The pioneering contribution of Conrad and Meyer addressed a simple, straightforward question. Was slavery profitable? Their positive answer directly confronted a view on the economics of slavery then current. Despite the important work of historians such as Lewis Gray (1933) and Kenneth Stampp (1956), it was still widely taken for granted that American slavery had become economically moribund by late antebellum period, the decades of the 1840s and 1850s. The interpretation then prominent in the social sciences had been promulgated by Ulrich Bonnell Phillips in "The Economic Cost of Slaveholding in the Cotton Belt," a journal article published

in 1905 in *Political Science Quarterly.* Phillips was born in Georgia in 1877. Although he was a life-long Southerner, he taught history at the University of Wisconsin from 1902 to 1908. Later, he joined the faculty at the University of Michigan and then at Yale University. Phillips was a racist, an apologist for slavery, and (in his time) a distinguished professional historian. Following publication, he emerged as the leader of a now-discredited academic campaign designed to excuse slavery as a positive good, portray the enslaved as largely contented, and celebrate the Confederate cause as noble. Phillips' belief in the Lost Cause was so strong it led him to change his given name from Ulysses to Ulrich.

Phillips' principal thesis was that slavery had become an economic burden to the last generation of antebellum planters. Based on his prejudice rather than evidence, Phillips believed that black people were inherently "unintelligent" and were incompetent laborers except under strict guidance and close supervision. Owning slaves, he suggested, had become a losing business when the price of slaves, driven by speculation, rose rapidly after 1845.[1] The failing system was nevertheless maintained and defended as a means to preserve racial peace. There was a cultural motivation behind the reluctance to end slavery as well. Slavery, in Philips' eyes, was a civilizing institution made necessary to kept black peoples' "savage instincts from breaking forth" (Phillips 1905: 274–275, 259). These ideas may seem absurd – shocking – today, but even as late as the mid-1950s, mainstream historians continued to portray black people as simple and carefree and slavery as a benign institution needed to civilize them and maintain social control.

Conrad and Meyer did not attempt to address the questions of the aptitude of black workers or the civilizing influence of the plantation. Instead, they focused on calculating the profitability of slavery. The only quantitative evidence presented by Phillips was the time series of slave prices plotted with a black line in Fig. 1.[2] Conrad and Meyer, adopting a standard econometric technique, demonstrated that the rising price of slaves was insufficient evidence to conclude that cotton growing was unprofitable. They specified two production functions specifying cotton output as a function of the plantation's inputs of capital, land, and out-of-pocket spending for food, clothing, medical care, taxes, overseers' wages, and cotton marketing expenses. One production function defined the output of cotton produced by male prime field hands. The second function defined the joint outputs of cotton and slave children produced by enslaved women. To put quantitative meat on these bones, Conrad and Meyer assembled data on slave prices (using Phillips' own data), the prices of cotton and land, and the out-of-pocket costs. Combined with estimates of yields per hand, "saleable children" per woman, and longevity (expectation of life at birth), they simulated the annual flow of revenue from an investment in slaves

[1]Phillips elaborated on his 1905 argument in Chapter 19 of *American Negro Slavery* (1918).

[2]Philips published a chart of prices (1918: 371) that he later revised (1929: 177). Figure 1 is based on visual inspection of the revised chart by Conrad and Meyer (1958: Table 17, p. 117). Time series on typical slave prices have since been further refined. Two alternatives to Phillips's series are also plotted in Fig. 1. For these data and a discussion of the sources and methods used to assemble them, see Ransom and Sutch (1988: appendix) and Engerman et al. (2006: Table Bb209–214).

separately for males and females (Conrad and Meyer 1958: Tables 9, 10, and 11). They calculated the rate of return from these hypothetical purchases and compared those numbers to the yields on various alternative capital investments in the American economy.[3]

An important feature of Conrad and Meyer's approach recognized that each of the variables and parameters needed for their calculation varied over some range, but remained interrelated. Land that generated higher yields of cotton per acre would rent for more than poor land. Cotton prices varied from year to year depending on the yields. Conrad and Meyer made calculations for 12 plausible cases involving different combinations of capital outlays, yields per hand, slave prices, and farm prices for cotton. Their estimates for the rate of return on an investment in males spanned a range: from 4.5% to 6.5% for the typical case, as high as 8% for somewhat better land, and over 10% for the very best land on Mississippi alluvium. For women their estimates ranged from 7% to 8%. Since alternative capital investments ranged from 6% to 8% or below, they concluded that slavery was profitable – as profitable as plausible alternative undertakings.[4]

[3]Of course, these calculations did not measure the actual profitability of a would-be planter who purchased slaves in the mid-1840s or after. With the Civil War and the abolition of slavery, slave owners lost the stream of income from owning slaves.

[4]Conrad and Meyer were not the first to recognize the profitability of slavery. Historians such as Lewis Gray (1933), Thomas Govan (1942), and Kenneth Stamp (1956) had reached the same conclusion. Their work on this and other features of the slave economy had undermined the Phillips thesis to such an extent that it toppled with the final blow delivered by Conrad and Meyer.

Conrad and Meyer demonstrated that more evidence than the rising price of slaves had to be considered to establish, as Phillips thought he had, that owning slaves was an unprofitable undertaking. An important point that Phillips had missed was that the price of a slave woman was justified only in part by the yields of cotton she could help produce but also by the value of the children born to her. This is true whether the children were sold when they reached young adulthood or were kept in the owner's plantation. In the latter case, the market value of the owner's holdings – his "portfolio" of enslaved black people – would rise as the enslaved population grew.

Conrad and Meyer concluded that slavery was profitable throughout the South, "the continuing demand for labor in the Cotton Belt ensuring returns to the breeding operation on the less productive land in the seaboard and border states" (Conrad and Meyer 1958: 121). Phillips had ignored the increase of the enslaved population because he was blinded by his insistence that slaves were not bred for sale (Phillips 1918).

Following Conrad and Meyer

The work on the profitability of slavery begun with Conrad and Meyer soon inspired critics and imitators interested in testing the reliability of their findings, thus underscoring cliometricians' self-image as practitioners of a true science. New data on the underlying variables and parameters were assembled, and alternative specifications for the profit simulations were proposed. This effort at reproducibility supported the conclusion that slavery was profitable. If anything Conrad and Meyer probably underestimated the rate of return from an investment in male slaves. Table 1 presents some of the alternatives reported in the literature. From today's vantage point, the best guess for the midrange of profits is between 6% and 8% as an average for the South as a whole.[5]

An oft repeated claim of the Lost Cause historians was that the Civil War was not about slavery but about states' rights, or the tariff, or something else. A key argument supporting this claim was the proposition, best articulated by Charles Ramsdell, that slavery was unsustainable and would have died out on its own in "a little while – perhaps a generation, probably less" (Ramsdell 1929: 171). The Civil War, lamented Ramsdell, was tragically unnecessary.[6]

What seems surprising in retrospect is that so much effort had been invested in establishing the profitability of slavery when all contributors to the cliometric research on the topic agreed from the beginning that profitability per se was irrelevant to the long-run viability of slavery. Viability was the key issue raised by Phillips and

[5]The most prominent cliometric contribution to argue otherwise was offered by Edward Saraydar who recalculated the Conrad and Meyer estimate for prime field hands and arrived at a rate of return between zero and 1.5% (Saraydar 1964: Table 1). For a number of reasons discussed by Sutch (1965), Conrad (in Conrad et al. 1967), and Fogel and Engerman (1971b), his results have been rejected (but see Saraydar 1965).

[6]For a discussion of the causes of the Civil War, see Ransom and Sutch (2001).

[a]Fogel and Engerman present evidence that Conrad and Meyer underestimated the productivity of prime-age males (1971: 327–328)

Ramsdell. Economic theory suggests capital values (slave prices) would adjust to expected returns. Thus, profitability was "more or less guaranteed," as Conrad and Meyer noted, "if the proper market mechanisms existed" (Conrad and Meyer 1958: 110). If Conrad and Meyer's calculations were wrong and cotton production employing enslaved men and women had become unprofitable, it would not mean that slavery was doomed. If no alternative uses for the labor of enslaved workers could be found, the price of slaves, the price of land, or both would have fallen until owning slaves and growing cotton once again became profitable. Slavery would always be able to compete with free labor through adjustments in the price of slaves (Evans 1962; Sutch 1965; Foust and Swan 1970; Yasuba 1961; Fogel and Engerman 1971b).

Despite the asserted irrelevancy of the profitability research, the initial foray by cliometricians into the economic history of slavery precipitated the collapse of the entire Phillips edifice. It was, of course, ripe for replacement based as it was on the presumed racial inferiority of black people and a whitewashed romanticized portrayal of plantation life.[7] Meanwhile, scholarly attention shifted to several related issues relevant to the economics of slavery: self-sufficiency, slave breeding, and the economic development of the antebellum South.

[7]An excellent review of the profitability and viability issues raised by Conrad and Meyer is provided by Hugh Aitken's commentary in his book, *Did Slavery Pay?* (1971). Aitken reprints the major contributions including those of Phillips, Conrad and Meyer, Yasuba, Evans, Saraydar, and Sutch.

Self-Sufficiency of the Plantation

Douglass North formulated an elegant model of antebellum economic development that proved influential for understanding the economics of slavery (North 1961). Starting from a theory of regional specialization and export-led growth he had previously formulated, North considered the American economy as if composed of three regional economies. The East specialized in the export of manufactured products (textiles, boots and shoes, locks and clocks, books and combs) as well as financial and commercial services. The West specialized in the export of wheat flour and corn (some considerable fraction of which was transported in the form of corn whiskey and salt pork). The South specialized in the export of cotton, sugar, and other staples produced by an enslaved labor force. Each region's economic prosperity, North argued, was tied to the success of its export trade and hence to the demand from other regions for the products of their predominant industry. The staple South imported food stuffs from the agricultural West to provision her enslaved population and relied on the industrial East for cheap cloth and shoes to clothe and shod the slaves as well as for banking, credit, and factorage. The South's cotton was sold to the East where it became raw input for the booming textile industry. The East was also a major consumer of Western agricultural products. The West imported manufactures and services from the East. The three interdependent regions were linked by these interregional trade flows, each region pursued its own comparative advantage, and each was more productive than it might have been if walled off and forced to be self-sufficient. The entire national economy, according to North's export-led model, was propelled throughout the antebellum era by the expanding exports of cotton to Europe during the era when England set out to clothe the world with cotton rather than animal skins.

Douglass North's model focused attention on a weak evidential link in Conrad and Meyer's calculations. Cotton output per slave would depend in part on how self-sufficient in food the typical plantation was. Self-sufficiency would imply that some labor effort had to be diverted from the staple crops to food production and home manufacture. North accepted the traditional view that the South depended upon the West "for a *large part* of its food supply and on the East for *the bulk* of its manufactured goods and *very largely* for the conduct of its commerce and banking."[8] The highlighted phrases suggest minimal self-sufficiency, at least on the large plantations. But, whatever the extent of the South's dependence on Western food imports, there is an implication for the profitability calculations. An important magnitude required by the production function approach is the magnitude of the out-of-pocket cost for food and clothing. That cost would vary widely depending on the degree of self-sufficiency. Conrad and Meyer considered three alternatives. One case imagined that plantations were almost completely self-sufficient with the annual cost of purchases required for maintaining a prime field hand estimated between $2.50 and $3.46. But that low cost would have come at the expense of a lower

[8]The quotation, with my emphasis added, is actually from Louis Schmidt. North quotes this passage with approval (Schmidt 1939: 820; North 1961: 103).

production of cotton per hand as labor had to be diverted from cotton to food production. Another possibility was that the out-of-pocket costs were between $7 and $10 "where some ready-made clothing and meat, fish, and other food 'delicacies' were purchased." And, if all provisions were purchased, the cash cost might be as high as $25 to $40 (Conrad and Meyer 1958: Table 5). In that last case, the output of cotton per hand could be maximized. It is important to specify the typical degree of self-sufficiency correctly and then to match that with the appropriate yield of cotton per hand. Conrad and Meyer *assumed* a cost of provisions in the middle range of $7 to $10 and then claimed the typical output would range between 3.5 and 4 bales of cotton per slave per year. However, they offered no evidence to justify the relevance of that yield to the assumed cost of purchased food and clothing. North's work was troubling since it implied the costs for food and clothing imported from outside the South should be higher, perhaps much higher, than the $7–$10 claimed.

