historical problems and advanced statistical analysis, with economic theory as bridesmaid and the computer as best man,"[79] while the *American Heritage Dictionary* lists it as "the study of history using economic models and advanced mathematical methods of data processing and analysis."[80]

If the predominant characteristic is therefore the use of certain methods,[81] it is consequently surprising that the criticism that cliometrics has attracted on the part of "traditional" economic history has not established methodological problems, in the strict sense of the term, as a subject for discussion. Discussions were centered on the question of whether the application of theoretical models and their verification was, if at all, the cognitive goal of economic history with respect to a specific time and place and whether historical data fulfilled the conditions for applying elaborate statistical methods. The methods themselves played no further role however.

One can say that cliometrics has followed, in terms of methodology, the "paradigm" of econometrics, thereby taking into account the problems described by this field.[82] If we start by assuming, as E. Heckscher (1939) did, that the purpose of

[76]Cf. Usher (1949, p. 148 and p. 155, note 29).

[77]Fogel (1995, S. 49): "The leading history journals, even in economic history, initially refused to accept articles with complex tables and even after such articles began to be accepted, equations were absolutely forbidden."

[78]Floud (1991, p. 452.

[79]Fogel/Elton (1983, S. 2), quoted by Floud (1991, p. 452.

[80]See above, p. 5.

[81]See also Fogel (1995, p. 52) on this subject: "By the early 1980s *cliometric methods* were so firmly established in certain fields of history that no scholar in these fields could afford to neglect them" (our italics).

[82]This is supported not least by the fact that cliometrics did emerge as an independent school of thought because an application for admission by a group of the founding fathers of cliometrics had been rejected by the *Econometric Society*. Cf. Hughes (1965).

economic history is not fundamentally different to that of economics (or econometrics), it becomes plain that the econometric tools available to it, which were already well developed and firmly established by the early 1960s, were accepted uncritically, because econometrics gave, at that time, the most complete impression of its entire history of development.

It is therefore surprising, against the background of this development, that the papers by A. Conrad and J. Meyer (1957, 1958), which are commonly regarded as the "starting pistol" of cliometrics, should go off in a completely different direction. The two economists presented, at a 1957 conference held jointly by the Economic History Association and the National Bureau of Economic Research, a paper entitled *The Economics of Slavery in the Antebellum South*, in which they expounded the thesis – based on statistical methods, data compiled from secondary literature, and a theoretical economic model – that the purchase of a slave in the period before the Civil War represented a profitable investment for a slave owner from the Southern United States. Their work, which was published the following year, raised a storm of protest – and not just because of their "econometric" approach.[83] Our intention here is not to follow this discussion however[84] but rather to examine their methodology. This was also pointed out by the authors in 1957, in a programmatic article on the relationship between economic theory, statistical inference, and economic history, which followed a surprisingly Bayesian line of argument.[85]

Conrad and Meyer set out here to emphasize the significance of a concept of causal orders, which should underpin every historical narrative. The denial of the possibility of causal explanations in history, which was put forward by a number of philosophers, is based mainly on the view that historical events are unique, complex, and unquantifiable.[86] They rightly pointed out that econometric modeling predetermines a causal order, which is only valid for the variables contained in the model[87]: "Causal order is an operational term, which does not require the involvement of any invisible forces or internal needs."[88] The claim that causal explanations are connected to the basic repeatability of an experiment, although historical events are unique, is likewise incorrect. Firstly, experiments are also essentially first-time events and, secondly, a science such as astronomy would no longer be capable of making causal statements, as it would then be dealing with non-repetitive phenomena.[89] This is where Bayesian reasoning came into play, as it is not based on the

[83]Conrad/Meyer (1958). The authors were at the time *assistant* professors of economics at Harvard. The expressions "starting gun" and "watershed" are therefore justified, since econometric methods were for the first time being applied to historical phenomena without any reference to the present.

[84]Cf. Conrad/Meyer (1964).

[85]Conrad/Meyer (1957).

[86]Cf. Conrad/Meyer (1957, p. 527).

[87]They refer here to an example given by Simon (1957) regarding the differing possible influences of the variables of weather, wheat harvest yield, and wheat price.

[88]Conrad/Meyer (1957, p. 147.

[89]They seek support, in this context, in the line of argument of H. Jeffreys.

repeatability of the events but is concerned rather with a subjective grasp of statements of probability:

> Explicitly, the formal tests attach an actual numerical probability to the correctness of the hypothesis in the light of the observed results. This introduces the question of relative plausibility into the empirical procedure and consequently helps the investigator to scale the degree of belief, an intrinsically ordinal concept at the very least, that should be placed in the hypothesis. There are, in sum, substantial advantages as well as disadvantages to the introduction of more formal procedures in the evaluation of historical hypotheses. The question therefore arises: Is there a satisfactory compromise that embodies maximum advantage with minimum disadvantage? Ideally, the best procedure would appear to be one in which the formal tests were adapted or altered to take account of a maximum of a priori information. This leads, admittedly, to an essentially Bayesian approach to statistical inference.[90]

They did indeed see it as problematic that the Bayesian approach was sinking into a "morass of subjectivism," in the immediate absence of a priori notions and probabilities. They were, however, confident that this could form a basis for creating guidelines and simplifying the communication of scientific results.

The discussion following the presentation of the paper, in which the economists present expressed their opposition to the application to historical data of econometric models and statistical tests, included (in the same manner as later papers on cliometrics) little evidence of this key difference with respect to the prevailing econometric approach.[91] Subsequent development tended rather to follow the path marked out by econometrics, albeit without influencing econometrics itself.

The cliometric (r)evolution, whose development had been swiftly gathering pace since the 1960s, then took over the methods of econometrics, along with its associated concepts. A way such as this was, for logical reasons, just as faintly compelling as the adoption by econometrics of "classic" statistical inference. The papers by Conrad and Meyer, which marked the beginnings of cliometrics, followed a Bayesian argument, although this was subsequently taken into account neither by cliometrics itself nor its critics. The course of econometrics was actually set by physicists in their role as "social engineers," harking back implicitly (or even explicitly) to Newton. We would like to conclude our overview by citing some criticism that is very revealing for statistical inference in the field of cliometrics: the critique of the mathematician Rudolf Kalman.

[90] Conrad/Meyer (1957, p. 544). Specific examples can be found in Conrad/Meyer (1964).

[91] Bayesian approaches were not to find fertile ground in the field of econometrics until several years later. It must however be emphasized that the line of argument maintained by Conrad and Meyer contained various terms and concepts (they speak of objective tests and significant differences, before returning to probabilities of hypotheses and a "morass of subjectivism") that cannot always be clearly differentiated from each other.

Fundamental Criticism: Rudolf Kalman

Rudolf Kalman took on a study, in the early 1980s, of the problem of model structure and inference in the field of econometrics and expressed fundamental criticism, in this context, from a system theory point of view.[92] In his opinion, econometrics mainly went along the following two paths:

1. Economic laws and relationships have been formulated as dynamic equations in terms of Newton's laws.
2. The coefficients of these equations have been determined quantitatively by the extraction, from real data, of statistically relevant information.

He establishes, with this development in mind, that the progress in knowledge subsequently achieved is, even in comparison to the 250 years that have elapsed since Newton, disappointingly low. He expounds the thesis (which requires, in his opinion, no discussion in terms of "hard" science):

> [. . .] that economics is not at all like physics and therefore that it is not accessible by a methodology that was successful for physics. Far from being governed by absolute, universal, and immutable laws, economic knowledge, unlike physical science, is strongly system (context) dependent; when economic insights are taken out of temporal, political, social, or geographical context, they become trivial statements with little information content. [. . .] Since economic 'laws' do not process the attributes of physical laws, writing down equations, in the style of physics, to translate economic statements into mathematics is not a productive enterprise. [. . .] System theory provides a simple but hard suggestion: Do not write equations expressing assumed relationships; deduce your equations from real data. [. . .] To put it differently, there will never be a Newton in economics; the path to be followed must be different.[93]

His opinion on the second step, the statistical determination of unique parameters, is even more negative. This only makes sense in his view if there are concrete, explicitly measurable parameters, as is the case, for example, with resistors in Ohm's law:

> Economists have often dreamed of imitating the simple situation characterized by Ohm's law just by hoping for the best, for example, by assuming that such a law (the Phillips curve) exists between inflation and unemployment. But unemployment and inflation, in any quantitative sense, are fuzzy and politically biased attempts to replace complex situations by (meaningless) numbers; consequently any hope that two such concepts can be tied to one another by a single coefficient is barbarously uninformed wishful thinking.[94]

[92] We rely mainly on Kalman (1982a, b) in this respect. We are therefore not concerned with the *application* of the so-called Kalman filter to econometrics.

[93] Kalman (1982a, p. 19f). Original author's italics.

[94] Ibid., p. 20.

Unique relationships such as these exist in astronomy, for example, where their parameters have a direct significance that is independent of any system, such as the determining of the position of an object as a function of moment and angle. It is not surprising, against this background, that Kalman is especially critical of Haavelmo's approach: "The aspiration of Haavelmo to give a solid foundation to econometrics by dogmatic application of probability theory has not been fulfilled (in the writer's opinion), no doubt because probability theory has nothing to say about the underlying system-theoretic problems."[95] He calls instead for a rigorous application of system theory. System theory does not set out from a directly measurable relationship between input and output: "instead of determining a single parameter, such as a resistance, system theory is concerned with the much more general question of determining a system."[96] Parameters contained in systems have, according to Kalman, a completely different significance to that hitherto assumed by econometricians; they are therefore to be defined only *locally*. It is by no means self-evident, for Kalman, that the cognitive goal of statistical analysis should lie in the obtaining of constant figures, such as with the application of maximum likelihood estimates or the method of least squares: "[. . .]common sense should tell us, that such a miracle is possible only if additional assumptions (*deus ex machina*) are imposed on the data which somehow succeed in neutralizing the intrinsic uncertainty."[97] The method of least squares is thus so popular in these terms because it delivers a clear ("unique") response. However, the assumptions associated with such an approach cannot normally be justified.

The common approach of using data that show variance to determine a specific value that reveals maximum likelihood or minimizes deviations (thereby making it preferable to all others) is, for him, "fundamentally wrong and extremely harmful to scientific progress."[98] Such an approach implies the following suppositions (or "prejudices"):

1. The data have been generated using a probabilistic mechanism.
2. This probabilistic mechanism is very simple; it is constant in terms of time, and a distribution function explains everything.
3. There is a "true" value, which can be regarded as the "particularly striking feature" of the hypothetical distribution function, such as the expected value, median, or modal value.
4. A single figure constitutes the response of a deductive process based on self-evident postulates.

[95]This sentence, which was supposed to appear in Kalman (1982c), was deleted at editorial request and included instead in Kalman (1982b, p. 194).

[96]Kalman (1982a, p. 23). Linearity and finiteness might be reasonable assumptions for such a system.

[97]Kalman (1982b, p. 162). Original author's italics.

[98]Ibid., p. 171.

The assumption of exact conformity to natural laws in probabilistic phenomena analogous to Newtonian physics, which is what such an approach is supposed to aspire to, has nevertheless long since proved to be an illusion. Apart from "mathematical artifacts," such as the law of large numbers, there have not been any universal laws of random phenomena – even in physics – but rather ones that depend on the very system that surrounds them.[99] A view such as this has profound implications:

> The implications of this situation for econometric strategy are devastating. Since the problem is to identify a system and since systems cannot be described in general by globally definable parameters, the whole idea of a parameter loses its (uncritically assumed) significance. [. . .] The Jugendtraum of econometrics, determining economically meaningful parameters from real data via dynamical equations supplied from economic theory, turns out to have been a delusion.[100]

This criticism of Kalman has not as yet – as far as we can see – had any impact on econometrics. Even if one does not wish to follow the path to its ultimate consequences, the fundamental reasonableness of applying physics-based approaches to economic developments should still be examined. It is surely a highly promising basis for inference statements in the field of cliometrics.

Trends, Cycles, and Structural Breaks in Cliometrics

Terence C. Mills

Contents

Abstract

The calculation of trends and their growth rates, along with the related calculation of cycles, is an important area of cliometrics. The methods traditionally employed to estimate trend were either the estimation of regressions containing simple functions of time, typically in conjunction with a method to deal with regime shifts or structural breaks, or simple unweighted moving averages. In both cases the cycle was determined by residual and, because the trend was, possibly locally, deterministic, the cyclical component took up most of the fluctuations in the observed series. The last 25 years or so, however, have seen major developments in both macroeconomics and time series econometrics and statistics on the modelling of trends and cycles that allow all components to be stochastic and

Introduction

The calculation of trends and their growth rates, along with the related calculation of cycles, is an important area of cliometrics. The methods traditionally employed to estimate trend were either the estimation of regressions containing simple functions of time, typically in conjunction with a method to deal with regime shifts or structural breaks, or simple unweighted moving averages. In both cases the cycle was determined by residual and, because the trend was, possibly locally, deterministic, the cyclical component took up most of the fluctuations in the observed series.

The last 25 years or so, however, have seen major developments in both macroeconomics and time series econometrics and statistics on the modelling of trends and cycles, with perhaps the first cliometric paper to use these new techniques being Crafts et al. (1989a). Since then Crafts and Mills (1994a, b, 1996, 1997, 2004) and Mills and Crafts (1996a, b, 2000, 2004) have provided a variety of extensions to the range of techniques and cliometric applications. This chapter outlines these developments and may also be regarded as an update of previous surveys of this area by Mills (1992, 1996, 2000).

Sections "History of Modelling Trends and Cycles in Economics" and "Modelling Trends and Cycles in Economic History" contain a brief history of the modelling of trends and cycles and of their traditional application in economic history, respectively. Section "Segmented Trend Models" introduces segmented and breaking trend models, while section "Filters for Extracting Trends and Cycles" considers the modern filter approach for extracting trends and cycles. The link between these filters and structural time series models is developed in section "Filters and Structural Models" and their link with ARIMA models in section "Model-Based Filters." Section "Structural Trends and Cycles" introduces the latest generalizations of structural time series models, while section "Models with Correlated Components" considers the implications of relaxing the identifying constraint of all these models that the components are uncorrelated. Section "Multivariate Extensions of Structural Models" looks at multivariate extensions of structural models and section "Estimation of Structural Models" briefly considers their estimation via a state space framework using the Kalman filter. The possibility of common breaks across a set of series, the phenomenon of co-breaking, is the topic of section "Structural Breaks Across Series," while section "Concluding Remarks" offers some concluding remarks on the nature of trends.

Several examples illustrate the methods introduced in this chapter and these use the British per capita GDP series recently provided by Broadberry et al. (2011), all calculations being done with the commercial software *Econometric Views 8* and *STAMP 8*.

History of Modelling Trends and Cycles in Economics

The analysis of cycles in economic time series began in earnest in the 1870s with the sunspot and Venus theories of William Stanley Jevons and Henry Ludwell Moore and the rather more conventional credit cycle theory of Clément Jugler (see Morgan 1990, Chap. 1). Secular, or trend, movements were first studied somewhat later, with the term "trend" only being coined in 1901 by Reginald Hooker when analyzing British import and export data (Hooker 1901). The early attempts to take into account trend movements, typically by detrending using simple moving averages or graphical interpolation, are analyzed by Klein (1997), while the next generation of weighted moving averages, often based on actuarial graduation formulae using local polynomials, are surveyed in Mills (2011, Chap. 10).

The first half of the twentieth century saw much progress, both descriptive and theoretical, on the modelling of trends and cycles, as briefly recounted in Mills (2009a), but it took a further decade for techniques to be developed that would, in due course, lead to a revolution in the way trends and cycles were modelled and extracted. The seeds of this revolution were sown in 1961 – a year termed by Mills (2009a) as the "annus mirabilis" of trend and cycle modelling – when four very different papers, by Klein and Kosobud (1961), Cox (1961), Leser (1961), and Kalman and Bucy (1961), were published. The influence of Klein and Kosobud for modelling trends in macroeconomic time series – the "great ratios" of macroeconomics – is discussed in detail in Mills (2009b) and that of Cox in Mills (2009a). It is the last two papers that are of prime interest here. As is discussed in section "Filters for Extracting Trends and Cycles," Leser's paper, in which he considered trend extraction from an observed series using a weighted moving average with the weights derived using the principle of penalized least squares, paved the way for one of the most popular trend-extraction methods in use today, the Hodrick-Prescott (H-P) filter. Kalman and Bucy, along with its companion paper, Kalman (1960), set out the details of the Kalman filter algorithm, an essential computational component of many trend and cycle extraction techniques (see section "Estimation of Structural Models"; Young 2011 may be consulted for both historical perspective and a modern synthesis of the algorithm with recursive estimation techniques).

Modelling Trends and Cycles in Economic History

The difficulties in separating out cyclical fluctuations from the longer-term, secular, movements of economic time series were certainly well appreciated by economic historians such as Aldcroft and Fearon (1972) and Ford (1981). However, the methods of trend and cycle decomposition used by them were essentially ad hoc, designed primarily for ease of computation without real regard for the statistical properties of the time series (or set of series) being analyzed: for statements supporting this position, see Aldcroft and Fearon (1972, p. 7) and Matthews et al. (1982, p. 556).

The underlying model in such analyses is that of an additive decomposition of the series x_t, observed over the period $t = 1, 2, \ldots, T$, into a trend, μ_t, and a cycle, ψ_t, typically assumed to be independent of each other, i.e.,

$$x_t = \mu_t + \psi_t \qquad E(\mu_t \psi_s) = 0 \quad \text{for all } t \text{ and } s \tag{1}$$

The observed series x_t is often the logarithm of the series under consideration, while the data are usually observed annually.

The trend and cycle components are, of course, unobservable and hence need to be estimated. The methods of estimation traditionally employed by economic historians are termed ad hoc above because they do not arise from any formal statistical analysis of x_t or its components. Perhaps the simplest model for μ_t that might be considered is the linear time trend $\mu_t = \alpha + \beta t$, which, if x_t is indeed the logarithm of the series, assumes constant growth. Estimation of the regression model

$$x_t = \alpha + \beta t + u_t \tag{2}$$

by ordinary least squares (OLS) then provides asymptotically efficient estimates of α and β. Given such estimates $\hat{\alpha}$ and $\hat{\beta}$, the trend component is then $\hat{\mu}_t = \hat{\alpha} + \hat{\beta} t$ and the cyclical component is obtained by residual as $\hat{\psi}_t = x_t - \hat{\mu}_t$.

The trend component will only be efficiently estimated in small samples, an important proviso given the often limited number of observations available on historical time series, if the cyclical component is, *inter alia*, serially uncorrelated. This is unlikely to be the case if cycles, often defined as "recurring alternations of expansion and contraction" (Aldcroft and Fearon 1972, p. 4), are in fact present in the data, in which case either generalized least squares (GLS) or an equivalent estimation technique should be used or Newey and West (1987)-type consistent variances should be employed with the OLS estimates.

Although the linear model (2) has been used on occasions, most notably by Frickey (1947) and Hoffmann (1955), economic historians have typically rejected the view that trend growth is constant through time, preferring models that allow for variable trend growth rates. The linear trend model can readily be adapted to allow trend growth to vary across cycles, or *growth phases* as they are sometimes referred to, the terminal years of which are chosen through a priori considerations. Thus, if T_1 and $T_2 = T_1 + k$ are the terminal years of two successive cycles, trend growth across the cycle spanning the years T_1 and T_2 is given by the OLS estimate of β_k in the regression

$$x_t = \alpha_k + \beta_k t + u_{kt} \qquad t = T_1, T_1 + 1, \ldots, T_2 \tag{3}$$

A variant of this approach was used by Feinstein et al. (1982), who preferred to estimate β_k by connecting the actual values of the series in the chosen terminal years. This estimate is approximately given by $k^{-1}(x_{T_2} - x_{T_1})$, but Crafts et al. (1989b) show that it is never a more efficient estimator than the OLS estimator $\hat{\beta}_k$.

The common feature of linear trend models of this type is that trend growth across cycles is regarded as being deterministic, so that *all* fluctuations in x_t must be attributed to the cyclical component. Furthermore, any fluctuation from trend can only be temporary: since the cyclical component is estimated by the regression residual, it must have zero mean and be stationary, so that shocks to x_t that force it away from its trend path must dissipate through time. A further drawback of models such as Eq. 3 is that the selection of the terminal years of the cycles could be subjectively biased.

Because of these shortcomings, many economic historians have favored an alternative method of trend estimation, that of using a *moving average*. The typical moving average used to isolate trend in annual macroeconomic time series is one of nine years (as used, e.g., by both Aldcroft and Fearon 1972 and Ford 1969, 1981). Formally, a trend component estimated by a $(2h + 1)$ year moving average of x_t can be defined using the lag operator B as

$$\hat{\mu}_t = M(B)x_t = \frac{1}{2h+1}\left(\sum_{j=-h}^{h} x_{t-j}\right) = \frac{1}{2h+1}\left(\sum_{j=-h}^{h} B^j\right)x_t \tag{4}$$

where $B^j x_t \equiv x_{t\,-\,j}$, so that setting $h = 4$ gives the 9-year moving average referred to above. An advantage of using a moving average to estimate the trend component, apart from the obvious one of computational simplicity, is that the trend now becomes stochastic and, although "smooth," is influenced by the local behavior of x_t: fluctuations in x_t are therefore not entirely allocated to the cyclical component.

A property of moving averages is that a $(2h + 1)$ year moving average will smooth out a $2h + 1$ year cycle in the data. Since many economic historians believe business cycles are between 7 and 11 years in duration, the setting $h = 4$ thus has a rational basis, at least in terms of prior beliefs.

One obvious disadvantage of moving averages is that $2h$ trend observations, equally allocated at the beginning and end of the sample period, are necessarily lost. As Aldcroft and Fearon (1972) note, this can cause major difficulties when the available number of observations is limited. An important illustration of this is the estimation of trends during the interwar years, when less than 20 annual observations are available: Aldcroft and Fearon have to resort to linear trends in their analysis of this period. A less well known disadvantage of using moving averages of the form (4) is that, although they eliminate a linear trend, which is certainly what is required, they also tend to produce too smooth a trend and thus a potentially distorted cyclical component.

Segmented Trend Models

A natural generalization of Eq. 3 is to incorporate the models for individual cycles into a single composite model, where it is assumed that the end points of the cycles are at $T_1, T_2, \ldots, T_{m+1} = T$:

$$x_t = \alpha + \beta t + \sum_{i=1}^{m+1} \gamma_i d_{it} + \sum_{i=1}^{m+1} \delta_i t d_{it} + u_t \tag{5}$$

where the d_{it}, $i = 1, 2, \ldots, m + 1$, are 0–1 dummies taking the value 1 in the ith cycle and zero elsewhere. As trend growth in the ith cycle is given by $\beta + \delta_i$, the hypothesis of a constant trend growth rate across the entire sample period is thus $\delta_1 = \delta_2 = \ldots = \delta_{m+1} = 0$, while the further hypothesis $\gamma_1 = \gamma_2 = \ldots = \gamma_{m+1} = 0$ restricts x_t to having a *single* trend path. However, if this second hypothesis is rejected, then the presence of nonzero γ_is will result in horizontal shifts in the trend, so that models of the form (5) are referred to as *breaking trends*. If it is thought that the trend function should be smooth, continuity can be imposed by considering the class of *segmented trend* models. A segmented linear trend can be written as

$$x_t = \alpha + \beta t + \sum_{i=1}^{m} \theta_i D_{it} + u_t \tag{6}$$

where

$$D_{it} = \begin{cases} t - T_i & t > T_i \\ 0 & \text{otherwise} \end{cases}$$

Thus, trend growth in the ith segment is given by $\beta + \theta_1 + \ldots + \theta_i$. Extensions to higher-order trend polynomials are straightforward: for example, Mills and Crafts (1996b) fit a segmented quadratic trend with three breaks to (the logarithm of) British industrial production for 1700–1913:

$$x_t = \beta_0 + \beta_1 t + \beta_2 t^2 + \sum_{i=1}^{3} \theta_i D_{it}^{(2)} + u_t \tag{7}$$

where

$$D_{it}^{(2)} = \begin{cases} (t - T_i)^2 & t > T_i \\ 0 & \text{otherwise} \end{cases}$$

and with the breaks selected to be at 1776, 1834, and 1874.

As an example of a segmented trend model, Fig. 1 shows the logarithms of UK per capita GDP for 1855–2010 upon which a segmented linear trend with two breaks at 1918 and 1920 has been superimposed. The fitted model is

$$x_t = \underset{(0.0184)}{0.7016} + \underset{(0.0006)}{0.0096}\, t - \underset{(0.0239)}{0.0975}\, D_{1t} + \underset{(0.0243)}{0.1068}\, D_{2t} + \hat{u}_t \qquad R^2 = 0.9927 \tag{8}$$

Figures in parentheses are heteroskedasticity and autocorrelation corrected standard errors, an important proviso here as the estimated cycle $\hat{u}_t$ is undoubtedly serially correlated. The growth rate pre-1919 is estimated to be 0.96% per annum,

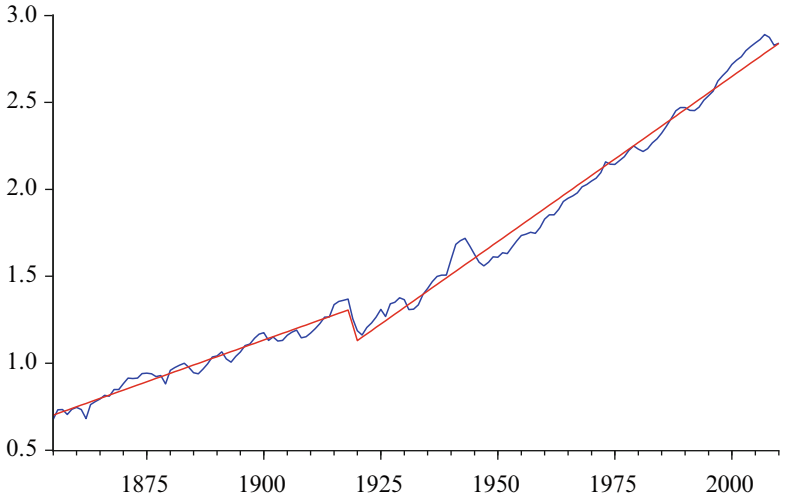

Fig. 1 Logarithms of UK per capita GDP for 1855–2010 with a fitted segmented linear trend having breaks at 1918 and 1920

while post-1920 it is estimated to be $0.0096 - 0.0975 + 0.1068 = 1.89\%$ per annum, with the decline in trend GDP in 1919 and 1920 being of the order of 15%.

On fitting a model of the form Eq. 6, say, various hypotheses may be tested. After the final break, the model becomes

$$x_t = \alpha + \beta t + \sum_{i=2}^{m} \theta_i (t - T_i) + u_t \tag{9}$$

which can be rewritten as

$$x_t = \alpha + \beta t + \left(\sum_{i=2}^{m} \theta_i \right) t - \sum_{i=2}^{m} \theta_i T_i + u_t \tag{10}$$

If both $\sum \theta_i = 0$ and $\sum \theta_i T_i = 0$, the time path of x_t after the final break at T_m will be the same as the path extrapolated from T_1. Crafts and Mills (1996) refer to this as the *Janossy hypothesis* after Janossy (1969), who argued that when the shocks brought about by the world wars and subsequent reconstruction had worked themselves out, growth would return to a historically normal path. If only the first of these restrictions holds, then growth returns to its original (i.e., pre-$T_1 + 1$) rate, so that the path of x_t after T_m will be *parallel* to the path extrapolated from T_1 (Crafts and Mills call this the modified Janossy hypothesis). The hypothesis $\theta_1 + \theta_2 = 0$ is clearly rejected in Eq. 8 so that neither of the Janossy hypotheses holds for the UK, as is clear from Fig. 1.

Of course, the break points in Eq. 8 have been selected a priori and so may be subjectively biased and, furthermore, there may be more than two breaks in trend.

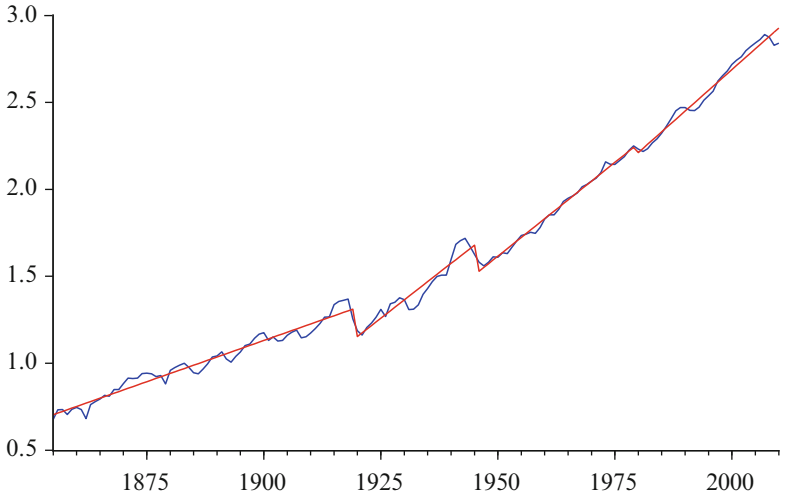

Fig. 2 Logarithms of UK per capita GDP for 1855–2010 with a fitted breaking linear trend having breaks at 1918, 1946, and 1979

Mills and Crafts (1996b) selected their three break dates in Eq. 7 "endogenously" by choosing ranges within which the breaks were most likely to fall and then using a goodness-of-fit criterion based on the fitting of regressions for alternative combinations of break dates. Since then the selection of breaks in such models has been the subject of much interest and research and there are now a variety of procedures with which to determine the number and dating of breaks in trend (key references are Bai 1997; Bai and Perron 1998, 2003a, b; Perron 2006, for a detailed survey of the area).

Figure 2 shows a breaking linear trend fitted to UK per capita GDP containing three breaks at 1919, 1945, and 1979, the number and dating being determined endogenously by several of the extant procedures. The fitted model is

$$\begin{aligned} x_t = {} & \underset{(0.0095)}{0.7039} + \underset{(0.0006)}{0.0095}\, t - \underset{(0.1311)}{0.2112}\, d_{1t} - \underset{(0.0538)}{0.4353}\, d_{2t} - \underset{(0.1158)}{0.7703}\, d_{3t} \\ & + \underset{(0.0017)}{0.0210}\, td_{1t} + \underset{(0.0005)}{0.0216}\, td_{2t} + \underset{(0.0008)}{0.0239}\, td_{3t} + \hat{u}_t \qquad R^2 = 0.9967 \end{aligned}$$

The trend growth rates are estimated to be 0.95% before 1920, 2.10% between 1920 and 1945, 2.16% between 1946 and 1979, and 2.39% from 1980. The Janossy hypotheses are here $\gamma_3 = \delta_3 = 0$ and $\delta_3 = 0$, both of which are clearly rejected. However, a test of the hypothesis $\delta_1 = \delta_2$ is insignificant (marginal level 0.74) so that the hypothesis that trend growth was constant throughout the period 1920 to 1979 may be accepted.

Figure 3 shows the "cycle," obtained by residual, from the segmented trend model. An interesting feature of this component is that, although it may be adequately modelled as a second-order autoregression, being $\psi_t = 1.060\psi_{t-1}$ $_t = 1.060\psi_{t-1} - 0.220\psi_{t-2} + e_t$, the roots of this autoregression are 0.78 and

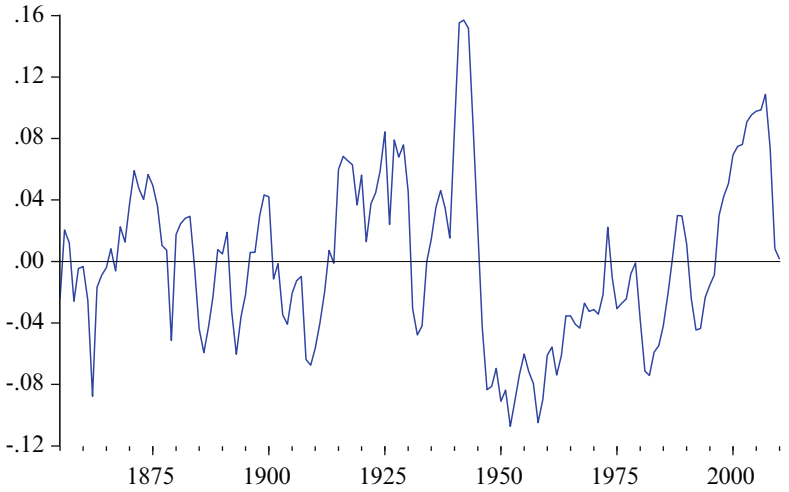

Fig. 3 Cyclical component of UK per capita GDP for 1855–2010 obtained by residual from the segmented trend model

0.28 and hence are both real, so that true "periodic" behavior, in the sense that an average period may be calculated, is ruled out.

All breaking and segmented trend models assume that the cyclical component ψ_t, given by the regression error u_t in Eqs. 5, 6, and 7, is stationary and hence does not contain a unit root. Thus, before these models can be entertained, tests of a unit root in the presence of a breaking trend need to be performed. This area of time series econometrics has attracted much attention recently, with Kim and Perron (2009) and Harris et al. (2009) being notable contributors, but it is not a subject that can be considered in this chapter.

Filters for Extracting Trends and Cycles

Dissatisfaction with the use of unweighted moving averages with preselected spans to extract trends led eventually to the consideration of more flexible moving averages. Their development may be traced back to Leser (1961), although earlier prototypes were proposed in the 1920s (see Mills 2011, Chap. 10).

Leser (1961) implicitly considered the additive decomposition Eq. 1 and invoked the penalized least squares principle, which minimizes, with respect to μ_t, $t = 1, 2, \ldots, T$, the criterion

$$\sum_{t=1}^{T} (x_t - \mu_t)^2 + \lambda \sum_{t=3}^{T} \left(\Delta^2 \mu_t\right)^2 \tag{11}$$

The first term measures the goodness of fit of the trend, and the second penalizes the departure from zero of the variance of the second differences of the trend, so that it is a measure of smoothness: λ is thus referred to as the smoothness parameter. Successive partial differentiation of Eq. 11 with respect to the sequence μ_t leads to the first-order conditions

$$\Delta^2\mu_{t+2} - 2\Delta^2\mu_{t+1} + \Delta^2\mu_t = (\lambda - 1)(x_t - \mu_t)$$

Given T and λ, μ_t will then be a moving average of x_t with time-varying weights, so that no observations are lost at the sample extremes. Leser developed a method of deriving these weights and provided a number of examples in which the solutions were obtained in, it has to be said, laborious and excruciating detail, which must certainly have lessened the impact of the paper at the time!

Some two decades later, Hodrick and Prescott (1997) approached the solution of Eq. 11 rather differently. By recasting Eq. 11 in matrix form as $(\mathbf{x} - \boldsymbol{\mu})'(\mathbf{x} - \boldsymbol{\mu}) + \lambda\boldsymbol{\mu}'\mathbf{D}^{2\prime}\mathbf{D}^2\boldsymbol{\mu}$, where $\mathbf{x} = (x_1, \ldots, x_T)'$, $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_T)'$, and $\mathbf{D}$ is the $T \times T$ "first difference" matrix with elements $d_{t,t} = 1$ and $d_{t-1,t} = -1$ and zero elsewhere, so that $\mathbf{D}\boldsymbol{\mu} = (\mu_2 - \mu_1, \ldots, \mu_T - \mu_{T-1})'$, then differentiating with respect to $\boldsymbol{\mu}$ allows the first-order conditions to be written as

$$\mu = \left(\mathbf{I} + \lambda\mathbf{D}^{2\prime}\mathbf{D}^2\right)^{-1}\mathbf{x} \tag{12}$$

with the rows of the inverse matrix containing the H-P filter weights for estimating the trend μ_t at each t. Setting $\lambda = 100$ is often suggested when extracting a trend from an annual series and other choices are discussed in, for example, Ravn and Uhlig (2002) and Maravall and del Rio (2007).

In filtering terminology the H-P filter Eq. 12 is a *low-pass filter*. To understand this terminology, some basic concepts in filtering theory are useful. Define a *linear filter* of the observed series x_t to be the two-sided weighted moving average

$$y_t = \sum_{j=-n}^{n} a_j x_{t-j} = \left(a_{-n}B^{-n} + a_{-n+1}B^{-n+1} + \ldots + a_0 + \ldots + a_nB^n\right)x_t = a(B)x_t$$

Two conditions are typically imposed upon the filter $a(B)$: (i) that the filter weights either (a) sum to zero, $a(1) = 0$, or (b) sum to unity, $a(1) = 1$, and (ii) that these weights are symmetric, $a_j = a_{-j}$. If condition (ia) holds, then $a(B)$ is a "trend-elimination" filter, whereas if (ib) holds it will be a "trend-extraction" filter. If the former holds then $b(B) = 1 - a(B)$ will be the corresponding trend-extraction filter, having the same, but oppositely signed, weights as the trend-elimination filter $a(B)$ except for the central value, $b_0 = 1 - a_0$, thus ensuring that $b(B) = 1$.

The *frequency response function* of the filter is defined as $a(\omega) = \sum_j e^{-i\omega j}$ for a frequency $0 \leq \omega \leq 2\pi$. The *power transfer function* is then defined as

$$|a(\omega)|^2 = \left(\sum_j a_j \cos \omega j\right)^2 + \left(\sum_j a_j \sin \omega j\right)^2$$

and the *gain* is defined as $|a(\omega)|$, measuring the extent to which the amplitude of the ω–frequency component of x_t is altered through the filtering operation. In general, $a(\omega) = |a(\omega)|e^{-i\theta(\omega)}$, where

$$\theta(\omega) = \tan^{-1} \frac{\sum_j a_j \sin \omega j}{\sum_j a_j \cos \omega j}$$

is the *phase shift*, indicating the extent to which the ω–frequency component of x_t is displaced in time. If the filter is indeed symmetric, then $a(\omega) = a(-\omega)$, so that $a(\omega) = |a(\omega)|$ and $\theta(\omega) = 0$, known as phase neutrality.

With these concepts, an "ideal" low-pass filter has the frequency response function

$$a_L(\omega) = \begin{cases} 1 & \text{if } \omega < \omega_c \\ 0 & \text{if } \omega > \omega_c \end{cases} \tag{13}$$

Thus, $a_L(\omega)$ passes only frequencies lower than the cutoff frequency ω_c, so that just slow-moving, low-frequency components of x_t are retained. Low-pass filters should also be phase-neutral, so that temporal shifts are not induced by filtering. The ideal low-pass filter will take the form

$$a_L(B) = \frac{\omega_c}{\pi} + \sum_{j=1}^{\infty} \frac{\sin \omega_c j}{\pi j}\left(B^j + B^{-j}\right)$$

In practice, low-pass filters will not have the perfect "jump" in $a_L(\omega)$ implied by Eq. 13. The H-P trend-extraction filter, i.e., the one that provides an estimate of the trend component $\hat{\mu}_t = a_{\mathrm{H-P}}(B)x_t$, where the weights are given by Eq. 12, has the frequency response function

$$a_{\mathrm{H-P}}(\omega) = \frac{1}{1 + 4\lambda(1 - \cos \omega)^2} \tag{14}$$

while the H-P trend-elimination filter, which provides the cycle estimate $\hat{\psi}_t = b_{\mathrm{H-P}}(B)x_t = (1 - a_{\mathrm{H-P}}(B))x_t$, has the frequency response function

$$b_{\mathrm{H-P}}(\omega) = 1 - a_{\mathrm{H-P}}(\omega) = \frac{4\lambda(1 - \cos \omega)^2}{1 + 4\lambda(1 - \cos \omega)^2}$$

Rather than setting the smoothing parameter at an a priori value such as $\lambda = 100$, it could also be set at the value that equates the gain to 0.5, i.e., at the value that separates frequencies between those mostly associated with the trend and those mostly associated with the cycle. Since the H-P weights are indeed symmetric, the gain is given by Eq. 14, so equating this to 0.5 yields $\lambda = 1/4(1 - \cos \omega_{0.5})^2$, where $\omega_{0.5}$ is the frequency at which the gain is 0.5 (for more on this idea, see Kaiser and Maravall 2005).

The ideal low-pass filter removes high-frequency components while retaining low-frequency components. A high-pass filter does the reverse, so that the complementary high-pass filter to Eq. 13 has $a_H(\omega) = 0$ if $\omega < \omega_c$ and $a_H(\omega) = 1$ if $\omega \geq \omega_c$. The ideal band-pass filter passes only frequencies in the range $\omega_{c,1} \leq \omega \leq \omega_{c,2}$, so that it can be constructed as the difference between two low-pass filters with cutoff frequencies $\omega_{c,1}$ and $\omega_{c,2}$ and it will have the frequency response function $a_B(\omega) = a_{c,2}(\omega) - a_{c,1}(\omega)$, where $a_{c,2}(\omega)$ and $a_{c,1}(\omega)$ are the frequency response functions of the two low-pass filters, since this will give a frequency response of unity in the band $\omega_{c,1} \leq \omega \leq \omega_{c,2}$ and zero elsewhere. The weights of the band-pass filter will thus be given by $a_{c,2,j} - a_{c,1,j}$, where $a_{c,2,j}$ and $a_{c,1,j}$ are the weights of the two low-pass filters, so that

$$a_B(B) = \frac{\omega_{c,2} - \omega_{c,1}}{\pi} + \sum_{j=1}^{\infty} \frac{\sin \omega_{c,2} j - \sin \omega_{c,1} j}{\pi j}\left(B^j + B^{-j}\right) \tag{15}$$

A conventional definition of the business cycle emphasizes fluctuations of between 1½ and 8 years (see Baxter and King 1999), which leads to $\omega_{c,1} = 2\pi/8 = \pi/4$ and $\omega_{c,2} = 2\pi/1.5 = 4\pi/3$. Thus, a band-pass filter that passes only frequencies corresponding to these periods is defined as $y_t = a_{B,n}(B)x_t$ with weights

$$a_{B,0} = a_{c,2,0} - a_{c,1,0} = \frac{4}{3} - \frac{1}{4} - \left(\zeta_{c,2,n} - \zeta_{c,1,n}\right) \tag{16}$$

$$a_{B,j} = a_{c,2,j} - a_{c,1,j} = \frac{1}{\pi j}\left(\sin \frac{4\pi j}{3} - \sin \frac{\pi j}{4}\right) - \left(\zeta_{c,2,n} - \zeta_{c,1,n}\right) \qquad j = 1, \ldots, n$$

where

$$\zeta_{c,i,n} = -\frac{\sum_{j=-n}^{n} a_{c,i,n}}{2n+1} \qquad i = 1,2$$

The infinite length filter in Eq. 15 has been truncated to have only n leads and lags and the appearance of the $\zeta_{c,i,n}$ terms ensures that the filter weights sum to zero, so that $a_{B,n}(B)$ is a trend-elimination (i.e., cycle) filter. The filter in Eq. 16 is known as the Baxter-King (B-K) filter, with further extensions being provided by Christiano and Fitzgerald (2003).

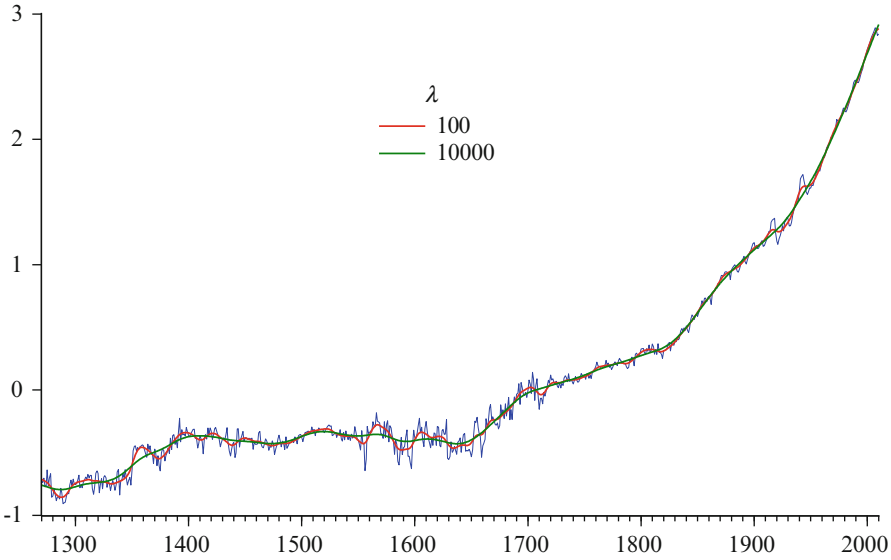

Fig. 4 Logarithms of British per capita GDP for 1270–2010 with H-P trends for $\lambda = 100$ and 10, 000

Figure 4 shows the logarithms of British GDP per capita from 1270 to 2010. Superimposed on this series are H-P trends for $\lambda = 100$ and 10, 000. Figure 5 shows the trend growth rates of these two H-P variants. The larger the value of the smoothing parameter λ, the smoother is the trend, and this is particularly noticeable in the growth rates, where the larger value produces much more stable growth rates than the "conventional" choice of 100 and may thus be more appropriate for examining trend growth over long historical time spans.

Filters and Structural Models

Several of the filters in common use can be shown to be optimal for the following class of *structural unobserved component* (UC) models:

$$x_t = \mu_t + \psi_t$$

$$\Delta^m \mu_t = (1+B)^r \xi_t \qquad \xi_t \sim WN\left(0, \sigma_\xi^2\right)$$

$$\psi_t \sim WN\left(0, \lambda\sigma_\xi^2\right) \qquad E\left(\xi_t \psi_{t-j}\right) = 0 \quad \text{for all } j$$

Here the notation $y_t \sim WN(0, \sigma_y^2)$ is to be read as stating that the variable y_t is white noise (i.e., identically and independently distributed) with zero mean and variance σ_y^2. For (doubly) infinite samples, the minimum mean square error

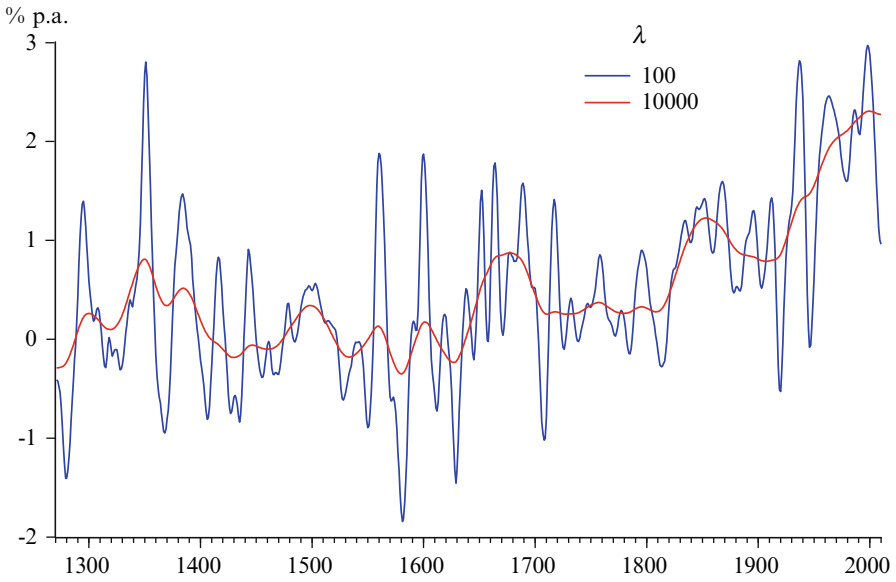

Fig. 5 Trend growth rates of British per capita GDP for $\lambda = 100$ and 10, 000

(MMSE) estimates of the components are $\hat{\mu}_t = a_\mu(B)x_t$ and $\hat{\psi}_t = x_t - \hat{\mu}_t = \big(1 - a_\mu(B)\big)x_t = a_\psi(B)x_t$, where

$$a_\mu(B) = \frac{(1+B)^r}{(1+B)^r + (1-B)^m}$$

and

$$\big|a_\mu(B)\big| = \frac{|1+B|^{2r}}{|1+B|^{2r} + \lambda|1-B|^{2m}} \tag{17}$$

and the notation $|\alpha(B)| = \alpha(B)\alpha(B^{-1})$ is used. This result uses Wiener-Kolmogorov filtering theory and its derivation may be found in, for example, Proietti (2009a). This filter is therefore defined by the order of integration of the trend, m, which regulates its flexibility, by the parameter r (which technically is the number of unit poles at the Nyquist frequency and which thus regulates the smoothness of $\Delta^m\mu_t$) and by λ, which measures the relative variance of the noise component.

The H-P filter is obtained for $m = 2$ and $r = 0$, so that $\Delta^2\mu_t = \xi_t$. If $m = 1$ and $r = 0$, $\Delta\mu_t = \xi_t$ and the filter corresponds to a two-sided exponentially weighted moving average with smoothing parameter $\big((1+2\lambda) + \sqrt{1+4\lambda}\big)/2\lambda$ (recall Cox 1961). If $r = 0$ then any setting of m defines a *Butterworth filter*, as does setting $m = r$, which is known as the Butterworth *square-wave* filter (see Gómez 2001).

Setting $m = r = 1$ and $\lambda = 1$ produces the multi-resolution Haar scaling and wavelet filters (see Percival and Walden 1999).

Using Eq. 17 and the idea that the cutoff frequency can be chosen to be that frequency at which the gain is 0.5 (as above) enables the smoothing parameter to be determined as

$$\lambda = 2^{r-m} \frac{(1 + \cos \omega_{0.5})^r}{(1 - \cos \omega_{0.5})^m}$$

Detailed development of the models and techniques discussed in this and the preceding section may be found in Pollock (2009) and Proietti (2009a).