Albert Fishlow reached a different conclusion about the magnitude of the South's imports from the West. Assuming that virtually all imports of Western products to the South traveled down river to New Orleans, he calculated from port receipts that "imports were truly minute compared with the [South's] production of foodstuffs." "The South was neither a major market for Western produce nor in dire need of imported foodstuffs" (Fishlow 1964: 352, 357).

Fishlow was challenged by Robert Fogel who countered with the suggestion that "a sizable" volume of Western products was shipped through New York and Baltimore and then down the coast to the South Atlantic states. He had no direct evidence of this alternative route but made rough calculations of the 1860 pork and beef consumption in the Southern seaboard states that implied a substantial deficit when compared to domestic production (Fogel 1964). The exchange between Fishlow and Fogel reached a stalemate however when it bogged down in a disagreement about the relative slaughter weights of Western and Southern hogs and cattle. Furthermore, the relevance of interregional shipments to the question of the plantation's self-sufficiency was not assured given the possibility that large plantations might have been supplied by local, small-scale, non-slave-owning farmers who specialized in grain and meat production.

The debate could not be resolved without new research. This had to wait several years until William Parker and Robert Gallman drew a statistical sample of 5,229 Cotton South farms and plantations from the 1860 census of agriculture. The census enumerators' manuscript returns from these agricultural operations were linked to each farm owner's returns from the population census and also to the slave census returns linked to the owners. The result was a cross-section micro-data sample. William Parker accurately described it as "the best-selected, most comprehensive, and most carefully processed body of statistical evidence which historians have ever employed in the study of history" (Parker 1970a: 2). Immediately the Parker-Gallman sample was applied to address the question: Did cotton farms grow their own food? The answer was "yes" (Gallman 1970; Battalio and Kagel 1970). The sample allowed the question to be addressed not in the aggregate, but farm-by-farm and plantation-by-plantation. Figure 2 presents Gallman's estimates of grain output and grain requirements by farm size. Grain is expressed in corn-equivalent bushels.

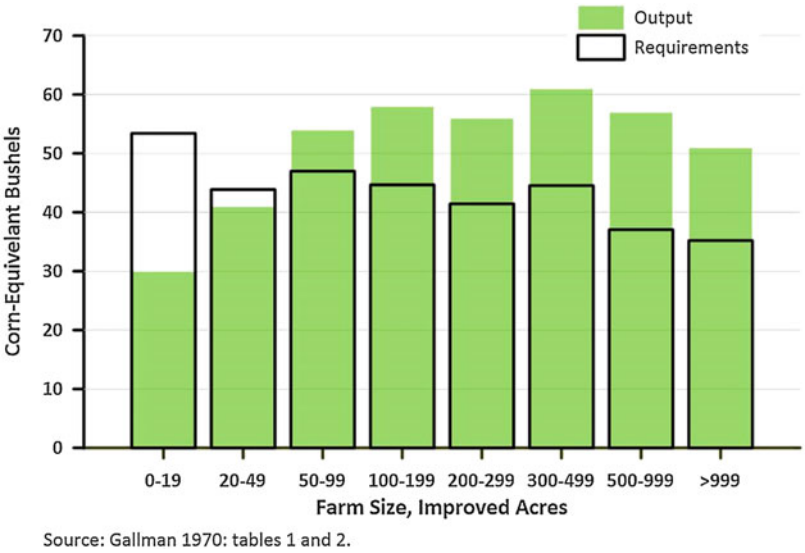

Fig. 2 Per Capia production of grain, Parker-Gallman sample, 1860

This measure aggregates corn, wheat, rye, barley, buckwheat, cow peas, and beans weighted by their nutritional contents. Per capita production (represented by the green bars) was significantly higher on the large farms than on small ones. There is no evidence in these findings that small farms were able to supply grains to large plantations.

Grain requirements were estimated by Gallman in the same units by aggregating estimated on-farm consumption by the enslaved and free populations, the work animals, cows, other cattle, sheep, and young animals – but not swine. Allowance was made for seed requirements, poultry, and on-farm waste. To avoid exaggerating self-sufficiency, Gallman made what he considered to be generous estimates of slave ratios – "more likely to be too high than too low" (Gallman 1970: 12–19). As illustrated in Fig. 2, farms with 50 acres or more of improved acreage had an estimated output in excess of consumption requirements. The residual was sizable. Gallman recognized that these residuals were likely converted to pork by feeding corn and other grains to swine. He assumed that it took 10 bushels of corn to produce 100 lbs of pork arguing that this would likely underestimate pork production. After considering whether his estimates of the pork produced were reasonable given the count of swine reported in the census and the extensive data he assembled on the slaughter weight of hogs, Gallman stated,

> we can have some assurance that the procedures by which claims on grain and output of pork were derived do not *underestimate* plantation demands nor *overstate* plantation production capacities. That is, the check suggests that my original object – to give the self-sufficiency hypothesis a strong test – has been met. (Gallman 1970: 16, emphasis in the original)

After estimating the quantities of meat consumed by both the enslaved and the free populations living on the farms, Gallman concluded:

> The surplus of all the farms in the cotton South (which the sample represents) would have been large enough to feed all of the slaves and one-sixth of the [free population] living in the South outside the sample universe. The farms of the cotton South, far from being dependent on external sources of basic foods, were in a position to supply food to outsiders on an impressive scale. (Gallman 1970: 19)

From an analytical point of view, one of the contributions of Conrad and Meyer was to view the slave owner as a businessman, a capitalist in a competitive business who retained slaves to employ them in a profit-making enterprise. The planter sought to engage the slaves at tasks that would earn a sufficient return to justify their price. That large plantations were self-sufficient in food production is not inconsistent with this view or the proposition that the Southern plantation had a strong comparative advantage in cotton production. Ralph Anderson and Robert Gallman pointed out that a slave was a form of fixed capital. The owner not only had access to the enslaved person's entire labor but was also responsible for his full maintenance (Anderson and Gallman 1977). The labor requirements of cotton production varied seasonally, heavy during planting season and again during picking season, but relatively light in between requiring only some animal husbandry and cultivating to remove weeds. The slave owner would not want his charges idle during the slack season since he was obliged to pay for their upkeep and since they might prove troublesome if left without work. The principal means by which the slave force was kept busy throughout the year was diversification into corn and pork production. This despite the fact that Southern yields per acre in corn were substantially below the yield achieved in the West (about 12.5 bushels per acre vs. 32.4 in both 1849 and 1859) (Parker and Klein 1966: Table 10). One explanation for the low corn yields per acre was that corn was planted and harvested at dates that did not interfere with those for cotton, but were not optimal for corn. During August when neither crop required much attention, the slaves were set to pulling fodder, stripping the corn stalks of their green leaves. The fodder provided cattle feed, but the practice wounded the growing corn plant and reduced grain yield between 10% and 18% (Ransom and Sutch 1977: 395–396, n62).

Other research projects provided evidence that subregions on the periphery of the South supplied grain and meats to the South's population not living on farms. Kentucky and Texas were both exporters of meat. The Upper South states of Kentucky, Tennessee, Virginia, and North Carolina produced a sizable grain surplus and "engaged in large-scale exportation of both wheat and corn" (Lindstrom 1970: 101). By implicitly redrawing regional borders and defining "The South" more narrowly and the West more broadly than had Douglass North, this work recovered the importance of interregional trade links that he had emphasized.[9]

[9]However, the role played by cotton exports to England in propelling US economic growth has been questioned. Irving Kravis argued that exports were supplementary factors: "handmaidens, not engines, of growth" (Kravis 1972: 405).

The Interstate Slave Trade and Slave Breeding

It is hard to question the widely accepted narrative evidence that the interregional slave trade operated by professional slave traders was substantial. The market functioned well and slave prices were flexibly determined. Slaves could be "reared on the poorest of land and then sold to those owning the best" (Conrad and Meyer 1958: 110). It is also clearly established that the slave traders preferentially selected prime-age slaves for removal to the new South.[10] In other words, the migration of complete plantation populations with their labor force intact including young and old, males and females, infants and children – together with their original owner and his family – was not the only way to transport slaves into the rapidly filling West. In case there was any doubt, Conrad and Meyer specifically addressed "the old historical question about whether the typical Southern gentleman planter could bring himself to indulge in the slave trade" (Meyer and Conrad 1957: 539). They argued that if a reluctance to sell slaves thwarted trade, the age and sex distribution of the enslaved population would be approximately the same in all states. Yet the census revealed that the "buying" states of the South had a larger proportion of slaves in the prime working ages than the "breeding" states (Conrad and Meyer 1958: 114–115 and Table 14).

Richard Sutch carried the argument a step further. He used census data and survival rate methods to calculate the volume of net exports (or imports) for each state by age and sex between 1850 and 1860. The overall export rates for Delaware, the District of Columbia, and Maryland ranged from 20% to 33% of the population. Six other states (in descending order: Kentucky, South Carolina, Virginia, Tennessee, North Carolina, and Georgia) were also exporters. During the final decade of slavery, over 10% of the enslaved population of these states was forced to take part in this remarkably large migration. Figure 3 presents Sutch's estimated exportation rate for each age and sex cohort during the last decade of slavery. This rate is defined as the number of enslaved persons living in the state in 1850 who were removed from the state over the decade as a percentage of the state's 1850 slave population that would have survived to 1860. The markedly higher rate of export for those 20–29 of age in 1860 (approximately aged 15–24 at the time of migration) is strong evidence that many slaves were sold singly into the domestic trade rather than making the move West in the company of their owner and their family members (Sutch 1975a).[11] The precise proportion of slave removals that were transferred by domestic slave traders was debated in the 1970s and 1980s without much progress. However, recent research by Johnathan Pritchett and Michael Tadman seems to have settled the

[10]The narrative literature (as distinct from the cliometric contributions) on the domestic slave trade is enormous. The classic is by Frederick Bancroft (1931). A modern treatment is by Ned Sublette and Constance Sublette (2016). Detailed documentary evidence on the trade that transported enslaved men and women from Maryland to New Orleans is provided by Ralph Clayton (2002). A blend of traditional and cliometric methods is employed in Michael Tadman's study which also provides detail on exports from South Carolina (1989).

[11]A similar pattern of exports by age was found by Tadman (1989: Fig. 2.4).

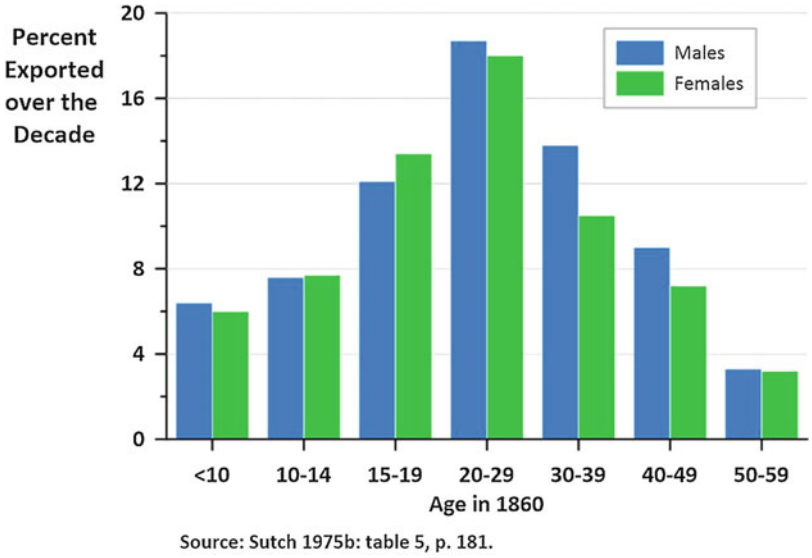

Fig. 3 Exportation rate, by age and sex of slave selling states, 1850–1860

issue with a more sophisticated analysis of the changing age and sex composition of the slave population. Pritchett calculated that approximately 50% of slaves transported across state lines had been sold to traders who resold them (Pritchett 2001). Michael Tadman put the percentage even higher at 60–70% (Tadman 1989: 29–31 and Appendix 3). For regions where exports were unusually large, the percentage sold to traders was probably even higher. Slaves shipped from Baltimore, for example, had been sold by their local owners to traders about 80% of the time (Clayton 2002: 641).

Despite statistics' matter-of-fact quality, these huge percentages considered together with the sheer enormity of the transplanted population focus attention on the misery and terror wrought by the slave trade. The young men and women sold South were separated from their families (parents, wives, partners), friends, and owner, forcibly transported to a foreign environment, sold to a new master not of their choice, and settled alone on an unfamiliar plantation. The numbers are heartbreaking. A teenager in 1850 born and raised in Maryland, for example, had about a 12–16% chance of being sold to a trader before 1860. Maryland was an extreme case. In Virginia, the chances were 11–14%, in North Carolina 9–10%, and those born in South Carolina faced an 8–11% chance.[12] For the exporting states taken together, the median age at sale was 16. Teenage males were 50% more likely than a woman to be sold during the decade. Stephen Crawford extracted reports of the sale of young slaves away from their families

[12]Calculated from the net exportation rates for each state (Sutch 1975a: Appendix Table 5) and the assumed probability of being sold to a trader of 60–70% (Tadman 1989: 31).

from the narratives related by ex-slaves in the 1920s and 1930s. Based on 42 reports, he concluded that "through age sixteen, the slave child faced roughly a 20% chance of being sold away from family" (Crawford 1992: 341–342, Table 11.6).

The teenager caught up in this trade would have been sold, perhaps at auction; jailed in a slave-holding pen in Baltimore, Charlestown, or another port city; then chained and marched into the hold of a ship; transported to New Orleans, a voyage of perhaps 30 days; chained again and marched to another "slave hotel"; sold at auction; and then moved to a new home.[13] Not only was the purchased slave uprooted, but those left behind were also devastated and terrified by their own obvious vulnerability. The children remaining behind could only look forward to facing the same brutal odds as they grew to adulthood. These forced travels West have been called, quite appropriately, the "Second Middle Passage."

No doubt remains about the general picture of a large coerced migration of enslaved black people from the "exporting states" to the "importing states" and the significant role played by professional traders in facilitating the movement. There remains, however, some concern about how to label things. Conrad and Meyer called importing regions the "buying states" and the exporting regions "breeding states." Although they were adopting established terminology, the term "breeding" seems unfortunate in retrospect. This emotionally charged term offended some, angered others, and led several less-than-careful readers to enormous misunderstandings about what practices constituted slave breeding. Conrad and Meyer's insight was that the enslaved were not only workers but also capital and, in the case of every child born to an enslaved mother, they were also product – "an intermediate good" in Conrad and Meyer's words. "Whether systematically bred or not, the natural increase of the slave force was an important, probably the most important, product of the more exhausted soil of the Old South" (Conrad and Meyer 1958: 96, 113–114).

Richard Sutch sought to bring some quantitative evidence to bear on the "breeding hypothesis." This is the idea that the existence of the interregional slave trade and the structure of slave prices established in that market gave slave owners an economic incentive to increase the number of children born on their plantations. The hypothesis entails the twin propositions that,

1. The increasing slave population was a by-product of the agricultural operation – not the main objective; and
2. The slave owner's incentive was to increase the number of children born for a given investment in working adults – not to maximize female fertility (children born per women of child-bearing age).

Female fertility in the antebellum South was astonishingly high. Sutch used the Parker-Gallman sample to estimate fertility on slave farms. The number of children, 0–14, per thousand woman-years of prime fertility experience was 295: 323 in the

[13]For a description of slave trading at the origin of the voyage, see Ralph Clayton's discussion of Baltimore (2002). For the receiving end, consult Walter Johnson's discussion of the New Orleans market (1999). Johnson also provides a narrative description of the forced journey West.

exporting states and 260 in the receiving states (Sutch 1975a: Table 10). In South Carolina where the calculated rate was highest, it reached 355. That would be close to the apparent biological maximum of 371 observed in the population with the highest gross reproduction rate ever recorded: the experience of the women of the Cocos-Keeling Islands born between 1873 and 1927.[14] For the exporting states, these numbers imply that on average, seven surviving children would be born during a woman's reproductive life. To reach levels of female fertility, this high would require early marriage, short lactation periods, and no economic pressure to restrain population growth.

This evidence by itself does not discriminate between two possibilities: that the high fertility on the plantations, like that on the Cocos Islands, was the natural result of ample resources, good health, and the early timing of first births or evidence that the planters were interfering in the sexual life of their slaves by encouraging (coercing?) early marriage and abbreviated breast feeding and discouraging abstinence. If the slave population's reproductive rate was "natural," as some slave owners insisted, how could individual planters increase the number of children born on their plantation when female fertility was already near the maximum? This could be done by skewing the sex ratio of adults toward women of child-bearing age. Since women as well as men worked in the fields, agricultural output could be maintained, while the number of children born *per adult worker* could be increased.

Before the Parker-Gallman microdata was available, the published census results seemed to undercut this possibility. The sex ratios of slaves, 15–39, in the exporting states were not different than that observed in the importing states, and both were almost precisely equal to 1.0. The sample of slave farms, however, told a different story. When farms without any women are excluded, the female-to-male ratio in the exporting states was 1.3 (1.2 in the importing states). Slaves employed in non-agricultural occupations were predominantly males, and farmers who owned only one slave had a revealed preference for males.

Table 2 illustrates the effectiveness of skewed sex ratios on farms with five or more adult women. Since children represent the "output" of a supposed breeding operation and the number of adults represents the "inputs," "productivity," measured as the ratio of children to adults, rises with the ratio of women to men. It is also remarkable that less than 40% of the larger farms in the exporting states had rough gender balance.[15] One-third had a ratio of women to men greater than 1.5; 17% had

[14]The number of years of "prime fertility experience" is an index of potential fertility. Each year of the woman's life during the preceding 15 years is weighted by the reproductive experience of the Cocos Island women at the same age. Sutch also presented calculations to suggest that the differences between exporting and importing states could not be explained by selective migration of women without children (Sutch 1975a: Tables 8–10).

[15]Stanley Engerman suggested in his comments on Sutch that moral influences led this minority of owners to noninterference and encouragement of family stability and that family stability might increase the female fertility rate (Engerman 1975). There is certainly evidence of that, as female fertility was actually higher on the farms with balanced sex ratios (Sutch 1975a: table 12). But the breeding hypothesis proposes that it is not female fertility that would matter, but the reproduction rate of the adult population on plantations, counting women and men together.

Table 2 Sex distribution and child-adult ratios, exporting states, 1860.

two or more women per man. Sutch raised the possibility that polygamy or promiscuity might help explain the high birth rates on these farms despite the gender imbalance. On the other hand, enslaved husbands might have resided off the plantation on neighboring farms. Fogel and Engerman asserted that this was "quite common" (1992b: 462). However, Ann Patton Malone's thorough study of the slave family and household structure in Louisiana found little evidence of off-plantation marriages. She suggests that the frequency of "abroad marriages" has been exaggerated, "perhaps out of an overabsorption with … heralding the standard nuclear family" (Malone 1992: 227–228, 262–263). In any case, the need to sell left many individual farms with more adult women than men.

The large number of children born on plantations with substantially more women than men raises the possibility that some of the women were impregnated by men other than their husbands, with or without their consent. Given the racial and sexual domination inherent in Southern society, enslaved women may have felt they had little choice but to submit to intercourse, particularly when approached by a white man (Steckel 1980; Bodenhorn 2015). There is some limited evidence that rape by overseers was not uncommon (Malone 1992: 221–222). These acts would be crimes of passion, not necessarily motivated by the supposedly dispassionate calculations of a slave breeder. However, it is worth noticing that the enslaved woman's best insurance against sexual abuse by a slave breeder was to marry early and produce many children within that marriage.

Economic Growth and Manufacturing Development of the South

That slavery was profitable and viable did not mean that slavery was compatible with economic growth or development. This point was raised by Douglas Dowd in his comment on Conrad and Meyer, and later became the subject of a famous panel

discussion on "Slavery as an Obstacle to Economic Growth" held at the Economic History Association meetings in 1967 (Conrad et al. 1967).[16] As Dowd put it, "slavery and all that it entailed was fundamental in inhibiting industrial capitalism – and economic growth – in the South" (Dowd 1958: 441). Indeed, there was little doubt in the 1960s that the antebellum Southern economy was backward and lagged behind the North. Northern and Southern observers of the time, abolitionists and slaveholders, all noted the contrast and all agreed that slavery was to blame (for a review, see Harold Woodman 1963). The cliometric literature on the topic opened with a challenge to this view by Stanley Engerman (1967).

For the purposes of his reinterpretation, Engerman reworked regional personal income relatives estimated by Richard Easterlin to produce rough estimates of personal income per capita (counting enslaved persons in the population total). His results are presented in Table 3.[17] Engerman directed attention to the growth rates he calculated for the global South and North. Between 1840 and 1860, by these measures, the Southern economy grew at the average of 1.45%. This is faster than the growth rate of 1.30 for the North.[18] How could the observations of contemporary witnesses and the calculations of cliometrics be so at odds? The answer is the nature of the economic growth experienced by the South was quite unusual. It was not really noticeable locally; it was only manifest at the interregional level. Engerman calculated the rate of economic growth for the South viewed as a whole, while the contemporaries were commenting on what could be seen from the perspective of a local observer ("on the ground," so to speak). Note that the calculated rate of growth for the South (1.45%) is higher than the rate of growth in each of the South's three subregions measured separately (1.21, 1.28, and 0.82%).[19] This counterintuitive phenomenon arises because the westward migration was away from regions of poor soil and relatively low per capita income to regions with rich soils and relatively high income. Much of the apparent antebellum Southern growth came from

[16]Panel members: Alfred H. Conrad, Douglas Dowd, Stanley Engerman, Eli Ginzberg, Charles Kelso, John R. Meyer, Harry N. Scheiber, and Richard Sutch. For a colorful, emotional, and hyperbolic description of the discussion that ensued, see Robert Fogel and Stanley Engerman (1974, volume 2: 11–19).

[17]Table 3 is based on numbers reported by Easterlin (1961: table 1), Engerman (1971), and Fogel and Engerman (1971b: 335) and calculations by Ransom and Sutch (1977). See Ransom and Sutch for details. The states included in each region by Easterlin are the following: *New England*, Connecticut, Rhode Island, Massachusetts, Vermont, New Hampshire, and Maine; *Middle Atlantic*, New York, Pennsylvania, New Jersey, Maryland, and Delaware; *East North Central*, Ohio, Michigan, Indiana, Illinois, and Wisconsin; and *West North Central*, Iowa and Missouri. In 1860, Minnesota, Nebraska, and Kansas are also included: *South Atlantic*, Virginia, (including present-day West Virginia), North Carolina, South Carolina, Georgia, and Florida; *East South Central*, Kentucky, Tennessee, Alabama, and Mississippi; and *West South Central,* Arkansas and Louisiana.