Model-Based Filters

The setup of the previous section is very assumption laden and implies, among other things, that the observed series is generated as

$$\Delta^m x_t = (1 + B)^r \zeta_t + (1 - B)^m \psi_t = \theta_q(B) a_t$$

i.e., as a heavily restricted ARIMA $(0, m, q)$ process, where $\theta_q(B) = 1 - \theta_1 B - {}_q(B) = 1 - \theta_1 B - \ldots - \theta_q B^q$ with $q = \max(r, m)$ (the subscript q denoting the order of the polynomial will be dropped when appropriate to simplify notation). A less restrictive approach is to begin by assuming that the observed series has an ARIMA (p, d, q) representation

$$\phi_p(B)\left(\Delta^d x_t - c\right) = \theta_q(B) a_t \qquad a_t \sim WN\left(0, \sigma_a^2\right)$$

where $\phi_p(B)$ has p stationary roots and $\theta_q(B)$ is invertible and to derive filters with the desired properties from this representation. This is done by exploiting the idea that a_t can be decomposed into two orthogonal stationary processes (see, e.g., Proietti 2009a, b, for technical details):

$$a_t = \frac{(1 + B)^r \zeta_t + (1 - B)^m \kappa_t}{\phi_{q^*}(B)} \tag{18}$$

where $q^* = \max(r, m)$, $\zeta_t \sim WN(0, \sigma_a^2)$, $\kappa_t \sim WN(0, \lambda \sigma_a^2)$, and

$$\left|\phi_{q^*}(B)\right|^2 = |1 + B|^{2r} + \lambda |1 - B|^{2m} \tag{19}$$

Given Eqs. 18 and 19, the following orthogonal trend-cycle decomposition $x_t = \mu_t + \psi_t$ can be defined:

$$\phi(B)\varphi(B)\left(\Delta^d \mu_t - c\right) = (1+B)^r \theta(B)\zeta_t \tag{20}$$

$$\phi(B)\varphi(B)\psi_t = \Delta^{m-d}\theta(B)\kappa_t$$

The trend, or low-pass component, has the same order of integration as x_t, regardless of m, whereas the cycle, or high-pass component, is stationary provided that $m \geq d$. The MMSE estimators of the trend and cycle are again given by Eq. 17 and its "complement." Band-pass filters may be constructed by decomposing the low-pass component in Eq. 20: see Proietti (2009a).

The H-P and B-K filters are often referred to as being ad hoc, in the sense here that they are invariant to the process actually generating x_t. This has the potential danger that such filters could produce a cyclical component, say, that might display cyclical features that are absent from the observed series, something that is known as the Slutsky-Yule effect. For example, it has been well documented that when the H-P filter is applied to a random walk, which obviously cannot contain any cyclical patterns, the detrended series can nevertheless display spurious cyclical behavior. The (ARIMA) model-based filters are designed to overcome these limitations.

Structural Trends and Cycles

An alternative approach to modelling trends and cycles is to take the UC decomposition $x_t = \mu_t + \psi_t$ and *assume* particular models for the components. The most general approach to *structural model* building is that set out by Harvey and Trimbur (2003), Trimbur (2006), and Harvey et al. (2007), who consider the UC decomposition

$$x_t = \mu_{m,t} + \psi_{n,t}$$

where the components are assumed to be mutually uncorrelated. The trend component is defined as the mth order stochastic trend

$$\mu_{1,t} = \mu_{1,t-1} + \zeta_t \qquad \zeta_t \sim WN\left(0,\sigma_\zeta^2\right)$$

$$\mu_{i,t} = \mu_{i,t-1} + \mu_{i-1,t} \qquad i = 2,\ldots,m$$

Note that repeated substitution yields $\Delta^m \mu_{m,t} = \zeta_t$. The random walk trend is thus obtained for $m = 1$ and the integrated random walk, or "smooth trend," with slope $\mu_{1,t}$, for $m = 2$.

The component $\psi_{n,t}$ is an nth order stochastic cycle, for $n > 0$, if

$$\begin{bmatrix} \psi_{1,t} \\ \psi_{1,t}^* \end{bmatrix} = \rho \begin{bmatrix} \cos\varpi & \sin\varpi \\ -\sin\varpi & \cos\varpi \end{bmatrix} \begin{bmatrix} \psi_{1,t-1} \\ \psi_{1,t-1}^* \end{bmatrix} + \begin{bmatrix} \kappa_t \\ 0 \end{bmatrix} \qquad \kappa_t \sim WN\left(0,\sigma_\kappa^2\right) \tag{21}$$

$$\begin{bmatrix} \psi_{i,t} \\ \psi^*_{i,t} \end{bmatrix} = \rho \begin{bmatrix} \cos\varpi & \sin\varpi \\ -\sin\varpi & \cos\varpi \end{bmatrix} \begin{bmatrix} \psi_{i,t-1} \\ \psi^*_{i,t-1} \end{bmatrix} + \begin{bmatrix} \psi_{i-1,t} \\ 0 \end{bmatrix} \qquad i = 2,\ldots,n$$

Here $0 \leq \varpi \leq \pi$ is the frequency of the cycle and $0 < \rho \leq 1$ is the damping factor. The reduced form representation of the cycle is

$$\left(1 - 2\rho\cos\varpi B + \rho^2 B^2\right)^n \psi_{n,t} = (1 - \rho\cos\varpi B)^n \kappa_t$$

and Harvey and Trimbur (2003) show that, as m and n increase, the optimal estimates of the trend and cycle approach the ideal low-pass and band-pass filters, respectively. Defining the "signal to noise" variance ratios $q_\zeta = \sigma^2_\zeta/\sigma^2_\varepsilon$ and $q_\kappa = \sigma^2_\kappa/\sigma^2_\varepsilon$, the low-pass filter (of order m, n) is

$$\hat{\mu}_t(m,n) = \frac{q_\zeta/|1-B|^{2m}}{q_\zeta/|1-B|^{2m} + q_k|c(B)|^n + 1}$$

where $c(B) = (1 - \rho\cos\varpi B)/(1 - 2\rho\cos\varpi B + \rho^2 B^2)$. The corresponding band-pass filter is

$$\hat{\psi}_t(m,n) = \frac{q_k|c(B)|^n}{q_\zeta/|1-B|^{2m} + q_k|c(B)|^n + 1}$$

Harvey and Trimbur (2003) discuss many of the properties of this general model. They note that applying a band-pass filter of order n to a series that has been detrended by a low-pass filter of order m will not give the same result as applying a generalized filter of order (m, n), as a jointly specified model enables trends and cycles to be extracted by filters that are mutually consistent. Using higher-order trends with a fixed order band-pass filter has the effect of removing lower frequencies from the cycle. However, setting m greater than 2 will produce trends that are more responsive to short-term movements than is perhaps desirable, and this might be felt to be a particular drawback in historical applications.

Replacing the zero component in the right hand side of Eq. 21 by a white noise uncorrelated with κ_t produces a *balanced cycle*, the statistical properties of which are derived in Trimbur (2006). For example, for $n = 2$ the variance of the cycle is given by

$$\sigma^2_\psi = \frac{1+\rho^2}{(1-\rho^2)^3}\sigma^2_\kappa$$

as opposed to $\sigma^2_\kappa/(1-\rho^2)$ for the first-order case, while its autocorrelation function is

$$\rho_2(\tau) = \rho^\tau \cos \varpi\tau\left(1 + \frac{1-\rho^2}{1+\rho^2}\tau\right), \qquad \tau = 0,\ 1,\ 2, \ldots$$

compared to $\rho_1(\tau) = \rho^\tau \cos \varpi\tau$. Harvey and Trimbur prefer the balanced form as it seems to give better fits in empirical applications and offers computational advantages over Eq. 21.

Trimbur (2006) shows that an nth order stochastic cycle admits an ARMA $(2n, 2n - 1)$ representation in which the AR polynomial has n pairs of roots, each given by the complex conjugate pair $\rho^{-1} \exp(\pm i\varpi)$.

If the cyclical component is not characterized by such "cyclical" behavior, the specification Eq. 21 may be replaced by a simple AR(1) or AR(2) process. Such a model with $m = 2$ and an AR(1) cycle is found to be the best structural model with which to characterize British per capita GDP for 1270–2010:

$$x_t = \mu_{2,t} + \psi_t$$

$$\mu_{2,t} = \mu_{2.t-1} + \mu_{1,t} = \mu_{2.t-1} + \mu_{1,t-1} + \zeta_t \qquad \hat{\sigma}^2_\zeta = 0.00058$$

$$\psi_t = 0.396\psi_{t-1} + e_t \qquad \hat{\sigma}^2_e = 0.00241$$

The trend growth obtained from this model is shown in Fig. 6 along with trend growth computed from the H-P filter with $\lambda = 10,000$. The latter is seen to be a smoothed version of the former, which might be thought to be too volatile to be considered as a viable estimate for "long-run" trend growth.

Models with Correlated Components

A feature of all the models introduced so far has been the identifying assumption that all component innovations are mutually uncorrelated, so that the components are orthogonal. Such an assumption can be relaxed: for example, Morley et al. (2003) consider the UC model $x_t = \mu_t + \psi_t$ with contemporaneously correlated innovations:

$$\mu_t = \mu_{t-1} + c + \zeta_t \qquad \zeta_t \sim WN\left(0, \sigma^2_\zeta\right) \tag{22}$$

$$\psi_t = \phi_1\psi_{t-1} + \phi_2\psi_{t-2} + \kappa_t \qquad \kappa_t \sim WN\left(0, \sigma^2_\kappa\right)$$

with $\sigma_{\zeta\kappa} = E(\zeta_t\kappa_t) = r\sigma_\zeta\sigma_\kappa$, so that r is the contemporary correlation between the innovations. The reduced form of Eq. 22 is the ARIMA (2, 1, 2) process

$$\left(1 - \phi_1 B - \phi_2 B^2\right)(\Delta x_t - c) = \left(1 - \theta_1 B - \theta_2 B^2\right)a_t \tag{23}$$

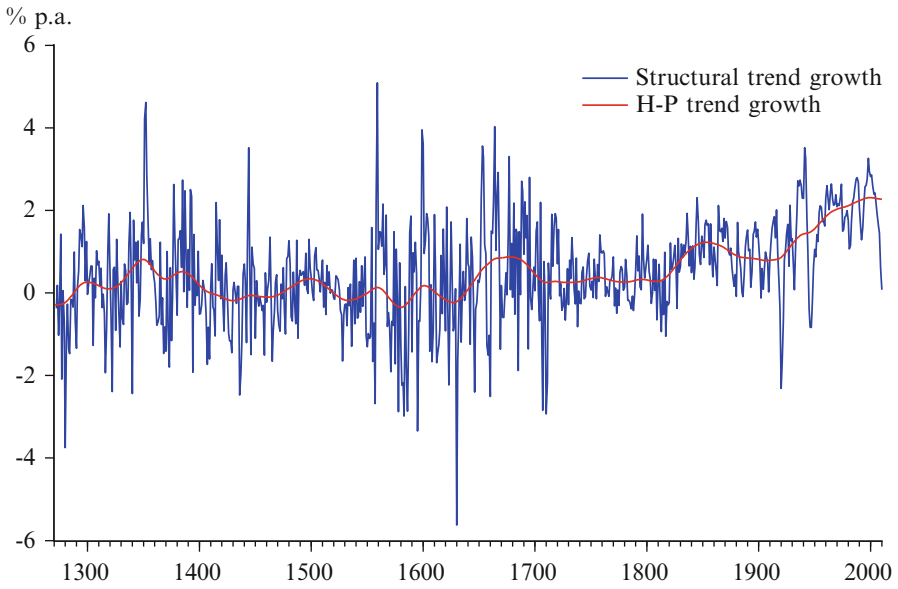

Fig. 6 Trend growth for British per capita GDP, 1270–2010, computed from a structural model, compared to H-P trend growth

Morley et al. (2003) show that the structural form is exactly identified, so that the correlation between the innovations can be estimated and the orthogonality assumption $\sigma_{\zeta\kappa} = 0$ tested.

A related model decomposes an ARIMA(p, 1, q) process $\phi(B)(\Delta x_t - c) = \theta(B)\, a_t$ into a random walk trend

$$\mu_t = \mu_{t-1} + c + \frac{\theta(1)}{\phi(1)} a_t = \frac{\theta(1)}{\phi(1)} \frac{\phi(B)}{\theta(B)} x_t$$

and a cyclical (or transitory) component

$$\psi_t = \frac{\phi(1)\theta(B) - \theta(1)\phi(B)}{\phi(1)\phi(B)\Delta} a_t = \frac{\phi(1)\theta(B) - \theta(1)\phi(B)}{\phi(1)\phi(B)} x_t$$

which has a stationary ARMA (p, max(p, q) − 1) representation. Thus, for the ARIMA (2, 1, 2) process (Eq. 23), the random walk trend will be

$$\mu_t = \mu_{t-1} + c + \left(\frac{1 - \theta_1 - \theta_2}{1 - \phi_1 - \phi_2} \right) a_t$$

while the ARMA (2, 1) cycle will be

$$\left(1-\phi_1 B-\phi_2 B^2\right)\psi_t=(1+\vartheta B)\left(\frac{\theta_1+\theta_2-(\phi_1+\phi_2)}{1-\phi_1-\phi_2}\right)a_t$$

$$\vartheta=\frac{\phi_2(1-\theta_1-\theta_2)+\theta_2(1-\phi_1-\phi_2)}{\theta_1+\theta_2-(\phi_1+\phi_2)}$$

The two components are seen to be driven by the *same* innovation, a_t, and hence are perfectly correlated. Whether this correlation is plus or minus one depends upon the *persistence* $\theta(1)/\phi(1)$: if this is less (greater) than one, the correlation is + 1 (−1). This decomposition is familiarly known as the Beveridge-Nelson (B-N) decomposition (Beveridge and Nelson 1981).

The following ARIMA (1, 1, 2) model was found to adequately fit the British per capita GDP data:

$$\Delta x_t=\underset{(0.114)}{0.486}+\frac{\left(1-\underset{(0.037)}{0.277}\,B^2\right)}{\left(1+\underset{(0.037)}{0.303}\,B\right)}a_t$$

Since $p=1$ the structural form (22) is no longer identified, but the B-N decomposition may be obtained: with $\phi_1=-0.303$, $\theta_2=0.277$, and $\phi_2=\theta_1=0$, the B-N random walk trend is

$$\mu_t=\mu_{t-1}+0.486+0.554a_t$$

and the ARMA(1,1) cycle is

$$(1+0.303B)\psi_t=(1+0.622B)(0.446a_t)$$

Proietti and Harvey (2000) define the B-N "smoother" as

$$\mu_t^{\mathrm{B-N}}=\left[\frac{\theta(1)}{\phi(1)}\right]^2\frac{\phi(B)\phi\left(B^{-1}\right)}{\theta(B)\theta\left(B^{-1}\right)}x_t$$

which will be a symmetric two-sided filter with weights summing to unity. For the model here

$$\mu_t^{\mathrm{B-N}}=0.307\frac{(1+0.303B)\left(1+0.303B^{-1}\right)}{\left(1-0.277B^2\right)\left(1-0.277B^{-2}\right)}x_t$$

Multivariate Extensions of Structural Models

Since co-movement between macroeconomic series is a key aspect of business cycles, many of the filters and structural models have been extended to multivariate setups (see, e.g., Kozicki 1999). Multivariate structural models have been introduced

by Carvalho and Harvey (2005) and Carvalho et al. (2007). Suppose there are N time series gathered together in the vector $\mathbf{x}_t = (x_{1t}, \ldots, x_{Nt})'$, which may be decomposed into trend, $\boldsymbol{\mu}_t$; cycle, $\boldsymbol{\psi}_t$; and irregular, $\boldsymbol{\varepsilon}_t$, vectors such that

$$\mathbf{x}_t = \boldsymbol{\mu}_t + \boldsymbol{\psi}_t + \boldsymbol{\varepsilon}_t \qquad \boldsymbol{\varepsilon}_t \sim MWN(\mathbf{0}, \Sigma_{\boldsymbol{\varepsilon}})$$

where $MWN(\mathbf{0}, \Sigma_{\boldsymbol{\varepsilon}})$ denotes zero mean multivariate white noise with $N \times N$ positive semi-definite covariance matrix $\Sigma_{\boldsymbol{\varepsilon}}$. The trend is defined as

$$\begin{aligned} \boldsymbol{\mu}_t &= \boldsymbol{\mu}_{t-1} + \boldsymbol{\beta}_{t-1} + \boldsymbol{\eta}_t \qquad \boldsymbol{\eta}_t \sim MWN\left(\mathbf{0}, \Sigma_{\boldsymbol{\eta}}\right) \\ \boldsymbol{\beta}_t &= \boldsymbol{\beta}_{t-1} + \boldsymbol{\zeta}_t \qquad \boldsymbol{\zeta}_t \sim MWN\left(\mathbf{0}, \Sigma_{\boldsymbol{\zeta}}\right) \end{aligned} \tag{24}$$

With $\Sigma_{\boldsymbol{\zeta}} = \mathbf{0}$ and $\Sigma_{\boldsymbol{\eta}}$ positive definite, each trend is a random walk with drift. If, on the other hand, $\Sigma_{\boldsymbol{\eta}} = \mathbf{0}$ and $\Sigma_{\boldsymbol{\zeta}}$ is positive definite, the trends are integrated random walks and will typically be much smoother than drifting random walks.

The *similar cycle* model is

$$\begin{bmatrix} \boldsymbol{\psi}_t \\ \boldsymbol{\psi}_t^* \end{bmatrix} = \left[\rho \begin{pmatrix} \cos\varpi & \sin\varpi \\ -\sin\varpi & \cos\varpi \end{pmatrix} \otimes \mathbf{I}_N \right] \begin{bmatrix} \boldsymbol{\psi}_{t-1} \\ \boldsymbol{\psi}_{t-1}^* \end{bmatrix} + \begin{bmatrix} \boldsymbol{\kappa}_t \\ \boldsymbol{\kappa}_t^* \end{bmatrix}$$

where $\boldsymbol{\psi}_t$ and $\boldsymbol{\psi}_t^*$ are N-vectors and $\boldsymbol{\kappa}_t$ and $\boldsymbol{\kappa}_t^*$ are N-vectors of mutually uncorrelated zero mean vector multivariate white noise with the same covariance matrix $\Sigma_{\boldsymbol{\kappa}}$. As the damping factor ρ and cyclical frequency ϖ are the same for all series, the individual cycles have similar properties, being centered around the same period as well as being contemporaneously correlated, on noting that the covariance matrix of $\boldsymbol{\psi}_t^*$ is

$$\Sigma_{\boldsymbol{\psi}} = \left(1 - \rho^2\right)^{-1} \Sigma_{\boldsymbol{\kappa}}$$

Suppose that $\Sigma_{\boldsymbol{\zeta}} = \mathbf{0}$ in Eq. 24. The model will have common trends if $\Sigma_{\boldsymbol{\eta}}$ is less than full rank. If the rank of $\Sigma_{\boldsymbol{\eta}}$ is one, then there will be a single common trend and

$$\mathbf{x}_t = \boldsymbol{\theta}\mu_t + \boldsymbol{\alpha} + \boldsymbol{\psi}_t + \boldsymbol{\varepsilon}_t \tag{25}$$

where the common trend is

$$\mu_t = \mu_{t-1} + \beta + \eta_t \qquad \mu_0 = 0 \qquad \eta_t \sim WN\left(0, \sigma_\eta^2\right)$$

and $\boldsymbol{\theta}$ and $\boldsymbol{\alpha}$ are N-vectors of constants. If $\Sigma_{\boldsymbol{\eta}} = \mathbf{0}$ the existence of common trends depends on the rank of $\Sigma_{\boldsymbol{\zeta}}$. When this rank is less than N, some linear combinations of the series will be stationary. A rank of one again leads to the model (25) but with

$$\mu_t = \mu_{t-1} + \beta_{t-1} \qquad \beta_t = \beta_{t-1} + \zeta_t \qquad \zeta_t \sim WN\left(0, \sigma_\zeta^2\right)$$

When $\boldsymbol{\theta} = \mathbf{i}$, where $\mathbf{i}$ is an N-vector of ones, there is *balanced growth*, and the difference between any pair of series in $\mathbf{x}_t$ is stationary.

A mechanism for capturing convergence to a common growth path can be incorporated by specifying the decomposition

$$\mathbf{x}_t = \boldsymbol{\alpha} + \boldsymbol{\mu}_t + \boldsymbol{\psi}_t + \boldsymbol{\varepsilon}_t$$

with

$$\boldsymbol{\mu}_t = \boldsymbol{\Phi}\boldsymbol{\mu}_{t-1} + \boldsymbol{\beta}_{t-1} \qquad \boldsymbol{\beta}_t = \boldsymbol{\Phi}\boldsymbol{\beta}_{t-1} + \boldsymbol{\zeta}_t$$

where $\boldsymbol{\Phi} = \phi\mathbf{I} + (1-\phi)\mathbf{i}\overline{\boldsymbol{\phi}}$ and $\overline{\boldsymbol{\phi}}$ is a vector of weights. With this setup, a convergence mechanism can be defined to operate on both the gap between an individual series and the common trend and on the gap in the growth rates of the individual series and the common trend. When ϕ is less than but close to unity, the convergence components tend to be quite smooth and there is a clear separation of long-run movements and cycles. The forecasts for each series converge to a common growth path, although they may exhibit temporary divergences. If $\phi = 1$ there will be no convergence.

Extensions to incorporate multivariate mth order trends and nth order cycles may also be contemplated, as indeed may multivariate low-pass and band-pass filters.

Estimation of Structural Models

All the structural models introduced here may be estimated by recasting them in state space form, whence they can be estimated using the Kalman filter algorithm. This will produce a MMSE estimator of the state vector, along with its mean square error matrix, conditional on past information. This is then used to build the one-step-ahead predictor of $\mathbf{x}_t$ and its mean square error matrix. The likelihood of the model can be evaluated via the prediction error decomposition and both filtered (real time) and smoothed (full sample) estimates of the components may then be obtained using a set of recursive equations. Harvey and De Rossi (2006) and Proietti (2009a) are convenient references for technical details, while comprehensive software for the estimation and analysis of structural models is provided by the STAMP package (see Koopman et al 2009).

Structural Breaks Across Series

While section "Segmented Trend Models" considered breaks in a single series, the focus of this section is on the recently developed modelling of breaks across a set of time series, known as *co-breaking*, as synthesized by Hendry and Massmann (2007). Their basic definition of co-breaking again focuses on the vector $\mathbf{x}_t = (x_{1t}, \ldots, x_{Nt})'$, which is now assumed to have an unconditional expectation around an initial parameterization of $E(\mathbf{x}_0) = \boldsymbol{\beta}_0$, where $\boldsymbol{\beta}_0$ depends only on deterministic variables

whose parameters do not change: for example, $\boldsymbol{\beta}_0 = \boldsymbol{\beta}_{c,0} + \boldsymbol{\beta}_{t,0}t$. A *location shift* in $\mathbf{x}_t$ is then said to occur if, for any t, $E(\mathbf{x}_t - \boldsymbol{\beta}_0) = \boldsymbol{\beta}_t$ and $\boldsymbol{\beta}_t \neq \boldsymbol{\beta}_{t-1}$, i.e., if the expected value of $\mathbf{x}_t$ around its initial parameterization in one time period deviates from that in the previous time period. (Contemporaneous mean) Co-breaking is then defined as the cancelation of location shifts across linear combinations of variables and may be characterized by there being an $n \times r$ matrix $\boldsymbol{\Omega}$, of rank $r < n$, such that $\boldsymbol{\Omega}'\boldsymbol{\beta}_t = \mathbf{0}$. It then follows that $\boldsymbol{\Omega}'E(\mathbf{x}_t - \boldsymbol{\beta}_0) = \boldsymbol{\Omega}'\boldsymbol{\beta}_t = \mathbf{0}$, so that the parameterization of the r co-breaking relationships $\boldsymbol{\Omega}'\mathbf{x}_t$ is independent of the location shifts.

Various extensions of contemporaneous mean co-breaking may be considered, such as variance co-breaking and intertemporal mean co-breaking, defined as the cancelation of deterministic shifts across both variables and time periods. Co-breaking may also be related to cointegration: the "common trends" incorporated in a VECM can be shown to be equilibrium-mean co-breaking, while the cointegrating vector itself is drift co-breaking.

To formalize the co-breaking regression approach, consider the following regression model for $\mathbf{x}_t$:

$$\mathbf{x}_t = \boldsymbol{\pi}_0 + \boldsymbol{\kappa}\mathbf{d}_t + \boldsymbol{\delta}\mathbf{w}_t + \boldsymbol{\varepsilon}_t \tag{26}$$

where $\mathbf{w}_t$ is a vector of exogenous variables and $\mathbf{d}_t$ is a set of $k > n$ deterministic shift variables. Assuming that the rank of $\boldsymbol{\kappa}$ is $n - 1$ allows it to be decomposed as $\boldsymbol{\kappa} = \boldsymbol{\xi}\boldsymbol{\eta}'$, where $\boldsymbol{\xi}$ is $n \times (n-1)$, $\boldsymbol{\eta}$ is $k \times (n-1)$, and both $\boldsymbol{\xi}$ and $\boldsymbol{\eta}$ are of full rank $n - 1$. There will then exist an $n \times 1$ vector $\boldsymbol{\xi}_\perp$ such that $\boldsymbol{\xi}'_\perp\boldsymbol{\xi} = \mathbf{0}$, which then implies that the linear combination $\boldsymbol{\xi}'_\perp\mathbf{x}_t = \boldsymbol{\xi}'_\perp\boldsymbol{\pi}_0 + \boldsymbol{\xi}'_\perp\boldsymbol{\delta}\mathbf{w}_t + \boldsymbol{\xi}'_\perp\boldsymbol{\varepsilon}_t$ will not contain the shift variables $\mathbf{d}_t$. Partitioning $\mathbf{x}_t$ as $(y_t \ \vdots \ \mathbf{z}_t)$ and partitioning and normalizing $\boldsymbol{\xi}_\perp$ as $(1 \ \vdots \ -\boldsymbol{\xi}'_{\perp,1})$ define the structural break-free co-breaking regression

$$y_t = \boldsymbol{\xi}'_{\perp,1}\mathbf{z}_t + \tilde{\boldsymbol{\pi}}_0 + \tilde{\boldsymbol{\delta}}\boldsymbol{w}_t + \tilde{\boldsymbol{\varepsilon}}_t \tag{27}$$

where $\tilde{\boldsymbol{\pi}}_0 = \boldsymbol{\xi}'_\perp\boldsymbol{\pi}_0$, etc. This co-breaking regression procedure may be implemented in two steps. First, test whether the k shifts $\mathbf{d}_t$ are actually present in each of the n components of $\mathbf{x}_t$ by estimating Eq. 26 and testing for the significance of $\boldsymbol{\kappa}$: second, augment Eq. 27 by $\mathbf{d}_t$ and test whether the shifts are now insignificant, with the co-breaking vector either estimated or imposed. Various extensions of this basic approach are discussed by Hendry and Massmann (2007), who also relax the assumption that the number of co-breaking relationships is known (assumed to be one above), so that the rank of $\boldsymbol{\kappa}$ is $n - r$, where r is to be estimated. Although such procedures are still in their infancy, they represent an important advance in the co-breaking framework, in which linear combinations of the form $\boldsymbol{\Omega}'\mathbf{x}_t$ depend on fewer breaks in their deterministic components than does $\mathbf{x}_t$ on its own.

Concluding Remarks

While cycles have been shown to be relatively straightforward to define, there is much less consensus on what actually constitutes a trend and trying to pin this down has attracted some attention recently for, as Phillips (2005) has memorably

remarked, "no one understands trends, but everyone sees them in the data" and that to "capture the random forces of change that drive a trending process, we need sound theory, appropriate methods, and relevant data. In practice, we have to manage under shortcomings in all of them." The variety of trend estimation methods discussed in this chapter would seem to bear Phillips out.

White and Granger (2011) have set out "working definitions" of various kinds of trends, and this taxonomy may prove to be useful in developing further models of trending processes, in which they place great emphasis on "attempting to relate apparent trends to appropriate underlying phenomena, whether economic, demographic, political, legal, technological, or physical." This would surely require taking account of possible co-breaking phenomena of the type discussed in the previous section as well, so producing a richer class of multivariate models for trending and breaking processes. It is thus clear that the modelling of trends and cycles will continue to be a key area of research in time series econometrics for some time to come and that any new developments should become part of the cliometrician's tool kit for analyzing historical time series.

Path Dependence

Douglas J. Puffert

Contents

Abstract

Path dependence is the dependence of economic outcomes on the sequence of previous outcomes, rather than simply on current exogenous causal elements. For a path-dependent process, economic explanation requires attention to the interplay of forward-looking optimizing behavior with the legacy of past conditions,

events, and choices. Sources of path dependence may include technical interrelatedness, irreversible investments, coordination costs, and various sorts of increasing returns. Influential or disputed cases of path dependence include the QWERTY keyboard, various information technologies, and railway track gauges. Path-dependent outcomes may be inefficient by some criteria but not by others.

Keywords

Path dependence · lock-in · Increasing returns · Technical interrelatedness · Non-ergodic processes · QWERTY

The term path dependence refers to the dependence of economic outcomes on the sequence of previous outcomes, rather than simply on current exogenous conditions. It implies that an allocation – a pattern of production and distribution – cannot be explained simply on the basis of current fundamental causal elements, typically listed as technological knowledge, resource endowments, preferences, and institutions. Rather, economic explanation requires the investigation of past conditions and events. In a shorthand expression, history matters.

The concept of path dependence has been invoked in historical explanations of numerous technical standards, including the QWERTY typing keyboard, various regional standard railway track widths (gauges), and numerous systems in information technology. Path dependence has also been applied to interpreting the evolution of institutions and other practices, economic geography, patterns of economic development, macroeconomic outcomes, and various concerns of political scientists and other social scientists. This chapter will give greatest attention to applications in microeconomics.

The Meaning and Significance of Path Dependence

Formally, a path-dependent process of economic allocation is a non-ergodic process (David 1999, 2001, 2007). In the physical sciences, a non-ergodic process is one in which a system becomes incapable of reaching all of the states that are consistent with the system's energy. In mathematical representations of such processes, the limiting distribution of potential states is itself a function of the evolution of the process. The process has branching paths, and at least some of the potential paths are nonreversible.

Likewise, in economics, early conditions, events, and choices direct a process of allocation along one potential path rather than another, limiting the range of later potential outcomes. This matters when the selected path of later outcomes exhibits, for example, an inferior technology or an otherwise lower pattern of payoffs than some alternative path would have yielded. The selected path also matters when alternative paths would bring different distributions of payoffs, with different

winners and losers. (Path dependence may also apply to non-consequential curiosities, such as driving on the left or right side of the road.)[1]

An economic non-ergodic process differs markedly from a physical process, of course, in that the selection among alternative paths involves, in large part, intentional agents who make choices on the basis of incentives and some degree of foresight. Properly speaking, if the early selection of a particular path is based "teleologically" on the foreknown payoffs of final outcomes, then the allocation process is not path dependent. (The earlier choice of a subsequent path exhibits what David (1997) called "moderate to mild" history, as opposed to "strong history" where a preceding path limits later choices.) An allocation process can be path dependent only if the early considerations that select among alternative paths are to some extent "orthogonal" to (i.e., less than fully aligned with) the system-level issues at stake in later outcomes. These early considerations are not random, in the sense of being economically inexplicable, although they might in some cases be partly the result of "historical accidents," as when the Liverpool and Manchester Railway company hired one engineer rather than another to build its track and choose its gauge (Puffert 2004, 2009). The key feature of the process is that the economic considerations that led to decisive early choices are not those that mattered later. The builder of the L&M Railway had reasons for his choice of track gauge, but most engineers soon had reasons to favor broader widths. In this case, the chosen gauge – the chosen path – was in part the result of imperfect foresight into the later implications of the choice.

The term path dependence has been applied not only to cases where "small" early considerations had "large" later system-level effects, but also to cases where the early considerations were themselves "large" and initially well aligned with system-level considerations, but where later conditions made early choices obsolete. In the case of Britain's small coal wagons, discussed below, the coal-wagon technology and related institutions established in the mid-nineteenth century served well for around half a century before becoming obsolete. Such a case may stretch the strict meaning of a non-ergodic process, as the small-coal-wagon path was perhaps the only one available at the earlier date, but it fits into the larger issue of whether the legacies of history are flexible for adaptation to evolving conditions.

The case also fits into a larger distinction between selection processes that are historically contingent and those that are teleological. Contingency is the normal mode of historical explanation. It explains event E as the result of earlier event D, which in turn is explicable (and even necessary) in terms of event C, and so on back to some event A (David 2001, referencing paleontologist Stephen J. Gould 1989). Teleology, on the other hand, is the normal mode of economic explanation. It explains an outcome on the basis of choices that are directed toward a present or future goal or end (Greek *telos*). A key issue in path dependence, then, is whether

[1]Even in that case, however, the emergence of different practices in different locations has later entailed costs.

the legacies of history are flexible for adaptation to evolving economic ends in the context of evolving exogenous or a priori conditions.

To say that an outcome is inflexible in the face of evolving conditions is equivalent to saying that the previously selected path is nonreversible or locally stable. The path of outcomes may then be called "locked-in." A standard typewriter keyboard or railway track gauge can be called locked-in, for example, if it continues to be adopted by new users and/or is retained by established users even when an alternative keyboard or gauge becomes inherently superior under evolving exogenous or a priori conditions. The causal elements that may give rise to this form of lock-in – increasing returns to scale of adoption, sunk physical or human capital giving rise to conversion costs, technical interrelatedness that requires the replacement of a whole system of obsolete components rather than their piecemeal replacement, coordination costs or transaction costs, and imperfect information – are discussed in some detail below. Also discussed below, skeptics of the importance of path dependence offer a different definition of lock-in that fits within their differing frame of reference.

The nature and significance of path dependence have indeed become matters of dispute. At the heart of the dispute are two questions: first, the extent to which later outcomes are objects of choice at earlier times when different potential paths branch apart and, second, the extent to which intentional actions can reverse an inferior path that was previously selected. Further questions include whether market failure (or institutional failure) may play a role in either the initial selection or the later nonreversibility of an inferior path, whether particular policies or sets of institutions may promote superior outcomes, and what efficiency criteria and counterfactual scenarios are appropriate for the evaluation of outcomes.

In presenting the literature on path dependence, this chapter will seek to clarify the points where interpretations differ as well as points where differing interpretations might be harmonized. This will require more attention to analytical issues than is usual in economic history. Indeed, it will also require careful attention to different usages of terms (beginning with "efficiency"), because participants in the dispute have frequently talked past one another rather than engage one another's arguments in the others' own terms. The analysis here will be grounded in historical case studies.

The Proposed Sources and Settings of Path Dependence

The concept of path dependence emerged through the confluence of two lines of economic analysis: the first focused on the concept of technical interrelatedness and the second focused on certain forms of increasing returns.

Technical Interrelatedness: The Analysis of Paul David

The analysis of technical interrelatedness traces back to Thorstein Veblen's (1915, 125–28) discussion of the small coal wagons used for contemporary rail traffic in

Britain but not elsewhere. Veblen attributed the continuation of an obsolete practice to the "facilities and all the ways and means of handling freight on this oldest and most complete of railway systems, . . . all adapted to the bobtailed car." Thus, while "the community at large" would profit from "junking" the small wagons and related facilities, individual firms would not find it profitable to convert only their own equipment while the complementary equipment remained unchanged. Marvin Frankel (1955) elaborated on the role of the interrelatedness of technical system components in preserving past practice, while Charles Kindleberger (1964) gave added attention to the role of institutions, particularly the separate ownership of different system components. This institutional pattern added coordination costs to the physical conversion costs of a potential change in practice.

Paul David (1975) made technical interrelatedness a theme in his historical studies of technical choice. He later incorporated the theme into his work on path dependence, beginning with his analysis of the emergence of the QWERTY keyboard as a technical standard (David 1985, 1986). David reflected the previous literature in specifying the first two of three conditions that, he said, may work together to make an allocation process path dependent: technical interrelatedness of system components, quasi-irreversibility of investment (or switching costs), and positive externalities or increasing returns to scale. The third condition had also arisen in the previous literature, but its implications were developed much further by an emerging line of analysis in the 1980s.

Increasing Returns: The Analysis of W. Brian Arthur

W. Brian Arthur (1989, 1990, 1994) and other economists in the 1980s explored the implications of certain sorts of increasing returns, where increased adoption of a product, practice, or technology led to rising marginal net benefits. They found, generally, that increasing returns can give rise to a multiplicity of potential equilibrium outcomes, and these equilibria might have differing patterns of payoffs. Arthur's unique contribution came through applying mathematical models, including models of stochastic processes, to treat the selection of a particular equilibrium as the result of sequential choices over time. His models exhibited path dependence.

Arthur emphasized two sources of "increasing returns to adoption": learning effects (learning by doing or by using), which increase the payoffs for a technology or product that has had greater cumulative adoption, and positive network externalities, which increase the value of a technology or product for each user as the total number of other users increases. For example, each user of a communication network (or today an Internet social platform) creates benefits not only for herself but also for other users with whom she exchanges messages.

In Arthur's main illustrative heuristic model, a technology or platform that gains a lead in market share even as a result of nonsystematic or stochastic "small events" (modeled in terms of the random order of arrival of heterogeneous adopters) becomes more valuable to later adopters, so that positive feedbacks raise its market share still further. If increasing returns are sufficiently strong, then even those new

adopters who might have a basic, stand-alone preference for a minority technology will adopt the majority one, so that it then sweeps the market and becomes "locked-in" as a de facto standard. Which technology or platform wins the market is not predictable on the basis of systematic causal elements; it depends rather on early nonsystematic events or stochastic fluctuations in choices. An ultimately inferior technology or platform can win if early temporary advantages or nonsystematic events had given it a sufficient early lead in adoptions over a technology or platform that ultimately proves superior. Such outcomes stand in contrast to the unique, predictable outcomes of standard economic models, where such "decreasing returns" features as increasing marginal costs and decreasing marginal utility (or consumer desire for variety) lead to an efficient, flexible sharing of markets among competing suppliers, so that outcomes are predictable on the basis of their superior payoffs or efficiency. The market dynamics of decreasing-returns models lead allocation processes to "forget" their history, while the market dynamics of increasing-returns processes lead them to remember their history.

In presenting his main illustrative heuristic model, Arthur (1989) noted that this model's results depend on two assumptions: first, that competing technologies are non-sponsored – not promoted by suppliers with stakes in outcomes – and, second, that the source of increasing returns is learning effects, not network effects, so that payoffs for each adopter depend only on cumulative past adoptions, not expected future adoptions. These assumptions effectively ruled out any role for forward-looking behavior in the evolution of outcomes.

Arthur did not incorporate forward-looking behavior into his modeling, nor did his economic papers usually address opportunities for such behavior when he discussed how his models might apply to specific cases. Nonetheless, he regarded the dynamic properties of his models as illustrative of a quite general pattern for allocation processes under conditions of increasing returns. Nobel economics laureate Kenneth Arrow wrote in his foreword to Arthur's (1994) collected papers that Arthur's models apply to contexts where foresight is imperfect, or "expectations are based on limited information," but Arthur himself did not interpret his models that way.

Writing later in the *Harvard Business Review*, Arthur (1996) did consider forward-looking behavior by the promoters of competing technologies. Addressing contemporary information technology markets, he asserted that successful firms base their competitive strategies on harnessing the underlying path-dependent dynamics that arise both in consumer choices and in the actions of the suppliers of complementary goods and services. His article offered extensive advice on how to understand and win such markets, and it has reportedly had great influence on the strategies of firms in Silicon Valley (Tetzeli 2016).

Other Analyses of Increasing Returns

Other economists have developed non-path-dependent models where increasing returns give rise to multiple potential equilibria, either in the initial selection of

one product or technology as a de facto standard (e.g., Katz and Shapiro 1985) or else in a potential switch from an established standard to a possibly superior alternative (Farrell and Saloner 1985). The solution concept used in these models is typically that of fulfilled rational expectations, with no role for time or sequential choices. Farrell and Saloner addressed lock-in in the context of a potential change in standards, not in Arthur's context of initial adoption. They also addressed how imperfect information might lead to excessive inertia in maintaining an established standard.

David (1993) explored models of path-dependent coordination among agents whose local interactions are represented by one- or two-dimensional network graphs. This approach enabled him to apply results from the mathematical theory of interacting particle systems or Markov random fields. In these models, agents sequentially adjust their "states" to the states of neighboring agents. Path-dependent fluctuations lead, in some configurations of models, to the adoption of a common state over the whole network, which might be interpreted as standardization on a common technology.

David also supervised (with further input from Arthur) the doctoral research of Douglas Puffert (1991, 2009), who developed a model of technical choice within a spatial network and applied it to the path-dependent selection of regional standards for railway track gauge. Puffert's model combined three innovative features: first, consideration within a single model of both initial adoptions of a technology (gauge) and subsequent conversions; second, costs for conversion; and third, the use of multiple numerical simulations by computer to explore the nature and range of potential outcomes. He used variations in parameters to simulate variations in the conditions that affected the gauge selection process in different historical-geographic contexts.

The Proposed Reasons for Skepticism About Path Dependence

The Analysis of Liebowitz and Margolis

The most prominent skeptics of the importance of path dependence, S.J. Liebowitz and Stephen E. Margolis (1994, 1995), argued that forward-looking optimizing behavior is likely to override Arthur's mechanisms for path dependence in any context where outcomes truly matter. In their analysis, adopters who choose among alternative technologies would typically have foresight into future payoffs of their choices, not just current payoffs. Furthermore, adopters and other agents would have opportunities to coordinate adopters' choices through communication, various sorts of market transactions, and the ownership and profit-seeking promotion of alternative competing products or technologies – in short, actions that internalize the mutual externalities of adopters' choices. Thus, they argued, purposeful, incentivized behavior can frequently override nonsystematic or random elements in a selection process, and path dependence can only affect aspects of the economy that no economic agent has an opportunity or incentive to change.

Liebowitz and Margolis allowed that path dependence might affect (1) aspects of the economy with no implications for efficiency or else (2) outcomes whose efficiency consequences had previously been unforeseeable and thus not subject to rational economic behavior. In the second case, agents might later express naïve regret that an outcome with higher payoffs had not been chosen, but Liebowitz and Margolis argued that it would not be meaningful to call the chosen outcome inefficient. Efficiency, they urged, should be defined in relation to what can be pursued on the basis of available information and feasible purposeful actions. In contrast to the first two cases, Liebowitz and Margolis expressed skepticism that path dependence would affect outcomes in a further case, where (3) an inferior outcome is locked-in despite the existence, at some point in time, of both the foresight and the means to direct a selection process to a superior outcome. In that case, they argued, path dependence would be the result of irrational errors, or inefficiencies that are (or had been) profitably remediable but nonetheless remain unremedied. They urged that economists cease looking for causal significance in small events or historical accidents, except perhaps in analyzing error-prone government actions, and focus instead on "the neoclassical model of relentlessly rational behavior leading to efficient, and therefore predictable, outcomes" (Liebowitz and Margolis 1995, 207).

Liebowitz and Margolis (1995) suggested, furthermore, that Arthur's illustrative model should be read as implying a claim to the unlikely "third-degree form" of path dependence, because forward-looking behavior would lead to a different outcome than the one that Arthur highlighted. The critics did not note how Arthur had explicitly stated assumptions that ruled out their proposed mechanisms for forward-looking behavior.[2] Liebowitz and Margolis also argued that proposed empirical cases of path-dependent lock-in, notably the QWERTY keyboard and the VHS videorecording system, likewise involve implicit claims for the third-degree form. Those two cases are addressed below.

The critics also urged that "lock-in" be defined solely on the basis of the third-degree criterion. That is, lock-in should refer to the unlikely case that an inferior technology predominates despite profitable opportunities to achieve a superior alternative.

Responses to the Skeptics

Arthur had ceased writing economic papers on path dependence by the time of the critique, and he did not respond extensively to his critics. In various interviews and one invited response paper (Arthur 2013), he reiterated his analysis that increasing-returns processes do not necessarily lead to the most "efficient" (i.e., highest payoff) potential outcomes in the way that decreasing-returns processes do.

[2]Those assumptions may indeed have limited applicability, but they do make it clear that Arthur was deliberately avoiding a remediable situation. He thus made no third-degree claim.

David (1999, 2001, 2007) responded more vigorously. His main contention was that Liebowitz and Margolis had not come to terms with, or ever properly addressed, the dynamic, non-ergodic nature of a path-dependent process, and thus they had misconstrued the issues. Opportunities for forward-looking choices within a path-dependent process would not be reducible to the static context of a single moment when agents might have the opportunity to select an optimal final outcome. Thus, optimizing behavior would typically achieve "path-constrained melioration" rather than unconstrained optimization. Moreover, a path-dependent process is properly defined by the dynamic nature of the process itself, not by the varying efficiency characteristics of outcomes. David therefore found the critics' redefinition of path dependence, in terms of "forms" or "degrees" based on a static criterion, to be tendentious and obscurantist rather than analytically meaningful and useful.

Likewise, David objected to the redefinition of lock-in as unlikely perverse error, when in the proper dynamic context the term can only refer to the local stability and irreversibility of an equilibrium path of allocation. This irreversibility, he claimed, is typically rooted in technical interrelatedness and in coordination costs that may be quite high, particularly under conditions of incomplete information.

Thus, David did not dispute the critics' analysis that inferior outcomes might be due to incomplete information. Indeed, he noted, the major policy implication that he had repeatedly drawn from path dependence is that government should seek to delay lock-in until the payoffs of alternative paths are better known.

More broadly, David argued that it is nonsensical to attribute significance, interest, and "efficiency" only to what remediation and optimizing market behavior can achieve. To do so, he quipped, is "tantamount to saying that market failure cannot happen, because if it did happen, markets would work to correct it" David (1999). Furthermore, David noted, Liebowitz and Margolis had not addressed how a path-dependent process might select among alternative outcomes that are each Pareto optimal, but with different sets of winners and losers.

Puffert (2004) responded to Liebowitz and Margolis by seeking to integrate their proposed means of forward-looking, profit-seeking behavior into an analytical framework that supports path dependence. In his interpretation, forward-looking agents can frequently influence but not fully control a dynamic allocation process, due to both imperfect foresight and imperfect opportunities to internalize externalities. The critics' taxonomy of three forms of path dependence leaves insufficient space (if any) between situations where there is no significant role at all for intentional action and situations where such action can fully supersede the legacy of history. Moreover, Puffert argued, the strategies of forward-looking firms frequently demonstrate an awareness and intentional usage of path-dependent dynamics by seeking to influence the early user choices that have a disproportionate effect on later outcomes. Intentional action, in Puffert's view, is fully part of path dependence.

Historical case studies illustrate the allocation processes that path dependence seeks to explain. They also offer tests of the views of both affirmers and skeptics of path dependence. Here we consider the most influential case studies, the most disputed ones, and a few studies that offer further lessons.

The Disputed Case of QWERTY

David (1985, 1986) introduced the theory of path dependence with his interpretation of how the QWERTY typewriter keyboard became established as a de facto standard. The skeptical critique of path dependence began with a response by Liebowitz and Margolis (1990).

David's Analysis

In David's telling, the QWERTY arrangement of keys was designed not for fast typing but rather for minimizing the jamming of clashing typebars on the first commercially successful typewriter, invented by Christopher Latham Sholes and brought to market by Remington in the 1870s. The 1880s saw a "rapid proliferation of competitive designs, manufacturing companies, and keyboard arrangements rivalling the Sholes-Remington QWERTY," and by the mid-1890s "it had become evident that any micro-technological rationale for QWERTY's dominance was being removed by the progress of typewriter engineering" (David 1985, 334) A few years after that, a new standard typewriter design arose, with front-stroke keys and a visible typing surface, which then fully displaced the Remington machine design for which the QWERTY keyboard had been designed.

Nonetheless, according to David (1985, 334), during "the fateful interval of the 1890s" the QWERTY keyboard became the industry-wide standard, adopted not only by Remington but also by rival manufacturers with differing machines featuring different typebar arrangements. QWERTY soon even displaced the superior Ideal keyboard, which had been designed for fast typing rather than for avoiding typebar clashes. (David noted that the Ideal keyboard was used on machines that eliminated typebars altogether by placing the type on a rotating cylindrical sleeve. Its home row DHIATENSOR could supposedly form 70% of English words.)

The reason for QWERTY's emerging dominance, according to David, was the happenstance that third-party instruction in eight-finger "touch" typing was promoted first for QWERTY. It was only then, in the late 1880s, that path dependence began to affect market competition. The best-trained typists used QWERTY, so office managers hired them and bought QWERTY machines to match. This, in turn, gave budding typists, typing schools, the writers of typing manuals, and typewriter manufacturers a further incentive to focus on QWERTY, to the exclusion of alternative systems. Positive feedbacks reinforced QWERTY's early lead until it gained virtually the whole market. (The role of typing schools and typing manuals is presented more fully in the longer 1986 version of David's paper.)

Critical to the emergence of QWERTY, wrote David, was that the "larger system of production," comprising typists, employers, manufacturers, and typing instructors, "was nobody's design"; it was characterized by "decentralized decision-making." David (1985, 334, 336) concluded, "competition in the absence of perfect

futures markets drove the industry prematurely into standardization on the wrong system."[3]

David's story ended in "the fateful interval of the 1890s" with QWERTY's "premature" establishment as a standard shortly before the rise of the new machine design that made QWERTY obsolete. In David's telling, technical interrelatedness, switching costs, increasing returns, and the absence of opportunity for centralized decision-making led to an inferior outcome.

David did not examine the later history of QWERTY, but he succinctly attributed the persistence of QWERTY to "decentralized decision-making." To establish that the QWERTY standard continues to matter, he cited claims that the Dvorak Simplified Keyboard, introduced in the 1930s, offers substantially faster typing speeds.

Liebowitz's and Margolis's Analysis

In their responding article, Liebowitz and Margolis (1990) gave attention to only part of David's account of the emergence of QWERTY as a standard. They gave more attention to popular accounts, not advocated by David, that QWERTY had been designed to slow typists down and that QWERTY won its market due to the publicity brought to QWERTY by a victory in a single typing speed contest. Liebowitz and Margolis showed that other contemporary contests were won by other typists using other keyboards, and so they claimed that they had refuted the "received history" that QWERTY had won its market due to the path-dependent consequences of an insignificant early event. They did not address David's argument that instruction in touch-typing was the starting point for path dependence in the rise of QWERTY.[4]

Instead, they noted that early typewriter manufacturers competed vigorously on features of their machines, and they inferred that QWERTY succeeded due to a market test of its relative fitness. They asserted that hypothetical suppliers of a superior alternative keyboard would have found a profit opportunity in providing training to offices where they sold their machines, and they offered evidence that the large typewriter companies of 1923 did provide such training.