[18]Engerman, departing from Easterlin, included Texas in the 1860 definition of the West South Central region. This adjustment boosted the South's growth rate to 1.67% (Fogel and Engerman 1971b: 335). Table 3 reports the figures for the South defined to exclude Texas. Texas was an independent republic in 1840. It became a state in 1845.

[19]Engerman's calculations probably exaggerate the progress made in the South's subregions between 1840 and 1860. They are primarily based on the census returns for the crops of 1839 and 1859, but 1859 was an unusually good year for cotton production.

Table 3 Personal income per capita by geographic divisions, 1840 and 1860.

1860 prices

Geograhic division	Personal income ($) 1840	Personal income ($) 1860	Annual rate of growth (%)	Population weights (US=1) 1840	Population weights (US=1) 1860
North	**109**	**141**	**1.30**	**0.62**	**0.65**
New England	126	186	1.97	0.13	0.10
Middle Atlantic	130	178	1.58	0.30	0.26
East North Central	64	90	1.72	0.17	0.22

territorial expansion onto more productive lands. This extensive growth would not be relevant to anyone who did not move West.

Still, Engerman's point is well taken. The South's slave economy was not stagnant. The transformations however were largely driven by the interregional slave trade and planter migrations. Physical productivity in cotton production rose throughout the antebellum period (Conrad and Meyer 1958). This was probably true at the local level, even on the "exhausted" soils of the Atlantic coast states. The advance is attributed to improvements in transportation and marketing, the application of guano as a fertilizer, the adoption of new cotton varieties, and improvements in the machinery for ginning and baling cotton. The real price paid for cotton was also rising as advances in technology for manufacturing cotton thread and textiles enabled manufactures to make more effective use of the South's upland cotton varieties. But the growth in the South Atlantic and East South Central regions was modest in comparison to the growth in the economies of New England, the Middle Atlantic states, and the East North Central region.[20] While the planters could reap the benefits of higher prices and the innovations in marketing and production, the slaves did not. In the North, by contrast, the local economies were markedly dynamic, growth was indigenous, intensive, and the benefits were widespread. Northern

[20]The frontier regions, the West North Central and West South Central, were thinly populated in 1840 with only 2 and 3% of the population, respectively.

agriculture was transformed, local manufacturing appeared, young women left farms to work in factories, cities grew, and a flood of "Yankee gadgets" were filed with the Patent Office.[21]

A westward migration was common to the histories of both the North and the South. In the North, however, the migration was from the high-income regions in the East (New England and the Middle Atlantic states) to regions in the West (primarily the East North Central division) with lower per capita incomes. Northern migration was not produced by individuals giving up high-paying jobs for low-income ones. Rather it was primarily a migration out of low-productivity agriculture to the more fertile agriculture of the West. Agricultural income per worker was 25% higher in the Old North West than New England in 1840 and 45% higher in 1860 (Easterlin 1974: Table B.1). The figures in Table 3 support the notion that the local Southern slave economies were indeed lagging behind the industrial economies of New England and the Mid-Atlantic and behind the new agricultural economy of the East North Central states.[22]

But why should this be? The South's relative lack of manufacturing, the absence of a connected network of towns and villages, and the nonexistent provision of public education for white children and laws actually prohibiting the education of slaves are acknowledged features of the Southern landscape.[23] If growth is equated with manufacturing development, urbanization, and education, there was obvious work for cliometricians. Why did the South miss out?

The study of Southern manufacturing was initiated by Fred Bateman, James Foust, and Thomas Weiss. Based on a sample of manufacturing firms drawn from the manuscript census of 1850 and 1860, they report two findings which, taken together, led them to a surprising conclusion. For the South as a whole, there was a lack of participation by planters in manufacturing enterprises. As the wealthiest members of Southern society, slave owners might be expected to have stepped into the role of local entrepreneurs and venture capitalists. But only 6% of planters engaged in manufacturing, and yet their investments comprised around 25% of all manufacturing capital. "This suggests the South suffered a very conventional but perhaps economically rational fate – a limited transfer of resources from agriculture to manufacturing" (Bateman et al. 1974: 297). The low participation is particularly surprising in light of calculations establishing that the rate of return was two to three

[21]Technological creativity affected every facet of Northern life. On the transformation of Northern agriculture, see Jeremy Atack and Fred Bateman (1987). On the "rain of gadgets" and the impact on agriculture, see Peter McClelland (1997).

[22]A recent re-examination of regional growth in the antebellum period over a longer period confirms that the South lagged far behind the North. Between the benchmark years of 1800 and 1860, Peter Lindert and Jeffrey Williamson calculate a growth rate for the South Atlantic region of 0.9% per annum (that is below the rate they consider required for "modern economic growth"). By comparison, New England grew at the rate of 1.94%, and the Middle Atlantic states grew at 1.66% (Lindert and Williamson 2016: 101–107 and Figs. 5.1 and 5.2).

[23]Despite law and custom, a small minority of slaves did learn to read and write. A non-cliometric history by Heather Andrea Williams tells the story (2003).

times higher in Southern manufacturing than in Southern agriculture. Clearly, the region did not live up to its economic potential. The authors describe the situation as one of entrepreneurial failure, "investor irrationality." Manufacturing opportunities would have been more remunerative, yet planters were unwisely plowing their earnings back into cotton agriculture and the purchase of slaves. "While the South was not nearly so devoid of industry as conventionally believed, it no doubt could have done better. That it did not, largely reflects upon the behavior of Southern investors" (Bateman and Weiss 1976: Table 13, pp. 26 and 39).[24]

The scarcity of manufacturing helps explain the South's low urbanization. Factory workers needed to live near factories, and the factories needed to locate at a power source (a mill stream perhaps). In the antebellum North East and North West, urban places grew up around these nonagricultural sources of employment. And these urban enclaves became self-propelling. They fostered a business culture. When technology changed and opportunities emerged, homegrown entrepreneurs and lenders of capital were willing to assume the risks (Parker 1970b). Without urban centers, the South lacked self-conscious businessmen and lenders that would provide the dynamics to industrialize.

Claudia Goldin tackled the topic of slavery in the cities. Her concern, however, was not so much with the lack of urbanization as with the relative lack of slaves in the few cities that did exist. In 1850, 10% of the white population lived in the urban areas of the South, but only 4% of the slaves were city residents (Goldin 1976: Table 1). Goldin also established that urban slavery was on the decline during the 1850s. According to her statistical analysis of the supply and demand for urban slaves, this was almost entirely explained by the "rapid increases in the price of slaves in general, which led urban owners to cash in on their capital gains" (Goldin 1975: 449).

Leaving aside the South's woeful investments in basic education, which in the case of the enslaved black population was clearly the consequence of slavery, the initial attempts to explain low levels of investment in manufacturing did not directly implicate slavery as the cause. Instead, they attributed the failure of industrialization to the shortage of entrepreneurial imagination. Extending this discussion into questions of distinctive regional character traits, planter irrationality, risk aversion, business culture, and the like would take this essay too far from its assignment. Economic development and its index of success, economic growth, are complex concepts. Questions such as "Why didn't the South grow faster?" and "Why didn't she develop a booming and diverse industrial sector?" require a comparative approach. Engerman set out to compare the growth of the South with that of the North. Bateman and Weiss explicitly compared Southern manufacturing with Northern industrialization. Goldin compared slavery in the cities with slavery in the countryside. Gavin Wright made yet another comparison. He contrasted the economic progress of the Old South before the war to the progress of the New South following the Civil War. Wright saw a "basic change in the principles and directions of entrepreneurial energies":

[24]Bateman and Weiss collect and summarize their work in a book (1981).

> When slavery was abolished, investment strategies, entrepreneurial designs, and political schemes whose end purpose was to increase the productivity and value of *land* came to the fore.

The real cause of the lackluster prewar performance, Wright argued, was the lack of saving:

> The level of savings is a function of wealth as well as income. By analogy to the burden of the national debt, capitalizing labor satisfies the desire to accumulate wealth over the life cycle, and hence reduces the savings available for investment in physical capital. This model could well explain the evidence recently presented by economists Fred Bateman and Thomas Weiss that rates of return in antebellum southern manufacturing were generally high, yet failed to attract investment on a large scale. (Wright 1986: 19–20 Emphasis in the original)

Wright cited a paper on slave owners' saving by Ransom and Sutch that relied on Franco Modigliani's life-cycle model of saving and its implication for the burden of the national debt (Ransom and Sutch 1988; Modigliani 1961). Life-cycle models predict the existence of a desired wealth-income ratio that depends upon the worker's expectations about the age profile of income over the life span and the need to build a stock of wealth. The wealth is required both to establish a rainy-day fund and to provide security in old age when earning power is anticipated to be low. Because the saver is indifferent to whether the accumulated wealth is in the form of physical capital or government bonds, an increase in "national debt will tend to displace private tangible capital on a dollar per dollar basis" (Modigliani 1966: 200). A lower stock of physical capital in the economy reduces the flow of output. If you replace the phrase "national debt" with the words "slave capital" in the preceding quotation you have the essence of Ransom and Sutch's point. Slaves were a form of wealth that took the place of manufacturing capital.

The life-cycle model not only helps explain the lack of Southern manufacturing investment, it also offers a partial explanation for the puzzling upward jump in aggregate savings rates that appeared following the Civil War. With emancipation, a significant fraction of the saleable wealth in the South evaporated. The value of slaves in 1860 was nearly 60% of the total capital invested in agriculture and completely overshadowed the physical capital invested in Southern manufacturing (Ransom and Sutch 1977: Table 3.5; 1988, Table A.1). When the wealth represented by slaves disappeared, the wealth-income relationship was catapulted far out of equilibrium. In response the savings rate accelerated (Ransom and Sutch 1988). The quickened pace of capital formation was first brought to the attention of the profession in 1966 when Robert Gallman published his estimates of gross national product for the nineteenth century (Gallman 1966). Capital formation rates rose from approximately 13 to well over 17% of GNP. Subsequent revisions by Gallman of the figures on output and gross saving are presented in Table 4. Physical capital formation jumped from less than 15% to well over 20% according to the revised estimates, and from 16% to 22% using the slave-economy concept of gross national product that includes the value of the increase in slave wealth in aggregate capital formation.

Table 4 Share of gross capital formation in gross national product, United States.

Gallman's estimates and slave-economy GNP
Decade averages, 1839-1888

Decade	Gallman's estimates excluding the increase in slave wealth		Slave-economy concept including the increase in slave wealth
	1966	Revised 2006	
1839-1849	11.5	10.8	14.0
1844-1854	12.9	13.0	14.9
1849-1859	13.3	14.7	16.2
1869-1878	17.4	22.1	22.1
1874-1883	17.3	20.8	20.8
1879-1888	18.9	23.5	23.5

Sources: Gallman's 1966 estimates computed from the underlying sources by Ransom and Sutch (1988: Table 4: 149) using methods described by Gallman (1966: 10–14). Revised Gallman-estimates are calculated as averages of annual data presented in Carter et al. (2006: Tables Ca192–207 (for 1869–1888) and Ca219–232 (for 1839–1858)). The pre-Civil War shares based on the slave-economy concept are calculated from the same source (Table Ca233–240). See Paul Rhode and Richard Sutch for a discussion of the slave-economy gross national product (2006: 16)

Simply put, the slave South did not establish the educational, social, and financial institutions upon which to promote innovation, entrepreneurship, and economic development. The South's impulse to invest and expand the stock of wealth was satisfied by the increase in the slave population. Slavery denied the South even the potential for modern economic growth.[25] Taking the long-term perspective, the South was in peril. Immigrants self-selected the North with its rapidly growing urban centers and her expanding industries as the obvious place to settle. The South provided few jobs for free labor and the entry costs for land and slaves made joining the planter class out of reach for the typical immigrant. As the flow of immigrants swelled the population of the Free States outpacing that of the slave South, the size of the South's congressional representation *vis-à-vis* the North was

[25]A reflection on the economic development of the antebellum South by Gavin Wright takes a refreshing step back from the cliometrics to provide insightful historical and comparative context (Wright 2006).

threatened, thus her insistence on the extension of slavery into the West (Ransom and Sutch 2001).

The Debate over *Time on the Cross*

The rich outpouring of cliometric research on slavery in the 1960s and 1970s was further stimulated by the appearance in 1974 of *Time on the Cross* by Robert Fogel and Stanley Engerman. The authors were intentionally provocative. They announced their work as a radical interpretation of the economics of slavery, reporting the findings of "almost a decade and a half" of methodologically sophisticated research based on "new techniques and hitherto neglected sources" (Fogel and Engerman 1974: volume 1, pp. 4, 226). Chief among the startling findings was the authors' claim that the physical and psychological well-being of American slaves was much greater than previously believed. Slaves were provided not just adequate food, clothing, and shelter but a material standard of living which compared favorably with that of free American workers of the time. Slave owners used cash rewards and other positive incentives rather than physical punishment to motivate a high level of work effort. Humane treatment secured the willing cooperation of the slaves. Slave breeding and sexual exploitation were abolitionist "myths." The trade and traffic in human beings did not break many family units. Large plantations were more efficient than free farms of the North because gang labor and economies of scale made them super productive.

After more than four decades, it is difficult to recapture the shock that greeted this work. The surprised reaction was in part the consequence of the book's brash style and structural eccentricities. There were two volumes. The primary volume, subtitled *The Economics of American Negro Slavery*, was intended for the general reader and employed what Deirdre McCloskey would call a forensic style, a rhetoric more reminiscent of the prosecutor's closing argument than a typical historical narrative with careful footnotes and references to primary sources (McCloskey 1985). While it claimed to be rigorously scientific, Volume One lacked the careful methodological description, empirical precision, and caveats necessarily associated with the presentation of novel scientific findings. That material, when provided, was left to Volume Two, subtitled *Evidence and Methods, A Supplement*. Volume Two was a collection of "technical notes" filled with algebraic symbols, intricate cross-references, and terse descriptions of statistical results that would certainly be inaccessible to all but a minuscule few of its general readers. Only someone trained in economic theory, the logic and methods of statistical inference, and cliometric analysis could reliably put the two parts of *Time on the Cross* together.

In a sense, Fogel and Engerman were ahead of their time. They wished to convince a large audience of lay readers that "the view that black Americans were without culture, without achievement, and without development" was false (Fogel and Engerman 1974: volume 1, p. 258) while at the same time persuading their scientific colleagues of the validity of their findings. Their effort to simultaneously address two audiences proved to be a failure not only because the physical and

rhetorical separation of findings and meaning was seen as an attempt to overawe readers but because the inferences and many of the technical details had not been vetted through peer review.

The initial shock over the two volumes' intimidating format might have been a temporary distraction had the authors delivered what they promised – novel interpretations derived from reliable findings based on hard data, sophisticated mathematics, and computational technology with the power to digest massive amounts of numerical data. Subsequent scholarship, however, would reveal that the findings were not reliable. When quantitative historians with the necessary experience and credentials began the process of replicating – or attempting to replicate – the cliometrics, they could not, for the most part, do so.[26] The rejections were many and came from multiple quarters. Paul David, Herbert Gutman, Richard Sutch, Peter Temin, and Gavin Wright prepared a compilation of the cliometric corrections and logical critiques of *Time on the Cross*, which they published as a book, *Reckoning with Slavery,* complete with a concordance. The conclusion was blunt:

> We have attempted, collaboratively, to reproduce every important statistical manipulation, check every significant citation, reexamine every striking quotation, rethink every critical inference, and question every major conclusion in Fogel and Engerman's book. To our surprise and dismay, we have found that *Time on the Cross* is full of errors. The book embraces errors of mathematics, disregards standard principles of statistical inference, mis-cites sources, takes quotations out of context, distorts the views and findings of other historians and economists, and relies upon dubious and largely unexplicated models of market behavior, economic dynamics, socialization, sexual behavior, fertility determination, and genetics (to name some).
>
> No work of scholarship, and certainly no work which undertakes to cover so broad a canvas, is unblemished by some errors. *Time on the Cross,* however, is simply shot through with egregious errors. Even more dismaying is the consistent tendency in the mistakes we have uncovered: all seem to work in favor of the particular "radical reinterpretation" of the institution of slavery that has been put forth by Fogel and Engerman. When the faults are corrected and the evidence is re-examined, every striking assertion made in *Time on the Cross* is cast into doubt. The effect in many instances is to restore and reinforce more orthodox conclusions hitherto shared by conventional and quantitatively oriented students of the peculiar institution. (David et al. 1976: 339–340)

The objections were not confined to errors of factual detail. The interpretations presented in Volume One, the critics charged, did not follow logically from the cliometric analysis; Fogel and Engerman had warned readers that their findings (presented in Volume Two) and their interpretations (in Volume One) do not stand on the same level of reliability. "Interpretation sometimes involves additional data which are quite fragmentary and assumptions which, though they are plausible, cannot be verified at present. Hence, even when readers accept the validity of one or another of the principle findings, they may disagree with the significance that we attach to it" (1974: volume 1, p. 10). The objection of the critics, however, was not to the use of additional assumptions or fragmentary data to broaden a finding into a

[26] I was more than a witness of the verification effort. I was a participant (Sutch 1975b).

conclusion. Rather the charge was that the interpretations presented with great fanfare in Volume One would not be warranted even if the additional assumptions and fragmentary data are accepted and the cliometric findings in Volume Two were valid. The illogic of Volume One became a major issue.

The forensic style Fogel and Engerman adopted for Volume One intended to leave no room for disagreement, but to meet that standard the "corrections" of the traditional characterization of the slave economy must follow directly from the cliometric findings. Unlike a true forensic investigator who examines all the evidence and then builds a case, it appears to me that Fogel and Engerman decided upon their conclusions and then assembled plausible, supportive evidence after the fact. In the process, they left out the logical apparatus that should have connected the interpretation back to the finding.

The Relative Efficiency of Slavery

Fogel long maintained that the most significant contribution of his work on the economics of slavery was the novel demonstration that slavery was efficient; indeed, more efficient than free labor. According to the numbers Fogel and Engerman reported, Southern agriculture was 35% more efficient than Northern farming in 1859 and Southern slave farms were 28% more efficient than Southern free farms. *Time on the Cross* described this result as a paradox. Productive efficiency is an important component of American values and often counts as one of the higher virtues of a capitalist economy.[27] By challenging the long-held and seemingly secure belief that slavery was inefficient without a clarifying caveat, Fogel and Engerman needlessly created the "paradox" seemly suggesting that slavery was virtuous and inherently desirable. Of course, they did not think so. In an epilogue they explicitly denied they were trying to "sell slavery" (Fogel and Engerman 1974: volume 1, p. 258). They acknowledged that the "great power that slavery gave one group of men over another was, in and of itself, sinful." In brief and scattered observations throughout Volume One, they noted that enslaving blacks was also exploitative, expropriative, and racist (Fogel and Engerman 1974: volume 1, p. 159, 144, 153, 215).[28]

[27]The idea that efficiency is unambiguously desirable is a holdover from the Progressive Era. Historian Samuel Haber wrote, "efficient and good came closer to meaning the same thing in these years than in any other period of American history" (1964: ix). President Theodore Roosevelt helped cement this view in a message to Congress, "In this stage of the world's history to be fearless, to be just, and to be efficient are the three great requirements of national life" (1909). Efficiency also is often thought by neoclassical economists to be a consequence of the pursuit of profits by business owners in a competitive capitalist economy.

[28]Fogel later conceded he had not thought deeply about the moral issues "because they seemed so obvious" and that the scattered observations on the morality of slavery in *Time on the Cross* "did not add up to an adequate statement of the problem" (Fogel in Fogel et al. 1989–1992: primary volume 1, pp. 391–393). *Without Consent or Contract* considers the issue at length in an "afterword" [primary volume].

If slavery was more efficient than free labor – as Fogel and Engerman maintained – the real implication should have been allowing humans their own agency, as with free labor, comes at the cost of lost output and must be defended on noneconomic principles (Wright 1978).

On the efficiency of slavery as on other issues, Fogel and Engerman's critics questioned virtually every element of their approach – their definition of efficiency, their measurement of output and labor inputs, the evaluation of farm land, the econometrics of production function estimation, and many technical details of measurement and inference.[29] The multi-round exchange that took place is worth considering despite its failure to reach a general consensus because it illustrates the problem of audience in cliometric research. The prose in Volume One of *Time on the Cross* left the meaning of "efficiency" to the reader's sense of common usage. Yet there are several common meanings. A farm that produces a given physical output of cotton with a minimum of wasted expense can be said to be efficient. This concept is known as "technological efficiency."[30] An individual worker is said to be personally efficient when he or she performs a task in a well-organized and competent way. A productive process is efficient if it avoids the wasteful use of a particular resource, energy for example. This is "resource efficiency." Calculating any one of these concepts does not provide information on the other two.

By not clarifying their definition of efficiency for the lay reader, Fogel and Engerman allowed a major confusion to enter their exposition. The index of efficiency calculated in *Time on the Cross* corresponded to none of the three common-sense definitions, but was actually a fourth concept, "revenue efficiency." Southern farms produced cotton (and corn), while Northern farms produced no cotton (but plenty of corn). Since the outputs of the two regions were different, direct comparison of their physical efficiency is not possible. Fogel and Engerman skirted this apples-and-oranges difficulty by calculating the total value of the crops and livestock products reported by the two regions for the crops of 1859 by evaluating each product using a uniform national price. They measured productivity with a "geometric index of total factor productivity," defined as the ratio of the value of output to a weighted average of the inputs of labor (slave and free), land, and capital. They measured "relative efficiency" by the ratio of the total factor productivity of Southern farms to that of Northern farms (Fogel and Engerman 1974: volume 1, Fig. 42, pp. 192–193). Defined in this way, "productivity" is a measure of *revenue* in 1859, and calculating relative efficiency with this definition of product gives an index of

[29]The list of back-and-forth responses is long. Gavin Wright provides a concise summary of the main issues but remarked that "this issue [of the relative efficiency of slavery] has been scrutinized so extensively, and along so many dimensions, that an attempt at exhaustive review of the debate would be foolhardy" (2006: 94–121).

[30]Technological efficiency is inherently a physical concept. It is used, for example, to compare the performance of one firm relative to another firm when both produce the same identical product, say pencils, measured in physical terms, the number of pencils produced per day. The firm that produces more pencils given the same quantity of each input is said to be the more technologically efficient firm.

"revenue efficiency" (David and Temin 1974: 775–778). Despite what many readers of *Time on the Cross* might have assumed, revenue efficiency is not a measure of physical efficiency nor can it be a standard for assessing resource efficiency, nor can it be taken as a gauge of the workers' proficiency or diligence.

Moreover, in Fogel and Engerman's application, revenue efficiency overstates the superiority of slave plantation agriculture. The crop year 1859 saw unusually high yields of cotton, while at the same, time cotton prices remained relatively stable. Thus, the 1859 revenues from cotton production were extraordinary. Conditions in the North were not unusual; thus, using 1859 outputs introduced a bias into the calculation that favored Southern farms over Northern farms. In fact, "there is no other year which would put the South in a better light in terms of the Fogel-Engerman version of 'efficiency'" (Wright 1976: 313–316; 1979).