Liebowitz and Margolis devoted most of their article to a topic that David had addressed only in passing, the persistence of the QWERTY standard in the face of competition from the Dvorak keyboard. They offered evidence that Dvorak offers typical typists no more than a few percentage points of increased typing speed. They

[3]In context, the absence of perfect futures markets seems to mean that there was no means by which adopters of the post-1900 generation of typewriters could have negotiated to prevent the widening adoption of QWERTY by users and manufacturers during the 1890s.

[4]In their original article, Liebowitz and Margolis (1990) cited the popular accounts of QWERTY's origin while not making clear how these accounts differed from David's interpretation. In later articles (e.g., Liebowitz and Margolis 1994), the critics presented only the popular accounts, not given by David, while citing only David's work as representing a single received history of QWERTY.

offered particularly strong evidence against claims, cited by David, that Dvorak's superiority over QWERTY was dramatic. If Dvorak really were so superior, they argued, then it would have offered substantial profit opportunities to offices that adopted it and retrained their staffs to use it.[5] Companies did not seize such opportunities, so they must not really have existed.

Liebowitz and Margolis concluded that QWERTY both won and kept its status as a standard by offering the superior realizable outcome.

Kay's Analysis

Recently Neil M. Kay (2013a) revived the literature on QWERTY with a study of the fitness of the keyboard in its original technological setting. Comparing details of the Remington machine's up-strike typebar configuration with statistical details of successive letters in typical English-language texts, he found that QWERTY was extremely well adapted for reducing typebar clashes and jamming. He inferred that QWERTY's inventor, Christopher Latham Sholes, had engaged in careful optimization in ordering the letters, going beyond "trial-and-error rearrangement" as described by David (1985, 1986). His statistical analysis also supported David's speculation that the letters spelling the brand name "TYPE WRITER" were placed deliberately on the same row; that arrangement would not likely have emerged by chance.

In Kay's analysis, the Remington typewriter's leading market share in the late nineteenth century made compatibility between "device" (machine) and "format" (keyboard arrangement) more important than compatibility between format and "user" (touch typist), and thus QWERTY was optimal for the time. Later, by contrast, the Underwood front-strike typewriter models of 1897 and 1901 made typing immediately visible to the user and thus improved compatibility between device and user, but its different typebar configuration ruined the compatibility of the QWERTY format with the device (Kay 2013b). Jamming problems then became frequent. The rise of the Underwood machine's general design, quickly adopted throughout the industry, allowed in principle a new freedom to redesign keyboard format for compatibility with the touch-typing user rather than the Remington device, but by that time, QWERTY had become a well-established standard.

Kay devised what he considered to be a test of David's argument that the typewriter industry standardized "prematurely … on the wrong system." He interpreted this as referring to the Dvorak keyboard as the "right" system. Thus, his test compared the simulated frequencies of typebar clashes, on the

[5]Liebowitz and Margolis (1995, 214) argued that David's attribution of QWERTY's persistence to "decentralized decision-making" amounted to an implicit claim for what they called third-degree path dependence. "This attribution … suggests that alternative, presumably centralized, decision mechanisms would correct the error."

It is difficult to follow the critics' reasoning. David had argued that there was no agent who could exercise centralized control over the larger system of production in which QWERTY was situated. David made no implicit claim that the relative inefficiencies of QWERTY were remediable.

Remington machine, for both the QWERTY keyboard and the Dvorak keyboard. As QWERTY led to far fewer clashes, Kay concluded that QWERTY was far fitter for the conditions of the 1870s–1890s, and thus that QWERTY would have won any hypothetical (albeit anachronistic) early competition between the systems.

Kay's account took the early leading market share of Remington's device with the QWERTY format as given, and he did not address David's argument that the contingencies of early touch-typing instruction were reinforcing this lead during the 1890s. Rather, Kay contrasted the demonstrated role of optimizing behavior in QWERTY's design with the supposed role of historical accident in the popular received history of QWERTY, where a single early typing contest had supposedly proved crucial. But this received history was not part of David's own interpretation, and David did affirm (albeit with less detail than Kay) that QWERTY was designed for fitness with the Remington device. The question that David had posed was: How a keyboard that was fit for the Remington device also became the standard for non-Remington devices? Kay affirmed David's interpretation of why a standard had to emerge eventually, and his ultimate disagreement with David may be in taking it as given that QWERTY became the standard as early as it did, before the introduction of the Underwood device.

In an invited response, Margolis (2013) regarded Kay's analysis as a vindication of the role of optimizing behavior rather than early historical accident. Arthur (2013) regarded Kay as supporting David's account of the origin of QWERTY.

Britain's Coal Cars

As noted above, the small coal cars long used in British rail traffic have been cited for a century as the paradigmatic example of technical interrelatedness. D.N. McCloskey (1973), however, called the example doubtful, because small cars were still widely used at his writing, 20 years after Britain had nationalized both the coal mines and the railways, bringing them into common ownership. Va Nee L. Van Vleck (1997) argued further that small coal cars in the early twentieth century were well adapted to the larger system of distribution at the time. They offered flexible delivery for small users of coal while economizing on the cost of road haulage that would have been necessary for small deliveries if railway coal wagons were larger.

Peter Scott (2001) argued in response that few coal users benefited from small, car-size deliveries. Rather, he wrote, the cars' small size, widely dispersed ownership (by collieries), antiquated braking and lubrication systems, and generally poor physical condition made them quite inefficient indeed. Replacing these cars and associated infrastructure with modern, larger wagons owned and controlled by the railways would have offered savings in railway operating costs of about 56%, yielding a social rate of return of 24% on the costs of new cars and the conversion of facilities. They were not replaced because regulations forced the railways to accept colliery cars at set rates or else buy out the cars at high prices and offer additional compensation. This transformed the sunk costs of obsolete cars into real

costs for the railways, and it reduced the realizable return for system-wide rationalization to around 10%. Furthermore, due to technical interrelatedness, the railways would not have saved much in operating costs until virtually all the antiquated cars were replaced, further increasing the transaction costs entailed in any transition.

In discussing how the persistence of small wagons was path dependent, Scott wrote that the technology embodied in the small cars and the institutions that supported fragmented ownership had long outlasted the earlier conditions to which they were a rational response. Ownership of cars by the collieries had been advantageous to both railways and collieries in the mid-nineteenth century, and government regulation had assigned rights in a way that protected car owners from opportunistic behavior by the railways. By the early twentieth century, these regulatory institutions were obsolete, as were the cars and physical facilities.

To situate Scott's analysis within the larger literature on path dependence, Scott did not argue that some alternative path of allocations featuring large wagons would have been just as feasible for early railways as a path featuring small wagons. He also did not argue that the original adoption of small wagons had been premature or that it was the result of imperfect futures markets. What he did argue was that technical interrelatedness and very high transaction costs resulting from the legacy of history had, together, locked in a path of outcomes that was highly inefficient relative to what alternative institutions in the early twentieth century might have made possible.

Videocassette Recording Systems

Another disputed case in path dependence was the competition between alternative videocassette recording systems from the mid-1970s to the mid-1980s. The VHS system, promoted by a coalition led by JVC (Japan Victor Corporation), became the standard, beating out Sony's Betamax. Arthur (1990) explained this as the result of positive feedbacks in the video film rental market: Video rental stores would stock more film titles for the system with the larger user base, while consumers would adopt the system for which they could rent more videos. Arthur suggested that, if the common perception that Betamax offered a superior picture quality is true, then "the market's choice" was not the best possible outcome.

Liebowitz and Margolis (1995) pointed out, however, that Sony had actually been first to market. If an early lead had mattered, they argued, then Sony should have won. They attributed the VHS victory to active product promotion and to the advantage of VHS in offering a longer playing time, and they offered substantial evidence against Arthur's suggestion that the winning system may have been inferior. In their view, purposeful, forward-looking behavior had driven the outcome, not path dependence.[6]

[6]Liebowitz and Margolis (1995) state that Arthur implicitly argued for their third-degree path dependence – remediable but unremedied error – in the case of VHS. Arthur, however, offered no analysis that might suggest that the outcome was remediable. It might be argued that Arthur's analysis was mistaken, but that does not amount to a claim.

In contrast, Cusumano, et al. (1992) argued that there was indeed a positive-feedback dynamic in the video rental market, but this market emerged late, after VHS had already gained a strong lead. The onset of positive feedbacks turned Betamax's small but stable market share into a fast-declining one, forcing it to exit the market.

More intriguingly, the authors attributed the earlier lead of VHS to path dependence in supplier choices, which was itself the result of suppliers' foresight regarding path dependence in consumer choices. Believing that consumer dynamics would lead to a single standard in the end, manufacturers and distributors increasingly supported VHS over Betamax as they saw others doing so, increasing their expectations that VHS, not Betamax, would later become the standard. Ultimately, the authors argued, VHS won as the result of differences in the promoters' early strategies. First, Sony initially pursued a go-it-alone strategy, while JVC built a coalition of suppliers in order to benefit from foreseeable positive feedbacks in market share. Second, JVC's partner Matsushita installed a large manufacturing capacity to solidify expectations among other suppliers. Third, Sony guessed that consumers would prefer a smaller cassette size, while JVC instead chose a larger cassette with longer playing time. In the event, a longer playing time proved more important to consumers in the early years, when only a VHS tape could record an entire American football game or a long movie. Distributors responded to this temporary advantage by joining the VHS coalition permanently.

Later, Liebowitz (2002) responded that the larger VHS cassette size offered a permanent rather than transitory advantage. A larger cassette with a longer tape, he argued, facilitated higher tape speeds and thus better picture quality for any given total playing time.

Information Technologies

Much of the attention of the literature on increasing returns and path dependence has been directed toward certain markets in information technology (Shapiro and Varian 1998). Network externalities (or network effects) in these markets make products with a larger market share more valuable to new users. That may give rise to bandwagon effects (Rohlfs 2001) that give competition a winner-take-all, or at least winner-take-most (Arthur 1996), character. Firms profit in such markets by developing and strategically promoting proprietary system "architectures" to become de facto standards (Morris and Ferguson 1993). Entering a market earlier matters, and new firms may have no opportunity to enter a market against an established incumbent (Arthur 1996).

Applying this sort of analysis, some observers have argued that either IBM or Apple Computer rather than Microsoft could have become the dominant firm in microcomputers, controlling the key architecture or system standard (Rohlfs 2001; Carlton 1997). However, only Microsoft leader Bill Gates had, and acted on, the foresight that control of an operating system standard would matter. Microsoft entered the personal computer industry as a contractor to IBM, supplying the

MS-DOS operating system to run on IBM's personal computers. Because IBM thought that its hardware expertise would matter more than software, it allowed Microsoft to retain intellectual property rights to MS-DOS and even to supply it to competing computer hardware firms. IBM thus lost control of what proved to be the essential architecture of its own product. When competing hardware suppliers proved able to match IBM's features without violating its patents, IBM was left mostly out of the market while Microsoft thrived.

Gates himself thought in the mid-1980s that Apple's Macintosh computer system, with its innovative graphical user interface, was particularly well suited to become the key system standard for the emerging personal computer market. It is perhaps particularly poignant that Gates even recommended what he considered a winning strategy to Apple executives in a famous memorandum sent in June 1985, a time when Microsoft gained most of its revenues from selling application software for Apple. The memo concluded, "Apple must open the Macintosh architecture to have the independent support required to gain momentum and establish a standard" (Carlton 1997, 40–43). In effect, Gates intuited and applied a concept of path dependence.

In the event, Apple preferred to keep tight control over the Macintosh's highly integrated hardware and software architecture, so it declined to follow Gates's advice. Gates then turned Microsoft's attention to developing its own open-architecture graphical user interface, Windows, built on the foundation of Microsoft's MS-DOS operating system. Microsoft indeed gained the independent support of partner firms to establish Windows as the key industry standard. Thus, Microsoft secured its dominant position in the market for personal computer operating systems.

Arthur's (1996) advice to information-technology firms included just such a strategy, and he later commended Microsoft for establishing a unifying platform that enabled the wider industry to develop and many firms to flourish (Tetzeli 2016). In response to industry concerns that Microsoft might use its leading position to stifle competition, Arthur (1996) said that Microsoft should not be penalized for winning its market, but it should be prevented from leveraging its dominant position in one market to gain competitive advantage in another market.

Arthur's caveat expressed a concern that motivated a growing opposition to Microsoft among some firms in Silicon Valley, as well as by the Antitrust (competition policy) Division of the US Department of Justice. Beginning in 1994 Silicon Valley-based attorney Gary Reback and colleagues wrote a series of White Papers, with consulting assistance from Brian Arthur and economist Garth Saloner, as submissions to the Antitrust Division. In one of these, the authors sought to convince the government to take action against Microsoft for bundling its Windows operating system with Microsoft's new Internet browser, Internet Explorer, arguing that this bundling prevented effective competition by the similarly new Netscape browser. They argued that Microsoft was using its dominance in computer operating systems to preemptively attain dominance in the then-emerging Internet market, stifling competition to the detriment of consumers. The White Paper received favorable attention from some antitrust scholars and attorneys as well as parts of the press, and it helped lead the Antitrust Division to pursue and obtain a consent agreement with Microsoft to restrict its competitive practices.

Liebowitz and Margolis wrote numerous op-ed articles and policy papers against the argument of the White Paper, culminating in a book (Liebowitz and Margolis 1999). Building upon their prior arguments about path dependence, they asserted that predatory bundling is an unsupportable concept. They further argued that Microsoft had gained its leading position in several software markets simply by offering superior products.

The broader basis for Liebowitz's and Margolis's (1994) argument was, in part, their perception that the network externalities that benefit users of information products are "pecuniary" externalities. Pecuniary externalities are the gains or losses that one economic agent causes for others when the agent's actions lead to changes in prices. Although other agents gain or lose, the change in price reflects the adjustment of a market to a new equilibrium outcome that is efficient. Liebowitz and Margolis argued that when externalities are mediated by market transactions with suppliers, they are pecuniary in character and thus have no implications for economic efficiency. The actions of suppliers to win their markets are, therefore, simply part of the benign process of vigorous competition in which the best products have the best opportunities to win. Restrictions on Microsoft's competitive practices would therefore harm consumers. More broadly, in the view of Liebowitz and Margolis, the literatures on path dependence and network externalities have little to contribute to the analysis of information technology markets.

A partial counterargument to Liebowitz and Margolis had essentially been offered earlier by Nobel laureate Paul Krugman (1991, 485) in a discussion of increasing returns in economic geography. In perfect competition, Krugman wrote, "pecuniary externalities have no welfare significance and could not lead to … interesting dynamics … [but] in the presence of imperfect competition and increasing returns, pecuniary externalities matter; for example, if one firm's actions affect the demand for the product of another firm whose price exceeds marginal cost, this is as much a 'real' eternality as if one firm's research and development spills over into the general knowledge pool." Expanding on Krugman's point, the familiar analysis that allows pecuniary externalities to be ignored holds only for perfectly competitive, price-taking markets with convergent dynamics and thus unique equilibria. It does not hold for the conditions that some industry analysts attribute to many segments of information technology markets, and it does not hold for the conditions that Arthur and others proposed in theories of increasing returns leading to path dependence. Under those conditions, Krugman's "interesting dynamics" might affect outcomes. Thus, in the view of Arthur and others, allowing Microsoft to bundle products and enter a market with an immediate lead in market share might prevent competitors from introducing and promoting superior products.

Economic Geography

Since 1990, there has been a flurry of applications of path dependence to explanations in economic geography. Most notably, Nobel laureate Paul Krugman (1991), Arthur (1994), and others have explained instances of industrial location as the result

of historical small events that grew in impact as a result of positive feedbacks. Agglomerations of activity such as Silicon Valley, for electronics and information technology, and Dalton, Georgia, for US carpet production, are interpreted as having begun with the settlement of a few initial firms for nonsystematic reasons rather than any inherent advantage in the location. The initial firms were joined by an increasingly thick web of specialized suppliers, industrial customers, and competitors as new firms found cost advantages in locating near other firms in the same industry. Particularly in Silicon Valley, the advantages have included sharing of technological knowledge and thick specialized labor markets that have facilitated the staffing of start-up firms while giving workers from failed start-ups quick opportunities for reemployment.

This literature has upended the traditional focus of economic geography on systematic reasons for industrial location. In modeling, agglomeration externalities (or effects) have functioned much like network externalities (or effects) in making allocation processes path dependent. Also similarly, Liebowitz and Margolis (1994, 1995) argued that the externalities are largely pecuniary in nature and/or internalized through such market mechanisms as ground rents, so that there are no substantial welfare implications for the industrial location process. Krugman (1991), by contrast, offered a model in which externalities lead endogenously to the separation of a core industrial region from a periphery, with differing productivities and incomes in the different regions. (His model employed pecuniary externalities, but he argued that it made no essential difference whether the externalities were pecuniary or not.)

In historical research, Bleakley and Lin (2012) investigated portage sites around rapids on rivers in parts of the United States. These sites became early centers of commerce and industrialization, due both to breaks in the progress of travel and to the availability of water power. More interestingly, Bleakley and Lin documented how these sites remained economically important and even increased in importance after the original advantages of the sites were made obsolete. They interpreted this finding using a model in which local increasing returns to scale gave rise to path dependence.

Nikolaus Wolf and various coauthors have written numerous papers on industrial location in Europe. N.F.R. Crafts and Wolf (2014) explained the location of Britain's cotton textiles industry in 1838 as a result of a combination of "first and second nature" features – both the original advantages of previous decades, including water power, and acquired advantages that resulted in part from sunk costs and agglomeration effects. Redding et al. (2011) addressed how the division of Germany following the Second World War caused the shift of Germany's national air transport hub from Berlin to Frankfurt. The reunification of Germany and the return of Germany's capital to Berlin have not caused any reversion of the hub to Berlin. The authors developed evidence that the relocation of Germany's air hub was not uniquely determined by economic fundamentals, but was rather a shift between multiple steady states.

Institutional Change

There is a growing literature as well on path dependence in the development of institutions. Douglass North (1990) was early in applying the concept of path dependence to institutional change, pointing to historical examples where

institutions persisted while changing conditions made them increasingly maladapted. David (1993, 1994) posited an analytical similarity of path dependence in technology, institutions, organizations, and other matters.

Eichengreen (1996) and Meissner (2005) argued that the international diffusion of monetary systems, such as the classical gold standard of the late nineteenth century, was path dependent. They interpreted the reduction in transaction costs from adopting a common monetary system in terms of positive network externalities.

Gary Libecap (2011) addressed long-term institutional path dependence in the property rights and distributional mechanisms for water supply in arid districts of the American West. He found that arrangements developed to address conditions of the late nineteenth and early twentieth centuries have reduced later opportunities to reallocate water to higher value uses or to respond to hydrological uncertainty.

Nuclear Power Reactors and Pest Control

In another early publication on path dependence, Robin Cowan (1990) argued that transitory circumstances and path-dependent learning effects led to the establishment of the prevalent "light-water" design for civilian nuclear power reactors. This design, adapted from nuclear submarines, was rushed into use during the Cold War due to the political value of demonstrating peaceful uses for nuclear technology. Thereafter, learning effects arising from engineering experience continued to make the light-water design the rational choice for new reactors. Cowan argued, however, that an equivalent degree of development would likely have made an alternative design superior.

Cowan and Gunby (1996) addressed path dependence in farmers' choices between the system of chemical pest control and the alternative system of integrated pest management (IPM). IPM uses predatory insects to devour harmful ones, and any drift of chemical pesticides from neighboring fields makes the use of IPM difficult or impossible. IPM must therefore be used on the whole set of farms that are in proximity to one another. Where this set is large, the transaction costs of persuading all farmers to forgo chemical methods often prevent adoption. In addition to these localized positive feedbacks, local learning effects also make the choice between systems path dependent. Local lock-in to each practice is sometimes ended by such developments as invasions by new pests and the emergence of resistance to pesticides.

Railway Track Gauge

Puffert's (2000, 2002, 2009) research on the emergence of regional standards for railway track gauge appears to be the most extensive case study yet undertaken of path dependence in technical choice. The large number of local realizations of the gauge selection process (in contrast to single realizations for QWERTY and other cases) helped to clarify the ways that various features of the process mattered.

The single most crucial event in the history of railway track gauge was the hiring of engineer George Stephenson to build the Liverpool and Manchester (L&M) Railway, opened in 1830. Stephenson used the 4 ft, eight and a half inch gauge of the primitive coal tramway where he had conducted early experiments with steam locomotion, while a rival team of engineers was proposing to build the line using the unprecedented 5 ft, 6 in. gauge that they thought proper for a new generation of railways. The L&M immediately became the model of best practice for other early railways in Britain, the United States, and Continental Europe, and its gauge was widely adopted. Within a decade of the L&M's opening, however, many engineers came to regard broader gauges as superior. Nonetheless, the Stephenson gauge has retained a lead in aggregate route length ever since.

Puffert identified both nonsystematic events and systematic developments that led to the introduction of particular gauges to particular regions. He addressed how positive feedbacks led to the emergence of regional standard gauges, as new railway lines generally adopted the gauges of established neighbors, while diversity in gauge emerged on a larger scale, because different regions within a country or continent initially adopted different gauges. As a result, two regional standard gauges emerged in Britain, six in North America, six in Continental Europe, three in Australia, and multiple gauges in other intercommunicating regions as well. Puffert considered how optimizing behavior subsequently led to conversions of gauge and improved network integration in some cases but not in others.

Puffert found that the cost of either coping with or resolving diversity was the main path-dependent inefficiency in track gauge, well outweighing the inefficiency of the prevalent Stephenson gauge relative to hypothetical broader standard gauges. Still, diversity was resolved most easily where it proved most costly, and the mechanism for resolving diversity was frequently the sort of coordinating behavior discussed by Liebowitz and Margolis (1995). Much of Britain's and North America's diversity, for example, was resolved by the growth of interregional rail systems under common ownership, which internalized the benefits of standardization. Still, this improvement took the form of what David (2001) called path-constrained melioration, not full adaptation to practices that engineers and railway officials regarded as optimal. Britain made the Stephenson gauge its standard at a time when the expert consensus favored gauges ranging from 5 ft (1524 mm) to 5 ft 6 in. (1676 mm). North America standardized on the Stephenson gauge when the expert consensus there favored 5 ft, the regional standard gauge that was then being turned away from in the southeastern United States. Government involvement assisted beneficial standardization in some cases while hindering it in others, sometimes for protectionist reasons.

Puffert identified roles in the gauge selection process for numerous idiosyncratic individuals making influential choices, some on the basis of acute foresight or purposeful learning, others with less thoughtfulness, but all constrained by the past while pursuing their future visions. Technology, geography, and market forces played important systematic roles, while positive feedbacks lent growing impact to nonsystematic features of the process. In contrast to what Kay (2013) wrote

of QWERTY, in a rerun of the tape of history, the Stephenson gauge would not always win.

One episode offers a particularly poignant example of how a path-dependent process might preserve and magnify the effects of an idiosyncratic error that would be easily weeded out by an ergodic allocation process. In 1850, the three main Australian colonies, New South Wales, Victoria, and South Australia, coordinated their choices of gauge in adopting 5 ft 3 in., the gauge recently chosen by the British government for Ireland. However, the engineer hired in 1852 to build the first line in New South Wales insisted on using the Stephenson gauge, and the colony's legislative council agreed. Railway companies in the other colonies protested furiously while proceeding with their plans to adopt the broader gauge, with the support of local governments. One notably perspicacious engineer in Victoria argued vigorously for adapting to the regrettable vicissitudes of New South Wales, but other railway officials and politicians stubbornly exaggerated the benefits of their preferred gauge. Both the Governor General of Australia and Britain's Colonial Office declined to intervene (despite expert advice favoring both the broader gauge and the necessity of standardization), reflecting a policy to promote autonomy in the colonies.[7]

In due course, as many indeed foresaw, Australia was saddled with a needless and costly diversity of gauge that has persisted to the present day. Efforts to standardize Australia's gauge began to bear fruit after a century of dispute, and so the national network has been rationalized to a substantial extent. However, the costs of first coping with and then partly resolving Australia's lack of network integration have been great. These costs might be regarded as a result of institutional failure – although not simply either market failure or government failure. More fundamentally, these costs are the result of an allocation process that neither systematically overrides errors nor assures an optimal technical choice or degree of network integration, even by the standards of the knowledge of the time.

Conclusion

The concept of path dependence offers a fruitful framework for investigating the impact of past choices and events on current features of the economy. It can be a tricky concept, as it requires close attention to ways that outcomes depend on both constraints arising from the past and goals oriented toward the future.

Path dependence involves both the branching of potential paths of allocation and the stability or lock-in of paths. The branching may be due in part to nonsystematic elements in the process, as well as to increasing returns giving rise to positive feedbacks. The stability may be due to coordination costs as well as the physical costs of a change in practice.

[7]Many features of this story are, of course, well known in Australia, but the recent research of John Mills (2007) clarified the interrelated choices of key actors during the early 1850s.

Some of the theorists of path dependence were arguably insufficiently attentive, early on, to ways that forward-looking behavior may override or greatly modify a path-dependent process. The skeptics have arguably been reductionistic in treating a fundamentally dynamic process as an essentially static one, while failing to see how the affirmers have their own sophisticated understandings of markets.

The test of an analytical concept, of course, is its fruitfulness in explanation. Does path dependence, along with such related concepts as increasing returns and positive feedbacks, offer insights that illuminate previously hidden facets of economic outcomes and processes of change? Are the contrasting explanatory modes of historical contingency and intentional teleology ultimately compatible and indeed synergistic? Is economic history merely the investigation of the past role of purposeful behavior? Or does economic history offer a new vision of how the economy and society work? One lesson may be that outcomes are not always the predictable result of an impersonal invisible hand – but rather the surprising result of persons whose choices take the path of history in one direction rather than another, for good or for ill or simply for different.

Analytic Narratives

What They Are and How They Contribute to Historical Explanation

Philippe Mongin

Contents

Abstract

The expression "analytic narratives" is used to refer to a range of quite recent studies that lie on the boundaries between history, political science, and economics. These studies purport to explain specific historical events by combining the usual narrative approach of historians with the analytic tools that economists and political scientists draw from formal rational choice theories. Game theory, especially of the extensive form version, is currently prominent among these tools, but there is nothing

This chapter expands on work begun when the author visited Wissenschaftskolleg zu Berlin in 2015–16. For useful comments and encouragement, the author thanks Steven Brams, Bertrand Crettez, Lorraine Daston, Claude Diebolt, Françoise Forges, Luca Giuliani, Michael Gordin, Michael Haupert, Benjamin Miller, Roger Ransom, Daniel Schönpflug, Frank Zagare, as well as the participants at the workshops "The Limits and Possibilities of Narrative Explanations" (Wissenschaftskolleg, 17–18 March 2016) and "Computational Models of Narrative 2016" (Krakow, 11–12 July 2016). Many thanks also to Ben Young and Michael Haupert for assisting in the preparation of the final draft.

inevitable about such a technical choice. The chapter explains what analytic narratives are by reviewing the studies of the major book *Analytic Narratives* (Bates et al., 1998), which are concerned with the workings of political institutions broadly speaking, as well as several cases drawn from military and security studies, which form an independent source of the analytic narratives literature. At the same time as it gradually develops a definition of analytic narratives, the chapter investigates how they fulfil one of their main purposes, which is to provide explanations of a better standing than those of traditional history. An important principle that will emerge in the course of the discussion is that narration is called upon not only to provide facts and problems but also to contribute to the explanation itself. The chapter distinguishes between several expository schemes of analytic narratives according to the way they implement this principle. From all the arguments developed here, it seems clear that the current applications of analytic narratives do not exhaust their potential, and in particular that they deserve the attention of economic historians, if only because they are concerned with microeconomic interactions that are not currently their focus of attention.

Introduction

The expression "analytic narratives" refers to studies that are located at the academic boundaries between history, political science, and economics. These studies purport to explain specific historical states of affairs by combining the usual narrative approach of historians with the analytic approach that is familiar to economists and political scientists. Being specific, and indeed often highly specific, the historical situations, events, or actions they cover rarely overlap from one study to another. If there is any unity to analytic narratives, it does not lie in the objects but in the method of explanation, and from this angle, they have two broad principles in common. The first is that analytic narratives jointly exploit the resources of narration and analysis, the presumption being that this can result in better solutions to explanatory problems than if either technique were used in isolation. The second principle is that the analytic component is drawn from the theories of rational decision-making, prominent among which is game theory; the presumption here is that the tools they offer do fit the purpose of combining narration and analysis. More needs to be said to characterize analytic narratives, but these two principles are part and parcel of their definition.

Both principles come out most clearly in *Analytic Narratives* (Bates et al. 1998), an important collective book that popularized the expression and provided the approach with a manifesto as well as illustrative case studies. These studies belong

to the historical branch of political science, and to get the full range of the genre, one must turn to the historical parts of those other fields – to wit, military studies, security studies, and international relations (IR) studies – in which analytic narratives have also undergone autonomous development. Proximate forms of analytic narratives had circulated there before the eponymous book came out. Besides giving retrospective structure to these significant, albeit unconscious, past attempts, *Analytic Narratives* pursues a specific program on political institutions, which it proposes to reconstruct as equilibria of individual interactions, these generally being modeled by game theory. The chapter is concerned with the connections between analytic narratives and history, and although it will mention this connection with theoretical political science, this will not be developed here.

We will explain what analytic narratives (AN) are by surveying, first, the five cases in the eponymous book and then five further cases drawn from military and security studies, to which we append a case that is again borrowed from political history but uses the same techniques as those in the latter group. In general, we follow a bottom-up approach, first summarizing the cases, and then attempting to capture their methodological features. As we journey along this inductive road, we will identify a third guiding principle of AN, which is less transparent than the first two, to the effect that the narrative component does not simply provide the data against which explanatory hypotheses are to be tested, *but also contributes to the explanation as such*. The chapter takes the third principle to be definitional, just like the first two, which amounts to defining AN more precisely than is usually done.

The emphasis on the third principle, and the upgrading of the narrative component more generally, is common to this chapter and other accounts by the same author, where this component receives even more emphasis. Along the same line of analysis, we will draw an internal distinction between different forms of AN. The crucial observation here is that some AN give the final explanatory word to a narrative, while others state their explanatory conclusions in theoretical language. Thus, although we regard it as being definitional, we take the third principle to be implementable in quite different ways from one AN to another.

Besides providing a definition, the chapter assesses the extent to which AN contribute to historical explanation. For this, we use the scheme of deductive explanation, which Hempel (1965) and other philosophers of science proposed to clarify the structure of scientific explanation. This scheme is popular among some AN contributors: however, we will argue that the AN themselves conform only very roughly and imperfectly to it. Here, however, the discovery of deductive failures in the explanatory arguments functions as a positive feature, as it prepares us for the claim that the narrative component of AN complements deduction in structuring their explanations. This is how the chapter connects its two topics, i.e., the definition of AN and the account of their explanatory capacity.

The chapter develops as follows. Section "The Five Studies of *Analytic Narratives*" summarizes the work by Bates, Greif, Levi, Rosenthal, and Weingast collected in *Analytic Narratives*. Section "Some Defining Characteristics of Analytic Narratives" exploits this material to make some progress with the definition of AN. In particular, it argues that AN should involve proper formalism, but that this formalism does not have

to be limited to the game theory employed in the book. This section merely makes explicit what the authors themselves suggest. Section "Analytic Narratives from Military and Security Studies" extends the sample with two military studies by Haywood and Mongin, a group of studies on the Cuban crisis, which are included here only to facilitate comparison, several security studies by Zagare (in particular taken from his 2011 reference book *The Games of July*), and a study of post-communist political transitions by Nalepa. Section "Analytic Narratives and Deductive Explanation" discusses how AN contribute to historical explanation, by reference to the deductive scheme of scientific explanation. Section "The Role of Narration in Analytic Narratives" deals with the narrative element of AN, arguing that it can make up for some of the failures of the deductive scheme that the previous section pointed out. This concludes our assessment of the contribution AN make to historical explanation, at the same time as establishing our proposed definition for this genre. The section also sets out a taxonomy of AN based on the way narratives enter the exposition, the three categories being alternation (of the narrative with the model), local complementation (of the narrative by the model), and analyzed narratives (in which the model and the narrative are merely juxtaposed). Section "Conclusion" briefly takes stock suggesting that AN may be a tool for economic history.

The Five Studies of *Analytic Narratives*

Here we simply review the five case studies presented in *Analytic Narratives*, following the chronological order adopted in that book. The next section will use this major sample to introduce a general discussion of AN.

Case 1 Middle-Ages Genoa (Greif) In the Middle Ages, the city-state of Genoa was first governed by elected consuls (1096–1194) and then by an appointed magistrate, the *podestà*, who was chosen from outside the city (1194–1334). Under the consulate, civil peace prevailed from 1096 to 1164 (period I), and then there was civil war lasting from 1164 to 1194 (period II). Under the *podesteria*, civil peace prevailed throughout (period III). Genoa's main economic activity was long-distance trade in the Mediterranean, and this activity was prosperous concomitantly with civil peace, i.e., for periods I and III, but with a noticeable peak at the end of the former. The main actors of economic and political life were the clans, which appear to have kept their identity and relative influence fixed for much of the period under study. In view of this fact, the time sequence emerges as problematic. Why did the clans first cooperate and then fight under the politically unchanged conditions of the consulate? Why did they cooperate most efficiently at the end of the first period of civil peace? How did the institutional move to the *podesteria* contribute to reestablishing the civil peace that prevailed henceforth and why did it occur when it did? These are Greif's main explanatory questions. He notes that the historians' work fails to answer them satisfactorily, or even to raise them in full clarity.

Greif responds by constructing two classes of extensive form games of perfect information. He then investigates their subgame perfect equilibria, as is classically

done for such games.[1] The first class, which relates to the consulate regime, has two games, both of which involve the clans as players; the difference between them hinges on whether the number of maritime possessions of Genoa is taken to be exogenous or endogenous. We will report only on the simpler of the two, which is the game with an exogenous number of possessions.[2] This game explains the changes from period I to II by using the external threat posed by the German Emperor as a variable parameter. Depending on whether the threat is absent or present, Greif retains a different subgame perfect equilibrium – here relabelled as *mutual deterrence equilibrium* (MDE). The presence of this threat pushes the clans towards *mutually advantageous* MDE by the following mechanism. In general, clans compete to gain control over the consulate, which would guarantee them a higher share of trade benefits, and this competition stabilizes peacefully only because they spend on deterrence resources they could more profitably spend on joint trade; this is what MDE formally captures. Now, the controlling clan also incurs the burden of external wars when they happen, so that the external threat changes the clans' *ex ante* net benefits of conquering the consulate; this is why MDE with fewer resources spent on deterrence, and more on joint trade, arise when there is such a threat. The chapter presents his first class of games only informally; a full treatment appears in Greif (2006, Chap. 8).

The second class has a single game, which is intended for period III and has the *podestà* as a third player. Among others, it captures a clan's two strategic possibilities of accepting the *podestà*'s authority or attempting to take control of Genoa, at the risk of starting a war against the *podestà* and the other clans. For relevant parametric conditions, this game has a subgame perfect equilibrium that explains the stabilizing effect of the *podesteria*. At this equilibrium, clan 1 (which makes the first move) abstains from challenging clan 2; clan 2 (which reacts to clan 1's move) fights if challenged; and the *podestà* (who reacts to the two clans' moves) joins forces with clan 2 against clan 1 in case of a fight, but colludes with clan 1 otherwise. That the *podestà* can possibly collude with clan 1 motivates clan 2 to fight, and that the *podestà* can possibly support a fighting clan 2 motivates clan 1 not to challenge in the first place. As entailed by subgame perfect equilibrium, these two threats are credible. The parameters on which the existence of this equilibrium depends are the players' probabilities of victory and defeat and the accompanying payoffs. Most important are the parameter values for the *podestà* since they ought to match his reward scheme and military means, as described by historians. Greif's chapter presents the *podesteria* model in complete detail (see also Greif 2006, Chap. 8).[3]

[1]For the game theory discussed in this chapter, see the texts by Morrow (1994) and Harrington (2009), and at a more advanced level, by Myerson (1991) and Osborne and Rubinstein (1994).

[2]Only the second game makes it possible to investigate the clans' trade-off between fighting a civil war to gain control of Genoa and peacefully collaborating to get more maritime possessions.

[3]Critics of Greif's approach to the *podesteria* have complained that this institution originated in a decision made by the German Emperor, not by the Genoese. See, however, fn 5.

Case 2 Ancien Régime Finances (Rosenthal) A classic historical problem concerns understanding why the pace of institutional change differed between France and England in the seventeenth and eighteenth centuries, with one country keeping the absolutist monarchy until its final disruption, while the other moved gradually towards representative government. Rosenthal reconsiders the problem in the light of the two countries' difference in fiscal structure. Given that the product of taxes was mostly spent on wars, this leads him to raise another question, i.e., how a country's style of warfare relates to its political regime.

The examination is carried out in terms of an informally stated model that an appendix makes formal. There are two actors, the King and the elite (an abstraction representing the parliaments in France and England, and the provincial estates in France, where they existed), who enjoy separate fiscal resources and try to make the best of them in fighting profitable wars. By assumption, the King alone has the power to launch a war, and if he exerts it the elite decides whether or not to participate financially. Since most wars need joint funding, there is a free rider problem, which, the model shows, is more acute when the fiscal resources are shared between the King and the elite than when they are in one player's hands. This translates into the prediction that wars are more frequent, the higher the King's share of fiscal resources. For Rosenthal, France's absolutism was a case of sharing, whereas England's representative government was one of near control by the elite. Hence, he has a rough prediction to test on the two countries and can address the issue of how their warfare relates to their regimes. His model also implies the correct prediction that the overall level of taxation was higher in England than in France. However, it is unclear how it addresses the initial question of the different pace of political change in the two countries.

Case 3 19th Century Conscription (Levi) In the nineteenth century, several Western states changed their regulations of military service, moving from conscription with provisions for buying out of the duty to more or less universal conscription. Historians have usually emphasized democratization and military efficiency as being the two likely reasons for this. However, the latter is technically doubtful (a professional army would have dominated all other arrangements), and the former is objectionable in view of the timing of reforms (they indifferently took place either before or after universal suffrage prevailed). Starting from these objections, Levi compares the changes in France, the United States, and Prussia, paying attention not only to the chronological pattern but also to the variable pattern of buying out (there were three distinctive forms, i.e., substitution, replacement, commutation). She does not mean to displace the previous explanations entirely, but rather to subsume them under her own.

To do so, Levi develops an informal analysis in the spirit of formal political economy, whereby three main actors contribute to shape national decisions on the conscription regime. They are the army, which wants only military efficiency; the government, which balances it against social and economic considerations, such as

employing the population efficiently; and the legislature, which aligns itself with the coalition among three social groups (traditional elites, middle class, and workers) that make up the constituent body. With this construction at hand, the pattern of reform in each country can be explained by hypothesizing changes in the actors' motivations. Levi proposes two such changes, i.e., the increased demand from army and government for troops and the legislature's evolving preferences, both of which push in the direction of universal conscription. She relates the latter change to a reshuffle within the politically influential coalition (the pivotal middle class turning away from the traditional elites and becoming allied with the workers), as well as to an increased taste for equality among the social groups. The two main hypotheses from the historical literature appear again, though included within a systematic explanation scheme. The study draws on Levi's (1997) thorough antecedent work on the same topic and thus includes rich historical evidence.

Case 4 Antebellum Federation (Weingast) Historians of the United States have long been puzzled by the relative stability of the federation through the decades that preceded the Civil War. Classically, they argue that slavery was at first not as divisive an issue as it would become, and that the Democratic Party after Jackson successfully managed a coalition of southern and northern interests. Others have emphasized the role of local political issues and changing economic conditions. Weingast includes these factors in a narrative that stresses explicit political arrangements, especially the following *rule of balance*: slave states should remain equal in number with free states, so as to provide the South with a veto power in the Senate. The narrative records the crises that the Union underwent each time the admission of a new state threatened the balance. The first crisis led to the emergence of the compromise rule, which helped resolve the second, but did not work with the third. This ultimate failure depended on an admixture of economics and politics: to keep an effective balance despite the continuing expansion to the West, the slave economy would have had to develop beyond its feasible limits.

Weingast includes three formal models in his narrative, the first of which is of the spatial brand of voting theory. This model aims at weighing the political influences on the politics of the Union of the agrarian South, commercial Northeast, and intermediate Northwest, respectively. When these three actors differ only on the economic dimension, the Northwest acts as an electoral pivot, and the Union as a whole inclines in the direction of agrarianism, because the Northwest is closer to the South than the Northeast on this particular dimension. However, if slavery enters the political debate, the last part of conclusion does not necessarily hold because the pivotal Northwest is closer to the Northeast than the South on that dimension. The spatial model makes it possible to clarify coalitional possibilities when the political debate is so enlarged. Following a related treatment, Riker (1982) had famously claimed that it was to some Northeast politicians' advantage to introduce slavery on the electoral agenda, and it became a political issue after 1830 precisely for that reason (the so-called *Riker thesis*). The other two models used in Weingast's study are extensive form games of a straightforward sort. Comparison of their subgame

perfect equilibria shows that giving the South a veto power has the effect of blocking the compromise between the Northeast and the Northwest that would otherwise prevail. This reinforces the general point that the rule of balance was an important component of federal stability in antebellum America.[4]

Case 5 ICO (Bates) From 1962 to 1989, the International Coffee Organization (ICO) regulated the international prices of coffee by setting quotas on the exports of its members, notably Brazil and Colombia, which were the main producers. Bates accounts for the birth, regular functioning, and final collapse of this institution. This involves him using, or at least mentioning, various game-theoretic tools, but the study nonetheless follows a classic narrative structure, with a beginning, an end, and intervening steps that exactly reproduce the objective sequence. While the other studies state their explanatory problems in advance and subject their narrative parts to the solution of these problems, this one lets its explanatory puzzles and answers emerge as the story unfolds.

The birth of the ICO raises one such explanatory puzzle. As early as the 1950s, Brazil and Colombia had a cartel policy of restricting quantities and boosting prices, and tried to attract other coffee producers to this policy. However, it is only at the beginning of the 1960s that they succeeded in doing so and thus became able to establish the ICO. Bates explains why success was delayed by arguing that the proximate cause of its establishment was that the United States became favorable to the cartel policy. This is a paradoxical answer because the United States was on the consumption not the production side. Bates makes this answer plausible by relating how Brazil and Colombia, having failed in their first attempt, turned to the US State Department brandishing the communist threat and the long-term advantages of a cartel organization, and eventually met with success when some large US coffee-selling companies decided to support their lobbying. Each of these small narrative segments is followed by an allusive formal argument that clarifies the strategic situation.

Some Defining Characteristics of Analytic Narratives

The five studies of *Analytic Narratives* have a common focus on institutions, and more precisely on institutions that either belong to the internal state organization (Cases 1, 2, 3, and 4) or indirectly depend on it (Case 5, which deals with

[4]Perhaps because its topic has been heavily researched, Weingast's study seems to have aroused special attention from readers of *Analytic Narratives*. Some have complained that it is not clear whether the rule of balance in the Senate was central to the stability of the Federation, and accordingly how much its collapse contributed to the civil war. A quick answer may be that the study selects one particular sequence of actions and events for investigation, and this provides a partial but real explanatory argument (which incidentally comes out most clearly at the post-modeling narrative stage, see section "The Role of Narration in Analytic Narratives").

international relations). They also embody a common approach to the understanding of institutions. The key idea is that institutions operate not only through the formal rules that overtly define them but also through implicit rules of behavior that guarantee their function given the way participating agents respond to them. As an example, the *podesteria* can be viewed either by considering the official terms of employment of the *podestà*, or, more relevantly for an explanatory purpose, as a system of mutual threats between the clans and the *podestà* that made it possible for the latter to fulfil his role effectively. This heuristic is implemented by representing institutions in terms of equilibria of interactive processes, and it is at this juncture that game theory comes into play. Thus, Greif devises a game in which the existence of an equilibrium demonstrates that mutual threats can credibly balance each other, which secures compliance of the clans with the *podesteria* institution.

Conceptualizing institutions, and more specifically political institutions, as *equilibria of interactive processes*, whether by game-theoretic or other means, is a significant contribution to the neo-institutionalist school of thought. Elsewhere, Greif (2006, Chap. 1) clarifies the differences between this "self-enforcement" conception and those of previous neo-institutionalists. These writers had already discussed institutions from the perspective of the agents' interests, but in a somewhat more naïve fashion, often simply assuming that institutions are imposed "top-down" on the agents (what Greif calls the "institutions as rules" conception).[5] Two other major differences, even with historically oriented neo-institutionalists such as North (1981, 1990), have to do with the method of case studies adopted in *Analytic Narratives* and the specific attention this work pays to the role of narratives.

More crucially for our purposes, the five studies illustrate the two principles stated at the opening of this chapter. Each exhibits a collaboration between narrative writing and the employment of analytic tools, and each borrows these tools from the theories of rational decision-making. In the rest of this section, we expand on the second principle, using the studies as reference material. We defer an examination of the first principle to section "The Role of Narration in Analytic Narratives," where the third principle will also be considered.[6]

[5] An answer to the objection echoed in fn 3 is forthcoming along this line. The *podesteria* may well have been imposed "top-down" upon the Genoese from the outside, yet the question arises nonetheless of why they made its functioning possible, a question that the "institutions as rules" conception addresses. Clark's (2007) otherwise critical account of Greif (2006) clearly recognizes this.

[6] *Analytic Narratives* has given rise to a rather large number of discussions, which space reasons prevent us from covering here. The reader may in particular consult *American Political Science Review*, 94, 2000, no 3, and *Social Science History*, 24, 2000, no 4, which contain one or more reviews followed by a rejoinder from the five authors. Some of these discussions express strong scepticism about either the individual contributions or the methodological project itself; among the reasons for this scepticism is the routine complaint that "rational choice theory" (whether formal or not) is either flawed or inapplicable. None of these discussions – even the favorable ones – properly recognizes the special function that narratives, as against other forms of reporting of historical events, fulfil in the AN methodology.

Formal models of varying precision and sophistication occur in Cases 1, 2, 4, and 5, though not in Case 3. One may thus wonder whether or not AN in general must involve a formalism. As for the studies that do employ one, they primarily rely on extensive form games of complete information, and one may thus wonder how much this choice of models matters to AN. This section answers these two questions by arguing that (i) *AN do require formal models* and (ii) *AN can borrow these models from any formal branch of the theories of rational decision-making*. These two answers spell out what the five authors have only suggested (in *Analytic Narratives*) or briefly stated (in their informative rejoinders to critics; see Bates et al. 2000a, b). Thus, they acknowledge that their "restriction of models to extensive form games limits the range of issues [they] address" (2000b, p. 691), and they endorse "the requirement of a formal model" (p. 693). This amounts to making claims (i) and (ii).

One argument for restriction (i) is that ignoring it would take the edge off the AN methodology. Historians already borrow from common-sense ideas on individual rationality to confer explanatory value on their narratives. But they rarely make these ideas explicit, and this may be for two reasons: they may regard them as being too banal to be stated, or they may consider that a fuller statement would break the narrative flow. As they are not subject to the same discursive constraints as ordinary narratives, AN can unfold the terse suggestions contained in the latter and thus attempt to enhance their explanatory value. To do that, AN bring in specialized concepts of individual rationality: but if they eschew formalization of these concepts, they may be hardly different from the scholarly expansions that historians append to ordinary narratives in the introductions, conclusions, and appendices of their works. Interestingly, when revisiting *Analytic Narratives*, Levi (2002, p. 109) claims that the essays in this book "do not represent a breakthrough." It seems more fruitful, however, to allow that they do introduce something new – for better or worse. With (i) included in their definition, AN create an unusual tension between the narrative and the formal modeling. How this tension can be managed is the most exciting problem AN raise for the methodologically minded social scientist.[7]

There is actually a more direct reason for supporting restriction (i). The AN methodology crucially relies on the concept of equilibrium, understood one way or another, and the full development of this concept plainly requires a formalism. Levi rightly observes that *Analytic Narratives* makes extensive use of comparisons of equilibria: "the emphasis is on identifying the reasons for the shift from an institutional equilibrium at one point in time to a different institutional equilibrium at a different point in time" (2002, p. 111). This is the method of *comparative statics*, which economists implemented and made famous before passing it on to other social scientists. However, the method will remain at a heuristic level as long as one does not select a formal theory – e.g., that of extensive form games of complete information – and specify a model within that theory – e.g., by fixing a set of players, a set of strategies and preference orderings that fully define the game to be studied. The comparative statics

[7]One of the first works to explore this tension is the collection by Grenier et al. (2001); it does not yet refer to AN.

exercise, which is quantitative by essence, is possible only if some of the data of the modeling stage – e.g., the preference data of the game – are stated parametrically, with a range of numerical values set for each parameter. The exercise then consists in deducing how the equilibria change as a consequence of the parameters varying within their ranges. Even more clearly than in *Analytic Narratives*, this will be illustrated in Zagare's (2011) *The Games of July* (see Cases 9 and 10 in next section).[8]

Having defended restriction (i), we move to the generalization proposed in (ii). A common thread between Cases 1, 2, 4, and 5 is their reliance on non-cooperative games of extensive form. In their introductory manifesto, the authors defend this particular form on the ground that they focus on "sequences of actions, decisions, and responses that generate events and outcomes" (Bates et al. 1998, p. 9; see also Levi 2002, p. 111). The implicit claim is that the sequence of moves in the game is capable of paralleling a concrete sequence of actions and reactions by historical actors. One may, however, doubt that such nice parallelism really takes place. Consider the *podesteria* game; it involves moves such as "to challenge," "to fight," "to prevent," which can hardly represent genuine actions by the clans or the *podestà*. If the moves are idealizations, their sequential ordering cannot represent the passing of historical time; and indeed, if the *podestà* plays last rather than first in the game, this is for theoretical convenience, not descriptive accuracy. Of course, this semantic observation does not entail that extensive form games are unimportant to AN but only that this genre has no privileged association with them. Cases 6 and 7 in the next section will show that games in normal form can be equally relevant. On a different note, Cases 1, 2, 3, and 5 share a limitation by only considering extensive form games of *perfect information* (or possibly extensions of these to exogenous uncertainty). This conveniently guarantees that solutions to the games can be found by backward induction, as the subgame perfect equilibrium requires in this case. As next section will also show (Cases 9, 10, and 11), AN can support the more sophisticated formalism of extensive form games of *incomplete, hence also imperfect information*, along with the perfect Bayesian equilibrium concept, which is commonly used to solve these games.[9]

AN can be developed in other technical directions than noncooperative game theory. Cooperative game theory may provide appropriate models when it comes to analyzing the formation of coalitions, as in the ICO case.[10] Furthermore, not every historical state of affairs that involves multiple individuals calls for a game-theoretic analysis: individual decision theory, whether of the expected utility form or others,

[8]In this paragraph, we imply the familiar conception of a *model* as a construct mediating between theories and real objects. The alternative conceptions canvassed in recent philosophy of science could also be brought into relation to AN.