When they first presented a relative efficiency calculation in 1971, Fogel and Engerman conjectured that a finding that Southern farms were more efficient than Northern farms might be explained by the "superior entrepreneurship and managerial ability" of Southern farmers (Fogel and Engerman 1971a: 364–365). In *Time on the Cross* they went a step further. To superior management of planters and overseers, they added the "the superior quality of black labor." In *Time on the Cross*, these explanations for the supposed efficiency of slavery were no longer casual conjectures; they were presented as logical inferences from the calculations of revenue productivity (Fogel and Engerman 1974: volume 1, pp. 209–210). This new interpretation then became the central theme of their book, a motif they emphasized throughout from the introduction to the conclusion. The typical field hand "was harder-working and more efficient than his white counterpart" (p. 5). Slaves were "diligent and efficient workers" (p. 263). "All, or nearly all, of the advantage [of plantations] is attributable to the high quality of slave labor, for the main thrust of management was directed at improving the quality of labor" (p. 210).

This inference is not warranted. Paul David and Peter Temin were quick to point out that the relative "quality" of productive factors and the efficiency of alternative production process are two analytically distinct concepts. Even if we accept the validity of the calculations, the comparative analysis of total factor productivity indexes cannot shed light on the comparative performance of the managers and workers operating in different environments (David and Temin 1974, 1979). Fogel and Engerman later abandoned their claims about the quality and diligence of enslaved labor, but continued to defend their efficiency calculations (Fogel and Engerman 1980). They allowed their general audience for Volume One to believe that high revenue efficiency – which is the same as high profitability – was inherently a good thing, both morally acceptable and a felicitous consequence of the capitalistic nature of American slavery.

Fogel and Engerman's critics did not accept the validity of the productivity calculations and their complaints were not restricted to revenue as the measurement of output. In their view, *Time on the Cross* underestimated the labor input on slave farms (David and Temin 1974; Wright 1979). For their estimates of labor, Fogel and Engerman employed the Parker-Gallman sample, which had first been engaged to investigate the issue of self-sufficiency. The age and sex detail available for the slave

population in that database allowed Fogel and Engerman to make a number of adjustments to the labor force estimate not possible with the published census data used in the North-South comparisons (Fogel and Engerman 1974: volume 2). The full extent of these adjustments was not evident until Engerman and John Olsen outlined the "basic procedures" in 1992 (Engerman and Olson 1992). Their description is not entirely clear, but it raises a number of questions. Slave labor was measured in "hand-rating" equivalents (Fogel in Fogel et al. 1989–1992: primary volume 73–74 and Fig. 13; Engerman and Olson 1992: Table 24.1). Where these age and sex adjustments came from is not revealed.[31] In any case, Gavin Wright has shown that the hand-rating equivalents for women greatly underestimated their contribution of labor and thus inflated the total factor productivity of slave farms (Wright 2006).

Critics also questioned Fogel and Engerman's valuation of land. Originally, they measured the input of land by the total acreage in farms (improved plus unimproved) without an adjustment for differences across regions in natural fertility or land use (for crops or pasture) (Fogel and Engerman 1971a). In *Time on the Cross*, a refinement was made to measure land at its cash value (Fogel and Engerman 1974: volume 2). This would be a poor measure in any case since it does not take into account the different proportions of improved and unimproved acreages. Significantly, though, it would artificially depress the apparent efficiency of Northern farms because Northern land values presumably capitalized their greater proximity to governmentally subsidized railroads (Wright 2006; David and Temin 1974). In their response to these criticisms, Fogel and Engerman attempted to correct for the locational component of land rents with a revised set of calculations (1977). David and Temin pointed out that the corrections "entirely eliminated land inputs from their production function!" (David and Temin 1979: 216, punctuation as in the original). Fogel and Engerman responded by charging that it was David and Temin who had called for the correction that had eliminated land (Fogel and Engerman 1980). Actually, David and Temin had not suggested such a correction. Instead, they reasserted their original argument that "the conceptual apparatus [used by Fogel and Engerman] is inappropriate to the task of ascertaining the relative technical efficiency of free and slave agriculture" (1979: 216). By this point, the debate had become mired in the cross purpose of how to properly measure inputs for a conceptual apparatus that the two sides could not agree was appropriate. The message, which should be retained, as Thomas Haskell emphasized, is that Fogel and Engerman in the course of the exchange had abandoned the major theme of *Time on the Cross*, their claim that the efficiency calculations established the diligence and

[31]Children under 10 and slaves 70 and over were assumed to be unemployed. The hand-equivalent measures are further reduced by subtracting a fractional measure of the number of male slaves engaged in nonagricultural pursuits. This adjustment is probably based on a sample of probate records, but that is not explicitly stated]. Inexplicably, farms without male slaves or with "unusual sex ratios" were dropped from the sample. A farm was also dropped, also without explanation, if it was not self-sufficient in grain production. Both of these deletions removed small farms (1–15 slaves) almost exclusively and probably distorted the measured productivity of that size class.

willing cooperation of enslaved black labor in the production of agricultural crops (Haskell 1979).[32]

Economies of Scale and Gang Labor

Although they had dropped their claim about the relative quality and diligence of slave labor, Fogel and Engerman continued to insist the productivity advantage of slavery was real and that their measure of revenue efficiency was a meaningful gauge of that advantage. They next asserted the relative efficiency of slave farms was the consequence of economies of scale in slave agriculture, an advantage not available on free family operated Northern farms and not possible with fewer than 16 slaves. They used the Parker-Gallman sample to calculate revenue efficiency for farms of different sizes, using the number of slaves owned as the measure of scale (1974: volume 1, Fig. 43).

Gavin Wright pointed out again that Fogel and Engerman's revenue efficiency "is largely a measure of who happened to be growing cotton during the most extraordinary cotton year of the nineteenth century." And significantly, Wright's calculations revealed that when "the crop mix is held constant, there is no productivity advantage for slaves and there are no scale economies for slave plantations" (Wright 1976: 317). Fogel nevertheless continued to emphasize the productivity advantage of scale, and he further claimed that a break can be observed when farm size exceeded 15 slaves (or 5 prime male hands), indicating to him that the source of the gains was the use of the gang system for field work (Fogel in Fogel et al. 1989–1992, primary volume: 26–29; Fogel 2003: 29–32).

Fogel and Engerman first introduced the idea that the gang system was common, even universal, on large plantations in *Time on the Cross.* They described the system as one in which the slaves were divided into several gangs based on their physical capabilities. The gangs were then driven through the field, one following the other with the lead gang setting the pace. Fogel and Engerman described the gang system in operation during cultivation:

> Field hands were divided into two groups: the hoe gang and the plow gang. The hoe hands chopped out the weeds which surrounded the cotton plants as well as excessive sprouts of cotton plants. The plow gangs followed behind, stirring the soil near the rows of cotton plants and tossing it back around the plants. Thus the hoe and plow gangs each put the other under an assembly-line type of pressure. The hoeing had to be completed in time to permit the plow hands to carry out their tasks. At the same time the progress of the hoeing, which entailed lighter labor than plowing, set a pace for the plow gang. The drivers or overseers moved back and forth between the two gangs, exhorting and prodding each to keep up with the pace of the other, as well as inspecting the quality of the work. (Fogel and Engerman 1974: volume 1, p. 204)

[32]In a baffling retort to Haskel published 13 years later, Fogel and Engerman merely contradicted Haskel without addressing the fundamental point made by David and Temin that the quality of labor could not be inferred from total factor productivity calculations (Fogel and Engerman 1992a).

This vivid portrayal of field work drew freely upon their imagination; it is not based on contemporary evidence. Yet, Fogel and Engerman went on and proposed that assigning slaves to "highly disciplined, interdependent teams capable of maintaining a steady and intense rhythm of work," was the "crux of the superior efficiency of large-scale operations" (Fogel and Engerman 1974: volume 1, p. 204).

The claim that the gang system was commonly employed on farms with 16 or more slaves is nothing more than conjecture. Fogel and Engerman provided no evidence that the gang system was widely used in the late antebellum period. Immediately following the passage just reproduced, they quote and paraphrase Frederick Law Olmsted's several contemporary descriptions of "slave driving," leaving the impression that they referenced the gang system just described, but none of Olmsted's observations referred to driving gangs. In these passages, Olmsted was reporting on the necessity of using beatings or the threat of whipping to compel slaves to work hard. None of his informants worked slaves in gangs (Olmsted 1856: 84, 205–206, 372–373).[33] Subsequent research on the organization of plantations, and the supervision of slaves, has produced only scattered references to the gang system (Metzer 1975). Gavin Wright warns that plantations exceeding some threshold scale cannot be associated with any particular form of organization. He also builds a case that the gang system was passing out of use by 1840 (Wright 2006: 95–96). Alan Olmstead and Paul Rhode report that they have "seen almost no slave era testimony extolling the productivity advantages of the gang system (under any name) in any cotton production activity" (Olmstead and Rhode 2008b: 1152). They also report there is little support for images of "assembly-line" pressure or the metaphor of "factories in the field" (Olmstead and Rhode 2015).

While the debates on relative efficiency, economies of scale, and the gang system left the original interpretations presented in *Time on the Cross* in tatters, it has so far failed to achieve a broad consensus about the technical efficiency of large-scale slave plantations relative to small slave farms, free Southern farms, or Northern farms. There have been a number of contributions attempting to settle the matter employing a variety of statistical techniques (Cobb-Douglas, translog, stochastic frontier, and translog ray frontier production models) with a broad and bewildering scattering of conclusions (Schaefer and Schmitz 1979; Fogel and Engerman 1980; Field 1988; Grabowski and Pasurka 1989, 1991; Hofler and Folland 1991; Field-Hendry 1995; Toman 2005). Given the limitations of the census data, I am tempted to conclude

[33]Fogel and Engerman quote Olmsted's description of a hoe gang working on a Mississippi plantation as evidence of "slave teamwork, coordination, and intensity of effort" (Fogel and Engerman 1974: volume 1, p. 205). However, they neglected to mention that Olmsted intended his description to illustrate the necessity of the threat of whipping ("the whip was evidently in constant use") not the typical organization of tasks on a large plantation (Olmsted 1860: 81–82; Gutman and Sutch 1976a).

that efforts to reach a satisfactory conclusion about the relative physical efficiency of small versus large slave farms have reached a point of greatly diminished returns. Basically, the question posed was poorly framed from the outset. It too narrowly focused on technical efficiency, a concept that proved difficult if not impossible to measure.

Taking a broader view, slavery is surely inefficient. American slaves were overworked and kept illiterate, denying them the opportunity to reach their full human potential. An investment in literacy and education and the acquisition of human capital have well-documented high rates of return (Goldin 2016).

Bondage meant slaves were not free to allocate their talents and labor time to their best advantage, barring them from contributing to the arts and sciences, barring them from leadership roles in a democratic society. Any economic system that so outrageously misuses its human resources cannot be called efficient.

The critics of *Time on the Cross* prevailed on the broader points since they were able to show that the cliometric results presented in Volume Two do not support the interpretations presented in Volume One, even if the cliometric results are taken at face value. In his "retrospective meditation" on the slavery debates, Fogel ultimately conceded that the efficiency calculations he and Engerman performed did not establish the superior management of planters and the superior quality of black labor. He rejected both the belief he once held that "technological efficiency is inherently good" and the notions entertained by some readers of *Time on the Cross* "that productivity is necessarily virtuous." Economic forces do not "automatically select moral solutions" (Fogel 2003: 46–47, 69). What cliometricians can safely conclude from the debate over efficiency is that the world got cheap cotton at the expense of the education, intellectual development, inspiring ambitions, and personal security of its enslaved producers.

The Stability of the Black Family

Fogel and Engerman's insistence on the efficiency of slavery had misled them into trumpeting the superior quality of slave labor. Their insistence on the personal efficiency of black workers then pushed them to suggest enslaved people were willing collaborators in the production of staple crops. The slaves' presumed contentment with their status would be plausible, they argued, if one recognized that the black family was the basic unit of social organization under slavery. The security and stability of family life would have been essential to gain the slave's compliant acceptance. This chain of inferences allowed Fogel and Engerman to announce one of their principal corrections was to overturn the belief that sexual abuse of slave women had destroyed the black family (Fogel and Engerman 1974: volume 1).

Fogel and Engerman denied that sexual abuse was common. They did this, first, by declaring without evidence that slave breeding was "myth"[34] and then by denying that white masters and overseers "ravished black women frequently," justifying that claim with the assertion that "white men who desired illicit sex had a strong preference for white women." The only fact offered to support this generalization (and indeed the only evidence that supported the entire house of cards) was "the failure of Nashville's brothels to employ slave women" (Fogel and Engerman 1974: volume 1, pp. 133–135). The phrasing is unfortunate. As Martha Hoffman noted in her discussion of the moral issues raised by *Time on the Cross*, the word "failure" implied to some readers that slave women "should have been" prostitutes (1992: 600). But surely, leaving that point aside, the conclusion that Southern white men's preferences in these matters would protect black women is naïve in the extreme.[35]

One of the first of Fogel and Engerman's claims in this chain of inferences to fall was the alleged "fact" that enslaved black women were not forced into prostitution. Yet, their source, David Kaser, had clearly noted that the 1860 census did not record the occupations of slaves (Kaser 1964). Even if Nashville had hundreds of them, they would not have appeared in the records. In the opening pages of *Time on the Cross*, Fogel and Engerman defended the robustness of the facts and findings they would report, saying "when persistent efforts to contradict the unexpected discoveries failed," they were forced to accept a "radical reinterpretation of American slavery" (Fogel and Engerman 1974: volume 1, p. 8). In the case of the Nashville prostitutes, the vetting could hardly have been persistent or even attentive.

After the Controversy

Replication is a normal part of the scientific method. If others cannot confirm reported findings, the new results are declared unproven and the research that produced them is deemed a failure. However, a focus exclusively on Fogel and Engerman's careless handling of their evidence and their arrogant claims of possessing a precise and powerful methodology unavailable to ordinary historians

[34]Fogel and Engerman ignored the evidence that I had presented, which I discuss elsewhere in this chapter (Sutch 1975a). They argued for a rejection of slave breeding with two conjectures: (1) that interference could have had little effect on the rate of population growth and (2) that high costs to slave breeding would have eroded away all profit in the business. Gutman and I countered these suppositions by pointing out that the first rested on the fact that the fertility of the slave population was close to the biological maximum. But those high levels might have been produced by breeding. They should have asked how much the fertility rate would have fallen had breeding been stopped. No evidence was offered to support the second argument other than the supposed loss of the slaves' willing cooperation in the production process (Gutman and Sutch 1976b).

[35]Fogel and Engerman claimed that the census data on the proportion of the slave children under 10 recorded as mulatto (estimated by Steckel at 10.1% in 1860) cannot be used as evidence of frequent impregnations of enslaved women by whites (Fogel and Engerman 1974: volume 1, pp. 131–133). However, the evidence they provided in volume 2 on this point is totally without scientific creditability (Gutman and Sutch 1976b). See Steckel (1980) and Malone (1992) for extended discussion of miscegenation.

would miss an important lesson. *Time on the Cross* was the product of a system that rewards with lavish attention powerful findings that seemingly offer either an outright rejection or strong support for conclusions the public finds comfortable. Eager to make a splash, Fogel and Engerman let their enthusiasm overwhelm their precautions. Practicing cliometrics, however, does not absolve the practitioner from adhering to the strictures and norms of science. It must be emphasized on the other hand that Stanley Engerman and Robert Fogel generously answered questions and provided raw data to their critics and welcomed the exchange of results and interpretations (Fogel et al., *Technical Papers*, volume 1, 1989, p. xvi). That openness to criticism and their willingness and eagerness to engage in the debate have now become the hallmarks of first-class cliometrics.

While considering *Time on the Cross* an interpretive failure, I do not want to overlook some of the positive contributions made by Fogel and Engerman. Among these is the valuable archival research that assembled data on slave values by age, gender, and location developed from probate records. Figure 4 presents the age-value profiles for Louisiana and compares those to the male profile estimated by Laurence Kotlikoff from his analysis of the selling price of slaves in the New Orleans slave market.[36]

[36]Fogel and Engerman 1974: volume 1, pp. 72–78, figures 15, 16, and 18; volume 2: 24, 79–82. The data plotted were provided by Stanley Engerman and are reproduced in Engerman et al. 2006: volume 2, p. 373, tables Bb209–214 and Bb215–218). The age profile of the New Orleans sale prices for 1850–1859 is based on the coefficients of a sixth-degree polynomial reported by Laurence Kotlikoff 1979: Table 4.

An even more significant contribution was Fogel and Engerman's multidisciplinary approach to their subject. This was fairly novel at the time, and their example inspired others to pursue opportunities to push ahead on those fronts. This openness to the perspectives of other disciplines had a profound influence on the cliometric investigation of many topics beyond those raised by slavery in the years that followed. Two examples of uniting disciplines to address the economics of slavery illustrate the importance of this reorientation. Richard Steckel looked at the fertility of slave women using the tools of demography (Steckel 1977). His exploration into this issue led to the collection of data on the heights of teenage slave women to judge the age of menarche (Trussell and Steckel 1978; Steckel 1979, 1986a). That statistic is relevant to judging how early in a woman's life, biologically speaking, was her age at her first birth – how soon after puberty. Ultimately, this line of research produced the anthropometric revolution in cliometric research. Steckel and many others collected comparative data on human stature and weight to evaluate the well-being of disparate populations throughout history (for a review, consult Komlos and Alecke 1996; Craig 2016).

Kenneth Kiple and Virginia Kiple's exploration of the mortality of slave children and my effort to critique the analysis of the slave diet in *Time on the Cross* led us to explore the basics of nutritional science (Kiple and Kiple 1977; Sutch 1975b). There is now an extended literature on the biologic and biomedical history of the black population both during and after slavery (Kiple and King 1981; Steckel 1986a, b; Troesken 2004). At the same time, multidisciplinary studies of the nutritional and medical histories of many other populations have applied the methods to a wide range of diverse settings (Steckel and Floud 1997).

Time on the Cross advanced the general discussion of slavery by extending it to topics well beyond the viability of the institution and its impact on economic growth. Fogel and Engerman brought cliometric evidence and methods to assess the provision of food, shelter, and clothing; the slave's family life; and punishments, rewards, and expropriation. Their provocative opinions on these topics, even as they were overturned, accelerated the general pace of research on the economics, sociology, and demography of slavery. As Fogel remarked, the public debate "was a debate in which there were no losers" (2003: 32). The new research and the collection of new data by Fogel and Engerman's critics and defenders greatly enhanced the credibility and acceptance of cliometrics by economists. Yet, there was an unfortunate consequence as well.

This outpouring of new work had little apparent influence on the discussion of slavery among historians. Alan Olmstead and Paul Rhode noted this disconnect:

> In the past, historians and economists (sometimes working as a team) collectively advanced the understanding of slavery, southern development, and capitalism. There was a stimulating dialog. That intellectual exchange deteriorated in part because some economists produced increasingly technical work that was sometimes beyond the comprehension of many historians. Some historians were offended by some economists who overly flaunted their findings and methodologies. (Olmstead and Rhode 2018: 14)

Apparently, the bitterness of the debate over *Time on the Cross*, the far too many factual errors in the book, and the ostentatious, yet imprecise, formalism of Volume Two led some historians to simply ignore the entirety of cliometric literature. Recently, two historians of American slavery, Sven Beckert and Seth Rockman, dismiss their own neglect with a single sentence. "The economic history of slavery has labored in the shadows of the interpretative controversies surrounding . . . Time on the Cross" (2016: 10). Presumably, this excused them from critiquing the cliometric literature and freed them to contribute to and celebrate an alternative economic history of slavery and American economic development. Their loss (and ours) has become glaringly apparent in the recent discussion by cliometricians of what historians have come to call the "New History of Capitalism and Slavery" (Murray et al. 2015; Olmstead and Rhode 2018).

In 1989, Robert Fogel responded to critics of *Time on the Cross* and the "crackling atmosphere" of the debates. This effort took four volumes collectively titled *Without Consent or Contract: The Rise and Fall of American Slavery* (Fogel et al. 1989–1992). The primary volume, by Fogel alone, begins with a review of several selected issues addressed in the debates. His tone is less polemical and the message less audacious than in the 1974 volumes. The revised portrayal of the slave system is more nuanced, more complex, somewhat subtle, and less contentious (for a review, see Clark Nardinelli 1994). Endnotes were attached. The primary volume also presented evidence relating to slave societies outside of the United States and expanded its attention to address ideological, religious, moral, and political issues. Three companion volumes, which appeared in 1992, provide a mixture of brief research memos together with technical papers, many of which had already been published years before in the journal literature.[37] Judged by citations, none of the new material on antebellum slavery in the companion volumes attracted rebuttal from the critics or attention from others.[38]

Fogel announced in 1989 that he had written his last words on slavery with the publication of *Without Consent or Contract* (Fogel et al. 1989: 13). That all but ended the debate over *Time on the Cross*. Most of the participants, like Fogel, moved on to other topics.[39] This finality, unfortunately, left the resolution of the

[37]For some insight into the organization of the "loosely structured" research project that produced both *Time on the Cross* and *Without Consent or Contract*, see Fogel and Engerman's "General Introduction" to the *Technical Papers* (Fogel et al. 1992: volume 1).

[38]In the primary volume of *Without Consent or Contract*, Fogel continued to report total factor productivity calculations like those in *Time on the Cross*, but he reframed the conclusion to claim "the superior efficiency of the big plantations was due not merely to inherent advantages of the gang system but also to the concentration of above-average ability in the ownership of such farms" (Fogel in Fogel et al. 1989–1992: primary volume, figure 14). Gavin Wright responded by noting that "the ability of the ownership is no more directly observable in census data than the gang labor system itself" (Wright 2006: 96).

[39]There was some continuing work by economic historians to provide quantitative data that might inform the short-lived reparation movement to redress the injustice of slavery (America 1990).

debate – and particularly Fogel and Engerman's joint view – somewhat muddled.[40] That may have had the effect of discouraging further cliometric research. Apart from the continuing work with anthropometric and biometric evidence already mentioned, the next quarter century produced only a thin list of cliometric contributions on American slavery. There were, however, two exceptions to the general lack of new research that I shall come to shortly. Apart from these contributions, the scholarly interest in slavery by quantitative historians switched away from the late antebellum South to topics like the Atlantic slave trade, colonial slavery, and slavery in the Caribbean, Brazil, and Africa. It is not clear why this should be so. Perhaps, the practicing cliometricians had exhausted themselves, if not the topic. Perhaps a younger generation of cliometric scholars had learned that the sensitive issues involved had best be avoided given the topic's history of rather acrimonious debate.