[9]On the logical relation between the concepts of perfect information and complete information, see the texts by Fudenberg and Tirole (1991), Harrington (2009), Myerson (1991) and Osborne and Rubinstein (1994). The first text in this list is the *locus classicus* for the perfect Bayesian equilibrium concept.

[10]Bates suggests considering the Shapley value for this purpose. For this and other concepts of cooperative game theory, see Myerson (1991) or Osborne and Rubinstein (1994).

may be sufficient for the modeling purpose. This is the case by definition when the multiple individuals face natural uncertainty, but also and more subtly when social uncertainty can acceptably be represented *as if it were natural*. When commenting on Clausewitz's military narratives, Mongin (2009) argues that some of his judgments can plausibly be reconstructed as expected utility comparisons; this is so despite the fact that the situations are strategic in an intuitive sense. There seems to be no rule to determine when game theory is indispensable to the analysis of interaction and when it is not. It is useful to register this indeterminacy, and then avoid restricting the technical apparatus of AN beforehand.[11]

Analytic Narratives from Military and Security Studies

While the previous AN belong to the historical part of political science, those covered in this section mostly belong to the historical parts of military studies (Cases 6 and 7) and security studies (Cases 8, 9, and 10). We distinguish between the last two fields as follows: military studies is concerned with actual war actions – battles, campaigns, guerillas, information wars, and the like – and security studies with actions taken under the shadow of war, i.e., facing the possibility of wars that may or may not break out. As two game-theoretic contributors to security studies write, "the games we analyze are not war games as such, but the choice that players make may precipitate conflict that leads to war" (Brams and Kilgour 1988, p. 3). This basic distinction is sometimes overlooked, which is unfortunate because military and security studies have different conceptual orientations.[12]

Case 6 World War II Battles (Haywood 1954) Shortly after World War II, Haywood, then a colonel in the US Air Force, discovered von Neumann and Morgenstern's (1944) work and made the first ever application of game theory to war events, publishing a sketch in Haywood (1950) and a detailed version in Haywood (1954). For this application, he selected a 1943 naval battle in the Pacific War and a strategic turning point in the 1944 Normandy campaign. His main concern was to connect the US military doctrine of decision, which was prescriptive, with von Neumann and Morgenstern's Min-Max solution for 2-person zero-sum games, which he also regarded as being prescriptive. He argued that the military doctrine of decision was right in prescribing officers to act on an estimate of the enemies' capabilities, not on a guess of their intentions – the argument being that if the game has no Min-Max solution in pure strategies, guessing intentions leads to an infinite regress of strategic calculations. Despite this prescriptive orientation, Haywood's inquiry has some bearing on historical explanation.[13]

[11]Schiemann (2007) promotes a further extension of AN to behavioral economics and illustrates this by a study of an event from the Yugoslav civil wars in the 1990s.

[12]See Betts (1997) for a more thorough discussion that includes a history of security studies.

[13]Haywood has rather mysteriously disappeared from the academic scene, despite Brams's (1975) and Harrington's (2009) supportive reviews of his contribution.

In the Bismarck Sea battle of February 1943, the US Air Forces destroyed a naval Japanese convoy that was sailing from Rabaul on New Britain Island to Lae on the New Guinea coast. Of the two possible routes, north of New Britain and south of it, the Japanese commander had chosen the former. Unaware of this, the US general in charge had to choose between concentrating his reconnaissance flights on one route or the other, and he actually took the northern option, whence his crushing victory. Haywood argues for the rationality of both moves, including the Japanese one. Having pointed out that the northern route was mistier than the southern one, he computes the number of bombing days associated with each of the four possible outcomes and solves the resulting 2×2 zero sum game using von Neumann and Morgenstern's solution. Here Min-Max reasoning on the two sides leads to an outcome that fit the facts, which confers some explanatory value on this reasoning. The other application is the Avranches battle fought between US General Bradley and the German general von Kluge in August 1944. Haywood analyzes it in terms of a 3×2 matrix, which this time has no pure strategy solution. As he does not quantify the payoffs, he cannot exhibit mixed strategies solutions, and this leaves one in doubt about what he achieves in terms of explanation.[14]

Surprising though it seems, game theory rarely enters military studies as properly defined. Applications of a prescriptive or instrumental nature certainly exist, the best-known being those pursued in the 1960s and 1970s for the RAND Corporation and some US military agencies (see, e.g., Erickson 2015). But it seems as if the historical part of military studies has no genuine game-theoretic application to offer besides Haywood's and the next case to be reviewed. This is not to say that scholars in this area have no interest in history. To the contrary, there is a long tradition among military strategists, which dates back to Jomini and Clausewitz, of basing their thinking on a careful examination of past battles and campaigns. However, this tradition is almost entirely narrative in the ordinary sense; so much so that it acted as a foil to the anti-narrative position epitomized by the *Annales* school historians in the middle of twentieth century, notably Braudel (1969).[15] By revisiting the Waterloo campaign, Mongin (2008, 2018) attempts to show that it is possible to turn even a worn-out example of military narrative into an AN.

Case 7 The Waterloo Campaign (Mongin 2008) As is well known, Napoleon's return to power in 1815 ended with his resounding defeat by Wellington and Blücher on the battlefield of Waterloo in Belgium. On June 16, the campaign began favorably for him, with the French beating the Prussians at Ligny, near Charleroi. On June 17, Napoleon decided to send a large detachment under Marshal Grouchy against the defeated Prussians, and he took the rest of his army to Waterloo, near Brussels, where the English and Dutch were ready for a defensive battle. On June 18, the French failed to break through the enemy lines and were eventually crushed when

[14]At any rate, a later historical discovery showed that Bradley had in fact been cognizant of the orders received by von Kluge, as the Allies had broken the German Enigma code (see Ravid 1990).

[15]Clark (1985) conveniently summarizes the position taken by post-war *Annales* historians; see also Stone's (1979) critical discussion.

the Prussians came as additional help. Despite innumerable histories, an explanatory gap remains in this sequence: why did Napoleon decide to send out Grouchy's detachment? By doing so, he ran the risk of not having it on his side when he faced Wellington, or, much worse, Wellington and Blücher together if they managed to join forces, a possibility that effectively materialized.

To make progress with this explanatory question, Mongin proposes a zero-sum game in normal form with two players, Napoleon and Blücher, allowing for uncertainty in several ways. First, both Napoleon and Blücher are uncertain of which battles will result from their independent decisions. Specifically, Napoleon can keep his army united, dispatch Grouchy for a pursuit of Blücher, or dispatch it for interposition between him and Wellington; and on his part, Blücher may either retreat to Germany or try to join Wellington at Waterloo. This is nothing but standard strategic uncertainty. However, a second form of uncertainty enters, since Napoleon does not know Blücher's type – here whether or not the latter was badly weakened after Ligny – and this means that the game is one of incomplete information. Third, external circumstances matter besides the players' decisions, and both are *ex ante* uncertain of the issue of each given battle. This is nonstrategic information, which is treated here as if it were objective and amenable to common expected utility calculations by Napoleon and Blücher.

Given suitable parameter restrictions, von Neumann and Morgenstern's Min-Max solution delivers a unique equilibrium, which involves pure strategies. As in Haywood's example, this arguably delivers not only an equilibrium but also rational choice recommendations. Napoleon should choose to dispatch Grouchy for interposition, and Blücher should try to join Wellington. That Napoleon effectively chose interposition, rather than mere pursuit, can only be conjectured from the historical record, but the game reinforces this hypothesis. The *ex post* failure is not an objection since it could result from an unfavorable resolution of objective uncertainty and from Grouchy misapprehending the plan – some historical evidence points in these two directions. Overall, the study exemplifies how an analytic narrative can be both formal and interpretive, since assumptions and conclusions are assessed in terms of evidential reports that are always incomplete, equivocal, and, given the high stakes, unavoidably biased. The conclusions adjudicate among existing positions, indeed by reinforcing classic pro-Napoleonic arguments against equally classic anti-Napoleonic ones.

Case 8 The Cuban Missile Crisis (Various Authors) Few diplomatic events have raised more scholarly interest than the crisis that took place from October 16 to 28, 1962, between the United States and the USSR. On 16 October 1962, President Kennedy was shown U2 photographs demonstrating that the Soviet Union was building missile bases in Cuba. Kennedy and his advisers pondered over several options, which included doing nothing, making a diplomatic move, bombing the missile sites, and blockading Cuba with the US Navy. Deliberation and further investigation led to the blockade decision of 22 October. Khrushchev was notified and the blockade was then publicly announced to the nation. In the ensuing days, the

crisis deepened, with some secret diplomacy nonetheless taking place. It was eventually resolved on 28 October, when Kennedy and Khrushchev managed to coordinate on a compromise solution. Essentially, in return for the USSR removing its missile systems from Cuba, the United States would lift the blockade, pledge not to invade Cuba, and – this was a later and secret part of the deal – remove missiles from Turkey.

Innumerable accounts of this famous sequence have circulated, with the flow being sustained by the appearance of declassified secret material (see, e.g., Allison's 1999 revision of his classic 1971 study). Among the accounts based on, or inspired by, game theory, none seems to us sufficiently rich in narrative content to qualify as an AN. Rather, they treat the Cuban Missile Crisis as a mere application of theoretical ideas, and, if we include this topic here, this is because it offers a touchstone of *deterrence models*, which recur in the AN literature. As Zagare (2014) has explained, the game-theoretic literature on the Crisis has gone through three essentially different stages. While the first authors, like Schelling (1960), gestured towards game theory rather than actually used it, a second wave from the mid-1970s onwards exploited 2×2 normal form games such as the Prisoner's Dilemma and Chicken, sometimes adding ingenious variations to them. A third wave, which began in the mid-1980s, adopted extensive form games, whether of complete or incomplete information, to analyze deterrence. Examples of the second wave appear in Brams's (1975) *Game Theory and Politics*, and at a more advanced level, in his *Superpower Games* (1985).[16] For the third wave, which he associates with a "sea change," Zagare (2014) mentions an early model by Wagner (1989) and his own "perfect deterrence theory" (as developed in Zagare and Kilgour 2000), both of which involve extensive form games of incomplete information. This leads us now to a specific examination of Zagare's contributions to AN.

Case 9 The Moroccan Crisis of 1905–1906 (Zagare 2015) After they had overcome their conflict over Sudan in 1898, France and Britain moved towards an alliance that materialized in formal agreements in April 1904 (the so-called *Entente Cordiale* agreements). The most important of them involved a trade of influences, with France supporting Britain's leading role in Egypt, and Britain supporting France's freedom of action in Morocco (with some role conferred on Spain in the northern part). Having not been consulted at all over Morocco, and also responding to the Sultan's wish to counter France's threatening influence on his country, Germany championed its sovereignty and an "open door" policy for foreign trade and investments. The German diplomatic pressures on the French

[16]In the latter work, Brams introduces a 2×2 game that schematizes the American and Soviet choices (Blockade and Air Strike, Withdraw and Maintenance, respectively) and applies his "theory of moves" to find that the Compromise issue (Blockade, Withdraw) emerges as a "non-myopic" equilibrium.

government led in 1905 to the resignation of foreign minister Delcassé and the reluctant acceptance by Président du Conseil Rouvier of an international conference. Officially devoted to the economic and administrative reforms that Morocco needed, the conference took place from January to April 1906 in Algeciras. While Germany hoped to drive a wedge into the Entente Cordiale and score a diplomatic victory over France, Britain supported its ally and Germany ended up almost entirely isolated, getting only limited concessions that would not suffice to curb France's colonial activism.

Zagare (2015) revisits the 1905–1906 events by appealing to the *Tripartite Crisis Game*, which belongs to his more general "perfect deterrence theory." This is an extensive form game of incomplete information with three players acting sequentially as follows. Challenger can either keep to the *status quo* or make a demand on Protégé, who can either concede or hold firm, in which case Defender enters the stage by either supporting or not supporting Protégé. If Defender has supported Protégé, Challenger plays again by either backing down or accepting a conflict, and if Defender has not supported Protégé, the latter plays again by either backing down or realigning on Challenger's side. Information is incomplete in that each player has two possible types: Challenger may be "determined" or "hesitant," Protégé "loyal" or "disloyal," and Defender "staunch" or "perfidious." This figurative terminology captures the fact that, for each nation player, some of its preferences over the terminal nodes are unknown to the other two players. To deal with the 1905–1906 crisis, Zagare specializes the Triple Crisis Game by assuming that Challenger – here Germany – is "determined"; this technically means that, at the last stage, Challenger prefers to accept a conflict rather than to back down. Thus, incomplete information is limited to Protégé and Defender – here France and Great Britain, respectively. Technically, Protégé is "loyal" if, at the last stage, it prefers backing down to realigning, and Defender is "staunch" if it prefers reaching the node where Challenger accepts the conflict to reaching the node where Protégé realigns. Fixing initial probability values for Protégé being "loyal" and Defender being "staunch," Zagare shows how they get revised at the perfect Bayesian equilibria he computes. In the Moroccan study as well as in other recent articles and in his 2011 book, Zagare explicitly claims to be using the AN methodology.

Case 10 The July 1914 Crisis (Zagare 2011) *The Games of July* (2011) investigates the diplomatic events that decisively contributed to the outbreak of World War I, particularly emphasizing four historical turning points. The first deals with a remote but influential decision made by Bismarck in 1879 to offer a military alliance to Austria, despite the tension this created with Russia, which was the main target of this arrangement. The second relates to the unqualified support – or "blank check" – Austria obtained from Germany in early July 1914 to crush Serbia, and the third to the escalation of conflict with the other powers once Austria began taking action. The fourth is devoted to the British decision to maintain an ambiguous policy during the July crisis, a decision that may have

misled Germany in believing in Britain's neutrality and thus may have contributed to the outbreak of the war. Each turning point raises specific explanatory problems that a brief narrative and review of historical literature helps locate. The book answers them through the instrumentality of game-theoretic modeling, in accordance with a methodology that the author distils in preliminary chapters and identifies with that of AN (see also Zagare 2009).

Each case relies on a game of its own, although all are taken from the common shelf of "perfect deterrence theory." The first, second, and fourth sequences are handled by means of relevant variations of the Tripartite Crisis Game, and the third by means of the *Asymmetric Escalation Game*, which also belongs to "perfect deterrence theory." We focus on the fourth case, which is concerned with British policy, because this permits comparisons with the Moroccan case, in which this policy had already played a crucial role. The Liberal Grey, who had succeeded the Conservative Lansdowne at the Foreign Office in the midst of the Moroccan crisis, essentially pursued his predecessor's policy of supporting France without making any military commitment to it. The persisting problem for the British was to secure peace on the continent by combining deterrence (of the Germans) and restraint (of the French, especially in their support to the Russians), and this led them to foster ambiguity on their final intentions. Whether it was to the point to maintain this carefully balanced policy in July 1914, as Grey did, is a major historical question. As is well known, it eventually needed Germany's invasion of Belgium on August 4 for Great Britain to engage militarily on the side of France and Russia.

As in Case 9, the game-theoretic treatment proceeds from the Tripartite Crisis Game. Germany, France, and Great Britain still occupy the roles of Challenger, Protégé, and Defender, but this time Defender is "staunch" and Challenger may be either "determined" or "hesitant" (the latter means that, at the last stage, Challenger prefers to back down rather than to accept a conflict). As the "blank check" issued to Austria was not known to the other players, endowing Germany with two types appropriately represents this uncertainty, but it is not obvious that the staunch type describes how Britain was perceived in July 1914.[17] However, interesting mixed equilibria occur even under this limiting assumption, and they are consistent with Grey's "straddle strategy," as Zagare (2011, p. 160) aptly designates it, thus providing the British diplomacy with a rationale (see also Zagare and Kilgour 2006). As these equilibria seem compatible with the strategic situation more broadly, they might serve to capture the protagonists' effective interaction. Supposing they are indeed the historically relevant ones, the war would have broken out not because of Britain's ambiguity, which had a serious

[17]The assumption made regarding Britain's type appears to be connected with a mathematical difficulty. The Triple Crisis Game can currently be solved only in limiting cases. Concerning the Moroccan crisis, the restriction was that Challenger was "determined," and here it is that Britain is "staunch" (Zagare 2015, p. 335, fn 7).

intent even though it was a gamble, but because in 1914, unlike in previous earlier crises such as the Moroccan one, the gamble turned out badly.

We close this section with another case that does not belong to either military or security studies but rather to historical political science. We include it here because it involves an extensive form game of incomplete information and the use of perfect Bayesian equilibrium as in Cases 9 and 10. The game belongs to the class of deterrence models, which bridges the work in security studies with some of the work in political science.

Case 11 (Nalepa 2010) During the transition from communism to democracy experienced by eastern European countries, communist officials had to choose, roughly, between opposing the trend as much as they could and seeking a deal with the democratic opposition. In this deal, they would retreat from power in return for a promise that they would not later be banned from public functions. Nalepa (2010) starts from the observation that, in some countries, the communists reached such a compromise with the democrats and the democrats kept their promise (at least by and large and for some period of time). This is puzzling because the democrats had every reason to renege on the compromise. However, as the author argues, the communists did have a way of avoiding this. The communist secret police had once infiltrated opposition movements, so the democratic parties, which were heir to these movements, were themselves in some danger of falling prey to a ban or similar "transitional justice" measures. Only the communists knew the extent of the infiltration, and this gave them an informational advantage over their opponents. An explanation of the historical puzzle is forthcoming along these lines, and Nalepa, who claims to be using the AN methodology, substantiates it by game-theoretic modeling.

The first model, which she attributes to Przeworski, is a perfect information extensive form game in which the communists anticipate the democrats' disavowal and choose opposition rather than compromise. This model is of course a strawman, since it never allows for the possibility of compromise. The second model, which is Nalepa's, introduces asymmetric uncertainty and comes close to a signaling game. By assumption, the communists know exactly the percentage of infiltration among democrats, who, being entirely ignorant, form a uniform probability on this parameter. If the communists choose to compromise rather than oppose, democrats read this move as a signal that they are infiltrated to a significant extent and revise their probability accordingly. This informational exchange is captured in terms of the perfect Bayesian equilibrium concept, which we have already encountered in Cases 9 and 10. The study closes by comparing some of the available equilibria obtained from this concept with historical situations. Unlike in Czechoslovakia, where the communists opposed the democrats until they collapsed, compromises prevailed in Poland and Hungary, and for relevant parameter values, there exist equilibria related to these situations.

Analytic Narratives and Deductive Explanation

The studies covered in sections "The Five Studies of *Analytic Narratives*" and "Analytic Narratives from Military and Security Studies" suggest some generalizations regarding the explanatory potential of AN. First, with the exception of Case 5, which belongs to recent history, and Case 6, which similarly belonged to recent history when it was written, they rely on an extensive scholarly record they use not simply to determine the factual data but also to suggest problems to be solved. The record is usually of the traditional narrative brand, and they identify the problems by noticing explanatory gaps within it. For example, Case 1 revisits the alternation of civil war and peace in Genoa with a view to explaining it, which had not really been done before. Case 3 revisits the establishment of universal conscription with a view of synthesizing explanations that hitherto had only been partial; and Case 7 revisits the Waterloo campaign with a view to arbitrating a classic disagreement among historians. Moreover, the problems appear to have been selected by carefully considering what the importation of analytic tools could add to the more traditional treatment. As Bates et al. (1998, p. 13) write, "our cases selected us, rather than the other way around." The only exception here appears to be Case 2, the topic of which – the Ancien Régime finances in comparative perspective – is arguably too wide for the analysis to get much grip on it. Mongin (2008, 2018) goes as far as to claim that starting from the extant historical literature, defining problems based on the lacunas therein, and restricting the models to limited fragments of it are preconditions for one's adopting the AN methodology.

One may observe, however, that the problems are not exclusively of an explanatory nature.[18] The Waterloo study aims not only at ranking competing explanations but also at substituting some missing data – what instructions Napoleon gave to Grouchy – with a deduction from the model. Here the gaps in the earlier narratives concern *the facts of the matter*, and not the explanation by itself. Less ambitiously than this substitutive role, though, AN can orient factual research in novel directions, as do other forms of problem-inspired history, like that promoted by the *Annales* school. However, original scholarship has thus far been exceptional among AN contributors, and they do not seem yet to have moved existing scholars towards new agendas.

From the angle of the philosophy of explanation, AN seem naturally to connect with the *deductive scheme* proposed by Hempel (1965), Nagel (1961), and many others.[19] Both the *Analytic Narrative*s team and Zagare mention this well-known scheme (though without detail).[20] Broadly speaking, it postulates that to explain a particular fact is to deduce the statement that the *explanandum* fact occurs from statements that other facts occurred, along with statements of generalities so as to effect a connection – these facts and generalities being offered as the *explanans*.

[18]Discussions of AN rarely make this point; see, however, Downing (2000, p. 91).

[19]Useful critical summaries appear in Salmon (1992) and Bird (1998).

[20]See Bates et al. (1998, p. 12; 2000a, p. 697) and Zagare (2011, pp. 5–7).

Besides requiring the logical correctness of the deduction, the scheme places epistemic requirements on the constitutive statements, and philosophers of science have dissenting formulations here. However, they all agree on the two basic points that the *explanandum* statement must be known to be true and the *explanans* statements must be, if not necessarily known to be true, at least empirically well supported. The rest of this section discusses the extent to which AN explanations fit with the deductive scheme; we will exhibit significant discrepancies, and thus prepare our ultimate claim that narratives are an essential component of these explanations. This discussion first singles out the *deductive requirement* of the scheme (not to be confused with the scheme itself) and then proceeds to the *epistemic requirements* that the scheme also involves. Since we mean to follow the existing literature, we focus on the use of game theory; but our conclusions can to a degree be generalized to the other formal theories discussed in section "Some Defining Characteristics of Analytic Narratives."

If the deductive requirement is to apply to AN effectively, it needs to be adapted to the distinction between *statics* and *comparative statics* that runs across them. One may consider a game either *specifically*, i.e., for fixed values of its parameters, or *generically*, i.e., by not restricting the parameters or (more commonly) restricting them minimally.[21] Although not entirely sharp, this distinction points towards two different possibilities for deduction. What can be deduced in the case of a specific game is that given outcomes occur as equilibria of that game, and in the case of a generic game, that different outcomes occur as equilibria when the instantiation of that game changes with the parameter values. This is the statics versus comparative statics distinction, as it emerges from the use of game theory.[22] Correspondingly, one may either explain a given historical fact by associating it with an equilibrium of a specific game or explain a change in historical facts by associating it with a change in the equilibria of a generic game. Comparative static explanations are logically more powerful than static explanations and should be preferred in principle. However, the AN literature makes it plain that comparative static explanations are not easy to come by. An exceptionally clear example appears with Zagare's multiple versions of the Triple Crisis Game, each of which is investigated in terms of comparative statics.[23] Haywood's simple analysis of two specific games represents the polar opposite case of a merely static explanation. Although more sophisticated, Greif's, Rosenthal's, and Mongin's analyses fall more on the static side, since they let parameters vary only in relation to given equilibria, so as to secure sufficient conditions for the existence of these equilibria, and they do not study the dependence of equilibria on parameter values across the full range of possible values.

[21]Game theory has another technical sense for the word "generic"; this will not be considered here.

[22]Other formal theories would specify the distinction somewhat differently.

[23]On the definitions given above, the Triple Crisis Game is not a generic game, but rather *a set* of such games. For instance, the specialized version for the Moroccan crisis is one such generic game, and the specialized version for Grey politics is another.

Having clarified this preliminary distinction, we can explicate two difficulties AN must face in seeking to satisfy the *deductive requirement*. The first has to do with the *multiple equilibria* occurring under most equilibrium concepts used by AN. When the multiplicity occurs in a specific game or – for some fixed values in the parameter range – in a generic game, the game-theoretic assumptions do not suffice for a definite conclusion, and the deductive machine needs supplementing by some external selection procedure. When the multiplicity occurs in a generic game simply because the parameters change, the situation turns out for the better; now the deductive machine works autonomously. Then the next step will be to compare the equilibria and their underlying parameter values with the available historical evidence. Contributors who claim that the deductive scheme is relevant to AN seem to have this favorable case in mind.[24]

Second, there is the troubling problem of deciding what in the games plays the role of the *generalities* that the *explanans* must contain if the deductive requirement is to come into effect. In a static exercise, the natural candidate for this role is the chosen equilibrium concept, e.g., subgame perfect equilibrium, the Min-Max solution, and perfect Bayesian equilibrium. In a comparative static exercise, it makes sense to consider as generalities not only the equilibrium concept but also the generic game (or, at a higher level, the class of generic games, the Triple Crisis Game being such a class). So, we do find general statements in AN explanations. However, they are general only in the sense of being expressible as logically universal statements, not necessarily in the deeper sense of being *nomological*, that is of counting as putative laws of nature. Hempel's (1965) paradigmatic version of the deductive scheme proposes various conditions, besides the logical form, for a generality to be nomological.[25] The question arises whether the game-theoretic statements singled out above meet these conditions, but we will not try to answer it here, being content with stressing its relevance. AN contributors who allude to Hempel (Zagare 2011, approvingly; Bates et al. 1998, disapprovingly) do not seem to have gone far into it. The common view among them is, more loosely, that the game-theoretic pattern uncovered in one study can be transferred with some success to other studies. Some go farther and claim to have at their disposal theories that apply across a significant range of historical states of affairs. This is the case with Greif (whose "theory of endogenous institutional change" includes the Genoa study as a particular application) and Zagare (whose "perfect deterrence theory" encompasses most of his studies relative to World War I and, as he suggests, can also be applied to some contemporary events).

We now consider how AN satisfy the *epistemic requirements* of the deductive scheme of explanation. As noted above, AN typically draw their problems from the extant historical literature and use little more than this corpus for checking their solutions empirically. To pass this empirical test, they need to answer three questions

[24]See Bates et al. (1998, p. 15) and Zagare (2011, p. 16).

[25]These and other conditions have been thoroughly discussed in the philosophy of science; see, e.g., Bird (1998, Chap. 1).

in the affirmative. (i) Do the equilibria of the games approximate what historians have observed concerning the *explanandum*? (ii) Do the game-theoretic assumptions that constitute the *explanans* draw support from what historians have observed concerning the circumstances of the *explanandum*? (iii) Is the *explanans* independently supported, i.e., does it also draw support from what historians have observed concerning other states of affairs than those under current investigation? We will review these questions in turn.

Regarding (i), there appears to be a gap between Cases 1, 2, 3, and 4 of section "The Five Studies of *Analytic Narratives*," and Cases 6, 7, 8, 9, and 10 of section "Analytic Narratives from Military and Security Studies." The *explananda* of the second group are narrowly circumscribed in time and space, directly bear on interactive decisions, and often if not always involve designated individuals, such as Bradley, Napoleon, or Grey. By contrast, the *explananda* of the first group extend rather widely across time, space, or both, bear on institutional or organizational facts rather than interactive decisions as such, and without exception involve collective actors, such as clans, political elites, or regions. To be linked to game-theoretic equilibria, the observable *explananda* of the first group need to undergo a more thorough abstraction process than those of the second group. This makes their explanations prima facie more debatable than the others are. Pushing this line, Mongin (2018) recommends applying the AN methodology preferentially to *explananda* that share with military and security *explananda* the convenient properties of being spatiotemporally well defined, and involving recognizable decisions made by recognizable historical actors. However – as also pointed out by Mongin – such recommendations threaten to trivialize AN. The explanations of the first group are more challenging than those of the second, which may remain too close to the historians' accounts to bring much illumination. It seems as if a balance needs to be struck between the two dangers of arbitrariness and pedestrianism.

When it comes to (ii), the question of the identity of players arises again, and there are now the further questions of endowing them with relevant *strategy sets* and *preference orders*. AN keep the number of players to a bare minimum. This may be easier to accept when players are hypothetical constructs, as in the first group of studies, than when they are identifiable historical figures, as in some studies of the second group. Indeed, somewhat shockingly, Grouchy does not enter the Waterloo game, and the games for the July crisis never include all major powers together.[26] Technical convenience explains these lacunas: thus reduced, the Waterloo game can accommodate some informational complexity, and the July 1914 games can be resolved despite their rich informational structure. For similar reasons, AN tend to rely on rather small sets of pure strategies. To allow for mixed strategies enlarges the players' possibilities, but like much of game-theoretic economics, the AN literature is reluctant to take this option; only Cases 9 and 10 make a significant exception.

[26]There were five at the time: Britain, France, Germany, Austria, and Russia. Zagare and Kilgour (2006, p. 635) address this objection.

Historians will no doubt complain that the definition of both players and strategies in AN impoverishes or distorts the historical evidence.

The definition of the players' preferences is even more problematic. A modestly sized set of strategies, and hence of outcomes, is already enough to turn preferences into complex objects. Thus, *podesteria* with seven outcomes, and Triple Crisis with six, induce 7! and 6! possible orderings, not small numbers. Moreover this computation assumes there are no indifferences. Zagare (2015, p. 332) contrasts two inferential methods to define preferences sensibly: one can try to infer them either from the historical actors' observable choices or from plausible general assumptions (such as the standard monotonicity and dominance assumptions of decision theory). Preferences are said to be "revealed" in the former case (which is loosely reminiscent of the revealed preference method in economics) and "posited" in the latter. We understand these two ways as being complementary rather than exclusive. Observed choices, even repeated under different historical circumstances, can hardly provide enough data, since preferences typically make counterfactual comparisons, and general assumptions are unlikely to be sufficient either. Whatever the chosen balance between "revealed" and "posited" preferences, historians will still no doubt complain – this time, though, not by arguing that AN *subtract* too much from the available evidence, but rather that they *add* too much to it.

Question (iii) plays an essential role in all formulations of the deductive scheme of explanation. As Nagel (1961, pp. 43–43) writes, for instance, the point here is "to eliminate explanations that are in a sense circular and therefore trivial because one or more of the premises is established (and perhaps can be established) only by way of the evidence used to establish the [*explanandum* statement]." To require that *all* statements in an *explanans* be tested independently would be exacting, but even the mild form of the requirement with "some" instead of "all" turns out to be challenging. Statements referring to historical particulars are the most recalcitrant, because of the paucity of historical data. Thus, one of the games in Case 1 postulates that clans strike a trade-off between the benefits of gaining control of Genoa and the costs of becoming responsible for its external security, but the sparse historical record does not contain any independent evidence for this assumption.

Explanans statements that are akin to generalities have a better chance of being tested independently. The Triple Crisis Game of Cases 9 and 10 illustrates this possibility. It underlies the *explanantia* proposed for no less than four different historical *explananda* (Germany's choice of an alliance with Austria in 1878, its diplomatic failure at Algeciras in 1906, its "blank check" to Austria in 1914, and finally, Britain's ambiguous policy in 1914). As Zagare and Kilgour (2000, 2003) argue, what is central to the Triple Crisis Game is *the assumption that Protégé can realign with Challenger at the final stage*. Strategically, this gives Protégé leverage over Defender while enlarging the room for maneuver of Challenger, and the Triple Crisis Game thus acquires a flexibility that makes it applicable across various historical situations. This assumption constrains the four *explanantia* above and thus provides a way of testing any of these individual *explanantia* by the empirical success or failure of its neighbor. This establishes that Zagare's explanations meet the independent testability condition at least in part. However, one should of course not confuse

independent testability with successful independent testing. The central assumption of the Triple Crisis Game runs into the historical problem that it applies more convincingly to the 1878 and 1906 contexts, in which Protégé's threat to realign was plausible, than to the 1914 contexts, where this threat made limited sense.[27]

To sum up this section, we have borrowed the classic deductive scheme from the philosophy of explanation and used it as a thread to investigate how AN contribute to historical explanation. This scheme recommended itself because game theory has a deductive machinery, and also because contributors to the field of AN often lay claim to it. We found that AN do not always involve proper deductions, and that they meet the epistemic conditions of the deductive scheme only imperfectly. The next section shows that the narrative component of AN can alleviate these failures. More generally, it considers the role of this component in fuller detail.

The Role of Narration in Analytic Narratives

Consider first the deductive failure connected with the *multiplicity of equilibria*. Authors of AN are aware of this difficulty, and typically resolve it by appealing to their narratives to decide among the possible equilibria.[28] This sketch of an answer needs to be refined by distinguishing between *different kinds of multiplicity*, as we did in section "Analytic Narratives and Deductive Explanation." Suppose the author of an AN wishes to devise an explanation in terms of some generic game. Narrative information has already established what the *explanandum* consists of and is now expected to say what parameter values of the generic game actually prevailed in the circumstances of the *explanandum*. If the generic game associates a unique equilibrium with these values, a dichotomy straightforwardly follows: either the equilibrium agrees with the *explanandum*, and the explanation can proceed further, or there is no agreement, and the explanation has failed. Now consider the case in which the generic game associates several equilibria with the historically relevant parameter values, and exactly one of these equilibria agrees with the *explanandum*. It is not clear whether one may still hope for an explanation. A standard move in applied game-theoretic work, for instance in industrial organization, is to check whether the unsuitable equilibria can be discarded on intuitive grounds. This informal procedure has sometimes led to new developments in game theory. However, AN contributors can regiment it less technically *by letting the narrative speak*. The pieces of narrative information to use for the selection task may overlap, but should not be identical with, those which have already served to determine the *explanandum*; otherwise, a gross circularity would result.

[27]Zagare and Kilgour (2006) and Zagare (2011, pp. 161–162) show awareness of this problem. Indeed, it would have been extraordinary if in July 1914 France had threatened Britain that it might align with Germany.

[28]See Bates et al. (1998, p. 15): "Repeated games, for example, can yield a multiplicity of equilibria. To explain why an outcome occurred rather than another, the theorist must ground his or her explanation in empirical materials." It is for "the narrative" to provide these "materials."

The last move illustrates how the recourse to the narrative may complement an imperfect deductive explanation. The selection it operates is conceptually different from that which consists in fixing parameter values. However, writers of AN are not always clear about which kind of multiplicity, and hence which kind of selection, they are concerned with. The reason for this seems to be that extensive form games of incomplete information entered the field only belatedly. Under complete and otherwise perfect information, backward induction provides the extensive form game with an essentially unique equilibrium once the parameters are fixed. Under incomplete, hence also imperfect information, backward induction is no longer available, and subjective beliefs are part of the definition of equilibria, which tends to make them non-unique even for fixed parameter values. The *Analytic Narratives* contributors were not yet in a position to clarify this necessary distinction, which, by contrast, comes out well in the introductory comments to *The Games of July*.

Let us now return to the problem of preference assumptions. Although it seems a good strategy to combine "revelation" (from choices) and "position" (of commonsensical comparisons), this will not always be sufficient to determine the players' preferences, and here again the narrative can help. For one thing, by granting that the historical actors have some internal stability, it enlarges the set of choice data on which "revelation" depends; for another, again granting stability, it offers a means of cross-checking what "position" suggests. To illustrate, Napoleon's preferences in June 1815 cannot be guessed only from his choices at the time plus the trivial notion that he preferred victory to defeat. His preferences included his risk attitudes, and to assess the latter, it is best to adopt some temporal distance and remember that he had been a bold and generally lucky gambler throughout his career. Thus, enlarging the narrative beyond the initial scope limits the arbitrariness of the preference assumptions in AN. This illustrates how the narrative can facilitate compliance with the deductive scheme – this time, when an epistemic, not a logical requirement, is concerned.

Still in the epistemic sphere, consider the problem of independently testing a generic game. One way AN contributors address this problem is by applying the game to spatiotemporally disconnected historical states of affaires, so as to explain them jointly. (This actually exceeds the usual demand for an independent test, which demands that one resort to control cases, but not to the point of devising a full-fledged explanation for these cases.) Besides Zagare's repeated employment of the Triple Crisis Game, we can exemplify the procedure with Nalepa's generic game, which she uses to account for three different democratic transitions (Case 11). Interestingly, Nalepa (2010) reinforces her joint explanation by selecting new facts from the narrative. She mentions that the communists began negotiating with the democrats at an early stage in Poland and Hungary, and belatedly in Czechoslovakia. This suggests that the communists believed in their bargaining power more strongly in Poland and Hungary, a suggestion that connects with another fact of the matter: they had infiltrated democrats more deeply in these two countries. Thus, the temporal pattern of negotiations indirectly supports the main explanatory point, which is that the degree of infiltration was crucial to the communists' success and failure in defending their position. Revisiting the narrative with an eye on independent testing has turned out to be productive.

Although it points in a clear direction, the previous analysis is not sufficiently specific, because it does not make clear why it is *narration*, rather than any other way of presenting historical evidence, that helps fill explanatory gaps. This suggests a more general question: why do AN contributors so strongly value this particular mode of exposition? The primary reason seems to be that they are concerned with *interactions*, whether directly or indirectly, and historical reports of actions typically come under narrative guise.[29] Now, it is still another question whether AN should *themselves* preserve the form of their existing sources. Arguably, by doing so, they are more objective than they would be if they reshaped these sources in non-narrative form. Presumably, reshaping would sometimes add and sometimes suppress too much information. Mongin (2008, 2018) illustrates this point with the sources on the Waterloo campaign. They all consist of narratives, from the witnesses' unelaborated testimonies to the military strategists' highbrow accounts, with a number of contextual variations in between, such as those of popular military history. To summarize this evidence in any other way than narration would distort it. Moreover, the problem addressed in the Waterloo study precisely consists of a gap found in earlier narratives, and a natural way to make this clear is to devise a summary narrative in which the gap becomes shockingly visible.

Related to these points is the fact that the formal theories of rational choice have privileged connections with the narrative mode of exposition. Models formulated with these theories typically come with *stories* to make their technical points salient or even simply intelligible. In the case of AN, these stories may or may not be realistic to the point of mapping onto parts of a historical narrative. In section "Some Defining Characteristics of Analytic Narratives," we argued that the actions in extensive form games were idealizations of concrete actions. Although complete similarity is beyond reach, the stories behind rational choice models, and in particular games, have sufficient common ground with genuine histories for relevant interchanges to take place between the two.[30]

There are many other reasons why it may be justified to value the narrative mode of expression, but they are not specific to the methodology of AN and belong rather to that of history in general, so we will not review them here.[31] However, one of these reasons deserves to be singled out. Philosophers of history often argue that narratives, properly understood, encapsulate causal claims in their reports of temporal succession. Here is a famous didactic example: "The king died, and then the queen died of grief." Whether causal claims such as that made by this sentence are satisfying from an explanatory viewpoint is a matter of dispute. Some philosophers, like Danto (1985), think that narratives are explanatory by themselves, while others, like Dray (1971), think that narratives are only occasionally so. An intermediary

[29]The novelist Philip Roth is said to have made this pronouncement: "Everything that matters comes to us in the form of a narrative." At least, every *action* that matters comes to us in this form.

[30]More on this in Grenier et al. (2001) and Mongin (2008).

[31]See in particular Roberts's (2001) collection, with classic pieces by Dray, Mink, White, and others and the 1985 collection of Danto's works in the philosophy of history, *Narration and Knowledge*.

position, which is probably White's (1984, 1987), is that the causal content of a narrative can always be extracted and subjected to separate scrutiny, so that the narrative will or will not be explanatory, depending on how the examination of the content turns out. This intermediary position seems promising for the methodology of AN. By stressing the possibility of extraction, it opens the door to the modeling stage of AN, and by making this extraction relative to causality, it reorients their assessment from their deductive towards their causal performance, an enrichment of the current discussion of AN.

We now complete our examination of the narrative component of AN by paying special attention to their *expository feature*s; for the main, this is borrowed from Mongin (2016). We will recognize three distinctive expository patterns for AN.

Case 1, concerning Genoa, follows a chronological order extending from the consulate period, with its succession of civil peace and war under the consulate, to prolonged civil peace under the *podesteria*.[32] The exposition of the consulate period follows a remarkable pattern. First, a standard narrative records the main facts and introduces the *explananda*; then comes a game-theoretic model with relevant variations, which suggests the *explanans* hypotheses; and finally a narrative consolidates the explanation. Unlike the first, this narrative borrows theoretical terms from the modeling part, e.g., "mutual deterrence equilibrium," and serves to clarify and empirically support the *explanans* hypotheses, thus assuming the function of problem-solver. Despite its special features, this is a narrative all right, so we do have an *alternation* pattern. This pattern also appears, though a little less transparently, in the rest of Case 1, as well as (albeit with some differences) in Cases 4 and 5.

In Case 6, on Waterloo, the exposition begins with a campaign narrative in the style of military history, which introduces the main facts and the (here unique) *explanandum*. Then, a game-theoretic model delivers the explanatory hypothesis, and a discussion follows that introduces more historical evidence. As a distinctive feature, this study considers the initial narrative as being essentially satisfactory, except for the explanatory gap it draws attention to. Thus, the model and its discussion are parenthetical, and the initial narrative can be resumed once the gap is filled. This pattern of *local supplementation* differs from alternation in being less ambitious, since it does not involve creating a new narrative. However, the two patterns locate the final explanation in a narrative, and this feature is more important than the difference between them.

Case 11, on "transitional justice," goes through the following expository steps. It introduces the historical problem of "transitional justice" in the early post-communist years, puts forward a theoretical hypothesis both informally and formally, proceeds to a narrative history of transitions, and finally compares facts from

[32]One may note the dramatic quality of this sequence, which reminds one of the triadic plot structure in many dramas or fictional stories: an initially stable situation, a conflict between the characters, and a positive or negative resolution of this conflict (see Freytag 1863, elaborating on Aristotle's *Poetics*).

this narrative with the theoretical hypothesis. Although well developed, the narrative here is only a provider of data, and the whole study obeys a standard hypothesis-testing scheme. What customizes it is that it gives a narrative form to its empirical evidence. We will call this expository pattern *analyzed narrative*. Unlike in the first two patterns, it does not entrust the final explanation to a narrative, whether ordinary or revised, but rather states it abstractly and theoretically.[33]

Starting from this contrast, one may conceive of AN in two different ways. In a *restrictive* view, they count as such only if they follow the alternation or local supplementation patterns; in a *liberal* view, they may also follow the analyzed narrative pattern. A reason for preferring the former is that it seems best to emphasize what is most specific about AN; we have already used such an argument in section "Some Defining Characteristics of Analytic Narratives." The thought-provoking move is to *make* narratives analytic, and this necessitates the return of the narrative at the end of the study. As they simply *juxtapose* the analytic and narrative components, analyzed narratives are less novel. For two reasons, however, this argument may be too stringent.

First, as we have mentioned, the three patterns share the feature of bringing in historical evidence narratively, and this is by itself an important specification, since not every work in economic or political history does that. There have even been voices in these fields, as well as in history more generally, calling for narration to be downgraded, an attitude that conflicts with the way it enters analyzed narratives. Well-known representatives of this anti-narrative stance are the members of the *Annales* school, who championed "problem-oriented" against "narrative-oriented" history, and the intransigent "new economic historians" whose flags were economic modeling and econometric techniques.[34] One reason for preferring the liberal view of AN is that they clearly illustrate the opposite stance of the "revival of narrative," to borrow a famous phrase by Stone (1979). Second, the beginning of this section has pointed out several means by which narration can rescue flimsy explanations, and these means are also available in the third pattern. In particular, Case 11 selects equilibria from narrative information in a manner no different from Cases 9 and 10. In terms of the principles stated in the introduction, the third one, whereby the narrative actively contributes to historical explanation, appears to be common to AN

[33]Crettez and Deloche's (2018) treatment of Cesar's death further illustrates the subgenre of analyzed narratives. Following the general AN methodology, they carefully review the historical evidence and extract from it a problem they solve with the aid of a formal model. How plausible is the suggestion made by Suetonius and others that Cesar was aware of the plot to murder him when he went to the Ides of March meeting of the Senate? The authors' two-person game of normal form has a single Nash equilibrium that is mixed, which in their view suggests a negative answer to this question. Here the narrative provides both the evidence and the problem, but the solution is stated in theoretical, non-narrative terms.

[34]The firm contrast that *Annales* postulates between narrative- and problem-oriented history appears among others in Furet (1981). The anti-narrative stand is also present among new economic historians, e.g., Kousser (1984), who defends "quantitative social scientific history" against a "revivalism" of narrative. Not every cliometrician has adopted this stance; witness the open attitude of the editors of this *Handbook*.

broadly understood, although the alternation and local supplementation patterns apply it more systematically and, as it were, more interestingly than the analyzed narrative pattern does.

These reasons can tilt the balance in favor of the liberal view of AN, and we will adopt this view here, thus completing our attempt at defining the AN genre. To make this definition more transparent, we may cite two groups of studies it does *not* cover. (i) Some studies are concerned with specific historical events, involve a significant amount of narrative information, and base their explanations on the outcome of complex interactions, but refrain from adopting a formalism and thus provide only promising sketches of explanation. Besides Case 3, Myerson's (2004) discussion of the Weimar disaster is a good example – and all the more so given that his informal comments are evidently made with a possible modeling in view.[35] Works like these are *proto-analytic narratives*. (ii) Other studies are also concerned with specific historical events, base their explanations on the outcome of complex interactions, and do develop these explanations by means of properly formalized models but do not confer an explanatory function on the narrative, nor even prioritize it among the sources of historical information. Two studies by Greif that antedate his adherence to AN methodology can serve as examples. Greif (1993) investigates the community of Maghribi Jewish traders who operated in maritime commerce in the eleventh and twelfth centuries, and Greif et al. (1994) investigate the connection between the merchant guilds of medieval Europe and long-distance trade. These studies focus on the commitment and coordination problems that traders faced in their dealings with official rulers or other traders, and they use game-theoretic models to show that well-designed informal (in the Maghribi example) or formal (in the guild example) institutions could overcome these problems. Their exposition mixes theoretical elements with historical evidence, which is only occasionally narrative, in a dialogue that clearly differs from the alternation pattern implemented in the Genoa case. Despite their emphasis on interactions and game theory, which likens them to AN, they are closer to other formalized works in historical political science or economics. Let us designate them *analytic non-narrative histories*.[36]

Conclusion

This chapter has defined AN in terms of three principles, the most intriguing of which is that AN call upon a narrative also at the explanatory stage. We have pursued our definitional investigation at the same time as making progress with the other topic of the chapter, i.e., how AN contribute to historical explanation. In this latter

[35]For instance, Myerson (2004) suggests treating the events of 1930–1933 in terms of a signaling game between the Allies and the German conservative leaders. To get rid of the reparations burden, the latter would try to impress the former by pushing forward Nazism as a political force (a dangerous game if ever there was one).

[36]More examples could be found in Greif's (2002) survey of game-theoretic economic history.

discussion, we have selected the deductive scheme of scientific explanation as a benchmark: overall, analytic narratives exhibit more deviation from, than conformity to, the deductive scheme, and this is precisely why they call upon the narrative for help. A more complete account of their explanatory performance would have clarified the kind of causal connections they can hope to establish, and this would have led us also to investigate the kind of counterfactual history they develop. The necessary brevity and thematic unity of this chapter made it impractical to go in these directions. Similarly, we refrained from explicitly defining what a narrative consists of. This would have required us to compare the narrative mode of discourse with the other modes, such as exposition, argumentation, and description, which historians also use, and thus to delve in the recent work of narratologists as well as the more traditional concerns of rhetoricians and literature teachers.

Thus far, political scientists have paid more attention to AN than other social scientists. This is easily explained by the fact that the two main currents that have shaped the development of AN, i.e., the equilibrium approach to institutions and the deterrence approach to national security, are primarily of concern in political science. But these disciplinary associations are in part a matter of contingency, and it is anyhow the case that "analytic narratives should have no boundaries with respect to subject or evidence" (Bates et al. 2000b, p. 690). In particular, there is no reason why AN could not also have a significant place in economic history. What might restrict their use therein is that they are concerned with fine patterns of actions and events, like the formal theories of rational choice they borrow from, and are thus unable to handle long-term historical processes, such as Britain's Industrial Revolution, or large-scale sets of social and economic relations, such as slavery in nineteenth century USA. But these wide topics are of course the bread and butter of today's economic historians; and if AN can teach them anything, it would be precisely by directing their attention towards the fact that it is possible to approach some microscopic structures no less rigorously than these topics, albeit by different formal means.

Abstract

Spatial modeling is a systematic approach to understand the spatial configuration of economic activity from a local to a global scale. This chapter begins with an overview of empirical tests of spatial correlation, including testing of spatial randomness, join-count statistics, and Moran's I. This leads to a discussion of spatial concentration measures and the usage of such tests and measures in the context of economic history. An overview of the development of spatial modeling, from von Thünen to Hotelling to the new economic geography demonstrates the abstract nature of modeling, its application in a wide range of settings, and the usefulness of economic history to validate theoretical approaches. The final section goes over a range of modeling components used in quantitative spatial economics and their relevance in economic history. The chapter concludes with an outlook to alternative modeling approaches, including spatial point processes and networks.

Keywords

Economic Geography · Agglomeration · Spatial Concentration · Spatial Correlation

Introduction

"Everything is related to everything else, but near things are more related than distant things." This quote from Tobler (1970) is commonly referred to as the first law of geography. Even if most empirical analyses in economics take this reciprocal influence to be completely negligible for all practical purposes, the question of spatial relationships has received much more attention again in economics and the economic history literature over the last three decades, which has triggered a renaissance in explicit spatial modeling.

While economists had not paid much attention to geographical aspects, the field of geography was alive and well. Nevertheless, when economists started to pay more attention, the approaches, questions, methods, and tools used in both fields continued to diverge. Economists focused on highly technical, theoretical, and quantitative tools to draw general conclusions. Geographers, on the other hand, moved to qualitative studies focusing on specific cases, which were strongly shaped by the field's "cultural turn"(Krugman 2010). While there is a literature that brings the approach of geographers to historical analysis, this chapter focuses on spatial modeling as understood by economists and quantitative economic historians. "The Development of Spatial Modeling" presents a history of formal spatial modeling from this viewpoint over the last two centuries and discusses its relationship and interaction with economic history.

This overview of the historical development of spatial modeling demonstrates that it has an extreme breadth without a clear theoretical center. The core theories of international trade, Ricardo, Heckscher-Ohlin, and the new trade theory with

increasing returns and monopolistic competition, are important components, yet they are only pieces of the puzzle. Preferences and amenities, production functions and local productivity, and the flows of people and ideas are just a few of the additional pieces. Consequently, this chapter does not present formal theories but utilizes a recent overview of the various components (puzzle pieces) used in location theoretic modeling in economics to place their relevance within the application of spatial modeling in economic history.

To start off, however, a more basic question is discussed, namely, how to detect spatial correlation and therefore a potential need for spatial modeling? After a short discussion and clarification of the relevant structures, in particular actors and space, the main empirical approaches to detect spatial correlation are introduced. This covers the distribution of events over space, the spatial distribution of binary characteristics of a set of locations, and similarly, the distribution of continuous characters. It concludes with a discussion of other statistical measures of spatial concentration and specialization and their use within economic analysis in economic history.

Basic Structures

Monads and Dyads

Probably the most famous model explaining an explicitly spatial economic phenomenon is the *gravity equation*. In practice, it resembles the physics theory modeling the force of attraction between spatially distinct objects. Applied to trade relationships, the equation explains the trade flows between two countries by modeling it based on the characteristics of origin and destination and the distance between them. The focus on flows between two countries implies that the modeling uses dyads, the combination of two actors, as the unit of observation. There are a number of other spatial relationships, such as trade agreements to military conflicts, where dyads are an appropriate modeling approach. For quantitative economic history, another important application is the analysis of *market integration*, focusing on the correlation of prices between two locations.

Lampe and Sharp (2016) thoroughly discuss foundations and the use of the gravity equation in economic history. Market integration has been discussed by a number of authors, including Jacks (2005). Consequently, this chapter focuses on individual actors, modeling the origin and impact of spatial relationships with monads, i.e., individual actors, rather than pairs of them.

Actors

The advent of modern data processing and computing also led to the development of *geographic information system* (GIS) software. Its purpose is to collect, combine, manage, and transform spatially referenced data. GIS data are categorized into two

different types, namely, *vector data* and *raster data*. Although each individual data series has to be in one of the two formats, it is possible to combine data from both categories as well as convert series from one to the other. These data formats reflect the nature of the underlying data and as such correspond to the units of observations representing actors within modeling approaches.

Vector data are geographic shapes mirroring empirical units of observations and come in three different types, namely, points, lines, and polygons. *Points* are usually used to locate individuals or individual units like firms or cities in space. *Lines* model links between points, for example, infrastructure, borders, or communication ties. *Polygons* represent areas, most prominently countries and regions.

Raster data use a different approach by parting the complete surface into a rectangular grid where each cell contains a single data point. Although each cell is associated with a single value, that value can actually imply a combination of others. One example is that each cell has a color value; however each color is a unique combination of the three base colors. The format resembles digital pictures, and important applications include mapping *nighttime light intensity* or geographic characteristics like elevation.

In terms of spatial modeling, it is straightforward to see vector data as representing units of observation and therefore actors in most modeling approaches. Raster data, in contrast, does not fit particularly well as representations of actors, whose actions are modeled. In this context it serves mainly as a data source that allows the determination and calculation of characteristics of vector-based units observations. As such it can be used as outcome data, for example, satellite data about nighttime light intensity is used to demonstrate modern consequences of historical events or long-term developments involving a number of spatial phenomena like borders (Michalopoulos and Papaioannou 2018).

Distance

Spatial modeling and empirical studies using spatial approaches, however, not only use *geographic distance* based on a two-dimensional representation of physical space but can accommodate other approaches to space and distance as well.

As shown in the discussion of Hotelling's model in "The Development of Spatial Modeling," one possible difference is the number of dimensions. Simple models might use one-dimensional distances, which can usually be represented by a single line and the distance between actors located on that line, while more complicated ones use multidimensional setups, where the relative locations of actors differ along multiple axes. Modeling policy differences between countries is an example, where the dimensionality of space depends on the number of policy areas under comparison, ranging from a single area to multiple policy fields.

Another possibility is to move away from physical distance and approach the relative spatial position of actors in different ways. The main approach is the idea of binary distance, where two actors are either directly linked to each other or not at all. In practical empirical terms, that type of relative positioning is for actors

representing areas, for example, countries or counties, which often exhibit some form of contiguity, for example, two countries sharing a common border. A related approach is thinking in terms of network structures. *Networks* are modeled as nodes and edges between these nodes, so if the node represents an actor, then the existence of an edge with another node implies that the two actors are connected, while the absence of an edge means that they are not.

Modeling Spatial Correlation

Although Tobler's law stated above is an assumption that "everything is related to everything else," it's not clear how strong those connections are and whether the correlation really matters or can even be empirically detected.

Any empirical exploration of *spatial autocorrelation* obviously requires a method to determine a summary statistic characterizing the presence, direction, or strength of any such correlation. The different types and characteristics of actors, different approaches to distance, and different statistical assumptions imply that there is no single way to characterize, determine, and test for spatial correlation. There is, however, a substantial literature in regional science and other geography disciplines that provides empirical approaches to explore spatial correlations that are adopted and used in quantitative economic history.

The following goes through commonly used measures in three different settings, namely, spatial correlation between the locations of actors, spatial correlation between binary characteristics of actors, and spatial correlation between continuous characteristics of actors. The application is practically demonstrated with a data set of villages and towns in Saxony and their population in the early nineteenth century. The data are based on Ploeckl (2012, 2017) and contains 3515 settlements, including 140 legal towns, with their respective population in 1834.

Spatial Randomness

The first considers cases where the interest is whether observations are located randomly on a two-dimensional surface. As Baddeley et al. (2015) describe, if the spatial distribution is indeed random, the underlying *spatial point process* is characterized by two key properties:

- *Homogeneity*: the points have no preference for any spatial location.
- *Independence*: information about the outcome in one region of space has no influence on the outcome in other regions.

Mathematically this can be formulated for a point process X and an intensity value λ as:

- The number $n(X \cap B)$ of random points falling in a test region B has mean value $En(X \cap B) = \lambda|B|$.

- For test regions $B1$, $B2$, .., Bn which do not overlap, the counts $n(X \cap B1)$, .., $n(X \cap Bn)$ are independent random variables.

In combination with the assumption that the counts within the test regions follow a Poisson process, these characteristics are referred to as *complete spatial randomness* (CSR). CSR implies that the expected number of observations within any area is linear in the size of the area. The constant coefficient, λ, is referred to as *intensity* (Baddeley et al. 2015).

The context of a point process and its intensity is relevant for a number of situations, probably more prominent in fields like biology (e.g., the abundance of virus particles on a cell surface), zoology (the location of ticks in a forest), forestry (spatial distribution of particular tree species), and climatology (lightning strikes). But it is also useful for economic history, from the productivity of agricultural crop production to the risk and occurrence of particular behavior, such as crime, to the presence of natural resources and other relevant endowments.

If the spatial distribution is not random and CSR does not hold, then there are two alternatives. First, the pattern can be more dispersed, which makes it appear more regularly spaced, and second, it can be grouped, which makes it appear more clustered.

As Baddeley et al. (2015) mention, there are a number of statistical approaches testing spatial randomness. A basic one is using *quadrat counts*, where the whole area is split into equal-sized quadrats. The number of points in each is then used in the test statistic. This also works with other shapes as long as they are of equal size and nonoverlapping. With m regions and $n = \sum_i n_i$ the total number of points, the formal test statistic is: $X^2 = \sum_i \frac{\left(n_j - n/m\right)^2}{n/m}$, which has under the null hypothesis a distribution that is approximately $\chi 2$ with $m - 1$ degrees of freedom.

The location of settlements within a region is an applicable situation where a test of spatial randomness is informative. Applying the quadrat counting test to the historical distribution of settlements in Saxony shows for 20 tiles a $\chi 2$ value of 407 and a p-value below 0.01. Clearly settlements are not randomly distributed. Specifying the alternative as one-sided and either regular or clustered shows that these spatial locations look as if they are clustered.

The exploratory tests about spatial randomness can only diagnose in which direction any violation runs but don't specify which of the two main assumptions, the featureless surface and the independence between observations, is the source of the deviations. The final section revisits approaches analyzing these types of statistical processes and structural factors shaping the spatial distribution of observations.

Join-Count Statistics

Most economic history analyses concern situations where the spatial location of actors, from individuals to firms, towns, counties, or countries, is taken as given. The interest is then in the spatial correlation of a particular actor characteristic, so in its distribution over the existing locations of the observations.

If the outcome of interest is binary, one approach is the *join-count statistic*. Examples for such outcomes are which firms went bankrupt and which survived, which cities adopted a particular policy or technology, or which countries were on the gold standard. The statistic assumes a static situation, so this approach is appropriate for empirical situations where the relevant binary data are given by a cross section.

Following the theoretical exposition by Cliff and Ord (1981), this can be illustrated for the case of countries on and off the gold standard. The central idea is to look at contiguous country pairs and count the connections (hence the "join") categorized by the status of the two states. Practically, the basis are separate counts of the number of neighboring country pairs where both are on gold (GG), where one is on gold and the other one is off (GO), and where both are off gold (OO). Based on the probability that a country is on or off gold, an expected number of joins for each of the counts can be derived. If the observed GG count and the corresponding expectation are close, the gold standard is randomly distributed; if the count is significantly higher, gold standard countries are clustered; and if it is negative, they are dispersed. The results for the three counts are not necessarily symmetric, so a spatial correlation of being on the gold standard does not imply a spatial correlation of being off gold. The difference between the expectation and the actual counts also indicates how strong such a spatial correlation effect is.

Cliff and Ord (1981) provide a generalized theoretical formulation as well as the necessary moments for significance testing. The latter requires two assumptions, first about the sampling process underlying the observations and second about the nature of the joins. The first has two possible specifications that mirror sampling with and without replacement: free and non-free sampling. *Free sampling* means each observation has the same probability of being on the gold standard, which is usually based on the sample average of countries on the gold standard. *Non-free sampling* is when each observation has again the same probability, but the total number of countries on the gold standard is restricted to that observed in the sample.

The other assumption is about *spatial weights*. Cliff and Ord (1981) show that the formulation holds for general weights, not only for the special case of binary zero – one joins as represented by contiguity. The decision which spatial weights to apply, however, is left to the researcher. The discussion about distance measures above indicates potential choices, while the nature of the data provides a certain guidance. Network models have an obvious binary link interpretation, area data like countries or counties point toward contiguity measures, and observations within regular space, such as firms, fit well with distance-based weights. The main point, however, is that for the same outcome data, different weights can result in different conclusions, since any spatial correlation is dependent on the weighting scheme.

The choice of a weighting scheme depends on the purpose of the calculation. If the intention is exploratory to determine the nature of any potential spatial correlation, then testing different weights to see whether any result exhibits spatial correlation at all is one approach. If the intention is to investigate a particular transmission mechanism or channel that should cause spatial correlation, then the weighting scheme should be specified accordingly.

The empirical example demonstrates the impact of the weighting scheme. The set of settlements in Saxony is split into towns and villages depending on whether or not a location had official, legal town rights in 1834. This results in 140 settlements designated as towns. The join-count test is conducted twice, once with binary weights based on the distance between the two settlements as less than 10 km and once based on the inverse distance as weight. The vicinity-based weights result in a statistic of 3.55 versus an expectation of 2.77 with a p-value below 0.01, indicating that there was positive, spatial clustering between towns. The distance-based weights result in a statistic of 225.96 with an expectation value of 235.94 and a p-value of 0.27. This indicates no significant evidence for that spatial correlation in this form.

There is also an extension of the join-count approach to discrete data with more than two outcomes referred to as J_{tot} (Cliff and Ord 1981).

Moran I

The counterpart to the join-count statistic for continuous outcome data is the so-called *Moran's I* (Cliff and Ord 1981). This test statistic is defined as follows where n is the number of observations and w_{ij} is the weight of the link between i and j:

$$I = \frac{n}{\sum_{ij} w_{ij}} \frac{\sum_i \sum_j w_{ij}(x_i - \bar{x})(x_j - \bar{x})}{\sum_i (x_i - \bar{x})^2}$$

As with the join-count statistic, the included weights w_{ij} have to be specified exogenously. The related discussion above about the specification and impact of the weight matrix applies here as well, so its precise form depends on the purpose of the calculation and should be informed by the research question and any implicit or explicit theoretical framework about the phenomenon in question.

The value of Moran's I ranges between -1 and 1. If there is no spatial autocorrelation present, it takes on the value of zero, while positive values indicate positive spatial autocorrelation (*clustering*), and negative values indicate negative spatial autocorrelation (*dispersion*).

As for the join-count statistic, it is possible to derive expectation and variance for Moran's I, which allows standard approaches to test the statistical significance of any empirical results.

Usage

The main usage of these indicators is to explore the possible presence and direction of *spatial autocorrelation* within a data set. Such an exploration can also be used to determine whether the spatial implications of a particular transmission mechanism are reflected in the observed data.

A further area of exploration is to understand changes in spatial correlation over time, between different outcomes or between different configurations. In the cases of join-count statistics and Moran's I, it is possible to trace and compare developments over time as long as the utilized distance weights remain constant. Because the development over time is only a special case of a comparison between different data sets, the same logic applies to such a situation; as long as the spatial weights are identical, it is possible to draw comparative conclusions about the relative strength and direction of spatial autocorrelation of the different data sets. The situation changes when spatial weights differ. The comparisons of the strength are only useful for identical data to determine whether a particular mechanism results in spatial correlation.

The three indicators only test whether spatial autocorrelation is present in the full sample. They do not identify characteristics of particular subsets, so, for example, they do not identify whether the same correlation holds for subregions or where particular clusters are located. There are approaches to explore local variations over space, in particular *local indicators for spatial autocorrelation* (LISA) (Anselin 1995).

Measures of Specialization

The described measures focus on the spatial aspects of the geographic distribution of some economic outcome. There are, however, also approaches that focus primarily on the strength of *spatial concentration* and have similarities with those looking at *market concentration*, like the Herfindahl index.

Krugman (1991) formulates a measure of *regional specialization*:

$$SI_{jk} = \sum_i \left| \frac{E_{ij}}{E_j} - \frac{E_{ik}}{E_k} \right|$$

where E_{ij} is the level of employment in industry i for region j, E_j is the total industrial employment for region j, and E_{ik} and Ej are the same for region k. The index compares regions j and k, which are completely despecialized if the index is zero and fully specialized if it is 2. Kim (1995) uses this to document the regional specialization of manufacturing in the USA between 1860 and 1987 and finds the average specialization increases until the interwar period, before it consistently decreases throughout the postwar period.

Kim also analyzes *localization*, the question of whether individual industries are more or less concentrated than manufacturing in general. He uses Hoover's *coefficient of localization*, which is based on a region's employment share relative to total employment in individual industries as well as total manufacturing employment shares, to show that the average localization level in the USA followed a similar trend over time as regional specialization.

Ellison and Glaeser (1997) take up this question of localization and incorporate firm and plant-level concentration into the calculation. Similarly, Duranton and

Overman (2005) propose an approach that shifts the analysis from regional units to continuous distance underlying the definition of agglomeration patterns. Another step is to modify the approach to determine *co-agglomeration* patterns between different industries (Ellison et al. 2010).

The calculation of these indices has a predominantly descriptive approach. It demonstrates the nature and level of spatial *agglomeration* in specific industries or economic activity in general. It is not only applicable to modern data but also allows a consistent description of historical and long-term developments.

The indices can also be used to infer either evidence about spatial models or particular economic factors driving location and specialization patterns. Kim (1995) shows that his results provide empirical support for models of *regional specialization* based on scale economies and resource use, Ellison and Glaeser (1997) show support for spillovers and natural advantage leading to agglomeration, and Ellison et al. (2010) provide evidence for the impact of three types of *Marshallian externalities* on industry agglomeration pattern, namely, input-output linkages, labor market pooling, and knowledge spillovers. In comparison to these conceptually oriented analyses, studies can also use such measures to understand historical developments. Gutberlet (2014), for example, provides a historical study demonstrating how the transition from water to steam power influenced and contributed to the geographic concentration of manufacturing in the German empire during the late nineteenth century.

The Development of Spatial Modeling

> Imagine a very large city in the midst of a fertile plain not traversed by any navigable river. The plain's soil is of uniform quality and capable of cultivation everywhere. At a great distance from the city the plain turns into an uncultivated wilderness separating this state from the rest of the world.
> The plain does not contain any other cities besides that large city. Consequently, it therefore produces all crafts and manufacturing products for the whole country while the city is supplied with food from the surrounding plain only.
> Mines and salines, which satisfy the demand for metals and salt, are assumed to be in the vicinity of this central city, which will be referred to as'the city' as it is the only one.
> The question is this: under these conditions what kind of agriculture will develop and how will the distance to the city affect the use of land if this use is chosen with the utmost rationality?
> von Thünen (1875) as translated by Beckmann (1972) and the author

Von Thünen's opening paragraph of his "Der isolierte Staat in Beziehung auf Landwirtschaft und Nationalökonomie" succinctly lays out the question and a set of assumptions for an economic model focusing on the spatial distribution of economic activity. Written in the early nineteenth century, his work is usually seen as the origin of formal spatial modeling, laying the groundwork for understanding the nature of spatial economic patterns in an abstract and conceptual way, yet keeping the analysis fully grounded in his agricultural and practical knowledge (Fujita 2010). His model assumes that:

- There is a single city representing the whole of the economy.
- The economy is closed and in autarky, no trade with other economies can take place.
- The plain surrounding the city is featureless, so no productivity differences for agriculture or differences in transaction and transportation costs.
- Only agricultural production is considered; all other sectors are located in the city and excluded from the analysis.
- Transport costs only depend on the distance from the city.
- Agents are rational and only maximize monetary profit.

Von Thünen first discusses the answer based on his knowledge about different agricultural knowledge but then formalizes his model using mathematical relationships.

He defines the relevant variables, measured either in weight as *Scheffel* or monetary terms as *Thaler*:

The return in grain is x, the net return is ax Thaler, the sowing costs are b Thaler, the cultivation costs are c Thaler, q is the share of costs in gross returns, p is the share of costs in money terms, and h is the local grain price.

He calculates the *Landrente*, the rent from producing a particular agricultural product depending on the associated costs and benefits, as:

$$\left(\frac{ax}{h} - \frac{b + (1-p)c + c(1-p)aqx}{h}\right) \text{ Scheffel and } p(aqx + c) \text{ Thaler.}$$

Switching from conceptual into actual calculations, von Thünen combines this rent expression with the *transport costs* to the central market. He formulates these transport costs in terms of grain consumed by the horses, which foreshadows the iceberg trade costs assumption used in the modern trade literature, where a certain amount of goods "melts away." Costs are assumed to be linear in distance, with a doubling of the distance leading to a doubling of transport costs in absolute terms. Given that locations are assumed to be identical in terms of production characteristics, the location rent falls with distance from the city.

Von Thünen consequently derives the distance at which the land rent, including transport costs, equals zero, which delineates the areas where the crop in question can be profitably grown and where such a land use would be unprofitable. Repeating the calculations for other crops and agricultural products results in a *land rent curve* for each product, which shows the profit for each crop depending on the distance from the city. At any distance the curve of one product has the highest value, so that product is the most profitable to be produced at that distance. The resulting pattern is the well-known *system of rings* around the city where the production in each ring is dedicated to a particular crop or product. The assumptions of the model are strongly simplifying, yet the model has a clear result explaining the spatial patterns of economic activity observed by von Thünen almost two centuries ago and still observable today.

Von Thünen's modeling approach with rent curves resulting in a set of rings around a central location has been used in a wide range of applications and fields, most prominently in agricultural economics, urban economics, and other fields in economics, as well as regional science. The model is further applied in a wide range of settings in other social sciences, from sociology to marketing to business.

Economic history is also influenced by von Thünen's ideas and modeling approach. Fernand Braudel (1981), for example, takes up the idea of rings in his Civilization and Capitalism, using them to analyze European development before the Industrial Revolution. The model, however, is not just taken up in qualitative analysis but is obviously used in cliometrics and quantitative economic history. Von Thünen himself does so with a quantitative, comparative analysis of agriculture in Mecklenburg and Belgium. Not only does he analyze the returns for agriculture in the two regions, but using a similar approach as Wrigley (1985), he also uses relative productivities and Mecklenburg's population density to derive how many inhabitants Belgium should be able to sustain with its agriculture. His prediction is not far off of Belgium's actual population at the time, demonstrating the viability and suitability of his approach for quantitative economic analysis.

One recent example of taking up his ideas and model in quantitative economic history is Kopsidis and Wolf (2012). They analyze the spatial pattern of agricultural productivity in Prussia to determine the role of urban demand in shaping agricultural development. As an aside, their analysis uses data from 1861 to 1865, just before Mecklenburg, and the area containing von Thünen's original estate became part of the Norddeutsche Bund and Prussia's control in 1866. They build a model based on von Thünen's logic to explain agricultural productivity as reflected by rent data from Prussian agricultural statistics. Using county-level data, they show that *market potential*, measured as distance-weighted urban population, has a substantially stronger explanatory effect than alternative hypotheses, such as institutional structures. Their model has further predictions about the spatial patterns of rents, labor intensity, farm gate prices, and crop mix with certain details clearly resembling von Thünen's ideas. Testing these hypotheses empirically confirms that Prussian agriculture was strongly shaped by urban demand, explaining thereby not only the spatial pattern around individual cities but also the spatial pattern of agricultural development on a national scale.

Although von Thünen's work was written in the first half of the nineteenth century, spatial modeling developed further only at the turn of the twentieth century and the following decades according to Fujita (2010). The next wave of models started to deal with *market area analysis*, delineating the boundaries of the market areas served by different firms. This was eventually extended to *spatial price policy*, which started to jointly determine spatial locations and prices of firms. In von Thünen's model, the farmers simply receive a certain price for their products independently of their own decisions. The new models incorporated this joint determination in a number of ways, with the model introduced by Hotelling (1929) being one of the most influential or at least well-known examples.

Hotelling's (1929) "Stability in Competition," in contrast to von Thünen, was not primarily set out as a spatial analysis but to investigate and demonstrate certain

aspects and characteristics of competition within a duopoly setting. He focused on the speed of adjustments in the market and reaching equilibrium. This was based on the discrepancy between the characteristics of influential models of competition that featured firms immediately capturing large parts of a market with small price changes and the real-world observations of substantial persistence and inertia in consumer behavior in such a situation.

His analysis starts with consumers uniformly distributed over a fixed length line and two firms randomly located at two points on the line. The firms sell identical goods to the consumers, who do not distinguish between either firms' goods except for transport costs, represented by the distance between the consumer and the respective firm. Hotelling then derives profit functions for both firms in terms of both their prices. With these functions he demonstrates that if each firm optimizes its profit by setting its price in response to the price of the other, both prices converge toward an equilibrium and with each step only a small subset of consumers shifts between the two firms.

The spatial aspect becomes more central in the second part of his analysis, where he considers not only the spatial extent of the market of each firm but also their location decisions. The analysis starts with one firm randomly located on the line and then considers where the second firm will locate in relation to the first. Hotelling argues that the second firm will choose to be as close as possible to the first while remaining on the side of firm one that constitutes the larger line segment. If firm one is in the middle of the line, so in the center of the complete market, firm two is indifferent between locating on either side. The reason for that location choice is that in this way firm two can capture as much as possible of the whole market by offering lower transportation costs for that segment than firm one.

Hotelling further addresses the location question in the contexts of *central planner* and *market outcomes*, or as he labels it: "capitalism v. socialism." He argues that to minimize the social costs of transportation, the two firms need to be located symmetrically at the quartiles of the market. This outcome, with the market split evenly across space between the two firms, implies that no consumer has to travel further than 1/4 of the length of the whole market to reach a firm. This is contrasted with the market outcome described above, in which some consumers have to travel at least 1/2 of the length of the market to reach a firm.

This difference between the two firms locating close to each other under market competition to maximize their profits and the regularly spaced distribution to minimize social transportation costs is magnified through additional firms entering the market. In a free-market situation, the entering firm will follow the same logic as the location decision of the second firm, consequently locating very close to the existing firms and thereby creating a cluster of firms. The social planner, however, would redistribute the firms along the market in a regular pattern. This demonstrates one force leading to agglomerations within free market economies.

Hotelling then describes different situations where the logic of the model is applicable. He starts with cider merchants who have to decide on the sourness of their product, so locating their firms within a particular product space. The measure of sweetness replaces distance, and transport costs are the mismatch between product

sweetness and consumer preferences. More generally, he argues that although it is not the main force leading to the standardization of many products, ranging from furniture to houses, clothing, automobiles, and even education, it is driving the effect that changes to goods are mainly small deviations designed to capture the market in order to get between one's competitors and a mass of customers.

Generalizing the approach further, he argues that real-world settings can be seen in terms of mathematical spaces, where firms locate in multidimensional spaces to maximize the mass of customers closest to their position. He acknowledges a number of conditions that could change the shape of the outcome and push firms apart, including an uneven distribution of consumers, particular shapes of transport costs, pricing structures, and some elasticity of demand considerations.

His generalization also demonstrates that his approach is not just suitable for "economic life" but for most diverse situations with competitive activity. Describing the application to one such area he writes:

> In politics it is strikingly exemplified. The competition for votes between the Republican and Democratic parties does not lead to a clear drawing of issues, an adoption of two strongly contrasted positions between which the voter may choose. Instead, each party strives to make its platform as much like the other's as possible.

Hotelling's model has been adopted in a range of fields and applications; the use in the political space he foreshadows is probably the most influential and well-known case. Downs (1957) takes up Hotelling's idea and formalizes its application in a political setting. The following list shows his main assumptions about the setup and explains how Hotelling's spatial modeling aspects are retained, yet framed in political terms:

- *The political parties in any society can be ordered from left to right in a manner agreed upon by all voters*.
  This assumption is equivalent to using a single, fixed line as space.
- *Each voter's preferences are single-peaked at some point on the scale and slope monotonically downward on either side of the peak.*
  This assumption implies that the only factor influencing consumer/voter utility is the distance to the firm/party location, modeled by Hotelling as transport costs and by Downs as closeness of the preferences.
- *The frequency distribution of voters along the scale is variable from society to society but fixed in any one society.*
  This assumption relaxes Hotelling's assumption of a uniform distribution of consumers /voters over the line but retains that the distribution remains fixed while firms/parties make their location decisions.
- *Once placed on the political scale, a party can move ideologically either to the left or to the right up to but not beyond the nearest party toward which it is moving.*
  This assumption states that firms/parties can move freely along the space. The "no jumping over" restriction is because of consistency and gradualness of change, as

it prohibits small position changes from leading to large changes in voting behavior.

- *In a two-party system, if either party moves away from the extreme nearest it toward the other party, extremist voters at its end of the scale may abstain because they see no significant difference between the choices offered to them.* This assumption models that there is a distance beyond which transport costs/differences in preferences are too expensive or prohibitive and consumers/voters prefer no action over purchasing/voting. It counteracts the above "no jumping" rule and moves parties from clustering at extremes to the center.

The consequences of these assumptions depend on the political system, in particular the number of parties, again mirroring Hotelling's discussion of the implications of the entry of more firms beyond the initial two. The best known case is majority voting, two sides vying for a victory by positioning themselves along the political spectrum. This results in the *median voter theorem*, which states that in the case of majority voting and single-peaked preferences, the outcome will be the one preferred by the median voter, so the point of the policy space that splits the population in half.

Around the same time as Hoteling and others developed models with non-competitive firms, a number of other relevant spatial approaches arose as described by Fujita (2010). Marshall presented his work on *industrial agglomerations*, stressing the role of *externalities* in the process. Lösch (1940) sets out to build a systematic model of *location theory*, including the development of market areas and economic regions. The *central place theory* of Christaller (1933) provides a description of a conceptual theory of central places with a spatial hierarchy of locations and markets.

Fujita (2010) also describes the further development of spatial economics, especially the attention paid to general equilibrium and competitive markets.

This did lead to the result of a *spatial impossibility* theorem, which, according to Fujita's description, implies that one of the following three assumptions needs to be made to describe and understand actual phenomena about agglomerations, regional specialization, and the general spatial distribution of economic activity:

1. Space is heterogeneous.
2. Externalities in production and consumption exist.
3. Markets are imperfectly competitive.

Spatial models that were developed in the wake of this often combine more than one of these, but each has certain implications.

- *Comparative Advantage Models*: These assume that space is heterogeneous and differs in some form, for example, endowments (immobile resources like natural resources), amenities (e.g., climate), or uneven transportation costs. This differentiation allows for comparative advantage, and consequently trade, between locations even under constant returns and perfect competition.

- *Externality Models*: Nonmarket interactions between firms and/or households (knowledge spillovers, communication, and interactions) generate endogenously spatial agglomeration and thereby trade, again allowing constant returns and perfect competition.
- *Imperfect Competition Models*: Firms no longer are price-takers, and spatial distribution patterns influence price policies, potentially resulting in agglomerations. There are two approaches:
  - *Oligopolistic competition*: These models assume a finite number of large agents (firms, governments, developers), who interact strategically including location decisions.
  - *Monopolistic competition*: Firms are price-setters and usually assumed to produce differentiated goods under increasing returns. Models tend to assume a continuum of firms, thus minimizing strategic interactions.

Although models in all of these directions have been developed in the last three decades, the most prominent is the last one, which started out by using a modeling framework based on the Dixit-Stiglitz model of monopolistic competition introduced by Dixit and Stiglitz (1977). Labeled the "new economic geography" (NEG), the emphasis was on developing a unified approach of general equilibrium modeling focusing on the interactions of increasing returns, transport costs, and the movement of production factors. The spatial scope of this approach was very wide, from the organization of cities, systems of cities, and regional structures to international and global models.

Paul Krugman (1991), one of NEG's pioneers and later Nobel Prize recipient, explains his interest in developing formal modeling approaches to geographic questions with the almost complete absence of spatial considerations in the contemporary international trade literature and economics more generally. Setting out to remedy that, he points toward methodological advances on market structures, in particular monopolistic competition models and *increasing returns* approaches, that had substantially reshaped international economics in the 1980s and which seemed well suited to overcome the constraints that had pushed economic geography to the back of the minds of economists.

Krugman cites a number of empirical phenomena as motivation: the large amount of domestic trade, the decrease in border relevance in a unifying Europe, and especially the existence of concentration and agglomerations, for example, the "manufacturing belt" in the USA. Nevertheless the resulting NEG and geographically oriented economics literature developed with a strong technical and methodological focus (Krugman 1991, 2010). This development was in sharp contrast to the work of economic geographers in geography and related disciplines, who moved away from mathematical modeling and quantitative methods. For example, Martin, as cited by Krugman (2010), claims that "economic geography proper" involves a rejection of abstract models in favor of "discursive persuasion" involving "a firm commitment to studying real places (the recognition that local specificity matters) and the role of historico-institutional factors in the development of those places."

While acknowledging that some criticism of the project is justified, Krugman does argue that this strong rejection is misguided by making two points. First, a central, practical intention was to reintroduce spatial thinking into the economics mainstream, and the formal modeling approach was the most successful way to do that. Second, a more conceptual argument for the approach was that it puts a stronger emphasis on "what-if" questions. Formal modeling allows the development of counterfactuals and scenarios, something that ultimately is substantially more suitable to analyze and evaluate policies, interventions, and other changes than an approach emphasizing the uniqueness of each case (Krugman 2010).

History and First and Second Nature Geography

The development of new economic geography modeling was strongly driven by the desire to understand agglomeration patterns of economic activity and population. What are the reasons that people cluster at certain locations rather than spread out evenly over the landscape?

The literature began to categorize the modeling components that were used to generate these patterns into two categories, namely, *physical geography* and *agglomeration forces*. Krugman (1993) popularizes these as "first nature geography" and "second nature geography" based on ideas by historian William Cronon in his economic and social history of Chicago, *Nature's Metropolis: Chicago and the Great West* (Cronon 1991). He outlines Cronon's argument that Chicago's rise to prominence is not primarily based on a distinctive natural advantage. The city is on a flat plain, its river barely navigable, and its harbor inadequate, but due to a self-reinforcing strength, Chicago established itself as a central market and focal point for transportation and commerce. Krugman summarizes:

> As Cronon puts it, the advantages that "first nature" failed to provide the city were more than made up for by the self-reinforcing advantages of "second nature": the concentration of population and production in Chicago, and the city's role as a transportation hub, provided the incentive for still more concentration of production there, and caused all roads to lead to Chicago. (Krugman 1993)

The new economic geography literature, and economic history research utilizing this modeling approach, usually associates "first nature" with physical geography, describing location characteristics and environments that are also referred to as endowments. These physical attributes, such as natural resource deposits, rivers, mountains, or rich agricultural soils, are usually location specific and immovable, thereby clearly distinguishing different locations in terms of their presence or extent.

"Second nature" refers to mechanisms underlying the spatial distribution of population and economic activity that are only dependent on the existing shape of the distribution. The main aspect is agglomeration and the emergence of spatial clusters. Krugman (1991) and Kim (1995) show that industries in the USA show strong agglomeration structures, rising from the middle of the nineteenth century

until a peak in the early twentieth century, and a consistent flattening out over time after that. Spillovers and externalities are potential sources, though the NEG approach focuses predominantly on the effects of *increasing returns* to cause agglomerations, in particular in combination with the impact of transportation costs and *market access*.

The question of first and second nature and the use of new economic geography models has two main contact points with economic history. The first is the use of historical developments and events to test the validity of model specifications, in particular the relevance and predictions of particular first and second nature phenomena. The second is the application of such models to understand the underlying reasons and consequences of historical developments. These uses of modeling are similar to the usage of spatial concentration indices mentioned above.

The modeling of the new economic geography is usually focused on cross sections and eventual comparative statistics; however this restricts the possibilities to empirically validate a number of model predictions and mechanisms. Consequently, a number of authors have turned to economic history, long-term developments, and historical events to test a number of models and mechanisms in quantitative economic geography.

One important example is Davis and Weinstein (2002). They use thousands of years of Japanese regional population density as well as population growth throughout the twentieth century, especially up to and in the wake of the Second World War and its devastating impact on the country. They don't build an explicit, formal spatial model but derive a number of stylized facts about spatial and other aspects of the characteristics of the regional population distribution and its change over time. They compare their empirical observations with the predictions coming from theoretical approaches in the literature grouped in three explanatory theories, namely, *increasing returns*, *random growth*, and *location fundamentals*. Their label "increasing returns" references a set of results predominantly from the new economic geography that stresses "second nature" mechanisms and the role of agglomeration forces. "Random growth" refers to an approach that sees the population growth as a random process rather than a structurally determined one. The theory is focused on explaining Zipf's law, a mathematical regularity of the city size distribution, by arguing that that distribution can be the outcome if city growth is a random walk and Gibrat's law, the independence of city size and growth, holds. "Location fundamentals" focuses on the effect of the "first nature" geography, so explains the spatial distribution with usually permanent geographic characteristics of these locations.

Davis and Weinstein summarize the fit of the stylized facts of Japan's spatial population history with these three theories as follows (Table 1).

The authors argue that no single theory clearly dominates. The existence of substantial spatial variation of Japan's population density for a long time, especially also before a tight market integration between regions and the rise of the industrial production, points to a substantial role for location fundamentals, while the increase in variation with the Industrial Revolution points to a role for increasing returns in shaping the modern distribution. For the random growth approach, however, they argue that the observed pattern after the shock of the Second World War, which

Table 1 From Davis and Weinstein (2002)

Stylized fact	Increasing returns	Random growth	Location fundamentals
Large variation in regional densities at all times	–	+	+
Zipf's law	–	+	+
Rise in variation with the Industrial Revolution	+	–	–
Persistence in regional densities	?	?	+
Mean reversion after temporary shocks	?	–	+

showed a mean reversion and a reversal of the shock, strongly contradicts the core assumption of the theory. If the growth process really were a random walk, then such a substantial shock should have left a permanent impact rather than a temporary one.

Redding and Sturm (2008) take a different approach. They focus primarily on the relevance of *market access*, a central aspect of increasing returns and the main agglomeration mechanism used in the new economic geography, construct a formal theoretical model, and then test its predictions empirically with a historical episode. Their formal approach is a multilocation version of a model initially developed by Helpman (1998) to explain the size of regions. They combine two agglomeration mechanisms: increasing returns in production and lower living costs due to a stronger competition in larger markets, with two dispersion forces – stiffer competition in larger markets and a fixed amount of a local, immovable amenity. They identify the effect of change in market access through a change in transportation costs while assuming that the level of amenity in each location is fixed. Empirically they test the model prediction, a stronger reduction in population in locations that see a larger decrease in market access, with the German separation after the Second World War. They calibrate their model with German data before the war, then introduce the shock to market access caused by the separation of the two German states, and demonstrate that the observed change in city populations is explained by that change in market access.

Redding and Sturm focus their model and analysis on the effect of agglomeration forces and the importance of market access without paying much attention to the role of endowments and location characteristics. Ploeckl (2012) takes this up and utilizes the model applied to the case of Saxony from the sixteenth to the nineteenth century to show empirically that the implied amenity values of the model can be explained by particular location characteristics. Conducting the analysis for a number of distributions over time shows that the relative importance of particular location characteristics changes. Similarly, Ploeckl (2015) uses the model and the German Empire of the late nineteenth century to empirically show that geographical characteristics like rivers, which are usually used to proxy for the "first nature" effect, can also influence the impact of market access and therefore the presence and strength of the "second nature" mechanisms. Both studies provide evidence for Davis and Weinstein's conclusion that first and second nature are not exclusive and that both together shape the spatial distribution of population and economic activity.

Explicit spatial modeling can also be used to revisit historical analyses that include spatial aspects without them being the main question of interest. Fogel's (1964) analysis of the impact of the railroad on American GDP uses a spatial approach in some parts. His idea to build a *counterfactual* based on changes in land value and use through the proximity of railroads echoes von Thünen's approach to land rents and the relative proximity to demand from the city. Donaldson and Hornbeck (2016) take up this spatial aspect and construct a spatial model that links the value of agricultural land in each US county with its market access in the rest of the country. A counterfactual analysis with market access based on a scenario of transport links without railroads results in a substantial decrease in agricultural land values and an economic loss in GDP terms only modestly larger than Fogel's comparable estimate.

Formal Modeling

As the median voter theorem and the growth impact of American railroads demonstrate, explicit modeling of space is done in many fields and situations. This wide range of application implies that the range of modeling approaches and included mechanisms is extremely wide. Even if the focus is only on location decisions, the discussion above about first and second nature geography implies that the relevant mechanisms are manifold and formal modeling needs to incorporate quite a number of them.

Redding and Rossi-Hansberg (2017) provide a survey about model components and assumptions, the building blocks used in models in quantitative spatial economics. They group their overview into a number of main aspects, namely, *preferences*, *endowments*, *production technology*, *trade*, *technology and idea flows*, *labor movements*, and *equilibrium* characteristics. The following discussion goes through each point listed and explained by Reading and Rossi, combining a short summary and discussion of the relevance and applicability of the these aspects for economic history.

Preferences

Homogeneous Versus Differentiated Goods

A first important implication of the structure of consumer preferences is the question of the homogeneity of goods. As indicated above, new economic geography models emphasize *product differentiation* and love of variety by consumers.

The international trade literature has shown the quantitative welfare gains from new varieties (Broda and Weinstein 2006), while economic history also looks at the gain from new goods, products, or technology from a social savings perspective (Leunig 2011). The relevance of modeling differentiated goods, however, has a dual purpose besides capturing these gains, namely, to include a mechanism that generates trade between locations without being purely based on endowment or technology differences.

Single Versus Multiple Sectors

Another dimension of the structure of consumer preferences is the range of goods produced in the economy. Technical constraints, in particular tractability of the model, mean that many models only use a single production sector or maybe large aggregate sectors like agriculture and manufacturing. With advances in modeling and computation, it is now feasible to expand on this and incorporate a larger number of sectors in the models.

The decision about the number of sectors involves trade-offs between the precision of the model and its complexity and tractability. Certain important economic developments relevant for economic history, for example, the structural transformation of the economy from agricultural to industrial as demonstrated for the USA by Michaels et al. (2012), fit well with just aggregate sectors. Consequently, an extension to a larger number is only preferable when the interaction between sectors is the central research question and there is enough differentiation in data and sector characteristics to exploit these.

Exogenous and Endogenous Amenities

Early new economic geography models assumed no real differences between the characteristics of locations, similar to the featureless plain of von Thünen. This implies that there are no ex ante differences for consumers in the locations themselves that could explain location decisions and the spatial distribution of economic activity. Certain geographic characteristics, for example, access to water or scenic views, however, are potentially relevant for productivity differences as well as affecting the utility of consumers directly. These influential factors, *amenities*, can therefore either be exogenous or arise endogenously, and recent modeling advances allow for the presence of both.

Fixed Local Factors in the Utility

A particular case of an exogenous "amenity" is an exogenous factor with a fixed supply. The central example for such a factor is residential land. The main contrast to regular amenities is the difference in access. This factor is rivalrous while regular ones are not. If such a factor is included in the utility of actors, then its fixed nature in conjunction with location size will act as an attraction or as a congestion or dispersion force, depending on the relevant size of the population to the amenity.

This particular case of an exogenous amenity serves primarily as a simple representation of amenities. This allows their inclusion in the modeling process and empirical estimation without requiring an explicit specification of which amenities to include (Redding and Sturm 2008; Ploeckl 2010). This is especially relevant for economic history as it allows for the inclusion of amenities without requiring a full set of relevant amenities or complete data for all observations.

Common Versus Idiosyncratic Preferences

This assumption models whether agents have identical *preferences* or whether there are idiosyncratic differences between them. These differences are usually directly

over locations, though differences in preferences over location amenities should have similar consequences. In combination with perfect mobility and no arbitrage, this assumption results in real wage equalization across locations in cases of common preferences and real wage differentials, if incomes paid to attract agents to a location differ with the heterogeneity of their preferences.

Differences in preferences and tastes have not yet received a lot of attention in economics and economic history. A major reason is that in contrast to differences in skills and productivity, the origins and measurement of these are rather problematic. One recent approach to explain regional differences in food preferences is presented by Atkin (2013), who models habit formation of consuming locally prevalent foods leading to a "home" effect similar to that in trade.

Production Technology

Constant Versus Increasing Returns

As indicated above, a central mechanism of new economic geography models is the presence of increasing returns to scale as a way to generate self-reinforcing agglomeration forces. This mechanism is usually linked with love of variety to result in specialization by and exchange over spatial locations. Recent modeling advances however have demonstrated that constant *returns to scale* production technology in combination with other mechanisms, in particular an Armington differentiation by location of origin and Ricardian technology differences, can result in a similar specialization.

The nature and shape of the production function, including the implied returns to scale, are the subject of interest in a number of fields, including economic history. The main motivation for the choice depends on the focus of the question, knowledge about empirical evidence, estimates of returns to scale in the sector, or the desired mechanism generating trade in the produced goods. One possibility is to model increasing returns as the combination of fixed and constant marginal costs (Redding and Sturm 2008), which allow the relative importance of fixed costs, and consequently the relative strength of increasing returns, to vary.

Exogenous and Endogenous Productivity Differences

Similar to the possible presence of exogenous and endogenous amenities, locations can differ in their *productivity* in both ways as well. The starting point of a featureless plain obviously is linked to a stronger focus on endogenous differences, for example, knowledge spillovers. International trade models and empirical observations, however, do emphasize the case for a role of exogenous productivity differences, such as access to local mineral resources. This is an important underlying mechanism for the differentiation of first and second nature effects, mirroring the modeling choice between exogenous and endogenous amenities.

This choice also affects a substantial number of other mechanism components. If the model includes endogenous productivity differences, the process underlying these differences needs to be included, for example, the transfer of ideas between

locations. Economic history has established productivity differences. However, the question about their endogeneity or exogeneity depends on the particular context, production process, and focus of the research question.

Input-Output Linkages

Assumptions about *input-output linkages*, especially over locations, are an important aspect explaining how locations are linked. They strongly shape how productivity shocks in particular regions and sectors spread through the wider economy. Such linkages also provide an additional mechanism for agglomeration.

Input-output linkages have been an important topic in economic history, for example, in Fogel's analyses of the railroad and its interaction with the iron industry in the USA (Fogel 1964). Another aspect is the importance of natural resources such as the availability of water power and access to coal for industrial development (Crafts and Wolf 2014). Baldwin (2016), however, contrasts the emergence of long value chains with intermediate goods as a result of modern communication technology with the first globalization with its comparatively short chains, clustered production, and transportation of final, tradeable goods. If the focus is on manufacturing as a sector rather than differences between individual industries, certain input relationships, in particular the relevance of local natural resources, can be modeled as exogenous regional productivity differences in the aggregate sector.

Fixed Local Factors in Production

Again, similar to utility, there can also be a fixed local factor in production. A fixed supply of land can apply not only to residential but also to commercial land used in production. This mechanism has similar consequences and can act as a congestion and dispersion force.

This mechanism is the production side equivalent to the fixed amenity factor. The main application in an economic history setting appears to be agricultural land, where the assumption of a fixed amount available as input for production sounds reasonable. The modeling purpose is then to include agricultural land availability as either an attraction or dispersion force.

Trade

The inspiration for the renaissance of spatial modeling in economics came from the field of international trade, and central trade theories remain at the core of the literature (Krugman 2009). The rise of NEG has focused attention to distinguish the relevant importance of endowment-based models linked to *Heckscher-Ohlin trade* structures and the increasing returns and *monopolistic competition models* underlying NEG. The afore described results by Kim (1995) and Davis and Weinstein (2002) indicate that a combination of both is applicable. Similar results are found by Wolf (2007) for Poland in an analysis following Midelfart-Knvarvik et al. (2000) who develop a model designed to test for H-O and NEG mechanisms. Recently, new models based on *Ricardian trade mechanisms* have been developed

that have seen successful adoption to economic history (Donaldson 2018). As trade itself is the result of the structure of the production process, endowments, and preferences, this section is focusing on trade costs and frictions affecting those trade patterns.

Variable Versus Fixed Trade Costs

Modeling the exchange of goods between locations requires some assumption about the cost structure of that trade. Commonly this is done by including so-called iceberg variable *transport costs*, which require that $d_{ij} > 1$ units are shipped from location i such that one unit arrives in location j (so that the difference "melts" away en route).

Von Thünen already included variable trade costs into his calculations by specifying them as the weight of the grains displaced by the fodder necessary for the horses pulling the grain carts to market (von Thünen 1875). Although there are a number of industries and sectors where fixed costs may seem more appropriate, most economic and economic history studies are utilizing variable trade costs. One reason is that the gravity equation, with its prediction of lower flows over longer distances, seems to hold even for industries that have distance-independent trade costs. One example is the communication sector. Individual phone calls and letters do not really cause substantially different costs depending on distance. This has led to the introduction of distance-independent transaction costs for consumers, most notably the penny post, and yet the volume of letters and calls decays with distance (Lampe and Ploeckl 2014).

Geographic Versus Economic Frictions

Differences and variations in trade costs arise in general due to some type of friction. The sources for these can be geographic (e.g., mountains with their elevations) or economic (e.g., institutional rules like borders or infrastructure like road and rail networks). The presence of frictions implies that a full set of transport costs between any two locations is usually not directly available. Empirical studies usually rely on geographic information system approaches to estimate these, either based on finding the cheapest path through a network (e.g., a railroad network) or the least-cost path over a cost surface (e.g., an elevation map).

One historical example for the estimation of transportation costs with GIS methods incorporating geographic frictions is Ploeckl (2010), who applies a least-cost path algorithm over a cost surface that includes geographic cost factors, such as elevation and rivers, and economic ones, like the road network. Jaremski (2012) and Donaldson and Hornbeck (2016) take a network approach by determining transport costs between two points by finding the shortest path through a network between linked locations. This requires a specification of costs for traversing each network link, and both papers assign those values based on transport infrastructure. This means that the geographical length of each connection is multiplied with a per mile cost based on available transport technology for the link, for example, wagons, canals, or railroads. Although the basic choice of different costs based on infrastructure type is an economic friction, geography has a potential influence through which links are available at all. A simple extension to include them more explicitly is to modify cost values for a link based on the geographic conditions of its location.

Economic frictions can have a wide range and depend on the scale of the analysis. One less obvious example is underlying social differences, like the ethnic composition of location populations, as Schulze and Wolf (2009) demonstrate for the Habsburg Empire. Language is another potential friction, even in the case of differing dialects (Lameli et al. 2015).

Asymmetric Versus Symmetric Transport Costs

One aspect of *transport costs* is the assumption that they are symmetric (so costs of transport from i to j are the same as those from j to i), which has consequences for patterns of trade and income as well as equilibrium outcomes. As indicated above, the standard formulation of iceberg trade costs is symmetric as d_{ij} only depends on the geographic distance between i and j, which is obviously identical to that between j and i. This is similar to the symmetry of the gravity equation, where the size of trade flows is also explained by simple distance between the two trade partners.

Geographic as well as economic frictions, however, may not have symmetric effects. Going up a mountain is different than going down; one country's tariff rates usually do not equal those of trade partners. There are instances where this is ignored, for example, many market integration studies use the correlation between prices even if the directions of underlying trade flows, and therefore applicable transport costs, are not identified. Depending on the setting, differences might be negligible. For example, Ploeckl (2010) demonstrates that transport costs in both directions converge to the same level, well approximated by plain distance, as certain frictions become less relevant the further is the total distance covered.

Role of Non-traded Goods

Another special case is the presence of non-traded goods, which represents a situation where the trade costs of these goods between locations is (or approaches) infinity. The presence of these goods nevertheless affects input-output linkages and the effects of productivity differences and shocks on expenditures.

Non-traded goods have a larger importance in international trade. On a more regional scale, they can be used as a model mechanism to retain production and population in certain locations.

Technology and Idea Flows

The incorporation of *technology and idea flows* into spatial modeling works predominantly through affecting local productivity. This implies that there must be productivity differences between locations that are at least partially endogenous.

Knowledge Externalities and Diffusion

One aspect is whether there are *externalities* with regard to knowledge and ideas and if so how and how far they diffuse. Going back to Marshall, such externalities are commonly seen as knowledge spillovers, externalities due to thick labor markets, and backward and forward linkages (Fujita 2010).

The economic history literature has established Marshallian externalities in a number of settings, especially in urban history and the development of particular industries and regions. An important modeling decision, in combination with the scale of the analysis, is the spatial extent of externalities.

Innovation

A related aspect is the question of *innovation*, which might affect local productivity as an endogenous, intentional investment. The main criteria for such investment in innovation is whether the returns can be successfully appropriated. This does depend on the speed with which ideas and innovations diffuse to other agents and locations. Modeling advances link the profitability of innovation investment to the size of the markets accessible to firms and agents, capturing the extent to which they can distribute the costs across consumers. Practical modeling is utilizing a competitive market and a potential capitalization of innovation returns in land rents as a mechanism.

Including innovation into the spatial model is predominantly relevant for situations where intentional research is assumed to play an important role. This points toward situations with larger geographical scopes, in particular countries. Historically, individual inventors have played substantial roles for technological progress, but spatial modeling is suited better for aggregating their inventive activity in locations or counties. For the return to innovation aspect, market access provides an empirical estimation fitting the historical evidence (Sokoloff 1988).

Transferability of Ideas

Another aspect is whether the *diffusion* of ideas between agents and locations is costless or not due to the presence of frictions. This is linked to international trade, where ideas transferred through foreign direct investment might not result in the same productivity improvement in other countries, or to mechanisms that require firms to face adjustment costs for transferring production innovations developed for a particular location.

The main aspect here in contrast to externalities is the intentional transfer of technology, a special version of innovation and the endogenous increase of productivity. Although technical knowledge, such as patents, was traded historically (Burhop and Wolf 2013), it is primarily relevant for questions dealing with multisite firms, including modeling the decisions between exporting or foreign direct investment. In other contexts it can be subsumed into the characteristics of the innovation mechanisms underlying endogenous productivity changes.

Labor Movements

Migration Costs

The ability of agents to move and change locations is an important condition for an integrated spatial model. The cost of such *migration*, however, can have implications. The presence of such frictions and moving costs provides a mechanism

explaining real wage differentials between locations, which requires some of the above described mechanisms such as idiosyncratic preferences to exist in the absence of migration costs. Empirically, moving costs and frictions are more strongly linked to settings with an international scale rather than local and regional analyses.

One particular setting where explicit moving costs become relevant is the modeling of international migration, especially the aspect of destination choice. Transatlantic mass migration in the twentieth century is one setting where real wage differentials act as an incentive to move, and particular moving cost components, for example, chain migration, affect location choice over different countries as well as locations within countries (Hatton and Williamson 1998).

Commuting

A more local, urban aspect of labor movements is the potential presence of *commuting*, so a separation of workplace and residence or production and consumption. Models explaining the shape of cities traditionally started with locating production activity at the center, while residential location and linked land prices are mainly determined by commuting costs to the center. More recent advances expand the analysis to non-monocentric patterns but retain a strong link between agglomeration forces and commuting costs. Commuting costs are consequently also a potential mechanism to explain differences in city sizes within systems of cities.

Commuting is the local equivalent of migration costs for regional and international settings. It is especially relevant as a separate mechanism if the focus is on urban settings and the explicit separation of residential and production location (Ahlfeldt et al. 2015). Historically, commuting is less of a concern due to constraints on individual mobility that made significant commuting very costly and fairly small. If the focus is not on commuting directly, it can be subsumed into local productivity differences, for example, von Thünen discusses additional production costs due to distance between estate and fields, or as a local amenity where commuting time influences the utility residents receive from particular locations.

Skills and Heterogeneity

Migration and commuting decisions are influenced by modeling decisions about common or idiosyncratic preferences and productivities of agents over locations. Idiosyncratic differences can be used to explain the empirically observed characterization of migration and commuting as following a gravity equation pattern. A closely related mechanism is whether there are systematically different types of agents who value location characteristics differently. Such a mechanism leads to equilibrium distributions of economic activity that are characterized by *spatial sorting*, in which agents of a given type self-select into particular locations based on the characteristics of the locations.

Spatial sorting according to particular migrant and location characteristics can be observed in transatlantic mass migration, where selection based on the presence of other immigrants from the same ethnic or cultural background occurred. Another important example is the spatial sorting based on preferences, as described by

Schelling's model of segregation (Schelling 1971). Racial segregation is one important application for this (Boustan 2010, 2012).

Congestion in Transportation

Another choice for models with explicit flows of people is congestion. Are travel costs linked to the volume of flows? Can infrastructure provision reduce congestion? In urban models this relates to issues concerning whether an increased provision of highways leads to an increase in vehicle travel without an impact on congestion and whether public transport significantly affects travel delays and congestion.

This is the labor flow equivalent of trade costs previously discussed and an endogenous version of commuting costs. It has a substantially more limited application in economic history as its main relevance is for scenarios about urban infrastructure, in particular in the context of residential choice.

Endowments

A number of previously described mechanisms build upon specific characteristics of locations. Their starting values need to be exogenously specified. *Endowments* in this context refer therefore to the initial distribution of these characteristics underlying the incorporated mechanisms.

Spatial Scope and Units

The model requires decisions about its scope and spatial units. Is it concerned with a local setting in a single city, a systems of cities, regions within countries, or international, even global structures? Is space a set of locations or continuous? And is it one- or two-dimensional? Spatial units are often discrete, based on available data as indicated above, but questions of aggregation need to be addressed. Clearly spatial scope and units are linked, and modeling decisions and data availability for each constrain available choices for the other. A related decision is the question of mobility of factors, which are mobile over spatial units and which are fixed, and if so at what level of aggregate units.

Population and Skills

The above described mechanisms covering idiosyncratic preferences, differential labor productivities, or multiple types of agents need to be reflected in the endowments in terms of population and the distribution of types and characteristics over locations.

While the differences in characteristics like skill level and productivity are implied by choices about other mechanisms above, the endowment structure and starting distribution of the characteristics can have a substantial impact on empirical economic history analyses. Particular aspects are spatial sorting mechanisms, for

example, the urban-rural distinction, racial segregation, and migration destination decisions that depend on the initial distribution for a sound understanding.

Capital and Infrastructure

The presence of *capital* as a production factor allows for these to be mobile across locations. For tractability reasons such physical capital is, however, usually assumed to fully depreciate in each time period. Besides capital as a production factor within locations, the structure, and therefore endowment, of an economy might contain *infrastructure* between locations. Depending on assumptions and modeling choices about movements of goods, ideas, people, and capital, the nature of costs and frictions about these movements can be linked to the infrastructure and transport networks in the economy, which are usually treated as exogenous in current models.

The impact of this infrastructure between locations, however, can be subsumed into the productivity or amenity differences of affected locations or into transportation and congestion cost frictions. This might be especially relevant for economic history since data requirements increase substantially with the number of locations, and necessary historical information may be incomplete or even unavailable.

Equilibrium

The *equilibrium* of spatial models may require a number of technical assumptions. These are contingent on the selection of particular mechanisms and components, but the most relevant are market structure, general versus partial equilibrium, rent distribution, and trade balance. Market structure is linked to, and needs to be consistent with, the returns to scale assumption, so increasing returns are usually connected with monopolistic competition. The second concerns the completeness of the imposed equilibrium conditions, where partial equilibrium allows for an exogenous outside of the model. The question of rent distribution concerns whether the distribution of land rents is fully incorporated in the model or takes a partial equilibrium approach using an "absentee landlord" outside the model. Finally, because most models include completely balanced exchange, yet empirical data show the existence of persistent imbalances, the balance of trade between locations must be considered. There are a number of fixes, though they are exogenously imposed rather than a full endogenous modeling of local consumption and savings.

Another aspect is the uniqueness of equilibrium. Spatial models may have multiple equilibria without a clear selection (Fujita et al. 1999). While in more theoretical settings the interest is on a particular statistic or other equilibrium characteristics that may not depend on selecting a particular equilibrium, the application of spatial models to economic history is usually focused on an empirical outcome and therefore requires the selection of an equilibrium. This might be done through specifying an initial distribution to determine the outcome, which does require a quantitative specification of values for the mechanism described in the Endowment section above.

Implementation

This long list of different potential model components obviously requires some approach or criteria in order to select among them. There are some obvious combinations, where the choice in one aspect determines the choice in another aspect.

A starting point is the relevance of the model for the available data. Unless the model is designed for primarily theoretical reasons, the empirical setting, the nature of the overarching research question, and the structure and extent of relevant data should motivate the model component selection.

Even if sufficient data are available, the formal model should remain analytically tractable. The inclusion of more components increases the difficulty in obtaining an analytical solution, ascertaining the uniqueness of an equilibrium, and deriving comparative statics. This also applies to computational aspects, where technological advances in computing power and speed have made it possible to solve large-scale problems. Nevertheless, it is not always clear a priori what the required computing resources are to achieve a solution.

The question of data and model complexity also includes assumptions about structural parameters required by certain modeling choices. A number of modeling choices require either the specification of constraints or even direct specification of parameter values. For example, the selection of standard iceberg trade costs assumes that the parameter specifying the "melting" costs is negative in the theoretical model. An empirical application of the model then further requires a specific value for the parameter. For some parameters, for example, those concerning trade costs, there might exist estimations of suitable values for historical contexts, while for others economic historians have to rely on modern estimates or even on informed guessing in their parameter choice. There is also the possibility that the model is designed to calibrate certain parameters as a first step. However, this does increase the complexity and complicates tractability.

A final decision is the delineation about where outside interventions, in particular policy interventions, affect components and which parts remain invariant. For example, a partial equilibrium setup might include an exogenous world price, which consequently requires an assumption about whether price changes in the domestic market as a result of some intervention have any implications for the world price. And if productivity is taken as invariant to interventions, is it completely exogenous, or do other modeling choices imply externalities and spillovers that could affect productivity as a result of an intervention?

Alternative Approaches

The discussion has focused on spatial modeling centered around location theory, that is, explaining the cross-sectional spatial distribution of people, firms, or economic activity more generally. However, as alluded to earlier, spatial modeling has a very broad application, and consequently there are other approaches that essentially model spatial relationships.

The most basic approach to spatial modeling is that spatial correlation is noise and nuisance, something to be ignored in formal analysis and simply corrected for in empirical estimation. This can be done through correction for spatial correlation in econometric analysis or through the inclusion of spatial variables, such as particular regional dummies or geographic coordinates.

As indicated there are tools and methods to analyze the randomness of events in space more extensively and systematically. The so-called *spatial point process* approach differs from the location theory approach in the main assumption about the nature of the outcome (Baddeley et al. 2015). Location theory sees the outcome as the choice of actors, while spatial point processes conceptualize it as the realization of an underlying random process. The methodology has substantial applications in fields like biology and epidemiology where the observed outcomes are phenomena and events, from disease cases to tree locations, that are not economic actors locating in space. Mirroring the first and second nature aspects, the methodology incorporates underlying covariates, usually in the form of surfaces like elevation or temperature, to represent the influence of endowments. As a result, the likelihood of an event at a particular location depends on the particular characteristics of that location, and the attraction process between events, where the likelihood that an event occurs at a particular location depends on the locations of the other events.

Similarly, the discussion about distance measures above mentions *networks*, which have begun to receive substantial attention within economics and economic history (Jackson 2008). Networks differ in their approach to space by focusing only on the relative position between the nodes rather than on the absolute position on a line, plane, or multidimensional space. While networks can reflect actual geographic links, for example, railroad tracks, the approach is usually much more suitable for spatial modeling within non-geographic spaces. These can be varied, from networks of family ties in medieval towns to interlocking directorates between banks to trade agreements between countries. Edges and nodes of such networks allow us to determine a wide range of spatial aspects, most prominently the importance of actors and how central they are within the larger network.

To conclude, one particular aspect that has not been explicitly addressed in this chapter is the question of dynamics. Spatial modeling is not only useful to understand cross-sectional structures but also explicitly dynamic developments. It has the potential to explain the dynamic decision processes underlying a large range of economic phenomena and developments from technology diffusion to infrastructure development to international agreement formation.

Historical Measures of Economic Output

Alexander J. Field

Contents

Abstract

Following an introduction this chapter provides an overview of the logic and conceptual underpinnings of national income and product measures (Part I). Part II describes developments beginning in the 1930s that led to the modern approaches and conventions regarding how we should measure these aggregates. Part III reviews contributions made by quantitative economists, new economic historians, and cliometricians to our understanding of economic epochs prior to the second half of the twentieth century. The principal focus is on the United States, although there is some reference to developments in other countries.

Keywords

Introduction

This chapter assesses the contributions of cliometrics and cliometricians to historical measures of economic output. The emphasis is on the United States. There has been considerable recent and exciting work on Europe, Latin America, Africa, and Asia. But we have available an excellent survey of these contributions (Bolt and van Zanden 2014), and it is unlikely that can be improved upon it at this point. Bolt and van Zanden are central participants in the Maddison Project, an attempt to keep alive and extend decades of work undertaken by Angus Maddison to develop estimates of both output and population back in time and to new areas of the world. After Maddison died in 2010, a number of his colleagues and other scholars banded together to make his estimates widely available and to provide updates as the result of new work. These data are available at Maddison Historical Statistics (2018), and the Bolt and van Zanden paper provides an accessible summary of the latest emendations, which involve the use of new methods as well as new data.

Maddison's basic approach was to start with a single modern cross-national comparison of income/output levels (his final benchmark year was 1990) and extrapolate backwards using country level estimates of rates of growth. Bolt et al. (2018) describe limitations of this method. As one gets further and further away from the benchmark, comparative levels in the past can become increasingly unreliable. These authors have thus developed two separate databases, one optimized to provide the best cross-national comparisons at different moments of time, the other optimized to provide the best growth rate measures for individual countries or regions *over* time.

Comparing output levels between countries at a moment of time (cross-nationally) can be challenging. Simply using exchange rates to convert output in the two countries may mislead. Valuing the outputs by a common set of prices can be better. But which prices? Comparing the product of a less developed country with one that is more developed using the less developed country's prices will generally exaggerate the income differences between them, whereas using the developed country's prices may make the gap seem unrealistically small. The trade-offs reflected in developing these new approaches to Maddison's legacy are a reminder of the challenges faced in generating historical measures of economic output, both cross-nationally and over time.

The focus of this chapter will be on developments within the United States. It was in the United States that the modern framework for national income and product accounting originated, although its progenitors can be found in a number of countries. The architecture of this system was to a considerable degree the work of Simon Kuznets, an immigrant from the Soviet Union. Kuznets won the Nobel Prize in Economics in 1971 for his efforts. He died in 1985.

In defining this chapter's scope, it matters how broad a net we cast in terms of who are to be considered cliometricians. Must the individual, for example, be or have been a card-carrying member of the Economic History Association or the Cliometrics Society? Cliometrics can be understood most generally as the application of statistical data and methods to historical studies of growth and

development. The term is also sometimes used synonymously with the new economic history, an intellectual movement that began in the late 1950s and flourished during the 1960s. New economic historians were certainly cliometricians, but they went beyond simply the examination of quantitative as well as qualitative data, also typically applying sophisticated econometric methods to such data, allowing hypotheses motivated by economic theory to be tested and model parameters estimated. Notable questions explored in the US context included the profitability and efficiency of southern slave agriculture and the contribution to US economic growth of the steam railroad (this involved estimating the railroad's "social saving").

This chapter casts a relatively broad net in terms of who is considered a cliometrician. Thus, Simon Kuznets and his students John Kendrick and Robert Gallman are considered cliometricians. So is Angus Maddison. Each applied statistical data and methods to the study of the historical process of growth and development. So too are Paul David, Peter Lindert, Christina Romer, Jeff Williamson, and Tom Weiss, among many others.

Cliometricians played central roles in developing national income and product accounting systems, in the process judging what should and should not be included and how certain production and payment flows should be handled. From the late 1930s onward, as the logic, methods, and objectives of these systems became more widely understood and accepted, the task of measuring economic output, previously undertaken by individual scholars or, in the early twentieth century, private research organizations, was assumed by government statistical agencies. Should government economists and statisticians be considered cliometricians? I think the answer, in general, is no, because their primary concern is to illuminate current, not historical conditions. But this distinction is not without ambiguity, because byproducts of government statisticians' efforts have been data that eventually illuminate economic history.

The entire twentieth century, in particular, is now history. The databases maintained by the U.S. Department of Commerce's Bureau of Economic Analysis (BEA), which contain quarterly macro data going back to 1947, annual data series extending back to 1929, fixed capital stock data back to 1925, and investment flow data back to 1901, greatly facilitate exploration of this period. A primary concern of policy makers is indeed to produce accurate and timely data, but they also have a subsidiary interest in history. Historical macro data is used to construct econometric models that may be used for forecasting or policy simulations. In some cases, interest in history goes beyond that, as policy makers try to reason by analogy in comparing current challenges to episodes in the past.

Nevertheless, the key driver in the transition to government responsibility was the desire of policy makers for higher frequency data available with a much shorter time lag. Government economists' and statisticians' first responsibility is to produce *current* estimates, because without such estimates, with preliminary numbers available soon after the end of a quarter, national income and product estimates are unlikely to have great value for those determining fiscal or monetary policy.

The priorities of government statisticians are thus not exactly the same as those of cliometricians. But even though refining the historical record is not a central concern of government statisticians, as a consequence of the work they do, our understanding of economic history has been and is greatly enriched, at a minimum, because contemporaneous estimates of product and income come eventually to define the (recent) historical record for us. The numbers may not be produced with the objective of helping us write economic history, but they ultimately serve this purpose. The same can be said of the decennial censuses of population in the United States, undertaken to determine representation in the lower house of Congress, as well as government censuses of agriculture, manufacturing, and other sectors. They did not have as their primary objective assisting future economic historians. But they have nevertheless done so, providing most of the raw materials from which estimates of product and income in the nineteenth and early twentieth century have been constructed.

This chapter begins with an overview of the logic and historical development of national income and product measures (part I). Part II describes the developments beginning in the 1930s that led to the modern approaches and conventions regarding how we should measure these aggregates. Part III reviews contributions made by quantitative economists, new economic historians, or cliometricians to our understanding of economic epochs in the United States prior to the second half of the twentieth century. Concluding section follows.

Part I: The Logic and Early History of National Income and Output Estimation

The best overview of the early history of national income and product accounting is still to be found in Kendrick (1970). Kendrick, drawing heavily on Studenski's (1958) book-length compendium of efforts in different countries, divided the intellectual history into two periods, with World War I the demarcation line. In the earlier (and much longer) period, estimates were constructed almost entirely by individuals and were limited to a few relatively advanced economies. With developing agreement on concepts and methods, and improved statistical data, responsibility was eventually shifted to teams of government statisticians and expanded to many other countries. After the Second World War, the United Nations, building on League of Nations efforts, played an important role in standardizing and diffusing these systems across the globe.

In surveying the history of national accounting systems, Kendrick, following Studenski, distinguished two main flavors, material product and comprehensive. Ultimately, it is the latter that has become the internationally accepted standard, but the former, which focused (as the category name would suggest) on tangible output, informed the statistical systems of the USSR and other COMECON countries throughout much of the twentieth century. Comprehensive frameworks aimed (and aim) to include not just physical goods, such as business equipment and structures and consumer durables and nondurables, but also services delivered to

final consumers. Examples of the latter include shelter (housing) services, personal care, and legal, educational, and medical services. Technically speaking, both transportation and the electricity producing sectors, for example, should also be considered part of services production, as are wholesale and retail distribution, finance, insurance and real estate, and communication. None of these sectors produces tangible goods. The COMECON countries included services that contributed to final goods production, but not those consumed directly by households: thus freight but not passenger transport, communication services purchased by firms but not individuals, energy consumed in the production of physical goods but not by households, etc.

Modern comprehensive national income and product accounting systems approach the task of measuring output flow using three distinct approaches. The first involves aggregating value added by individual economic units. Value added is defined as gross sales less purchased materials and services (what is subtracted is referred to by the Bureau of Economic Analysis (2017) as "intermediate purchases"). Intermediate purchases include raw or semi-processed inventories as well as fuel or energy inputs. They also include labor services provided by outside contractors or businesses. In considering the deduction for services bought, it is important to distinguish between those provided by employees of the organization itself and those purchased or rented from other individuals or organizations. Only the latter are to be deducted from gross receipts. Thus legal services purchased from an outside law firm would be deducted from gross sales in calculating value added whereas those provided by in-house counsel would not.

If one calculates value added in this fashion for every unit engaged in producing goods and services for the market, and then aggregates, one will have an approximate measure of gross domestic output. It is approximate because a few imputations for nonmarketed services, such as the housing services produced in owner-occupied residences, are, by convention, added to this. It is gross because it includes that portion of private investment necessary to maintain the physical capital stock against the ravages of wear and tear and other forms of depreciation. It is domestic because it calculates value added irrespective of the nationality of the owners of the factors of production. National, or citizenship measures, such as gross national product, exclude value added attributable to foreign-owned factors of production but include value added by factors of production, both labor and capital, owned by nationals but situated outside of the country.

This value added approach is sometimes called the production method of measuring output. It measures value added as it is generated by corporations, partnerships, and individual proprietorships. Economic organizations add value to purchased materials and services by combining these with the services provided by the organization's employees and owned physical capital. The goods or services produced are sold forward, ultimately (perhaps after further transformation or change in physical location) reaching a final consumer.

With proper aggregation, the approach yields data on the respective shares of different sectors (e.g., manufacturing, transportation, agriculture) in gross value added or output.

Kendrick and others call this, perhaps confusingly, the "income originating method," because it is out of the flow of value added at each stage of production and distribution that organizations generate flows of income to the labor they employ as well as the households that own the economic entity, and thus its capital assets. The identity of gross income originating with value added for each economic unit guarantees the equality between aggregate measures of gross domestic product (GDP) and gross domestic income (GDI). An economic unit makes wage and salary payments to the labor it employs. If a corporation, the entity will, on behalf of its owners, hold title to buildings, equipment, stocks of inventories, and other nonhuman assets such as patents or trademarks. In addition to the wages and salaries it pays out, it will ultimately generate income flows to the owners of these assets.

Subtracting wage and salary payments and indirect business taxes (taxes on production and imports less subsidies) from value added yields what the BEA calls gross operating surplus. Deducting corporate income tax and capital consumption (depreciation allowances) takes one to net after tax income. Deducting net interest payments arising from debt finance yields net after tax corporate profits, which will be distributed to owners of the corporation as dividends or retained as net saving done on behalf of the households that own the company. Unincorporated businesses/individual proprietors make periodic withdrawals from business accounts to owners' accounts, distributions which reflect compensation both for the labor services provided to the business and a return to the capital invested.

Thus, as economic units produce goods and services reflected in and measured as value added, they simultaneously generate income flows to the owners of factors of production. Measuring value added as it is paid out to owners of factors of production is sometimes called the income method, or as Kendrick and others put it, the "factor income" method. This second method, which underlies the construction of "social tables" described below, requires measuring and then aggregating the income flows generated by each organization as they are actually received by households. This approach to tracking value added produces aggregates for wage and salary income, including pension and health insurance contributions, as well as the employer portion of social insurance payments. It also includes payments to nonlabor factors or production, income to capital (and a small amount to land). Value added less employee compensation yields the gross flow of income to capital. With aggregation and deduction for capital consumption, this second approach allows the calculation of the share of labor or capital in national income.

The BEA defines gross operating surplus as value added less employee compensation less taxes on production and imports (see also Sutch 2006). These indirect business taxes are taxes not levied directly on corporate or personal income. They include excise taxes, import duties, state and local sales taxes, and local property (real estate) taxes. Subsidies, such as those paid to farmers or to some public housing authorities, are subtracted from indirect business taxes: in a sense, they are the opposite of indirect business taxes. Why? Taxes are payments made to government for which no directly identifiable excludable good or service in the current period is provided in return. Subsidies or other transfers are the opposite, for they are payments from the government to households for which no corresponding good or service is tendered, at least during the current period.

Subtracting capital consumption allowances from gross operating surplus leaves net operating surplus. Subtracting the costs of debt finance (net interest payments) yields corporate profits, which ultimately flow into one of three bins: corporate income tax payments, dividends to equity holders, and retained net business earnings, which represent corporate saving on behalf of the households that own the corporation. Rent paid to real estate corporations shows up as part of the gross operating surplus of such corporations. The remainder flows directly to households as rental income of persons. Income to unincorporated businesses, which represents a return to both labor and invested capital, is listed separately in the accounts as proprietors' income. At least for the modern period, product measured from the output or expenditure side is generally considered more accurate than that from the income side. The totals developed using the income method tend to come in slightly below those reached using the product or expenditure methods (see below); the difference is treated as a statistical discrepancy.

National income is simply gross national income less consumption of fixed capital, or gross domestic income plus net factor income from abroad less consumption of fixed capital. (Note: Contrary to what is stated in many textbooks, taxes on production and imports are now included in national income, rather than part of the wedge separating national income from gross national income. See BEA NIPA Table 1.7.5, for example.) It should be noted from the previous discussion that not all gross income flows immediately and directly to households, or is available to them for consumption, or is actually consumed. Taxes leak out, and these include indirect business taxes less subsidies, corporate income tax payments, and personal income tax or payroll tax flows. Saving is another leakage and includes firm depreciation allowances, a component of national (gross) saving. Nor will all after-tax corporate profits necessarily be distributed to households as dividends. Some may be retained as net business saving, a component, along with personal saving, of private saving. Not all of a business unit's gross interest payments will necessarily find their way to households, since businesses borrow and lend amongst each other.

Personal income measures what actually flows to households. Like national income, it includes all labor compensation, all proprietors' income, and all rental income of persons. It also includes personal income receipts on assets, which is the form 1099 dividend and interest income actually received by households, and personal current transfer receipts, which consist mostly of government transfer payments (Social Security and Medicare benefits, interest on the national debt, etc.). Thus, a substantial portion of the payroll taxes from the household sector to the government are remitted to the (consolidated) household sector as social insurance transfer payments. Similarly, a portion of the remaining gross government tax receipts (corporate and personal income taxes, etc.) is remitted to the consolidated household sector as interest on the national debt. In both cases, the government effects interhousehold transfers: from those working to those aged or retired, and (largely) from those working to bondholders. Unlike national income, personal income does not include corporate profits, indirect business taxes, payroll taxes for government social insurance programs, except those distributed as dividends, and a couple of other minor items.

Personal income ultimately resolves itself into one of three bins: personal income taxes, consumption, or personal saving.

The third method of reckoning output is the expenditure approach. It is not obvious why gross expenditure should necessarily be equal to gross domestic income, given the leakages into taxes and saving described above. There is moreover an additional leakage: some spending will be on goods and services produced outside of the country (imports).

The reason GDE (gross domestic expenditure), if measured correctly, should nonetheless be equal to GDI and GDP, subject to small statistical discrepancies, is that there are, as pioneers of national income accounting came to understand, three sources of spending that don't emanate directly from households. These are traditionally considered injections, and the sum of these injections should just match the sum of the leakages. Why? Each leakage category has a corresponding injection category. In the case of taxes, it is government spending on goods and services. In the case of imports, it is exports, and in the case of saving, it is investment (understood in the macroeconomic sense as acquisition of new structures, equipment or net accumulation of inventories). Nevertheless, there is no guarantee that each of these pairs will balance; indeed it is likely they will not. There can, for example, be a government deficit or surplus or a current account deficit or surplus, and private saving might fall short of or exceed private investment. But the sum of the injections must just equal or balance the sum of the leakages.

How do we know this? Because the gross income flowing to individuals must ultimately resolve itself into one of three bins: consumption, saving, or net taxes: $Y = C + S + T$. And on the output side, breaking down the aggregate by type of expenditure, we know that the total will equal the sum of consumption, investment, government spending, and net exports: $Y = C + I + G + X - M$. Setting the two right hand sides equal to each other, and subtracting C from each side, we have $S + T = I + G + X - M$. Rearranging by adding imports to both sides, we have $S + T + M = G + I + X$ or, in a useful rearrangement, $S = I + G - T + X - M$: private domestic saving must finance the sum of gross private domestic investment, the government deficit, and the current account surplus, which represents the net acquisition of foreign assets.

We can all apparently breathe a sigh of relief. In what seems like an affirmation of Say's Law, supply does indeed seem to create its own demand.

Not so fast, however. It turns out that there is a bit of a trick involved in guaranteeing this balance, and that is to consider any net acquisition of inventories, whether intended or otherwise, as part of gross expenditure as well as gross private domestic investment. Firms are viewed as purchasing additional inventories on their own account, whether or not their acquisition was planned. During the 1930s, the decade during which Kuznets was developing the logic of the national income and product accounting system, Keynes was working on the *General Theory*. By distinguishing between inventories voluntarily or involuntarily acquired, and assuming some sluggishness in price adjustment, one could develop a coherent explanation of how sizable output gaps (a difference between actual and potential output) might persist. Most nineteenth century and earlier economists were not

excessively concerned with output gaps (Malthus was an exception) and whether or not there might be a deficiency of aggregate demand predisposing toward recession, even though at every moment of time expenditure would match output and income. We cannot claim that they understood the detailed logic of why the three different national income and product accounting approaches should sum to the same annual magnitudes. Precursors to moderns did, however, stumble upon each of the three estimating approaches used by modern national income and product accountants.

The expenditure approach measures final expenditure flows, including spending by households on goods and services (personal consumption expenditure, or PCE), by businesses on plant and equipment plus any inventory investment (gross private domestic investment, or GPDI), by governments on goods and services (G), and by foreigners on a country's exports less what is spent on imports (net exports). This approach facilitates the calculation, for example, of the share of output appropriated by government at different levels, or the share of consumption in gross domestic product.

Part II: Historical Antecedents

Kendrick makes the point that antecedents for each of these three approaches (output, income, and expenditure) can be found in the pre-World War I period. The three approaches were refined during the second quarter of the twentieth century. In the process, understanding of their interrelationship improved, permitting a coherent explanation of why, in principle, each should total to the same magnitude. To review: why should total income, for example, necessarily equal total output? Because for each economic organization, it is out of the flow of value added that gross income flows to owners of both labor and capital originate. If income generated equals value added for each economic unit, then in principle it should be true in the aggregate. Why should aggregate expenditure (including any change in inventories, considered spending by the firm that accumulates them) equal total output, given the leakages out of gross income that flow to taxes, saving, and imports? Because the sum of these leakages will be matched by the sum of three categories of spending that don't originate directly in domestic households: spending by governments on goods and services, investment spending by businesses, and exports.

Those studying economic output prior to the twentieth century did not understand all of this, but they understood enough, at least intuitively, to go about making estimates of output and income. Kendrick, following Studenski, counts 13 countries for which measures of economic output had been calculated prior to 1920. Seventeenth century pioneers in England, especially William Petty and Gregory King, approached the problem from the income side, constructing social tables and using an approach that has come to be known as *Political Arithmetic*, and which we will see resurrected in work by Lindert and Williamson (2016). King and Petty's work provides a useful contrast with much of the work on the nineteenth century in the United States, which is built up from the production side.

Petty (1691) published estimates for Britain in 1665 of what we would now call national income. He estimated income from land at £8 million, and from other personal estate at £7 million, with total income, based on an informed guess about population and average income, equaling £40 million. With the "Annual Proceed of the Stock or Wealth of the Nation," consisting of rent, interest, and profits, at £15 million, he attributed the residual of £25 million to the "Annual Value of the Labor of the People."

Several decades later (1696), Gregory King calculated national income by dividing the population into 26 occupations or classes, estimating the number of families in each grouping, the average number of persons in each type of family, and the average per capita income for each type of household. He multiplied within each category, aggregated, and then added in an estimate of the revenues of the Crown. He did this first for 1688, and, based on estimates of spending, was able to calculate the gap between income and consumption, which yielded saving or capital accumulation.

He subsequently constructed a time series through 1698, using it to cast light on the capital consumption engendered by military conflicts with France. He used similar techniques to estimate income for France and Holland in 1688 and 1695, and the relative burden of the wars in each of the three countries. Unfortunately, his work, although circulated privately at the end of the seventeenth century, and utilized by Adam Smith in the *Wealth of Nations* (1937), was not available publicly until 1802. To the degree that their income estimates were proxies for output, neither Petty nor King denigrated the output of final services. They can thus be considered as falling into the "comprehensive" camp in terms of their conception of output.

The same cannot be said of the French Physiocrats (Quesnay 1972; Gide 1948), who believed that only agriculture was capable of producing a net product. The Physiocrats reflect a unique and unusual variant of the material product approach, focusing on income and product within agriculture, which was of course the bulk of the French economy. Since they studied intersectoral flows, the Physiocrats can be interpreted as foreshadowing Leontief's work on input-output matrices. They also contributed an understanding of the necessity of reserving a portion of a country's gross product (in their case, grain) for the replenishment, and ultimate expansion of a country's physical capital stock. That understanding would ultimately be reflected in the distinction between gross and net product or income.

Adam Smith should also be placed in the material product camp. Acknowledging his views, in particular his distinction between productive and unproductive labor, also helps us understand why Karl Marx was a classical economist, and how Smith, in spite of his opposition to Mercantilism and association with laissez faire economics, can be said to have foreshadowed the accounting system of the former Soviet Union more so than that of the United States. Smith believed that productive labor fixed itself in vendible material products, whether structures, equipment, consumer durables or nondurables. Labor generating services for final consumers was for Smith unproductive, a view that was shared more or less by Ricardo and Mill and eventually by Marx.

One might try to explain Smith's biases as based on his desire to deepen capital (increase the physical capital to labor ratio) through saving and accumulation, combined with the obvious fact that only goods can be accumulated. Services, as he noted, perish in the instant of their own creation. It does not follow, however, that favoring goods production at the expense of services will necessarily result in higher levels of capital accumulation (and, presumably, welfare), since goods can also be consumed.

Smith is revered today for his rejection of Mercantilist views. Mercantilism stressed that a country desirous of aggrandizing its national power should aim to accumulate precious metals by running export surpluses. Smith, in contrast, argued that the strength of a nation's economy should be measured not by its holdings of precious metals but by its stocks of productive resources: labor, capital, and land, and the flows of output and income they enable. We should also, however, acknowledge that Smith's emphasis on the distinction between productive and unproductive labor, a leitmotiv of classical economics up through and including Ricardo, Mill, and Marx, represented a detour, with detrimental consequences for countries committed to it. Thus, for example, the material product system of national accounting can be plausibly blamed in part for stinting wholesale and retail distribution sectors within socialist economies, resulting in enormous waste.

Marx built on Smith's distinction between productive and unproductive labor, and also used it as a vehicle for focusing on the desirability of accumulating physical capital. Among the classical economists he had distinctive views about the objective of production in a capitalist economy, which was, he argued, to produce a net income (or surplus value) only for the capitalist class. In his view, nonwage income (rent, profits, dividends, interest) did not represent a legitimate return for the employment of a productive factor, but the extraction of surplus value made possible via the employment of wage labor. If Ricardo viewed landlords as living at the expense of the rest of society, for Marx it was industrial capitalists who were the principal parasites.

Marshall represented the decisive turning away from variants of the material product approach in Anglo-American economic thought, refocusing on the comprehensive approach to product and income accounting reflected in Petty and King, and emphasizing that the objective of an economic system was ultimately to satisfy household wants, and that the accumulation of physical capital should be understood only as a means to that end.

Part III: US Estimates of Output and Income Prior to the Second Half of the Twentieth Century

Samuel Blodget (1806) is generally credited with producing the first estimate of US national income. Using methods echoing those employed more than a century earlier by Gregory King, and more recently by Lindert and Williamson, he divided the US employed persons into classes, in his case seven, estimated annual per capita income for each, multiplied, and aggregated (see Blodget 1806; Rhode and Sutch 2006).

The 1840 US census was the first to ask a series of detailed questions providing a more solid basis for income and output estimation from the production side. George Tucker (1843) used that census to estimate commodity output in the aggregate and by state. He updated his work in 1855 based on data from the 1850 census. Ezra Seaman (1868) published similar estimates based on the 1840 and 1850 censuses. For the years 1880 and 1890, Charles Spahr (1896) developed more comprehensive estimates, and included calculations of the size distribution of incomes in the 2 years, which he used to draw conclusions about inequality trends. Wilford King (1915), using Spahr's framework, extended estimates to 1910. He concluded that labor's share of income was rising, leading him to doubt that inequality was increasing, although the former is not necessarily evidence against the latter proposition.

Simon Kuznets' work during the early 1930s helped define the architecture of a more fully developed, logically consistent accounting system for national output and income. Not all of the decisions he made about what to include and what to exclude, however, were ultimately incorporated into what became the now internationally accepted approach.

Here is the history. As the Depression worsened in 1931, government economists complained that estimates of output and income from the National Bureau of Economic Research appeared many months or years after the fact and were consequently of little use for business cycle forecasting or policy analysis. The National Industrial Conference Board published somewhat more timely estimates, prepared under the direction of Robert F. Martin, but they still were not available soon enough to be of real assistance to policy makers.

In February of 1932, officials in the Department of Commerce's Bureau of Foreign and Domestic Commerce joined forces with individuals working with Senator Robert LaFollette, a progressive senator from Wisconsin. These discussions resulted, on June 8, 1932, in the introduction of a Senate resolution calling for the production of annual estimates of national product and income for the years 1929, 1930, and 1931. The work was to be conducted within the Bureau of Foreign and Domestic Commerce and was begun under the direction of J. Frederick Dewhurst. When, by November of 1932, it became clear that Dewhurst and his limited staff would not be able to carry forward the project, an agreement was reached with the NBER for Kuznets to take over. Kuznets had been working on estimates of national income for the NBER since 1929 and was in the process of developing improved procedures more explicit about definitions and more careful about citing original data sources. He transitioned to the government in January of 1933, and on January 4, 1934, roughly a year later, delivered his report to the Senate. *National Income, 1929–1932* detailed two measures of national income, one excluding and one including retained business earnings. Within 8 months, approximately 4,500 copies had been sold (Carson 1975, p. 159). For a Senate document, it was a bestseller. Almost immediately, the Commerce Department took steps to assume responsibility for maintaining these estimates on an ongoing basis.

In these estimates, Kuznets excluded some categories of income that King had included. Among these were service flows from consumer durables, the value of

services provided within the household economy, earnings from illegal employment or the informal economy, capital gains, and relief and charity payments. For the first three of these, estimation was difficult and including them risked introducing a good deal of noise. Leaving them out might provide a less conceptually satisfying measure of levels but enable a more reliable calculation of growth rates.

Nonmarket services provided within the context of the household economy services were one of these categories, although Kuznets noted that in the circumstances of the Great Depression, their exclusion did not necessarily enable changes in national income to be a better proxy for changes in welfare. The narrower measure he provided, which excluded services provided within the household, fell sharply between 1929 and 1932, as the unmeasured household sector grew to take up "some of the slack imposed by the shrinkage of the market economy" (Kuznets 1934, p. 4). So the measures Kuznets reported suggested a decline in welfare more extreme than what probably occurred. Although the estimates in his report spanned only a 4-year period, Kuznets was also concerned that the practice of excluding the value of household production could bias the welfare implications of long run increases in per capita output, since the importance of such production tends to decline with the process of economic development. For the same reasons, cross-national comparisons of regions at different stages of development might be jeopardized, to the degree that output per capita measures were interpreted as proxies for welfare.

Kuznets' reasons for excluding capital gains were varied. On the one hand, he argued that including them would represent double counting, since it would reflect "both changes in national income and its capitalization." He also says it would "distort" the calculation of national income (1934, p. 5). The most compelling argument for excluding capital gains is that they do not represent value added as a result of current period production. To include them as part of income disrupts the posited equality between aggregate income and product.

In common with his treatment of the service flow from consumer durables, Kuznets also excluded the value of owner occupied real estate. His view was that "... there is some doubt as to the propriety of including this item, since the ownership of a home combined with its possession does not constitute a participation by the proprietor in the economic activity of the nation in the same recognized fashion as does his work for wages, profit or salary" (1934, p. 12) Ultimately, the Department of Commerce thought otherwise, treating homeowners as in the business of producing housing rental services, whether they chose to consume them or not. Accepted practice today is to make an imputation for the service flow from owner occupied housing, incrementing the aggregates for product, income, and expenditure. An argument for doing this is that it would make little sense for the GDP growth rate to change simply because of a change in the housing tenure rate, which could be the consequence of accepting Kuznets' approach.

His largest deviation from current practice was to treat government spending on goods and service as intermediate goods, arguing that it would be double counting to include in measures of output and income both government spending and the private sector final output it facilitated. Gilbert et al. (1948, pp. 182–183) pointed out, however, that Kuznets was using the concept of intermediate goods

quite differently when applying it to government public goods like national defense, justice systems, fire and police protection than was the case when it was applied to the purchased materials and (nonwage) services deducted from an entity's gross sales to obtain value added. In the latter case, payments to suppliers were associated with the delivery of specific goods or services. To the degree that taxes support a judicial system, for example, it seems a stretch to call this a fee for service, a point that takes on particular salience in the event we end up being prosecuted.

Kuznets, however, saw little difference, but on this he was opposed by many economists, and the conventions adopted by the Department of Commerce reflected these objections. Goods and services produced by government directly, as well as government purchases of goods and services, were all considered part of final output, and after 1942 were included in measures of gross national product and expenditure as well as income.

Kuznets' position was consistent with his continuing concern that we not assume that national output and income measures were necessarily good proxies for welfare. In particular, he did not see trillions spent on the military as satisfying human needs as directly or in the same way as spending on (and production) of food, clothing, or shelter. Similarly, and perhaps less controversially, he observed that "occupational expenses" such as commuting, although counted as part of consumption, really reflected an intermediate input into the production of goods and income that did satisfy human needs. The commuting itself did not directly contribute to welfare but only indirectly through its facilitation of our ability to earn income.

Kuznets stressed several times that since value added was measured at market prices, the aggregate depended not only on the vector of output but also on relative prices, which could be influenced by the distribution of income. For that reason as well, he said, per capita output should not be interpreted as a measure of welfare. All of these concerns are well and good and certainly valid. But it was probably unreasonable to expect economists and others to refrain from calculating per capita output over time or across different countries and make inferences from these numbers about material welfare.

Kuznets' point about the possible influence of the distribution of income on relative prices, and therefore on the value of production aggregates, received little emphasis in subsequent decades. Perhaps economists believe the impact of variation in income distribution on market prices to be relatively minor. On the other hand, it is often noted that, from the standpoint of assessing how well a society meets human needs, it matters (on the income side) how unequally that product is distributed among households. For example, adult height, a reflection of consumption/nutrition through adolescence, is strongly correlated cross-nationally and over time with the log of per capita income (Steckel 1995). But for a given per capita income, a higher Gini coefficient (a measure of inequality) is associated with lower average height. Kuznets' concern is related but not exactly the same, since it involves the impact of inequality on the estimation of the aggregate itself, which appears in the numerator of an output per capita measure.

Finally, Kuznets' estimates were of nominal income. In the 1934 Senate report, he made no attempt to convert nominal estimates to measures of real output

and income, attributing his reticence to the absence of an appropriate deflator that would cover both goods *and* services purchased by households. He called attention to the poor data for household expenditures on services but did not stress a need for a broader deflator that would also cover investment goods (structures and equipment) and government goods, which as noted, he chose to treat as intermediate. Let's assume a CPI or PCE deflator is the right price index with which to deflate consumption spending, which bears the most direct connection to human welfare, and that we were to follow Kuznets in treating government purchases as intermediate goods. In measuring changes in real output, we would at least for some purposes still want to use a broader deflator that also covered the roughly one-sixth of output that typically goes to producing investment goods (structures and equipment). Robert F. Martin's 1939 publication included estimates of real output going back to 1799 using either the CPI or a broader price index as a deflator (1939, Table 1, pp. 6–7). By 1937, as evident in *National Income and Capital Formation*, Kuznets was including estimates of real output in 1929 prices.

Interestingly, the term gross national product appears to have originated with Clark Warburton (1934), not Kuznets. The main difference with national income is that the gross measure included that portion of output devoted to maintaining the physical capital stock and thus compensating for depreciation. It is often argued that the preference for gross rather than net measures allows a more reliable estimate of growth rates, because calculating economic depreciation is difficult and often somewhat arbitrary – as much art as science. By 1937, Kuznets had adopted Warburton's approach and terminology (Kuznets 1937).

Kuznets' 1934 Senate report, although not the final word on procedures for calculating national income and product, was a milestone in their development. It also has some value for historical research, since it included a variety of observations about the differential impact on the income side of the worst years of the Depression. He found, for example, that income to property holders (in the form of interest and dividends) held up much better than labor income or income to entrepreneurs (p. 14), and that, although both income to capital and income to labor declined, labor's share dropped (p. 41). Over and over again, he reported that, for those industries where this could be distinguished, salary incomes between 1929 and 1932 declined less in percentage terms than did the income of those receiving wage incomes. Entrepreneurial income (what we call today income of proprietors) dropped sharply because it was heavily dominated by farmers and those working in construction. The main cause of the decline in proprietors' income was the drop in grain prices (p. 49), although surely the collapse in construction spending didn't help. The effects on income were aggravated because neither group tended to exit when incomes dropped (p. 33).

Some occupations or sectors did very well during the Depression in terms of real incomes. If you kept your job in government at any level between 1929 and 1932, your real income went up, as did those working in private higher education. Between 1929 and 1932, the number employed in private higher education as well as their per capita compensation went up quite substantially in real terms (p. 148). More generally, if you were a salaried worker and kept your job in the

Depression, your standard of living improved. Overall, Kuznets's report documented the reality that those on the lower rungs of the income distribution suffered disproportionately: "The Depression seems to have put its greatest burden upon those who, in view of their already low position on the economic scale, could least afford to lose" (p. 19).

Other miscellaneous notes: Mining, manufacturing, and construction suffered the greatest employment losses (p. 23). Finance had the highest average per capita compensation (p. 28). Technical change in steam railroads was "a thing of the past" (pp. 86–87). Motor transport (trucking) felt the effects of the depression much less severely than steam railroads. Interest payments declined hardly at all, in contrast to dividends. Defaults on mortgages (and cessation of interest payments) were much larger than defaults on corporate debt (p. 120).

Finally, Kuznets included an interesting discussion of cyclical effects on productivity within manufacturing. In food and tobacco, output per worker continued to increase between 1929 and 1932. The same was true in chemicals and petroleum refining through 1931 (p. 72). In most other industries, particularly industries where the quantity of output fell absolutely, labor productivity also declined, perhaps reflecting the impact of initial labor hoarding.

Kuznets followed his Senate report and 1937 publication with work extending his estimates first to 1919 (*National Income and its Composition*, published in 1941), and ultimately to 1869 (*National Product Since 1869*, published in 1946). As scholars worked out the logic and debated the conventions of national income and product accounting, they also began to work to extend their more systematized understanding of methods to construct income and output aggregates in earlier periods. In the process, they both critiqued and built upon earlier efforts. Because the 1840 and subsequent US censuses enabled calculations of value added for the material product portion of output (commodity output), the estimating technique for someone interested in a comprehensive measure of output required making informed guesses based on data from later periods about the ratio of services output to goods output and using this to "mark up" the commodity totals.

This was the basic approach followed by Kuznets in constructing annual estimates back to 1869. His pre-1919 estimates were based on commodity (goods) data from Shaw (1947), which Kuznets marked up by assumed margins for transportation and distribution. The size of those margins, and more generally the question of whether service sector (noncommodity) output varied roughly one for one with goods output, lay at the heart of Christina Romer's subsequent questioning of how much more moderate had been post-World War II business cycles relative to those that preceded them (Romer 1989, 1994).

For 1919–1929, however, Kuznets was able to construct his estimates from the income side, rather than the incomplete data on the product side, and his estimates for these years are generally assumed to be of higher quality than the pre-1919 estimates. Romer also endorsed income side estimates for 1909–1918 contained in an appendix to Kuznets (1961), although Kuznets believed these numbers to be less accurate than those for 1919–1929, and ultimately judged his product side estimates for 1909–1918 to be superior (see Weir 1986, p. 355).

John Kendrick (1961) made adjustments to the treatment of government expenditure in Kuznets' GNP series to make them more comparable to the annual series from 1929 onward maintained by the BEA. As noted, Kuznets' practice had been to treat government expenditure as an intermediate good, not part of final product. Kendrick's have since become the standard series referenced by students of the 1920s. Romer's annual GNP series for 1919–1929 are Kuznets' income side estimates with Kendrick's adjustments and some other minor adjustments.

Most of Romer's revisionism applies to the pre-1909 data. Her big differences with Kuznets involved how much pre-1909 GNP was likely to have varied with changes in commodity output. Kuznets used freehand regression to estimate the elasticity of GNP with respect to goods production using data for the years 1909–1938 (Kuznets 1961, pp. 536–37). Based on data from these years, he concluded that the elasticity approached one and used this to backcast a GNP series using goods data for the earlier years. Romer reestimated the elasticity using data from 1909 to 1985 but excluding the years of the Great Depression and the Second World War (1929–1946). She made a number of other minor changes – using log differences rather than ratios, allowing the elasticity to vary over time, and using what she described as "normal" rather than peak years to establish trend from which deviations might be calculated.

Based on these regressions, she found that the elasticity was not in fact very time sensitive: "the time varying coefficient measuring the sensitivity of GNP to commodity output fell from 0.583 in 1909 to 0.527 in 1985" (Romer 1989, p. 20). The more important aspect of her results was not the small difference in these two numbers but rather their moderate size. Kuznets had concluded that GNP varied almost one for one with commodity output. Romer argued that the elasticity was closer to 0.5 or 0.6. Thus her estimates of pre-1909 GNP are much less volatile than Kuznets', which is what underpins her conclusion that the pre-World War I business cycle was not markedly more severe than the post-World War II cycle.

Romer justified excluding 1929–1946 from her regression on the grounds that we could expect the elasticity of GNP with respect to commodity output to have been unusually large during these years because the fluctuations in both series were so substantial. She maintained that it would be inappropriate to extrapolate backwards from this "abnormal" period to more "normal" years between 1869 and 1908, and she attributed Kuznets' high elasticity estimate in part to his inclusion of the years 1929–1938 in his estimating regression. Weir (1986, p. 355) questioned Romer's exclusion of 1929–1946, arguing that there was little evidence of a structural break during the depression years. Nevertheless, Romer's argument about the relative severity of the pre-World War I business cycle, and her means of reaching that conclusion, have subsequently been widely accepted.

It should be kept in mind that Kuznets was adamant that although he thought his annual estimates back to 1869 were useful for calculating trend growth rates, he did not think they were sufficiently accurate to form the basis for the exploration of cyclical variation (Kuznets 1961; Rhode and Sutch 2006). Robert Gallman, Kuznets' student, who extended estimates to 1834, took the same position (Gallman 2000). Kuznets, along with Gallman, also did pioneering work estimating the growth

of the US physical capital stock. Gallman, extended both series back to 1834, continuing Kuznets' tradition of careful attention to detail, crosschecking of calculations, and documentation of sources and data transformations. With respect to the capital stock, Gallman emphasized the dominance of structures in both the capital stock and net investment flows, a theme emphasized in Field (1985). Gallman also considered investment in land clearing as equivalent to the creation of a reproducible tangible asset, thus a capital good, and emphasized how empirically important it was in the nineteenth century.

For the 1909 period and earlier, Kuznets and Gallman did not have access to better data than did Tucker, Seaman, Spahr, or Wilfred King. Nor, for the most part, could they use electronic spreadsheets or other data processing conveniences, which might have made their job easier. What they did have was a more solid understanding of the logic of national income and product accounting, an essential starting point for those wishing to do research in this area.

Extending the aggregates much before the 1840s, however, continued to strike these scholars as daunting. The first serious effort to venture further back in time is reflected in estimates published by Robert F. Martin in 1939. Martin provided decadal numbers starting in 1799 and then annual data from 1900 through 1938. He concluded that real per capita income had fallen during the first three decades of the nineteenth century, beginning to rise again only in the 1840s (Martin 1939, Table 3, pp. 14–15). Because of the absence of reliable production data for commodity output prior to the 1840 census, the years before this are commonly referred to as a statistical dark age.

Using an approach suggested by Kuznets (1952), who had been critical of Martin's estimates, Paul David (1967) attempted to shed light through what he described as controlled conjectures. He took aim at what he perceived as a consensus, based on Rostow's work (1960) and apparently supported by Martin's estimates, that there had been a marked acceleration in the rate of growth in output per head sometimes between 1800 and 1840. This would have been consistent with Rostow's claim that a takeoff typically accompanied entry into sustained economic growth. David pushed for a more gradualist perspective on the entire 1790–1860 period, emphasizing instead a post-Civil War acceleration associated with, among other things, a rise in the national saving rate.

He began by observing that growth in output per head would equal the sum of growth of labor force participation and growth in output per worker, and the advance in the former was relatively modest (about 0.3% per-year). On the other hand, there were, across the antebellum period, major shifts in the sectoral shares of agriculture and the nonagricultural sectors. Following Kuznets, his conjectures were driven by data from later in the nineteenth century suggesting that value added per worker in nonagricultural sectors was twice (or more) what it was in agriculture. David assumed that growth within each sector (and thus the average for the economy) could be proxied by the rate of advance within agriculture. Using these moving parts, he assembled an engine to "retrodict" growth in output per hour, and in combination with the data on modest increases in participation rates, output per head. His conclusion: growth in output per head between 1790 and

1860 at about 1.3% per year. Having begun by endorsing Kuznets' criticisms of Martin's estimates, and aiming to soften Rostow's takeoff, David's numbers nevertheless still showed acceleration between the first two decades of the century and decades three and four (0.28% per year between 1800 and 1820 vs. 2.0% between 1820 and 1840), although this was earlier than Martin or Rostow had suggested.

When incorporated into a similar Kuznetsian framework, Thomas Weiss's revisions to Lebergott's labor force data suggested somewhat higher levels of output per capita at the start of the nineteenth century, slower growth between 1820 and 1840, and consequently somewhat lower overall growth rates over the first six decades of the century (Weiss 1992, Table 1.2, p. 27). One should be careful in concluding that such revisions necessarily reflected poorer economic performance. If US residents in the first decades of the century enjoyed higher levels of output per capita than was previously suggested, this is not necessarily a less rosy picture, simply because the growth rate was lower.

In an unpublished working paper written decades after his original contribution, David articulated some second thoughts (David 2005), expressing reservations about his earlier uncritical acceptance of Kuznets' reading of relative productivity levels in the agricultural and nonagricultural sectors. David now argued that the growing share of labor outside of agriculture contributed to rising output per head not because output per hour was higher outside of agriculture, but because people worked so many more hours per year once they left agriculture. He still pressed for a more gradualist reading of trends in output per head in the first six decades of the nineteenth century than had been suggested by Martin or Rostow but was now using a much modified retrodictive engine to arrive at these results. If David's revisionism about relative productivity levels are to be taken seriously, they pose issues for much other work.

The seventeenth and eighteenth centuries, which include the colonial and revolutionary periods in US economic history, have in recent decades attracted a remarkably wide range of inquiries aimed at estimating levels and growth rates of output and/or the standard of living across this long period. Both economists and historians have contributed. The energy and range of interest in these explorations may partly reflect the relative paucity of data, and thus the premium placed on creative inferences from that which is available. In the absence of comprehensive data on commodity output, the starting point for most nineteenth century estimates, scholars have used different means to extrapolate output per capita levels and rates of growth. Alice Hanson Jones, for example, whose research had built up estimates of wealth using probate records, assumed a wealth to income ratio to estimate income (1980). Others have tried to infer income or product from data on imports (for example, Egnal 1998, but see Mancall and Weiss 1999). Steckel (1995, 2006) drew inferences about consumption levels from height data.

Rosenbloom and Weiss (2014) provide a useful overview of research on the colonial period and the different data sources and methods of drawing inference from them, along with a comprehensive set of references. Their main agenda, however, is to estimate product per capita and its growth in the Mid-Atlantic Colonies (Pennsylvania, New Jersey, New York, and Delaware), using the

framework that David and Kuznets exploited: inferences about the respective growth rates of output per person in agriculture and nonagriculture, combined with estimates of shifts between the sectors and changes in labor force participation rates. Their research is echoed in the Lindert-Williamson conclusion that a significant retrogression in economic growth took place during the revolutionary and Articles of Confederation periods (1775–1790) (see below). It is also notable for acknowledging the important role the service flow from the housing capital stock (whether owned or rented) makes to aggregate output, and thus the contribution of the accumulation of residential housing to increased actual and potential output. This treatment is a valuable counter to those who dismiss residential capital as nonproductive. Such capital is indeed unusual in comparison to that employed in agriculture, manufacturing, or transportation because it contributes to aggregate product largely without the cooperation of labor. But historically, as is true today, it makes a significant contribution to output and consumption. They conclude that growth in the Atlantic colonies between 1720 and 1800 was modest. Using a similar approach, Mancall et al. (2004) estimated output growth in the lower South, with a similar conclusion, and Mancall and Weiss (1999) develop the no growth argument for the entire colonial period.

Growth, however, is not all that matters. Levels do as well, which brings us to Lindert and Williamson (2016). Their book attempts a grand synthesis, providing an overview of, and new perspectives on, output growth as well as inequality trends from the seventeenth through the twentieth centuries. I focus here on their contribution to our knowledge about historical trends in output, particularly in the period up to 1800. Kuznets and others, including David and Weiss, had built most of their estimates for the period prior to 1919 from the production side. Lindert and Williamson reverted to the political arithmetic tradition associated with Petty and Gregory King (as well as Blodget). They built income side estimates by dividing the population into groups, searching for information on their respective labor and property earnings, and constructing "social tables," as had Petty and Gregory King. Aggregating estimates of free labor earnings, property incomes, and (up to 1860) slaves' retained earnings (the costs of their subsistence), Lindert and Williamson constructed five social tables for the years 1774, 1800, 1850, 1860, and 1870. Their work is a vivid illustration of the challenges involved in building estimates of the aggregate from the income as opposed to production (value added) side.

Their most radical conclusion is that "the US had reached world leadership long before the founding fathers constructed their new republic" (2016, p. 2). It did not grow very fast during the colonial period, but the level of per capita output throughout the epoch was high (this is consistent with data on heights). They find that America's per capita income exceeded Britain's in the colonial period, fell behind during the years of the Revolutionary War and the Articles of Confederation (1775–1790), when per capita income may have declined by 30%. With the resumption of growth after the adoption of the Constitution, the country had recovered the lead over Great Britain by 1860, although it lost it during the regression associated with the Civil War and then again during the Great Depression of the 1930s.

Their overall conclusion is this: Maddison was quite wrong to argue that it was not until the start of the twentieth century that US income per capita overtook Britain's (2016, p. 9). Lindert and Williamson point out that transatlantic migration was overwhelmingly from Britain to the United States rather than vice versa, US population growth was very rapid, with women enjoying the highest fertility in the world and children experiencing the highest survival rates in the world.

Conclusion

As the modern apparatus for estimating national output, income and expenditure was developed and rationalized, cliometricians, new economic historians, and government statisticians have refined our understanding of the historical record of US economic growth. By exploring the genesis of modern national accounting systems, their main principles and conventions, and their application to historical data, this chapter has emphasized opportunities to improve our understanding of the past, not always or necessarily by using previously unavailable data but also by innovating in using known data sources and developing new ways to draw inferences from them.

The Census of Manufactures: An Overview

Chris Vickers and Nicolas L. Ziebarth

Contents

Abstract

This chapter provides an overview of the Census of Manufactures (COM) from the early nineteenth century through the late twentieth century. The focus is on research that uses the original establishment-level schedules. After summarizing how the COM has changed over time in terms of content and quality, the chapter demonstrates the usefulness of the COM in studying a variety of economic questions. These questions include the sources of long-run productivity growth, the causes and consequences of business cycles, and changes in the

income distribution. It then highlights the value of collecting additional establishment-level data from other sources.

Keywords
Great Depression · Manufacturing · Business Cycles · Establishment data

Introduction

Manufacturing has played a crucial role in the development of the American economy. While its fraction of employment has declined in recent decades, it has maintained a stable share of real GDP over the past 50 years, as the growth in computers and electronics balanced falls in other sectors (Baily and Bosworth 2014). It remains perhaps the central sector in the imagination of the public and policy makers. It is unsurprising then that the US federal government has carried out a regular Census of Manufactures (COM) since 1810, only 21 years after the constitution came into effect. The data from these censuses have informed numerous policy debates as far back as disputes over nineteenth century trade policy. Moreover, they have been used extensively by academics to understand the American economy. In light of this interest, we provide an overview of the COM through the years, with particular focus on the insights gleaned from the *establishment*-level schedules.

This chapter begins by discussing the focus on manufacturing, and having done so, why we then center on establishment-level data rather than published tables. One reason to focus on manufacturing is simply its importance in the American economy since at least the middle of the nineteenth century. Employment counts and share of value added in GDP underestimate the centrality of manufacturing in the economy. One reason for this is that manufacturing has historically been at the heart of technological change. While technological change has swept through agriculture and services as well over the last two centuries, those changes were dependent on the striking developments in the production of manufactured goods embodying these technological changes.

A second, related motivation for studying manufacturing is the crucial role it has played in the history of economic thought, going back to Adam Smith's famous pin factory. Intuitions about, for example, returns to scale are more often than not intertwined with how a manufacturing establishment works. A factory seems more amenable to economic theorizing compared to, for example, a bank. It generally has more clearly defined inputs and outputs as well as a clearer process linking the two. Understanding how production occurs at the level of the factory then provides important insights into these economic concepts. How production of goods occurs is particularly important when one thinks about the major technological innovations of the past, such as electricity. To fully reap the value of these innovations required that factories be completely rethought and reorganized (David 1991).

Having decided to study manufacturing, why work with establishment-level data rather than the published volumes, which, in many cases, provide a remarkable level

of detail? The tables often tabulate many important variables as well as provide relatively fine levels of disaggregation, and they have the large advantage of being far easier to collect. One obvious reason for going further down to the establishment level is it simply provides more data. The published volumes do not contain every single possible cross-tabulation or level of geographic or industry disaggregation. For example, the published volumes in many cases do not provide information for a particular industry by town. Other times the Census Bureau, for reasons not known today, collected a particular variable and never tabulated it. This may not be a truly compelling motivation for why all the schedules need to be collected, as estimates of these cross-tabulations could be obtained with a random sample of the subpopulation of interest. Of course, collecting all of the records for this subpopulation may allow for greater precision in the estimates, but this is not really an *economic* reason to do it. For example, questions about the length of the workweek were asked during the Great Depression but do not appear in the published reports. One could estimate this variable over time, conditional on covariates such as industry and geography, without fully transcribing all of the schedules.

This chapter emphasizes the importance of the establishment-level returns themselves to answer questions that are central to economic history and simply cannot be addressed with the published volumes. For us, the essential reason to collect these establishment-level records is to exploit the *establishment*-level variation. In introductory microeconomics, students are introduced to the concept of a representative establishment (or consumer) and that abstraction, while tremendously useful, wipes away all of the differences that define a particular establishment. It is not that economists thought there were no differences between establishments but questioned whether the differences mattered. The value of establishment-level data, in the end, is an empirical question.

There are a variety of reasons why these differences might matter. First, this variation is central to answering questions that might properly be classified as ones of industrial organization. For example, how do establishments within an industry compete with one another? Second, differences across establishments are useful for identifying causal macroeconomic relationships a popular use of establishment-level data recently. For example, Fuchs-Schuendeln and Hassan (2016) discuss the use of natural experiments to identify parameters, such as the fiscal multiplier, or to identify causal factors in economic growth. Third, those differences are useful for answering questions precisely about the *differences*. In thinking about earnings inequality, a natural question is how much wage dispersion occurs due to differences between establishments. In addition, understanding the sources of these differences can inform other critical questions. For example, evidence on price changes at the firm level has become an important input into models of the effects of demand shocks and monetary policy (Nakamura and Steinsson 2013).

This chapter proceeds as follows. First, there is a short history of the earliest COMs in the first part of the nineteenth century focusing on its creation and evolution up to the first "real" COM in 1850. The chapter then discusses in more detail three separate "eras" of the COM: (1) the late nineteenth century, (2) the Great

Depression, and (3) the modern era. This discussion includes the leading samples collected from these eras as well as the main questions that have been addressed. Throughout the focus is on how the *establishment-level* returns have been utilized. There are additional papers based on the published volumes that are not reviewed here.

Early Nineteenth Century COMs

The history of the COM stretches back to 1810 when it was taken in conjunction with the third Population Census. In fact, James Madison proposed that the 1790 Census include occupational statistics more than 20 years before that (Fishbein 1973). Thomas Jefferson requested similar questions be added to the 1800 Population Census. Congress rejected these proposals, but the proposals show the keen interest in collecting information on economic variables going all the way back to the founders. While the Census of Agriculture covered a much more economically important sector in the nineteenth century, it was not first taken until 1840. In some ways, the existence and persistence of the COM is remarkable. The Constitution mandates that the Population Census be undertaken for apportionment purposes each decade, but the COM has no such authority. Yet throughout the nineteenth century, there was wide support for the COM, with many politicians seeing the need for accurate data on this important sector. Fishbein (1973) discusses how the "dumping of European goods on the American market after the Napoleonic Wars and the depression of 1819 led to increasing demands for [just this type of] data" and was a main motivator for President Madison's request to Congress to authorize the 1820 Census. The existence of the COM is even more striking when one considers the stinginess of early Congresses in using funds from the public purse.

At the same time, given this lack of a clear constitutional mandate or permanent bureaucracy, it is perhaps not surprising that the completeness and quality of these earlier COMs was spotty and inconsistent from census to census. The first one in 1810 offered enumerators little by way of training and, remarkably, no actual questionnaire. This COM appears to have experienced resistance on the part of business owners in providing information, and there was no penalty for refusing to answer the questions. Fishbein (1973) goes so far as to say that because of so many inaccuracies, this census' "usefulness for research may be seriously questioned." These problems were evident contemporaneously, and numerous writers including Tench Coxe, who was tasked with tabulating returns, highlighted the myriad problems, including underreporting, misreporting, and transcription errors (Coxe 1814).

Adam Seybert, a congressman from Philadelphia, pushed the next COM in 1820. In responding to the deficiencies of the 1810 COM, Seybert successfully argued that the next one be based on an explicit questionnaire and that the enumerators receive clear instructions on the type of businesses to be enumerated. Unfortunately, these modifications did not change the overall outcome of the COM, which was still grossly inaccurate to the point where a journal of the time, the *Niles Register*, stated that "it will have been better if the subject of the inquiry had altogether been

omitted." (Fishbein 1973). There was no COM taken in conjunction with the 1830 Population Census. The 1840 COM was simplified in an important way by removing the qualitative questions. For example, the 1820 COM asked for "general remarks concerning the establishment, as to its actual and past condition, the demand for, and the sale of its manufacture." The COM no longer asked the establishment or owner's name, a change intended to increase response rates. Unfortunately, like the one before it, the 1840 response rate was terrible for the same reason as before. While effort was put into formulating the questionnaire, there was basically no effort put into organizing the actual data collection. The result was the same, with Frank Bowen, a leading economist at the time, criticizing the government for even attempting the census in the first place (Fishbein 1973).

To the best of the present authors' knowledge, there is no major collection of the establishment-level records for the COMs from the first half of the nineteenth century. Fishbein (1973) states that it had been believed that most of the 1810 schedules were lost in the War of 1812 when the British burned part of Washington. Some schedules did survive, as they were written on the population schedules, which were not all in Washington at the time. Sokoloff (1982), in his dissertation, collected a sample of these records from 1820 for the Northeast. Subsequent work by Sokoloff (1984, 1986) explored the productivity differences across establishments based on these schedules. The former work documented that smaller establishments were more productive, a seemingly puzzling finding of decreasing returns to scale.

Late Ninetieth Century COMs

The COM in 1850 was the first of sufficient quality for modern econometric study. The Census Act of 1850 provided for a comprehensive enumeration of manufacturing establishments. After this, the COM was taken decennially in hand with the Population Census through 1900. It switched to a quinquennial schedule with 1905, the first census taken separately from the Population Census, and then to a biennial cycle starting in 1919. This section focuses on the COMs from 1850, 1860, 1870, and 1880. These censuses provide insights into a key period in American economic history, with the demise of slavery and the rise of manufacturing.

Congress was cognizant of the data limitations of earlier COMs and instituted a number of reforms (Fishbein 1973). They established a Census Board to prepare schedules, and this body consulted with leading statisticians. Enumerators were paid (though inadequately) for each firm reported, and penalties were instituted for noncompliance. Further reforms in the tabulation process reduced tabulation errors in the published reports. These reforms were kept in place and further modifications and improvements made. By 1880, experts were hired to gather data and special schedules prepared for particularly important industries.

These censuses asked questions about output broken down by type, quantity, and value, as well as inputs in the form of labor, capital, and raw materials. As Atack and Bateman (1999) point out, the quality of these data is directly related to the

Table 1 Comparison of variables available

Century	Physical output	Value of capital	Hours	Employment breakdown
19th	Yes	Yes	No (half time)	Men, women, children
Early 20th	Yes	No (some physical)	No (shift length)	White, blue collar
Late 21st	Yes	Yes	Yes	Production, nonproduction

Notes: nineteenth century includes 1850, 1860, 1870, and 1880 COMs. Early twentieth century includes 1929, 1931, 1933, and 1935 COMs. Late twenty-first century includes all COMs after 1962

instructions given to the enumerators. Relative to the COMs from earlier in the nineteenth century, census officials made an effort to write clear questions for establishments and provide clear instructions to the enumerators on how to ask the questions. Even then, refinements and modifications were made to the questions to simplify the process for establishments and enumerators.

Table 1 summarizes the availability of certain variables throughout the years. For the nineteenth century, the Census instrument contains remarkably detailed information. It includes information on physical output, a limitation in some modern establishment-level datasets; capital, a limitation in the 1930s Censuses; and hours worked. At the same time, an important point emphasized by Atack and Bateman (1999) is the changes in wording of certain questions from census to census. For example, the question for "hands employed" evolved from 1850 to 1860, with much more precision in the instructions to the enumerator. In particular, rather than letting the number reflect an average over the whole year or selecting a particular day when "an average number was employed" as it was in 1850, enumerators were required to report on the "average number employed throughout the year" starting in 1860.

As is shown in the discussion of the 1930s censuses, it was not always the case that the clarity of the questions asked in COMs improved over time. Part of the problem is that there was not a permanent Census Bureau before 1902, which led to inconsistencies across censuses. For example, in 1880, "no specific instructions were given to the enumerators collecting manufacturing data beyond the questions on the forms." (Atack and Bateman 1999). There are also the perennial questions surrounding the quality of the enumeration without access to a master list of the establishments to be enumerated. This problem is compounded for the nineteenth century censuses, for which no central repository exists. Many of the schedules for particular states have been returned to their respective state archives. The National Archives in Washington, DC has a very large collection, but the poor quality of the microfilm and the fact that the forms were hand written, not typed, makes it difficult to read the text in many cases.

Atack-Bateman-Weiss Sample

The sample from the nineteenth century COMs that has served as the basis for all work at the establishment-level was originally collected by Jeremy Atack,

Fred Bateman, and Thomas Weiss (ABW) . Fred Bateman and Thomas Weiss originally collected the data from 1850 to 1870. Jeremy Atack and Fred Bateman subsequently added the 1880 data and extended the 1850–1870 series to construct nationally representative samples. These are available from ICPSR as Atack and Bateman (2004) and Atack et al. (2006). As discussed in more detail in the paper by Atack and Bateman (1999), this dataset consists of representative samples from the 1850, 1860, 1870, and 1880 COMs. "The sampling scheme was based on the number of establishments reported in each state in the summary census statistics. The goal was a sample size of between two hundred and three hundred firms from each" (Atack and Bateman 1999, p. 183).

The sample was constructed when digital storage was much more expensive than today. This led the creators of the sample to make a number of decisions on what to actually record. For example, the sample does not record the name or other identifying information of the establishment beyond the town in which it is located. This makes it impossible to link an establishment over time to study, say, the turnover of establishments. Of course, given the overall desire to construct a representative sample with "adequate microlevel diversity" (Atack and Bateman 1999, p. 183), the probability of actually being able to construct a link even for an establishment that was able to survive 10 years would be low.

Table 2 summarizes the sample, reporting only industries that have more than 50 establishments in one of the years. As is clear, the sample covers a wide variety of industries, from less technologically advanced industries like carpentry to "high tech" ones of the time like "iron forges and steel." These differences in the level of technology are reflected in differences in the scale of the operation. The average size of an "iron forges and steel" establishment is 39 times larger in terms of installed capital and about 13 times larger in terms of employment. One interesting note about the employment variable here is that it is derived from the sum of employment for men, women, and children, separately. These questions provide fascinating insights into the segregation of sexes (and children) within and across certain industries.

Value for Understanding the Development of the American Economy

Even with the limitations in terms of the size of the sample constructed, questions asked, and worries over the quality of the returns, the ABW sample has proven enormously valuable for understanding the long-run development of the American economy. One paper by Ziebarth (2013a) using this sample specifically contrasts nineteenth century America with two developing economies today, China and India, in terms of the allocation of resources between establishments. He finds similar levels of misallocation using the accounting framework of Hsieh and Klenow (2009) across these three countries. This is particularly striking given the belief that the USA had (and still has) better economic institutions than these countries and that these institutions are central to an efficient allocation of capital.

Others have used these schedules to trace the process of capital deepening and the diffusion of key technologies. Atack et al. (2005) focus on the role of establishment size and its relationship to capital per unit of labor. In light of the growth in the

Table 2 Summary statistics of the nineteenth century sample

Conglomerate enterprises	299	0.327	371.287

Notes: All statistics are calculated over the four census years. Establishments is the total number of establishments, Employees is the average number of log employees summing men, women, and children. Capital is in units of 100. The statistics are unweighted. We only report statistics for industries with more than 100 establishments over the 4 years

average establishment size during this period, these authors interpret this relationship as a shift from the artisan shop to the factory system. Atack et al. (2008) study the relationship between steam power, establishment size, and labor productivity, while Atack and Bateman (2008) examine establishment size and profitability. Using these records along with information on the rollout of the railroad network, Atack et al. (2011) link the transportation network to the growth in the average size of a manufacturing establishment. All of these works depend essentially on the information present in the establishment-level schedules that does not appear in the Census published tables.

Another major application of these data has been to return to the puzzle of a *negative* association between size and productivity, a relationship that is completely reversed in modern data. This was documented going back to the early nineteenth century by Sokoloff (1984). He argues that this "small firm effect" was due to under-reporting of the so-called "entrepreneurial labor" input. Sokoloff attempts to "solve" this problem by adjusting labor inputs upwards for the smallest firms. With this correction, he finds strong evidence for increasing returns to scale, which he takes as evidence for the returns to division of labor. Margo (2015) focuses on the adjustment made by Sokoloff and argues that there is no basis for it and, hence, the puzzle remains.

Great Depression COMs

While there were COMs taken between 1880 and 1929, as far as the present authors know, the underlying schedules have been lost due to accidents such as the fire that destroyed much of the 1890 Population Census, bureaucratic neglect, or active destruction to conserve space at the National Archives. The next COM with available establishment-level schedules is from 1929, the first of the Depression COMs. The COM had switched to a biennial schedule starting in 1919 after working on a quinquennial schedule between 1904 and 1919. For reasons that remain unclear to this day, this COM as well as the subsequent ones in 1931, 1933, and 1935, covering the first half of the Great Depression, were preserved. The physical schedules at the National Archives are organized by industry and year so it is much easier to collect industry-level samples rather than, say, state-level ones, which require going through all of the industries to find, in most cases, just a few establishments for a given industry in the state of interest. In fact, given the order on the returns, constructing a random sample is somewhat complicated with a random number generator. For example, consider the following procedure for constructing a random sample: simply sample every fifth establishment. Though sensible, this will not generate a random sample because it will under represent state-industry pairs with only a small number of establishments. In particular, think about a case where a particular state-industry pair had less than five establishments. Then the probability under this sampling strategy of having strictly greater than 1 of these establishments

is 0, whereas under a simple random sampling scheme, this probability would be strictly positive.

The schedules provide a wealth of detail about key variables on both the output and input sides of an establishment. The schedules contain information about sources of revenue by product, including not only revenue but physical output, product by product. For inputs, there is a set of questions about labor use including total wage and salary bill, number of wage earners employed at a *monthly* frequency, and average shift length for the hourly employees. The schedules ask about the number of days the establishment was in operation and the cost of intermediate goods used, allowing for a value added calculation. Finally, the intermediate goods category includes not just products used directly in the process, like timber in making furniture, but also electricity and other fuels for generating power. The intermediate goods used are, in some cases, broken down into quantity and value used in production. See Table 1 for the availability of various questions.

One issue to keep in mind when working with these records is the year-to-year variation in the wording of the questions asked. For example, the most basic question on revenue was modified in 1929. For all preceding years and all years hence, the question asked the "economist's version" inquiring about the value of output *produced that year*. In 1929, they instead asked a question about the value of products *sold that year*. This could in principle make a big difference depending on changes in inventories, particularly as it interacts with the peak in the business cycle. The COM after 1929 went back to the production-based question since the returns were found to be "unsatisfactory" as reported by the Census. At the same time, the Census stated that the switch did not invalidate comparisons of 1929 to other years. The present authors' suspicion is that establishments simply ignored the different phrasing of the question and continued to report production totals. This is based on the evidence from the cement industry where the output totals on the forms have been compared to outside sources. The differences, which are small to begin with, do not appear to be systematically larger in 1929 (Chicu et al. 2013).Turning to labor inputs, the COM provides some breakdown into white- and blue-collar labor inputs as well as information on the intensive margin of blue collar labor with information on hours worked. It is important to stress that these variables must be approached with great care because of the variation in questions across years. First, the 1931 COM does not include white-collar workers at all. For blue-collar workers, there are two different choices for the employment number. In each of the years 1929, 1933, and 1935, the census asks for the total number of wage earners on a particular date in December, with a further breakdown in 1929 between men and women. It additionally asks for the number of wage earners employed in each month. Note that "blue-collar" here does not refer to "unskilled" labor. The census forms in 1929 and 1933 ask establishments to include "skilled and unskilled workers of all classes, including engineers, firemen, watchmen, packers, etc." along with "foremen and overseers in minor positions who perform work similar to that done by the employees under their supervision" (Bureau of the Census 1932, 1936). The question for this group in 1935 was somewhat different, asking respondents to include "all time and piece workers employed in the establishment," not including

employees included in the other enumerated categories of officers, managers, clerks, and "technical employees" (Bureau of the Census 1938).

For white-collar workers, the variation across years is more complex, even setting aside the omission of information for 1931. As for blue-collar workers, the employment counts were based on a particular date in December for 1929, 1933, and 1935. Each census asks about the amount paid to officers during the year and included a count of, but not income to, proprietors. For the remaining white-collar workers, in 1929, the census includes the number of "managers, superintendents, and other responsible administrative employees; foremen and overseers who devote all or the greater part of their time to supervisory duties; clerks, stenographers, bookkeepers, and other clerical employees on salary," as well as the total amount that this group was paid (Bureau of the Census 1932). In 1933, managers and clerks are reported separately, along with their total wage bill. There is no mention there of foremen. In both 1929 and 1933, the census specifically includes foremen in "minor positions who perform work similar to that done by the employees under their supervision" as wage earners (Bureau of the Census 1932, 1936). For 1935, the same three white-collar categories of officers, managers, and clerks are reported, with the total number of clerks being reported for four separate months. For this year, there is also an entry for the number of "technical employees" including "trained technicians, such as chemists, electrical and mechanical engineers, designers, etc.," which is not asked in any other year, along with the income they are paid (Bureau of the Census 1938).

The biggest missing piece of information on the schedules regards the book value of the capital stock employed, a key production factor in any industry. Furthermore, there is no information about investment made by the establishment with which it might be possible to infer something about the capital stock. That said, there are some questions for various industries on the "quantity" of capital employed, particularly in 1929 and 1935. For example, in the ice industry, the schedule asks the establishments to report the number of compressors and the horsepower of those compressors used to make ice. Similarly, the schedules for the bakery and timber industry contain information respectively about the number of ovens and capacity of saws. Theoretically, one might back out implied investment for later years by comparing, say, the number of compressors at a particular ice establishment over time by assuming some depreciation rate. The practical difficulty with this is that the intermediate years of 1931 and 1933 have, in general, even less information on the capital stock.

To get a sense of the richness of these schedules, it is useful to compare them first to the modern establishment-level datasets including (1) the modern COM and (2) the ASM. Both the ASM/COM have similar information on employment, hours worked, wages broken down by blue- and white-collar workers, materials and energy inputs, and revenue. However, they dominate the 1930s COM with additional information on inventories, investment, and age along with establishment and firm identifiers. Each of these modern sources has their own unique drawbacks as well. The modern COM is taken every 5 years making it ill-suited for research on business cycles. The ASM, on the other hand, is at an annual frequency but lacks

the comprehensiveness of a Census, though it is representative. The bigger limitation of the ASM is the lack of information regarding prices and physical quantities of products, as establishments report only total revenue by product. The modern COM classifies the labor force into production and nonproduction workers, quite similar though not identical to the 1930s COM. All of the salaried workers would fall into the category of nonproduction workers. Some hourly blue-collar workers, such as janitors, are classified as nonproduction workers in the modern taxonomy.

There are a number of questions that can be asked about the quality of these data. Perhaps most prominently: How complete are the returns? This is really a two part question: (1) How well did the enumerators canvas all the establishments? (2) How well did the archives keep all of the schedules collected? Ziebarth (2015) contains much greater detail on these questions. On the first question, Chicu et al. (2013) compare the set of Portland cement establishments enumerated by the COM to the *Pit and Quarry Handbook*, which, among other things, contains a directory of all cement establishments. They find almost perfect concordance between the two. For the second, there are cases where particular states for individual industries are completely missing. For example, the 1931 returns from Texas in the manufactured ice industry have not been located at the National Archives.

While completeness is crucial, nearly as important is the quality of the data reported on the forms. Though there were penalties for not filling out the forms (whether they were actually enforced is a separate question), these were self-reported numbers with no checking against administrative data. By examining the schedules themselves, it is clear there was editing of the returns. Numbers are crossed off and replaced with other numbers. Sometimes it is clear that this was fixing computation errors on the part of the establishment. For example, there is a total costs field, which should just be a sum of three other components. In some cases, the establishment simply made a mistake in totaling those costs and some clerk at the Census Bureau fixed it. In other cases, for inscrutable reasons, a number is crossed out and replaced with a totally different one with no clear precedent from the form.

Probably the best one can hope for is that measurement error takes a classical form. A priori, this seems unlikely. At least today, the largest firms have account managers assigned to them whose job is to ensure a good response from those firms. According to the official documentation for the 2007 Economic Census (Gauthier 2007, p. 49):

> To identify companies requiring telephone follow-up calls after the response deadline, the NPC periodically generated and updated a list of delinquent companies (sorted by size of payroll). The Census Bureau contacted nonrespondent companies in descending payroll order (the largest companies first) and attempted to speak with the person the company had designated as its census contact.

This sort of measurement error process would be consistent with measurement error being zero on average across all establishment sizes assuming positive and negative misreports are equally likely to be identified. However, it would generate

heteroskedasticity in the measurement error as a function of the establishment size. To formalize this worry, consider the following econometric model:

$$y_i = \beta_0 + \beta_1 x_i^* + \epsilon_i$$
$$x_i = x_i^* + \eta_i$$

where $\mathrm{E}\left[\eta_i \middle| x_i^*\right] = 0$, $Var(\eta_i) = \sigma\left(x_i^*\right)$, and only (x_i, y_i) is observed. The difference with the classical measurement error case is that the variance of the measurement error depends on x_i^*. Assuming that $\sigma\left(x_i^*\right)$ is decreasing, then consider running the regression restricting attention to observations with $x > \bar{x}$. Then, under some conditions, the OLS estimator converges to $\beta_1\left(1 - \frac{Var\left(\eta \middle| x > \bar{x}\right)}{Var\left(x \middle| x > \bar{x}\right)}\right)$. If $Var(\eta | x > \bar{x})$ is assumed to be decreasing, the classical measurement error bounds become tighter as $\bar{x}$ gets larger. Without making more assumptions like $Var(\eta | x > \bar{x})$ goes to zero or that it decreases at certain rates as $\bar{x}$ increases, this is the best that can be done. This setup also generates an interesting bias versus variance tradeoff. By conditioning on values of x big enough, this reduces the bias but also reduces the effective sample size and the variance of the estimate. The same thing would be true if $\sigma(x^*)$ were decreasing. Then one could condition on values small enough with the same resulting tradeoff.

The question then is how big a problem this could be. To provide some empirical evidence, this present chapter studies a dataset generated by randomly sampling 25 establishments from each of 26 industries for which the authors had pictures of the original schedules. The test for the presence of editing is whether the revenue variable showed markings of edits done by the Census Bureau on the schedules. The idea is that if there is differential measurement error along these lines, there should be more markings for larger establishments. The size of the revisions in terms of the percentage of the revenue numbers by size when changes are made was also recorded.

The first regression is of the probability of a correction on size, and whether or not a form was "nonstandard." Occasionally firms received a "general form" rather than either the normal form for 1929 or the industry-specific form. This form contained considerably less information than the others. The results are in the first column of Table 3. The size of an establishment as measured by the decile of an establishment's final revenue does not strongly predict whether the figure for total revenue on the schedule form was corrected by the census.

The second regression examines if these characteristics determined whether the regression was upward, conditional on there being a revision. A third regression examines the magnitude of the change. These regressions are in columns two and three of Table 3. Size is not a predictor of these variables either. Note that the sample size is smaller here for two reasons. First, these regressions condition on there being a change in reported revenue. Second, in many cases, the original value of the revenue variable could not be deciphered, as the scratched out value was illegible.

Table 3 Predictors of edits to revenue variable

	Corrected	Revenue revised up?	Log change
Nonstandard form?	−0.08	0.85***	−0.13
	(0.05)	(0.13)	(0.31)
Decile by size of final revenue	0.01	0.03	0.02
	(0.01)	(0.03)	(0.05)
N	627	90	71
Adj. R-Squared	0.069	0.158	0.113

Notes: These data are from the 1929 COM. All regressions include industry fixed effects and standard errors are robust. The last two regressions are conditional on a change in the establishment's revenue in the first place. The nonstandard form indicator is for establishments that received a form other than the industry-specific form, so-called "Form B"
***1% significance level

One conclusion from these results is that perhaps measurement error with conditional heteroskedasticity is not much of a problem.

Bresnahan-Raff Sample

The first sample from these returns comes from the work of Timothy Bresnahan and Daniel Raff. They focused on the complete returns from particular industries. The two that they focused on in their published work were the automobile (Bresnahan and Raff 1991) and blast furnaces (Bertin et al. 1996) industries. They published the data for the cotton goods and automobile industries as Bresnahan and Raff (2011). Subsequent revisions to the cotton goods data in collaboration with Changkeun Lee and Margaret Levenstein was published as Raff et al. (2015a, 2015b). In addition, Bresnahan and Raff collected the returns from the cork, matches, soap, oil refining, tires, glass, steel, and cigarettes industries. The present authors were able to obtain their original Excel spreadsheets from Margaret Levenstein at ICPSR. One issue with those spreadsheets is that for some industries, such as the glass industry, there are variables missing.[1] For the sample discussed below, these missing variables have been reentered.

Vickers-Ziebarth Sample

The Vickers-Ziebarth sample was built over a time for a variety of projects, both by the present authors and collaborators as in Chicu et al. (2013), Vickers and Ziebarth

[1]One theory is that the original spreadsheets were transferred to Excel format, but earlier versions of Excel limited the number of columns a spreadsheet could have, thus cutting off a number of variables in industries with many products listed on the schedules.

Table 4 Summary statistics of the 1930s sample

Industry	Establishments	Log employees	Incorporated	Durable
Beverages	14,907	1.25	43.7	0
Ice cream	10,105	1.38	54.0	0
Ice, manufactured	13,242	1.47	78.9	0
Macaroni	1,269	2.09	49.3	0
Malt	131	3.04	96.8	0
Sugar, cane	279	4.45	71.9	0
Sugar, refining	77	6.40	88.3	0
Cotton goods	4,483	5.03	91.7	0
Linoleum	23	6.15	100	1
Matches	82	4.87	93.8	0
Planing mills	12,582	2.27	66.9	1
Bone black	223	3.13	98.1	0
Soap	1,004	2.38	80.9	0
Petroleum refining	1,547	4.05	94.9	0
Rubber tires	224	5.40	95.2	1
Cement	638	4.56	98.6	1
Concrete products	5,733	1.51	57.5	1
Glass	923	4.95	94	1
Blast furnaces	329	4.97	100	1
Steel works	1,720	5.62	98.5	1
Agricultural implements	916	3.17	80.4	1
Aircraft and parts	379	3.30	92.0	1
Motor vehicles	627	4.99	93.9	1
Cigars and cigarettes	145	3.97	77.2	0
Radio equipment	786	3.91	86.9	1

Notes: This table is taken from Benguria et al. (2017). All statistics are calculated over the four census years. Establishments is the total number of establishments, log employees is the average number of log employees across establishments. Incorporated is the percentage of establishments that are incorporated. Durable is whether we coded an industry's product as durable

(2014), and Ziebarth (2013b), and other such as Lee (2014) and Morin (2016). The initial set of industries included manufactured ice, cement, and macaroni. Over time, the sample came to include the original Bresnahan and Raff sample as well as the set of industries they collected but which to our knowledge are not used in published research. Table 4 shows some basic summary statistics of the combined sample. This shows the varied nature of the sample with many different types of industries covered. It has "high tech" industries such as aircraft and radios. It includes durables such as cement and steel and nondurables such as ice cream or manufactured ice. In addition, there are differences in whether the industries are mainly consumer oriented, like beverages, versus business oriented, such as planing mills. In addition, as the table shows, there is considerable variation across the industries in the relative importance of establishments that are part of multiplant (MP) firms; that is, firms comprising two or more establishments. The fraction of

Table 5 Percent of national manufacturing total of 1930s sample

Year	1929	1931	1933	1935
Establishments	11.3	10.5	9.91	9.48
Total wages	20.5	18.2	19.0	20.7
Value of product	20.5	18.4	21.0	18.8

Notes: This table is taken from Benguria et al. (2017). All of the national totals are from the 1935 published report on the Census of Manufactures, which reported the previous years totals as well

establishments in an industry which are part of an MP firm ranges from 0% in macaroni to 72% in rubber tires. When looking at the share of industry employment or revenue rather than number of establishments, the number from MP firms can be even higher: in soap, 95% of employment and 96% of revenue comes from MP firms.

The dataset includes harmonized variable names as well as establishment identifiers and, in a select set of industries, firm identifiers. Besides the cement industry, where directories from the Cement Institute were employed, we manually link establishments into their parent firm using the name of the parent company. If firms change their names over time, this can be a difficult process. Almost surely, the errors in the process of matching lead to an underestimate of the fraction of establishments that are part of MP firms. This is because it is much more likely to miss a legitimate match than it is to mistakenly make a match. This will generate the usual attenuation bias.

Table 5 shows the coverage of this dataset in terms of the fraction of manufacturing establishments as well as total manufacturing revenue and wages. In each of the four censuses, the data includes about 10% of all manufacturing establishments. Because our sample is skewed toward more large-scale industries, it ends up covering nearly twice as much of manufacturing revenue and wages. A separate question is geographic coverage of our sample. This is difficult to do because the published industry-county totals are still in the process of being collected. However, the 1930 Population Census asked a question about a person's industry of employment, allowing us to compare our total employment numbers to it. Figure 1 then shows the fraction of 1930 manufacturing employment represented in the sample by county. Obviously, one should not expect 100% coverage since we only have a select set of industries, but we do have reasonably good geographic coverage.

Value for Understanding Business Cycles

These schedules have proven immensely useful in understanding the contours of the Depression as well as the effects of numerous New Deal policies. The earliest work here by Bresnahan and Raff (1991) focused on the "cleansing" nature of the Depression. Focusing on the automobile industry, they argued that the least productive establishments exited at a higher rate. The least productive establishments

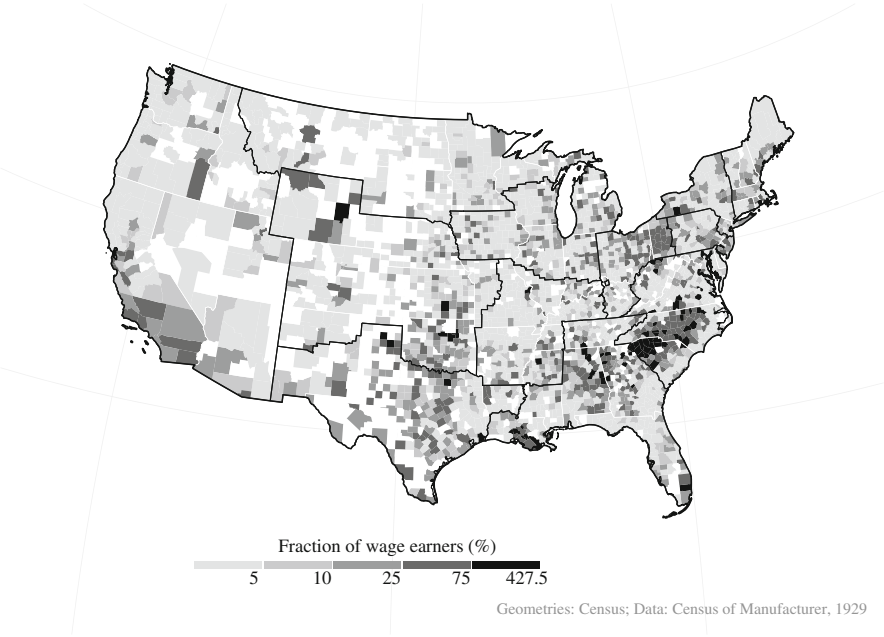

Fig. 1 Geographic coverage of 1930s sample. (Notes: This figure is taken from Benguria et al. (2017). The fraction of wage earners is the total number of wage earners in our sample in 1929 relative to the total number of manufacturing wage earners reported in the 1930 Population Census from Haines (2010). Totals may sum to over 100% if counties employ more wage earners than live in the county or if there were large declines in manufacturing employment between 1929 and 1930)

tended to be those that were craft producers. Subsequent work by Lee (2014) has challenged their interpretation that productivity was the most important selection criterion in the automobile industry. Scott and Ziebarth (2015), in a study of the radio industry, echoed Lee's point that selection seemed to be related to sheer size of the establishment rather than productivity per se. Bresnahan and Raff's original work showed the immense value of the establishment level returns. The questions they addressed were simply not answerable with the published volumes. Raff (1998) emphasized many of these same points.

Besides this work on questions of industrial organization, the establishment-level schedules have been useful in understanding productivity dynamics during the Depression. There is a marked decline in productivity from 1929 to 1933, which is much larger than one would expect given the decline in output (Ohanian 2001). Bertin et al. (1996) attempt to identify the role of short-run increasing returns to scale through a study of the blast furnaces industry. Ziebarth (2017) approaches the puzzle from a different direction by focusing on the role of misallocation of resources across heterogeneous establishments. This dovetails with subsequent work by Loualiche et al. (2017) that studies the role of firms' internal capital markets in the process of resource allocation.

Finally, a set of papers have used the establishment-level returns to better identify the causal effects of macroeconomic shocks. For example, Ziebarth (2013b) uses variation within the state of Mississippi in the extent of local bank failures, building on a natural experiment first outlined by Richardson and Troost (2009). He finds that bank failures had a negative effect on output and employment consistent with some form of nonmonetary effects of the banking crisis. Mathy and Ziebarth (2017) focus on the border of Louisiana and Mississippi to identify the effects of the political uncertainty induced by the sometimes erratic actions of Huey Long. They are not able to identify any deleterious effects, at least through this uncertainty channel.

Modern COMs

The COM continued in 1937 and 1939, was suspended during World War II, and resumed again in 1947. The timing of the COM was sporadic then for a decade with surveys done in 1954, 1958, and 1963. Finally, in 1967, the COM switched back to a quinquennial schedule that still persists today. In addition, the Census conducts an annual survey, the ASM (Nucci 1998). Longitudinally linked microdata are available through the Census' network of Research Data Centers for 1963, 1967, and 1972–2015 (United States Census Bureau 2015). Note that getting access to these data requires obtaining a security clearance and physically going to one of these secure research data centers. It had been thought that much of the data for the 1950s and 1960s ASMs had been lost, but recent work at the Census has recovered these files, which "were stored on tapes readable only by an old, archaic, and rather frail Unisys Clearpath IX 4400 mainframe that was a descendant of some of the earliest mainframes ever in existence" (Becker and Grim 2011). As Becker and Grim note, a tremendous amount of work remains to actually transform these recovered files into datasets useable for researchers. This mainframe has also been used to recover information on imputation in recent COMs, including imputation flags for total employment, total value of shipments, total cost of materials, and the wages and hours for production workers (White 2014).

Background on the Modern COM Instrument

The COM instrument for this period of time has basically all of the questions from instruments from earlier COMs including information on output by quantity and value as well as information on investment. The drawback of the COM is that because it is taken only every 5 years, it is not that useful for addressing business cycle questions. Instead, researchers have to rely on the ASM, which as the name suggests is done annually. This timing is still somewhat of a limitation since business cycles do not often last longer than a year. More problematic is the fact that the ASM is a survey and asks a limited number of questions. The ASM is not a strictly random or even stratified survey. The largest establishments are always surveyed while

smaller establishments rotate in and out based on some probability of being sampled. This makes it difficult to study *within* establishment changes over time except for the largest establishments, though the randomly selected small establishments are surveyed for a period of time.

The additional problem of the limited set of variables is reflected in the fact that the ASM does not provide information on physical output, rather it only reports revenue. If establishments all set a constant markup of price over marginal cost, this would not be a problem, since relative comparisons of revenue would reveal relative differences in physical output. Under this pricing rule, establishments that are more productive should charge lower prices and, in the end, productivity based on *revenue* rather than physical output per unit of inputs should be equal across establishments. However, as shown by Foster et al. (2008), this is certainly not the case. In fact, using the COM where there is information on physical quantity and price, they find for a set of industries that sell homogeneous products that the dispersion of *physical* productivity is much greater than *revenue* productivity while at the same time, revenue productivity is much more predictive of an establishment's survival.

One clear benefit of using the modern COMs is much clearer documentation of the procedures used to collect the records. For example, while presumably there was some list of establishments to canvas for the 1930s and earlier COMs, such a list has not been located. This would be very useful in testing the joint hypothesis that the Census did a good job of canvasing the full set of establishments as well as whether the National Archives did a good job holding onto all of the establishments. For the modern COM, this is not a problem since the canvas list is based on IRS records of establishments in existence.

Research from the Modern COM

The modern COM has proved immensely important for a number of areas of inquiry. This section focuses on the use of these data in identifying the role played by employers in generating earnings inequality. For good reasons, labor economists going back to Mincer (1975) have tended to focus on the role of characteristics of employees in explaining wage dispersion. It has only been more recently in the work of Davis and Haltiwanger (1991) that economists have begun to explore employer-level determinants of earnings beyond simply industry. For example, they find evidence that the age of an establishment is an important predictor of pay with older establishments paying more. This work cannot address *employee* characteristics in determining wages since the Longitudinal Research Datafile they were working with did not have that information. Benguria et al. (2017) study similar questions for the Great Depression.

One way in which these records have proved immensely important is in uncovering facts that are completely obscured by aggregate numbers. A particular case of this is the distinction between net and gross job flows. Obviously, economists have known that an increase in net employment over a year does not mean that there were no job losses. Instead *gross* flows exceed net flows. However, economists did

not have any idea of how much bigger these gross flows were until the work of Davis and Haltiwanger (1990). They find that while net employment growth rates (in manufacturing) between 1947 and 1993 were on average around 0, the total of job destruction and creation rates was over 12%. Even this understates the size of these gross flows because Davis and Haltiwanger (1990) were not able to use matched employee-employer data. Therefore, they are unable to distinguish an establishment with no net growth because of neither job creation nor destruction, from another establishment where there was positive but equal amounts of job creation and destruction.

Understanding these jobs flows has also had impacts on how economists think about the sources of aggregate productivity growth. As noted earlier, there is a large dispersion in productivity at the establishment level, and hence, there is potential for aggregate productivity increases by reallocating workers from low to high productivity establishments. The question then is quantifying how these gross flows contribute to the reallocation of workers and production away from the least productive establishments to more productive ones. Baily et al. (1992), among many others, find that these reallocation effects, and net entry in particular, explain an important fraction of productivity growth.

Directions for Future Work

For a long time, economic historians had to pass over in silence crucial questions regarding the development of American manufacturing due to a lack of data or, more precisely, a lack of ability to collect data. By comparison, the present is a Golden Age, at least when it comes the ability to gather, store, and sift massive amounts of historical data that were always there but just out of reach. This is reflected in the growing literature drawing on the original COM schedules surveyed here and, more broadly, in the style of leading work in economic history. This work has attempted to summarize the incredibly valuable data drawn from the establishment-level returns of the COM. These schedules have provided great insights into a number of key questions in economic history from the development of manufacturing to the role of competition policy to the sources of wage inequality.

There appears to be no reason why this quantitative turn in economic history will slow down anytime soon. If anything, with the rise of algorithms that can extract information from relatively unstructured images, “Big Data” in economic history will only get bigger. So where does the profession go from here when it comes to the COM, in particular? There is the always the obvious: just more of what is there. This seems particularly compelling for the nineteenth century COMs where the size of the Atack, Bateman, and Weiss dataset really limits the extent to which the sample can be restricted along different dimensions while still maintaining enough power. This should be relatively simple since FamilySearch.org in conjunction with the National Archives has completed the first (and most time consuming in terms of work hours) step by digitizing the nineteenth century schedules for a number of

states and made them freely available. All that would be required is having the data from those images entered into a spreadsheet.[2]

While no doubt useful, more is not enough. Instead, there seems to be great scope for collecting other information from establishment-level datasets. Economic historians will never have datasets like the Census' Longitudinal Business Database that include matched employer and employee datasets, but there is little doubt that there remain numerous creative uses pairing the COM with other data sources. These pairings can help fill in gaps with the COM. For example, one drawback of the nineteenth century COMs is their low frequency. An establishment is, at best, observed every 10 years making it unlikely that any establishment will be observed in multiple COMs. One possible way to fill in this gap would be to use the records from Dun & Bradstreet, which was a credit rating agency at the time. The information beyond existence of an establishment in these volumes, which actually covers all businesses, not just manufacturing, are limited to variables for credit rating and an estimate of net worth. Still, being able to identify when an establishment exits and even these somewhat meager financial variables would be tremendously useful. Hansen and Ziebarth (2017) do this for the Great Depression.

Another way in which matching other sources would be useful is in providing information not covered by the COM. For example, the COM is sorely lacking when it comes to financial information on the establishments beyond a question about capital invested in the nineteenth century COMs. One possibility would be linking to sources such as Moody's Manuals that would cover the largest establishments with bonds issues in financial markets. These records have very detailed information on the maturity of bonds as well as the amount. For example, Benmelech et al. (2016) examine the effects on employment of those businesses that had the unfortunate occurrence of having a bond come due during the Depression.

The present authors are optimistic that even though economic historians have been working with these schedules for nearly 30 years now, the best is yet to come. Digital cameras, cheap data storage, and outsourced (and perhaps in the near future, automated) data entry have revolutionized economic history, and this looks likely to continue far into the future.

Decolonizing with Data

The Cliometric Turn in African Economic History

Johan Fourie and Nonso Obikili

Contents

Abstract

Our understanding of Africa's economic past – the causes and consequences of precolonial polities, the slave trade, state formation, the Scramble for Africa, European settlement, and independence – has improved markedly over the last two decades. Much of this is the result of the cliometric turn in African economic history, what some have called a "renaissance." While acknowledging that cliometrics is not new to African history, this chapter examines the major recent contributions, noting their methodological advances and dividing them into four broad themes: persistence of deep traits, slavery, colonialism, and independence. We conclude with a brief bibliometric exercise, noting the lack of Africans working at the frontier of African cliometrics.

Introduction

Africa was not always the poorest continent. Although by 2016, Sub-Saharan per capita incomes (at 1632 constant 2010 US$) was the lowest of the seven major world regions (The World Bank 2017),[1] this was not true, at least for certain parts of sub-Saharan Africa, only five decades earlier. This is demonstrated in an award-winning *Journal of Economic History* – article by Dutch scholars Ewout Frankema and Marlous van Waijenburg - a paper that has done much to showcase the contribution that quantitative African economic history can make to improve our understanding of Africa's development path. Frankema and Van Waijenburg show that mid-twentieth century urban unskilled real wages were well above subsistence levels, rising significantly over time. They also show that in parts of West Africa and Mauritius, wages were considerably higher than those of Asian laborers at the same time (Frankema and Van Waijenburg 2012).

We also have good reason to suspect that Africa was not the poorest continent five centuries earlier. In what is now a seminal contribution, Acemoglu et al. (2002) famously described a "reversal of fortunes"; the dense populations in parts of precolonial sub-Saharan Africa suggested high living standards around 1500, on par or even above living standards elsewhere. After the onset of the Industrial Revolution in Europe and then North America, and the consequences of colonization, these fortunes were reversed (Acemoglu and Robinson 2010).

What, then, were the reasons for the demise of Africa's comparative fortunes? Where and when did living standards rise, and why did it falter? What inhibited Africans from reaping the benefits of the technological and institutional innovations of the last two centuries? And, given the continent's existing low living standards, to what extent can African economic history inform contemporary policy-making?

These are only some of the questions that have sparked a "renaissance" in African economic history over the last decade (Austin and Broadberry 2014). A new generation of economists and economic historians are rewriting African economic history, aided by larger datasets and innovative empirical techniques (Fourie 2016). This is a sharp turnaround from the "recession" in African economic history scholarship that began in the 1980s, the result of formalization in economics, the cultural shift in history, and the "Afro-pessimism" related to the poor economic performance of many African countries (Collier and Gunning 1999; Hopkins 2009;

[1]Only slightly below per capita income in South Asia, at $1690.

Austin and Broadberry 2014). It is therefore no surprise that with the rise in Africa's fortunes post-2000, and with the expectation of a demographic dividend in the coming century[2], interest in understanding Africa's economic past is at an all-time high. To give one example: in the period 1997–2008, only 10 papers on Africa were published in the leading five economic history journals. Since then, 35 papers have appeared.

The "renaissance" has been characterized by two approaches. The "history matters"-school usually seek to establish a causal relationship between a variable in the (deep) past – like settler mortality in the case of Acemoglu et al. (2002) and an outcome variable in the present (or recent past). These approaches rely on rigorous econometric techniques, seek to establish singular causal relationships, and typically use already-published source material, such as the Roome map, the Murdock Atlas, or FAO crop suitability indicators, instead of collecting new primary materials from archives. It mainly exploits within-African spatial variation in development outcomes at one point in time rather than fluctuations and trends across time. In the econometric jargon, these are "small T, large N" studies.

By contrast, the "historical reconstruction"-school typically seeks to fill gaps about our knowledge of Africa's economic past, such as long-term trends in population, taxation, wages, inequality, biological standards of living, education, social mobility, etc. Frankema and Van Waijenburg's (2012) contribution is an excellent example of this approach. In these studies, historical accounting and basic quantitative methods are often preferred to econometric techniques that allow for causal interpretation. Although these studies are also comparative (British versus French, settler vs. peasant economies), their comparisons typically have a fairly small N. In other words: small N, large T.

This chapter will showcase the breadth and depth of both schools, noting, in particular, the use of cliometric analysis in understanding the causes and consequences of African historical development. We first discuss the latest evidence on Africa's fluctuating fortunes. We then turn to the possible explanations for the divergence of African economies in the late twentieth century. These include factors and events deep in African history, including the spread of agriculture, disease, and cultural attributes. Slavery in Africa has received much attention as a cause for Africa's slow growth – and we review the literature on that in section four. In section five, we review the colonial impact of missionaries, settlers and the rise of post-colonial states, and its contribution to African economic performance. Finally, we discuss African economic history scholarship. Who gets to write about Africa's economic past? We conclude that more needs to be done to draw African scholars into the field.

[2]Today, one out of six people on Earth live in Africa. That is likely to increase to one in four in 2050, and to one in three by 2100. See Pison (2017).

Fortunes, Reversed and Revised

Africa was not always the poorest continent but measuring its fluctuating fortunes has not been easy (Jerven 2018). The lack of written records, especially for the precolonial period, complicates any long-run analysis and has forced economic historians to find creative approaches to measure the trajectory of living standards across time.

Unreliable population estimates, especially for the precolonial period, is one example of the difficulty of plotting continent-wide historical living standards. Frankema and Jerven (2014, p. 908), in an attempt to backwardly project sub-Saharan population estimates, conclude: "For the pre-colonial period the empirical evidence is so thin that it suffices to point to Thornton's work on baptismal records from missionaries in the kingdom of Kongo. The colonial censuses are in turn widely discredited, and therefore not used as authoritative benchmarks, and while the population in post-colonial Africa is better recorded, census taking has remained uneven, irregular, and incomplete." Despite these shortcomings, Frankema and Jerven (2014) calculate that sub-Saharan Africa housed 240 million people in 1950. They then rely on population growth rates of other regions, notably South-East Asia, to arrive at a population estimate of 100 million in 1850. This is in sharp contrast to earlier revisions by Manning (2010), who had used Indian population growth rates to calculate a much higher precolonial population number for sub-Saharan Africa. Figure 1 compares the two revised estimates.

Getting population numbers right is necessary to understand the process of economic development in Africa. Population density is frequently used as a proxy for precolonial prosperity; more densely populated areas, it is assumed, live off a greater surplus (Acemoglu et al. 2002). But as Frankema and Jerven note, population

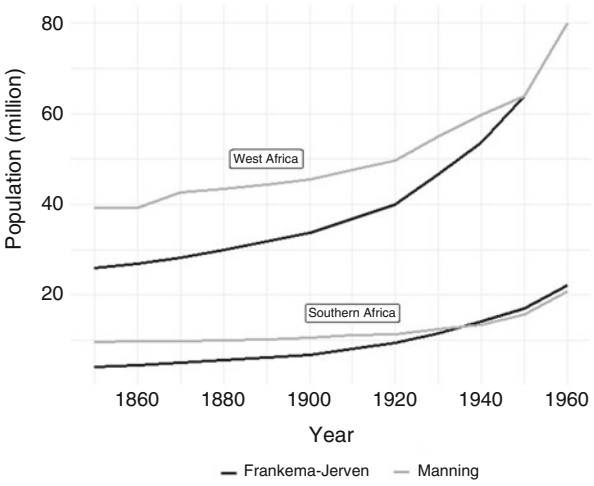

Fig. 1 Population size for Southern and West Africa. (Source: Frankema and Jerven (2014), redrawn)

numbers, even into the colonial era, may be severely biased and thus result in incorrect assertions about economic outcomes. Fourie and Green (2015) offer one example. They combine household-level settler production in the eighteenth-century Dutch Cape Colony with anecdotal accounts about Khoesan farm laborers to show that the Khoesan, while not formally recorded by the colonial authorities, was an important component of farm labor on settler farms. By obtaining more accurate population numbers, Fourie and Green (2015) show that previous research had overestimated slave productivity, social inequality, and the level of gross domestic product.

Gross domestic product, of course, provides a far more reliable picture of the rise and fall of living standards than mere population numbers. But such estimates are notoriously unreliable, even today. Morten Jerven (2010 p. 147), analyzing historical gross domestic product (GDP) estimates of African territories, agrees: "Data on the post-colonial period are less reliable than is commonly thought." In a widely acclaimed book, Jerven (2013) warns against the uncritical use of postcolonial GDP statistics in cross-country regressions, noting the errors and biases in the sources from which these estimates are generated. For these reasons, and despite some attempts to construct historical GDP series of African countries or regions (Fourie and Van Zanden 2013; Bolt and Van Zanden 2014; Inklaar et al. 2018), few African countries can boast a long-run GDP series.

In the absence of reliable GDP statistics, wages offer an alternative. Frankema and Van Waijenburg (2012, p. 896) note that real wages have "the advantage that they better reflect the living standards of ordinary African workers... they focus on the purchasing power of African laborers leaving aside the significantly higher income levels of European settlers and/or Asian migrant workers." While they were not the first to calculate real wages in Africa (Bowden et al. 2008; De Zwart 2011; Du Plessis and Du Plessis 2012), they were the first to do so across several countries and for multiple years of the colonial period. Using a standardized basket of goods to calculate real wages (Allen et al. 2011, p. 922), their results were the first to reveal the unexpectedly high relative living standards of West Africans compared to unskilled laborers in Asian countries during most of the colonial period, a result, they suggest, that calls "for a reinterpretation of the path-dependence nature of African economic development."

One concern is that their results only capture urban laborers. De Haas (2017) reconstructs typical farm size, production, and income to calculate real income from farming activities in Uganda. His novel approach suggests that rural farmers, similar to their urban unskilled counterparts, were living well above subsistence levels at a level remarkably constant over time. De Haas (2017) also shows that during the 1950s and 1960s, urban wages and rural incomes strongly diverged. Internal and external political pressures in the wake of independence drove urban wages upwards, but cash crop prices and resultant rural incomes did not experience a similar sustained improvement. Increasingly, urban laborers became an economically privileged group. If the experience of Uganda can be generalized, the large rural-urban income gap that characterized many postcolonial African economies

may find its roots in this period. Bossuroy and Cogneau (2013) use backward projection of present day household survey data to show that rural-urban income gaps were particularly large in three former French colonies compared to three former British colonies. Cohort analysis, as employed by Bossuroy and Cogneau (2013), is an innovative way to uncover trends during the late-colonial and post-colonial period.

In response to the poor aggregate data quality of African economic history, an exciting development is the turn to a "history from below," or the use of individual-level records (Fourie 2016). More precise measures of income, wealth, and production are available, for example, in probate inventories and tax censuses. These records are expensive to transcribe but are invaluable in studying the transfer of wealth across generations, notably in populations where almost all individuals are farmers. Fourie (2013) uses more than 2500 probate inventories of the eighteenth-century Dutch Cape Colony to show that earlier depictions of the Cape as a "social and economic backwater" are not supported by the empirical evidence. These records are, unfortunately, limited to settlers only.

Economic historians are becoming more creative. Individual-level records that survive in government or church archives, like military attestation records or baptism and marriage records, encoded information that can now be used for reasons orthogonal to its original purpose, circumventing the potential biases of the colonial authorities. Church records, for example, allow investigations into social mobility (Meier zu Selhausen et al. 2017; Cilliers and Fourie (2017) and gender inequality (Meier zu Selhausen 2014; Meier zu Selhausen and Weisdorf 2016). There are several new, large research projects underway to digitize and transcribe more of these and similar records.

Attestation forms often include the height of recruits. Human height, or stature, is widely used as a proxy for living standards, as it captures not only genetic traits but also environmental conditions like access to nutrients and the disease environment (Steckel 1995; Baten and Blum 2012). While stature was first used to document the living standards of Africans shipped to the Americas as slaves (Steckel 1979; Moradi and Baten 2005; Moradi 2010) were the first to use African heights, obtained from twentieth-century household surveys, to plot living standards and inequality on the continent. The challenge was to find evidence for the early colonial and even precolonial period. Moradi (2009) turned to individual-level records to do this. Using the attestations of Kenyan army recruits, Moradi (2009, p. 719) finds an upward trend during both the colonial and postcolonial period. His results suggest that "however bad colonial policies and devastating short-term crises were, the net outcome of colonial times was a significant progress in nutrition and health." More recently, Mpeta et al. (2018) have used a combination of military attestations, cadaver records, and household surveys, to plot the changes in the heights of black South Africans over the twentieth century. As earlier sources that measure height are uncovered and transcribed, the living standards of Africa's diverse people will be traced deeper into history.

Deep Roots of Divergent Development

The lack of empirical evidence at the individual level for the precolonial period has not prevented a new generation of social scientists from investigating how deep historical factors still shape African economic development today. In fact, the ability to now spatially map environmental, political, and cultural factors in deep history and overlay it with contemporary outcomes allow economists to expose correlations – and even causality – that were simply not possible in the age before sufficient computing power, accessible software and, most importantly, rigorous econometric techniques. The deep roots of divergent development have indeed attracted most interest from cliometricians of Africa.

These deep roots, some argue, go back as far as the migration of *Homo sapiens* out of Africa 70,000 years ago. In a seminal, if controversial study, Ashraf and Galor (2013) present empirical results that show an inverted-u correlation between the distance from Ethiopia – considered the route by which *Homo sapiens* left Africa – and incomes today. They argue that too much and too little genetic diversity is bad, which is why Native American and African populations have lagged behind Europe and Asia.

In response to Ashraf and Galor, anthropologists and other social scientists noted several inconsistencies in their data quality and assumptions (Guedes et al. 2013). They note, for example, the poor data quality used for calculating population densities in 1500 – Ashraf and Galor use figures, they show, that are largely outdated. Ashraf and Galor also make assumptions inconsistent with research in other fields; Guedes et al. (2013) point to the lack of research that links genetic diversity to general diversity.

Some have attempted to replicate Ashraf and Galor's methods in different settings. Using African countries only, Asongu and Kodila-Tedika (2017) find contrasting results, suggesting that "poverty is not in the African DNA". Others have used the migratory distance, the instrument used by Ashraf and Galor, to investigate outcomes like cultural traits instead of genetic inheritance (Gorodnichenko and Roland 2017; Desmet et al. 2017), or have used more precise genetic traits, like DRD4 exon III allele frequencies, to infer its impact on economic development (Gören 2017). As more precise genetic information becomes available, especially in Africa, with its diverse genetic composition, deep history as reflected in genetic inheritance is likely to be a fertile area for new research.

The reason for Africa's genetic diversity is, inter alia, the result of a rich variety of environmental conditions and its effect on natural selection. But it was not only humans that evolved to fit their environment. Insects did too. The TseTse fly, found in tropical areas throughout Africa but not on any other continent, transmits a parasite that is harmful to humans and lethal to livestock. Alsan (2014) is the first to investigate empirically the long-run effects of the TseTse fly on economic outcomes. She first shows, repeated in Fig. 2, that the TseTse fly was predominantly found in the regions most suitable for agriculture. Alsan then demonstrates that the presence of the TseTse fly reduced the agricultural surplus of farmers, as they were

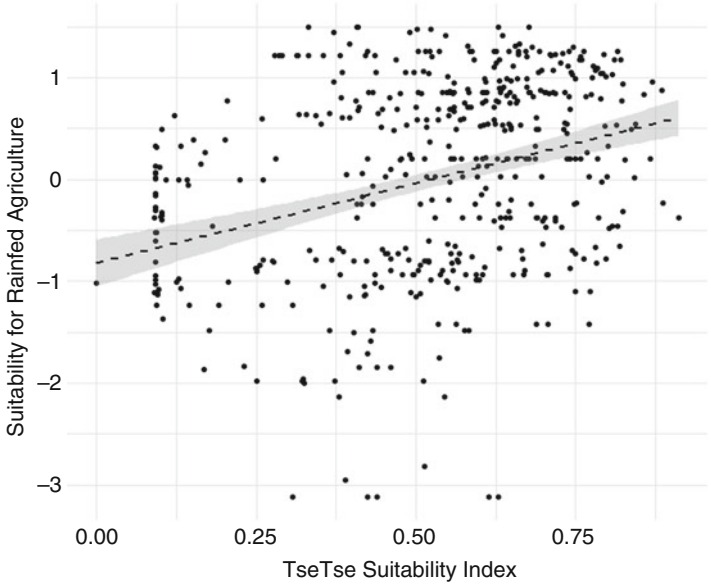

Fig. 2 Correlation between rainfed agriculture and TseTse fly suitability. (Source: Alsan (2014), redrawn)

less likely to use domesticated animals and the plow, had lower population densities, and were less politically centralized.

Climate and environmental conditions also shaped the type and speed of agricultural adoption. Michalopoulos et al. (2016) find that individuals from ethnicities that derived a larger share of subsistence from agriculture in the precolonial era are today more educated and wealthy. The reasons for this, they suggest, are differences in attitudes and beliefs and differential treatment by others. One alternative mechanism through which these early agricultural practices may persist is the complexity of precolonial political regimes that resulted from them.

Gennnaioli and Rainer (2007) show that the strength of precolonial political institutions was an important factor in the capacity of colonial and postcolonial governments' provision of public goods. In a groundbreaking study, Michalopoulos and Papaioannou (2013) show how the spatial distribution of precolonial ethnicities affects contemporary economic performance. Areas that had higher levels of political centralization in precolonial times today exhibit more economic activity, as proxied for by satellite images of light density at night. This association, they find, is independent from geographic features or other observable ethnic-specific cultural and economic variables.

The persistence of political centralization – or formal institutions – and their interaction with attitudes and cultural norms and beliefs – or informal institutions – within Africa is the subject of a large recent research project on the Kuba Kingdom of Central Africa. Lowes et al. (2017) conduct experiments on

descendants of individuals that lived within and just outside the borders of the seventeenth-century Kuba Kingdom, a centralized state with an unwritten constitution, a judicial system with courts and juries, a police force, taxation, and public goods provision. The experiments – the Resource Allocation Game and the Standard Ultimatum Game – are performed on 499 individuals. One subgroup of these individuals are the descendants of the Woot, a group of culturally similar people that had lived both inside and outside the Kuba Kingdom. Lowes et al. find that the descendants of those groups that settled outside the Kuba Kingdom are today *more* likely to have strong norms of rule-of-law and a lower propensity to cheat than the descendants of those that lived within the Kuba Kingdom, with its strong formal institutions. They argue that this is consistent with a "model where endogenous investments to inculcate values in children decline when there is an increase in the effectiveness of formal institutions that enforce socially desirable behavior" (Lowes et al. 2017, p. 1065).

Reflecting their novel methodological contributions, both the Michalopolous and Papaioannou (2013) and Lowes et al. (2017) studies are published in *Econometrica*. They reflect the frontier of cliometrics in Africa; first, in using innovative contemporary outcome variables – satellite images and experiments – and, second, their careful use of *causal* interpretations. Michalopoulos and Papaioannou (2013, p. 114) explicitly acknowledge that their evidence should not be interpreted causally – "(s)ince we do not have random assignment on ethnic institutions, this correlation does not necessarily imply causation." While Lowes et al. (2017, p. 1089) can exploit the random assignment of those treated in the Kuba Kingdom and those outside its borders, they are careful to note that their experiment can only test the "causal impact of a particular bundle of state institutions." The exercise of causally linking anthropological evidence of the precolonial period to both formal and informal institutions today are fraught with difficulties. Carefully selected instruments may offer a solution. Next we will see how this strategy was used to investigate the consequences of Africa's most infamous historical episode: the Atlantic slave trade.

The Slave Trades: Causes, Consequences, and Controversies

Historians of Africa have long studied the devastation caused by Africa's slave trades. With an approximate 12 million Africans shipped in the Atlantic slave trade, and another combined 6 million in the 3 other trades – the trans-Saharan, Red Sea, and Indian Ocean – between 1400 and 1900, the population of Africa, according to some estimates, was only half of what it would have been without the slave trades (Manning 1990).

The study of Africa's slave trades was one of the first topics in African economic history that made use of large data sets and statistical analyses (Eltis 1977; Eltis 1987; Inikori 1976). A generation later, and with the advancement of computing power and easily accessible statistical software, the African slave trades remains one

of the most studied topics in African history. We separate these studies into two main focus areas: first, the study of the trade itself, its size, causes, and mechanics, and, second, its consequences.

Demand and supply explain why the Atlantic slave trade, by far the largest of the overseas trades, arose in the sixteenth century, and why the majority of slaves was of African origin. On the demand side, African labor was highly productive in much of the New World, "discovered" and colonized by Europeans from the late fifteenth century. Eltis et al. (2005, p. 696) calculate that, in the Caribbean over the period 1674–1790, "total factor productivity in slave agriculture increased markedly, and the demand for slave labour increased by a factor of at least four."

On the supply side, Africans' resistance to tropical diseases and their proximity to the Americas made them more attractive than European, Indian, and Chinese laborers (Bertocchi and Dimico 2014; Angeles 2013). This was possible, Angeles (2013) argues, because of the low costs of slave capture in Africa, which was mostly undertaken by Africans themselves. Because slaves were mainly obtained from different ethnic groups, Africa's ethnic fragmentation, itself the consequence of few large states and limited penetration of any of the world's major religions, is one reason for the low cost of slave labor on the continent, and the profitability of the slave trade.

Climatological conditions also affected slave supply. Fenske and Kala (2015) find that more slaves were exported in colder years along the African coast. This is because lower temperatures reduced mortality and raised agricultural yields, lowering the costs of slave transport. Their results suggest that a temperature increase of one degree celsius reduced annual exports by roughly 3000 slaves per port. Rainfall, or the lack thereof, also mattered. Levi Boxell (2017) shows that nineteenth century drought increased the number of slaves exported from a given region. He also uses geocoded data on nineteenth century African conflicts to show that drought increased the likelihood of conflict, but only in the slave exporting regions of Africa.

European technology, notably guns, played a key role in the slave trade too. Whatley (2017) use a Vector Error Correction Model of annual slave and trade statistics to show that gunpowder imports and slave exports were co-integrated in a long-run relationship. Gunpowder imports "produced" additional slave exports, and additional slave exports attracted additional gunpowder imports. He makes use of several placebo tests, as well as an instrumental variable of excess capacity in the British gunpowder industry to support the Gun-Slave hypothesis.

The slave trade itself was highly inefficient. Dalton and Leung (2015) find that voyage output, measured as the number of slaves that disembarked in the Americas, varied substantially across voyages within a European country. The dispersion in output was the highest across Portuguese voyages, lower across French voyages, and lowest across British voyages. Dalton and Leung (2015) then calculate the total factor productivity gains had the dispersion of distortions disappeared. Their results show that the dispersion of distortions had the smallest damage to total factor productivity in Great Britain, followed by Portugal, and then France.

While historians are interested in the causes of African slavery, economists tend to focus on its consequences.[3] What had been difficult to ascertain, however, was the extent to which the slave trades were responsible for the poor economic performance of many African countries by the late twentieth century. Nathan Nunn's job market paper, published in the *Quarterly Journal of Economics* in 2008, was a first attempt at a *causal* interpretation (Nunn 2008). Nunn first shows that countries that had higher numbers of slaves removed are also poorer today. He then makes two arguments in favor of a causal relationship: first, from historical and basic descriptive evidence, it would seem that it was the more prosperous regions, and not the poorest regions, that selected into the slave trades. The novelty of Nunn's contribution, however, rests on his second approach, the use of an instrumental variable. His instrument is the distance from each African country to the slave markets in the Americas: the greater the distance, the lower the number of slaves shipped from that African country. This requires the author to make the assumption that the distances are unrelated to economic outcomes today, except through the effect of the slave trade. Nunn's IV-estimates support the OLS-estimates and his argument: the slave trade still had a negative effect on African economies in the late twentieth-century.

Nunn's causal interpretation ignited interest in identifying the *mechanisms* that explain the persistent effect of slavery he had found. Nunn himself first attempted to address this in the final section of his 2008 paper, noting ethnic fractionalization and state development as two plausible explanations. But it would be his later work, on ruggedness and trust, that would offer more sophisticated explanations for slavery's persistence.

With Diego Puga, Nunn postulated that one mechanism through which the slave trades could affect present-day outcomes is geography (Nunn and Puga 2012). Rugged terrain, they argue, afforded protection to those being raided during the slave trades. Many Africans thus escaped to rugged areas, terrain that is "tough to farm, costly to traverse, and often inhospitable to live in" (Nunn and Puga 2012, p. 20). These areas, however, while offering protection, were less likely to generate large surpluses or offer better trade opportunities. Africans' economic prospects were thus stymied by their rugged location, a consequence of the centuries' long slave trade.

Soon after Nunn and Puga (2012), Nunn published another paper, this time with Leonard Wantchekon, that postulated a second mechanism to explain the persistent effects of the slave trade. Nunn and Wantchekon's "Slave Trade and the Origins of Mistrust in Africa," published in the *American Economic Review* (2011), argues that the greater involvement of the slave trade resulted in lower levels of trust, as seen in Fig. 3, and that these cultural norms persisted over time. They use the distance of ethnic groups from the coast at the time of the slave trade as an instrument for the number of slaves taken. A number of falsification tests that examine the reduced-form relationship between distance from the coast and trust inside and outside of Africa suggest that the exclusion restriction is satisfied. Nunn and Wantchekon

[3]See Bertocchi (2016) for an extensive review of the slave trade legacies.

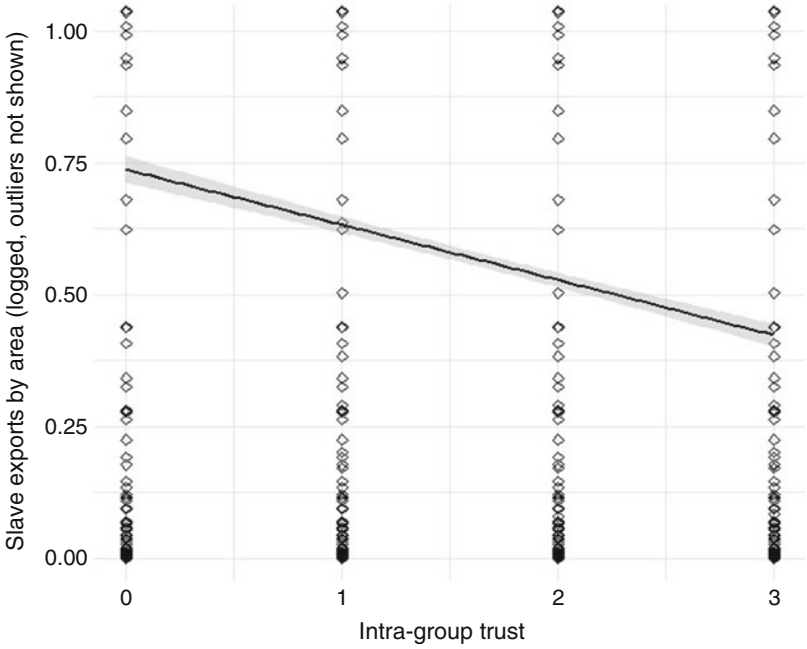

Fig. 3 Correlation between slave exports and intragroup trust. (Source: Calculated from Nunn and Wantchekon (2011))

(2011, p. 3223) explain: "Places farther from the coast had fewer slaves taken, and therefore exhibit higher levels of trust today. If distance from the coast affects trust only through the slave trade, then there should be no relationship between distance from the coast and trust outside of Africa, where there was no slave trade. This is exactly what we find."

That the slave trade causally affects trust several centuries later is an important empirical finding, but it still does not explain the mechanism – or channel – that is responsible for this persistence. Nunn and Wantchekon (2011) put forward two possible explanations. First, the slave trade altered the cultural norms of the ethnic groups exposed to it, making them less trusting of others. Second, the slave trade may have caused the deterioration of legal and political institutions. Individuals in heavily affected regions may be less trusting today because their leaders and institutions are less trustworthy. The authors conduct three exercises to measure the size and significance of each of these two mechanisms. All three exercises show that both channels are important, but that the internal channel – the effect through cultural norms – is at least twice as large as the external channel.[4]

[4]In a replication study with an updated dataset, Deconinck and Verpoorten (2013) confirm the authors' results.

Did the slave trade perhaps bring beneficial outcomes for African traders and farmers? Rönnbäck (2015) argues that the demand for provisions from the external slave trade was too small to have any substantial effect on African commercial agriculture. Focusing on the Gold Coast, he shows that some African laborers located in the coastal European enclaves experienced an initial boost to living standards, but then their conditions declined. It was only a small group of highly privileged employees that benefited consistently, exacerbating social stratification. Dalrymple-Smith and Frankema (2017) agree. Exploring the provisioning strategies of 187 British, French, Dutch, and Danish slave voyages conducted between 1681 and 1807, they show that during the eighteenth century, an increasing share of the foodstuffs required to feed African slaves were taken on board in Europe instead of West Africa. Although there was considerable variation in provisioning strategies among slave trading nations and across main regions of slave embarkation, the average slave trade-induced demand impulse was weak.

The focus, however, has been on the long-term persistent consequences of the trade, and the mechanisms through which the shock of slavery persists into the present. Education is one example. Using slave data and colonial censuses of Nigeria and Ghana, Obikili (2015) finds a negative and significant correlation between slave export intensity before the colonial era and literacy rates during the colonial era. Using contemporary data, he shows that this relationship persists into the present.

Violence and conflict, and how it reinforces itself in a low-level equilibrium, is another channel. Fenske and Kala (2017) find a discontinuous increase in conflict after 1807 in areas affected by the slave trade. In areas where the slave trade declined, they argue, political leaders resorted to violence to maintain their influence. The slave trade shifted south and east, associated with an increase in violence in those regions. The slave trade also resulted in political fragmentation. Although this channel was first proposed by Nunn (2008), it has found additional support in Obikili (2016). He shows that villages and towns of ethnic groups with higher slave exports were more politically fragmented during the precolonial era, and that this fragmentation is reflected in political outcomes today.

And then there are the myriad social beliefs, norms, and other informal institutions that were affected. Obikili (2016) shows, for example, correlations between slavery, political fragmentation, and the propensity to bribe or be corrupt. The slave trade also helps to explain different rates of polygamy in western and eastern Africa. More male slaves were exported from western Africa, while more female slaves were exported in the Indian Ocean trade. Dalton and Leung (2014) link historical slave trade data with current rates of polygamy and find that the transatlantic slave trades cause polygamy at the ethnic group level while the Indian Ocean slave trades do not.

And its long-term consequences can even affect outcomes like access to finance. Pierce and Snyder (2017) show that the slave trade is strongly correlated to reduced access to the formal and trade credit markets. The effect is particularly strong for capital investment in smaller firms that are not business groups. Because the slave trade cannot explain any other business obstacle, the authors argue that its effects persist through informal institutions like mistrust and weakened institutions. Levine

et al. (2017, p. i) confirm this channel, noting that the "slave trade is strongly, negatively related to the information sharing and trust mechanisms but not to the legal mechanism."

In the end, Nunn's cliometric contribution not only sparked interest in the consequences of African slavery, but also caused some debate in the field of African economic history, notably from historians concerned with the quality of the source material (Reid 2011; Austin and Broadberry 2014). Gareth Austin (2008), for example, while welcoming the new interest in Africa's past, cautioned against the "compression of history," the practice of conflating different data-generating processes across decades or even centuries. Anthony Hopkins, too, welcomed the new approaches for "their boldness, their freshness and their potential for re-engaging historians in the study of Africa's economic past" but criticized them on methodological and empirical grounds (Hopkins 2009, p. 155). He notes, in particular, the poor data quality – "the population figures they assemble ... are insufficiently robust to carry the explanatory weight placed on them" (Hopkins 2009, p. 166) and then notes that the "regression analysis is only as robust as the numerical evidence it draws on" (Hopkins 2009, p. 168).[5]

Debates about data quality and source bias are not limited to slave data, of course. Colonial-era written records would introduce new forms of measurement error and bias that would have to be accounted for.

Colonialism and Independence

The age of slavery was followed by the age of colonialism. By the nineteenth-century, European missionaries and explorers were entering deeper into the African interior in search of souls and treasure. They were soon followed by settlers and imperialists, claiming large parts of the continent for European powers.

There are at least two economic questions that deserve our attention: First, what explains the emergence of colonialism? Colonialism – or colonization – was, of course, not one thing**.** It was a heterogenous *process* of political, economic, and psychological subjugation and dispossession with the aim of advancing the political and financial power of the colonizer.

But why did it emerge when it did, and what explains the variety of colonial regimes? A second question, perhaps more difficult to answer, is: What were its consequences? What did missionaries do, and how would that shape Africans' attitudes, beliefs, and freedoms? What was the response to the arrival of European settlers, with new crops, technologies, and diseases, and how did it affect local production systems, labor markets, and demographic trends? These are difficult

[5]Hopkins' empirical concerns would trigger a response from James Fenske, then a young Economics PhD graduate from Yale University. Fenske cited the interest in African economic history that Nunn's work had generated, noting that these studies are "not distinguished by their broad theories, but by their careful focus on causal inference"(Fenske 2010, p. 177). Both Hopkins and Morten Jerven responded, with another response by Fenske (Hopkins 2011; Jerven 2011; Fenske 2011).

questions to answer, of course, because, as Heldring and Robinson (2012, p. 4) observe, "we have to think about what the trajectories of African societies would have been in the absence of colonialism." Such counter-factual thinking requires us to be precise about our assumptions and honest about the potential biases. This is where the rigor of cliometrics can be of great value.

To elucidate these two questions, we first consider the effect of missionaries, take a detour to preindustrial South Africa, and then consider the Scramble for Africa and colonial era. Christian missionaries brought profound changes to African societies.[6] New religious beliefs are, of course, the most obvious change. Nunn (2010) shows that Africans who inhabit regions where European missionaries settled are today more likely to be Christian. In other words, missionaries seem to have had the effect that was, ostensibly, their main intention – to convert souls. But missionaries also brought education. Gallego and Woodberry (2010) use regional data for 180 provinces in African countries to show that Protestant mission stations in the past are more correlated with schooling variables today than similar measures for Catholic mission stations. The reason, they argue, is the increased competition between Protestant and Catholic stations within Catholic colonies. Although the overarching aim of mission stations may have been for religious conversation, Frankema (2012) uses the Blue Books to show that prior to 1940, mission stations explain nearly all of the variation in school enrollment rates for African countries. Says Frankema (2012 p 336): "Christian education was effective in leading indigenous people into the Christian faith and essential to raise the number of converts over time, because educated converts helped spread the Christian message in the local vernacular."

Missionaries not only created a demand for reading but also the ability to supply books. Cagé and Rueda (2016) build a geocoded dataset of Protestant missions and their printing investments in 1903. They show that regions that were close to mission stations with an early printing press have higher newspaper readership, trust, education, and political participation today. The concern, of course, is that missionaries are not randomly assigned across the continent. Most authors acknowledge this shortcoming but mostly assume that it is unlikely to affect their results. And even if placement was random, the mechanism of persistence remains unclear. Was it indeed early educational attainment that paved the way for current generations to have higher years of schooling and incomes, or were there are unobservables that may explain the correlation? Fourie and Swanepoel (2015) use mission stations in South Africa to argue that migration may explain much of the persistence. Mission stations attracted the best and brightest, often from afar. Once migration is controlled for, they show, the effects of early education disappears. Another concern is the use of missionary maps that are partial to European missionaries. In new work, Jedwab et al. (2018) show that a more careful analysis of mission activity in colonial Ghana

[6]Missionaries had already arrived in South Africa during the eighteenth-century, setting up stations like Genandendal aimed at converting indigenous Khoesan people, but the expansion of Christian missionaries in South Africa and throughout the continent would mostly be a late nineteenth-century phenomenon.

reverses many of the research findings when a map of only European missionaries are used. What is clear is that much more careful work is required to ascertain not only the impact of missionaries but also the mechanism through which the impact persists.

Before the Scramble for Africa at the end of the nineteenth century, Europeans had already settled the southern tip of the continent. As the Dutch East India Company expanded their reach in Asia in the seventeenth century, ship traffic around the Cape of Good Hope increased rapidly. They needed refreshments of fresh water, food, and fuel, and so the Lords XVII decided to establish a station in Table Bay that would supply passing ships. In April 1652, a motley crew of officials and workmen arrived to build a fort, farm vegetables, and trade meat with the indigenous Khoesan. The plan was poor, and the Company was soon forced to settle more land and release workmen to become free farmers. Colonization at the southern tip of Africa had begun.

Fourie (2013) uses probate inventories to ascertain the wealth of the settlers at the Cape. He finds evidence of "remarkable wealth"; the average Cape farmer owned, for example, 54 head of cattle and 350 sheep. The high level of wealth was both a consequence of demand for Cape goods (Boshoff and Fourie 2010) and low production costs, notably the acquisition of land at low cost and the use of imported slaves as farm labor. Human capital and strong property rights, in both land and slaves, also mattered (Fourie and Von Fintel 2014; Fourie and Swanepoel 2018). But access to inexpensive labor was critical to the success of the Cape economy. Malaysia, Indonesia, India, Madagascar, and Mozambique were the main places of origin for Cape slaves. Combining court records with slave records, Baten and Fourie (2015) calculate numeracy rates for the different regions of slave origin, providing an estimate of comparative living standards in the eighteenth-century Indian Ocean economies.

For most of sub-Saharan Africa, though, the colonial experience is tied to the Scramble for Africa at the end of the nineteenth century. A first, obvious question is about the timing of the Scramble. Frankema, et al. (2017) use a new trade dataset to show that nineteenth-century sub-Saharan Africa experienced a terms-of-trade boom in the five decades before the Scramble for Africa (1835–1885). Given the larger weight of West Africa in French imperial trade, the authors argue, it made economic sense for French conquest of the interior of West Africa.

Even though a more systematic process of exploration and annexation was well under way by the 1860s, it would be the Berlin conference, organized by Otto von Bismarck from November 1884 to February 1885, that would embody European colonization in Africa. In a seminal paper, Michalopoulos and Papaioannou (2016, p. 1807) investigate one consequence of the Berlin conference, the arbitrary partitioning of land: "While the Berlin conference discussed only the boundaries of Central Africa (the Congo Free State), it came to symbolize ethnic partitioning because it laid down the principles that would be used among Europeans to divide the continent. The key consideration was to preserve the status quo preventing conflict among Europeans for Africa, as the memories of the European wars of the eighteenth and nineteenth century were alive. As a result, in the overwhelming

majority of cases, European powers drew borders without taking into account local conditions." They employ this exogenous shock as a "quasi-natural" experiment to assess the impact of ethnic partitioning on civil conflict. Using a dataset that reports georeferenced incidents of political violence between 1997 and 2013, they show that the likelihood of conflict is approximately 40% higher in areas where partitioned ethnicities reside as compared to homelands of ethnicities that have not been separated by national borders. In short: the arbitrariness of the colonial partitioning helps explain some economic and political outcomes today.

It is now widely agreed that colonialism had many undesirable economic and political consequences, most notably through its effect on institutions. Acemoglu et al. (2002) famously described a "reversal of fortunes" in global incomes between 1500 and 2000 – and that the *extractive institutions* of colonialism were one reason for this reversal. But what exactly these extractive institutions were, remains the subject of debate. Econometric techniques that allow causal inference can help. As discussed, Michalopoulos and Papaionnou (2016) show an effect working through the arbitrariness of colonial borders. Acemoglu et al. (2014) use a survey of village elders combined with regression analysis to show that the distribution of ruling families in Sierra Leone, first recognized by British colonial authorities, explain development outcomes today. Lowes and Montero (2016) use a geographic regression discontinuity design along former concession boundaries in the Congo Free State to show that one specific type of extractive institution – private companies that used violent tactics to collect rubber – have persistent negative effects on education, wealth and health outcomes today. Lechler and McNamee (2017) use spatial discontinuity of colonial rule within Namibia to show the effect of direct versus indirect colonial rule on democratic participation. Archibong (2018) shows that current ethnic inequalities are the result of historical heterogeneous federal government policies towards different groups in Nigeria.

In some colonies at certain times, European powers, mostly out of self-interest, invested in physical and social infrastructure. Railroads were one such investment. Herranz-Loncán and Fourie (2017) calculate that railways in the Cape Colony can account for between 22% and 25% of the increase in the Colony's labor productivity from 1873 to 1905. Jedwab and Moradi (2016) exploit the construction and eventual demise of colonial railroads in Ghana to study how colonial infrastructure affected later economic outcomes. They show that railroads had a large effect on the distribution of economic activity during the colonial era, and that these effects, despite the railroads falling into disuse, have persisted to date. Replicating the methodology for Kenya, they show how railways determined the location of European settlers, Asian traders, and the main Kenyan cities at independence (Jedwab et al. 2017). Despite the decline of the railways, the spatial distribution of the colonial era persists. Bertazzini (2018) finds similar spatial persistence for the road network built in Ethiopia by Italians between 1935 and 1940.

Education also improved, although, as we have seen, that was mostly as a consequence of missionary activity. Huillery (2009) shows that current educational outcomes in French West Africa have been more specifically determined by colonial investments in education than health and infrastructure. This is because of the strong

persistence of investment: "regions that got more at the early colonial times continued to get more" (Huillery 2009, p. 176). Cogneau and Moradi (2014) use the partition of German Togoland after World War I as a natural experiment to test the impact of British and French colonization. Data of recruits to the Ghanaian colonial army 1908–1955 allow them to show that literacy and religious affiliation diverge at the border between the parts of Togoland under British and French control as early as in the 1920s. This, they claim, is because of policy differences towards missionary schools.

Bolt and Bezemer (2009), on the other hand, argue that the impact on education was not driven only by missionary activity but also by broad exposure to Europeans and European-style education. The find that the colonial education influenced subsequent development and that was influenced by the density of the European population. Wantchekon et al. (2014) use the random allocation of regional schools in colonial Benin to assess the impact of colonial education on the descendants of those that first attended school. They find a significant effect on the first and later generations, as well as large village-level externalities: "Descendants of the untreated in villages with schools do better than those in control villages" (Wantchekon et al. 2014, p. 705).

Colonial governments also invested in health. Lowes and Montero (2017) use medical campaigns by French colonial governments to examine the effects on health attitudes and outcomes today. They show that in places were villagers were forcibly examined, inhabitants today have less trust in medicine, and World Bank projects in the health sector are less successful.

How costly, then, was colonization for the European powers? Huillery (2014) uses France as one case study. She shows that French West Africa took only 0.29% of French annual expenditures, of which only 0.05% was for development. West Africans, instead, carried the heaviest burden, disproportionately funding French civil servants' salaries as a share of local expenditure. Gardner (2012) came to the same conclusion for most of British Africa.

Decolonizing with Data

The data and cliometric revolutions have significantly improved our knowledge of Africa's economic past. There are at least two reasons for this. First, where African histories are largely based on colonial documentation and where such scholarship is often undertaken by non-Africans, the fear is that these histories could suffer from the implicit biases of both the source material and the researcher. Quantitative records often used for purposes orthogonal to its intended reason for collection – suffer less from such biases. Second, in areas where both quantitative and qualitative source material is weak or completely missing, economic historians have uncovered and used innovative alternatives. For example, climate data going back into the distant past can help explain the slave trade (Fenske and Kala 2017), or tree rings in Zimbabwe may help show how an Indonesian volcano caused a period of tribal warfare in early nineteenth-century Southern Africa (Hannaford and Nash 2016).

Such quantitative records help to "decolonize" African economic histories often distorted by the imprints of the colonial regime.

But a second aspect of "decolonization" is to encourage greater participation of scholars from the continent. African cliometrics is mostly a non-African field. To show the relative shortage of African scholars, we use data from ISI Web of Science (WoS) and Elsevier's SCOPUS database to conduct a simple bibliographic exercise. We make use of WoS and SCOPUS for the simple reason that they include information about the attributes of both the authors and the papers they have published in accredited scholarly journals.[7]

Because Economics journals also frequently publish Economic History papers, we take advantage of the available information on author names, paper titles, abstracts, and keywords as organized in WoS and SCOPUS to classify Economic History (EH) papers separately from mainstream Economics papers. To accomplish this, we build up a database of EH papers that include the words "economic history" or "history" in their title, keywords, or abstract, from a sample of journals. The rest we classify as ECON papers. We then use a random 70% (5643) of the EH and ECON papers to train a Support Vector Machine (SVM) machine learning algorithm on the words used in the respective titles, abstracts and keywords of the two groups. We use the remaining random 30% (2419) of the papers to test the prediction accuracy of the resulting algorithm. Below is the Confusion Matrix from the test indicating a 98% prediction accuracy for ECON papers with a 2% confusion for EH papers and 96% prediction accuracy for EH papers with 4% confusion for ECON papers (Table 1).

We then apply the algorithm to the 49,444 papers in a database of 17 Economic History journals[8] and the top 25 Economics journals published since 1992, and classify them as either ECON or EH. We obtain 18,835 EH papers with a 96% accuracy. We then write a function that selects from this list all the papers that mention Africa or any of the current or historical names of African countries in their titles, keywords, or abstracts. This leaves us with a list of 238 papers published in both Economics and Economic History journals. It is from this list that we compile

[7]In parallel to these two databases on research output, Google Scholar has risen to prominence lately. Unlike WoS and SCOPUS, Google Scholar gathers information about any published document – even those published as Working Papers. It therefore has a more extensive list of citations. It follows that the number of citations accounted for in this analysis will be significantly less than what may appear in a Google Scholar search.

an H-index and an Euclidean index of the top economic historians working on Africa.

It is important to note that our method is not perfect. Nunn and Wantchekon's (2011) paper on slavery and trust is, for example, classified by our algorithm as ECON rather than EH, despite the clear relevance to Economic History.[9] Despite these concerns, though, we believe that the analysis provides a fair reflection of the state of the field.

Table 2 reports the results for the top 20 authors in African economic history, ranked according to their Euclidean index (Perry and Reny 2016). Several trends are immediately apparent. Besides two authors affiliated with Stellenbosch University in

[9]We tried several versions of the algorithm, but because the word "History" is not included in either their title, abstract, or keywords, our algorithm fails to classify the paper as EH. For future work, it might be useful to include historical topics – like the Atlantic slave trade, or colonialism – as part of the training algorithm.

South Africa, the leading African economic historians are based outside the continent. Of the 18 scholars based outside, not one is African. This trend is mirrored in the citations of this chapter, with only a handful of African authors cited for their cliometric contributions. Fourie (2016) notes two ways to address this clear imbalance: First, more should be done to recruit African scholars to good PhD programs, notably those in the USA and Europe where most of the leading scholars are based. Second, more should be done to appoint qualified African scholars in these scholars' research programs – as postdocs or tenure-track faculty. Large research programs on African economic history funded by European or US donors still frequently lack African participants. Building stronger networks with African universities can help speed this process (Green and Nyambara 2015; Austin 2015).

Conclusion

The study of African economic history has received a much-needed resuscitation from the cliometric turn in economic history. The combination of innovative statistical techniques that allow for causal analysis, access to larger and more reliable data sets, a growing interest in the histories of developing regions, and the rising fortunes of many African economies have spurred interest in Africa's fluctuating fortunes, past and present. This chapter has provided an overview of the most important contributions of the last two decades.

More can be done, though, to attract African scholars into the field. The good news is that this seems to be happening. More than half of participants at the African Economic History Network Meetings in 2017 were African, many of them Masters or PhD students. A free textbook project, coordinated by Ewout Frankema, Ellen Hillbom, Ushehwedu Kufakurinani, and Felix Meier zu Selhausen is one attempt to expose younger scholars to African economic history. As African countries become wealthier and funding for tertiary education improves, the study of African economic history is likely to gain popularity. The future of African cliometrics hinges on the ability of the field to draw these young scholars into their networks and equip them with the scientific tools and academic freedom to explore the economic histories of their own continent.