Group Sales and Price Discounts in the Market for Slaves

A new issue dealt with after the controversy had died down was the puzzling price discounts for intact slave families when sold on the New Orleans market. Under Louisiana law, enslaved blacks were analogous to real estate, and the recording of deeds ensured the title to this form of property. One of the contributions of the Fogel and Engerman project had been the digitization of a large sample of the bill-of-sales recorded for slaves in New Orleans (Fogel and Engerman 1974: volume 2, Table B.1 (data set 9)). Over 5700 invoices covering the period 1804 to 1862 were recorded (less than 5% of the total number in the archives). Analysis of the structure of the sale prices by Laurence Kotlikoff revealed that a well-functioning ("rational") market existed. Kotlikoff noted that the hump shape of the age-price profile (see Fig. 4), the premium prices paid for males, and for warranties of good conduct "all point to careful, calculating transactors operating in a highly developed market in human beings." In a point that should not be passed over lightly, he also took note of the degrading physical inspections of the men and women by the "careful" and "calculating" potential buyers. Slaves were stripped of all clothing and closely examined to assess muscle development and to discover physical defects such as whipping scars (Kotlikoff 1979).

It was a surprise, however, that the sales records also revealed that very few family groups were sold. Of the 5,785 sales in the sample, only 40 involved a husband and wife sold together (in 22 of these cases, the couple was accompanied by their child). Another 94 were mothers sold with her accompanying child or children. Seventy-seven percent of the sales were slaves sold individually (Kotlikoff 1979: 513). There was little apparent regard for preserving enslaved families intact. More

[40]The primary volume of *Without Consent or Contract* was written by Fogel alone. Engerman writing jointly with Kenneth Sokoloff seems to have retreated from *Time on the Cross* and accepted the view that in the years before the Civil War, the South "lagged behind the North . . . in evolving a set of political institutions that were conducive to broad participation in the commercial economy" (Engerman and Sokoloff 2002: 61).

surprising was that, except for the 22 husband-wife-child combinations, slaves in family groups sold for deep discounts compared to their value if they had been sold separately. This suggests either that buyers in New Orleans did not place much value on the behavioral benefits in terms of demeanor and submission that Fogel and Engerman thought would protect family units, or that the families sold at a discount (predominately mother-child pairs) were in less than prime condition when they arrived in the Crescent City.

Jonathan Pritchett, together with several colleagues, undertook a re-examination of the New Orleans sales data to explore the puzzle. He joined with Herman Freudenberger to point out that the slaves sold in New Orleans had been selected by traders for transport to New Orleans because of their high value. They were better able to bear the cost of transport by ship. Not only were the slaves clustered in the prime ages (10–30), but they were in prime condition, noticeably taller than slaves transported by their owners. Presumably, they were stronger and in better health than average. This selection bias was particularly noticeable for children and adolescents (Pritchett and Freudenberger 1992). Pritchett and Richard Chamberlain confirmed this result by comparing the price of slaves in estate sales, which would include both high-valued and other slaves, with the prices in the New Orleans sales records. They found no evidence that adverse selection had put slaves with hidden defects on the New Orleans market (Pritchett and Chamberlain 1993). Charles Calomiris and Pritchett analyzed the deep discounts for mother-child pairs. Noting the relative rarity of such sales (74% of children, 4 to 13, shipped by traders were unaccompanied), they explored the possibility that the typical mother-child unit was not in prime condition. Pritchett and Freudenberger had earlier found that children shipped to New Orleans were taller than other children of the same age and gender, but they had not distinguished between those children who were shipped with their mother and those who were unaccompanied. Returning to the ship manifests and identifying likely mother-child pairs, Calomiris and Pritchett discovered that accompanied children were shorter than the unaccompanied by one and one-half inches (for children under 10), confirming the hypothesis that the discounts reflected perceived quality differences (Calomiris and Pritchett 2009: Table 4). The few observations of a mother sold together with a child in New Orleans were likely cases where the child was evidently poorly nourished or in otherwise poor health. The New Orleans data do not support the hypothesis that slaveholders valued and respected the human bonds of affection and mutual responsibility that define a family. When money was involved, many masters seemed willing to break families apart.[41]

[41]The legal historian, Thomas Russell, has assembled convincing evidence that Southerners believed that slaves sold separately would bring higher prices. Southern courts ruled that estate executors had a fiduciary duty to break up slave families in order to maximize the sales revenue (Russell 1996). His study of South Carolina suggests that court-supervised slave sales comprised one-half of all slave sales in that state (Russell 1993).

Biological Innovation and Southern Agricultural Development

The debates over the rates of antebellum economic growth in the South and North had established that a significant factor in the case of the South was the shift of population from the South Atlantic states to the East South Central states (as demonstrated by the comparison made in Table 3).[42] The advantage of the Western states had been attributed to the naturally high fertility of the soil: the black-belt soils of Alabama and the alluvial soils of the Mississippi basin. Alan Olmstead and Paul Rhode, in an important post-controversy contribution, insist that this summary ignores the role biological innovation played in Southern agricultural development. With the move onto virgin land in the West, planters needed to adapt the cotton plant to the local conditions. To this end, they experimented with different varieties and selected the most advantageous. Yields were increased, fiber quality was improved, and taller plants, which flowered and formed larger bolls further from the ground, were developed. Since the labor requirement for hand picking was the primary constraint on productivity per slave, the taller, more prolific varieties markedly increased the number of pounds of cotton that a worker could pick in a day. When superior varieties were perfected, they spread East and West and North and South, thus increasing productivity throughout the South (Olmstead and Rhode 2008a, b, 2011).

Olmstead and Rhode quantified the advances in productivity by collecting daily records of cotton picking. Plantation overseers recorded the weights of individual worker's pickings to monitor each slave's performance, reward high effort, and discipline slackers.[43] Their data collection totaled 704,800 individual daily reports covering 6,200 slaves working on 142 plantations. These data when plotted and averaged reveal a threefold improvement in productivity in the Western states between 1811 and 1860 and a doubling of productivity for the Atlantic Coast states. The time trends are plotted in Fig. 5.[44] A statistical analysis of the data by region revealed that the dynamics of Southern development were driven by the interaction of biological innovations with the Western movement to alluvial soils:

> Most of the new cotton varieties were invented in the West, and they were undoubtedly best suited for the area where they first evolved thereby enhancing the West's comparative advantage. The new varieties gradually were adapted to displace older varieties in a wide spectrum of geoclimatic conditions, but the new technologies were particularly suited for more fertile lands. The large plantation regions of the West had better soils to start with, but in a sense biological innovation made these soils even better. (Olmstead and Rhode 2008b: 1156–1157)

[42]Another factor was the extraordinary growth of the demand for cotton emphasized by Gavin Wright (1975)

[43]"Discipline" may be a euphemism here; slaves were not infrequently whipped for below par performance (Olmstead and Rhode 2008b: 1143).

[44]The four Atlantic coast states are Georgia, North and South Carolina, and Virginia. The seven Western states are Alabama, Arkansas, Florida, Louisiana, Mississippi, Tennessee, and Texas.

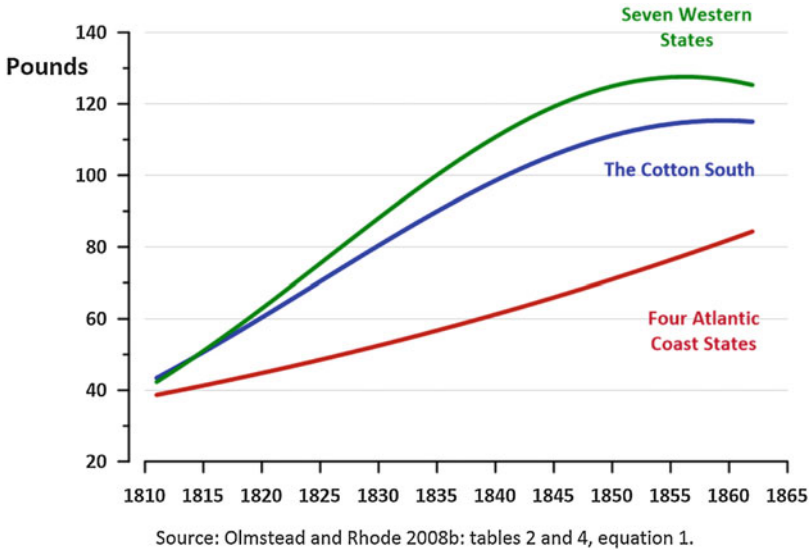

Fig. 5 Daily cotton picking rates, 1811–1862. Mean pounds harvested per worker per day

Olmstead and Rhode consulted an extensive set of primary sources to support and contextualize their statistical findings. Newspaper accounts, agricultural journals, letters from planters and overseers, and treatises on plant biology and scientific farming established that the biological advances were the work of slave-owning planters who molded the cotton plant to their geoclimatic conditions, soil types, and the evolving requirements of textile manufacturers. Earlier characterizations of slave owners as "uninventive" rested on the planters' failure to experiment with mechanical inventions. A broader view of invention challenges this view.

An Assessment

American slavery was a brutally cruel and highly exploitive system. It was also a racist institution. No whites were slaves and the presumptive status of every black person was slave.

Those facts are disturbing. They make it impossible to regard American history as one of unblemished freedom, equality, and democratic community. After a 60-year-long investigation of the economics of slavery by economists and cliometricians, it is also impossible to deny the complicity of America's economic system based on the inviolability of private property, strict contract enforcement, and an unregulated labor market in propelling and sustaining the slave regime.

The Southern planter was a capitalist – a capital owner, who made decisions to buy or sell slaves and to employ them at one task or another guided by a profit motive and the constant pressure of competition. The major contribution of

cliometrics to the economic history of slavery was to view the planter as a capitalist. Only the slave owner willing to employ his slaves in the most efficient manner would earn a return sufficient to justify their price. Achieving high output required that workers be engaged in intensively hard work for long hours under the constant threat of corporal punishment (as acknowledged by Fogel in Fogel et al. 1989–1992, primary volume: p. 34). Each slave owner had to replicate those features on his own plot of land to remain in business. If maintaining a profitable enterprise necessitated the disrespect of marital status and family bonds, few planters could afford more empathetic treatment. Those unwilling to continence the inhumanity of the system left the business to those who could. To those who became and remained masters, a blind-eyed belief in racial inferiority served to excuse and justify racial degradation and brutal treatment. The absence of contrary voices in the South allowed the racism to fester and intensify. Racism poisoned antebellum society and, as we know all too well, it still poisons American culture today. The true burden of slavery defies quantification.

Acknowledgments I thank Howard Bodenhorn, Susan Carter, Alexander Field, Michael Haupert, David Mitch, Jonathan Pritchett, Roger Ransom, Paul Rhode, Alan Olmstead, and Gavin Wright for encouragement and helpful suggestions.

Institutions

Philip T. Hoffman

Contents

Abstract

Institutions clearly play a major role in economic growth and political development. But much more needs to be done to verify and to clarify their role, and to show that it is causal, and not the result of other factors. The necessary work will involve careful historical research, the assembly of large data sets, and careful econometrics and formal modeling. And it should also involve cooperation with other social scientists, from experimental economics to anthropology and political science.

Keywords

Institutions · Economic growth · Politics · Property rights · Political science · Culture · Glorious Revolution · Douglass North · Political economy

Introduction

Institutions matter for economic outcomes, and they matter a lot. The contrast between North and South Korea makes that crystal clear. It is admittedly only an example, but it is a striking one, at least for believers in revealed preference. Residents of the North risk their lives to escape the penury and malnutrition in North Korea – and the political repression too – in order to live in the South, where the 2016 per-capita GDP (corrected for purchasing power) is about the same as that in Italy or New Zealand. The yawning gap in living standards is obviously not caused by cultural differences or major differences in the level of education. Rather, it is the result of autocratic political institutions in the North. No one wants institutions like that.[1]

If social scientists now concur that institutions have a big effect on economic outcomes, their agreement comes only after a long debate over the impact institutions have. The debate began in economic history, where Douglass North was the evangelist arguing for the importance of institutions. As his message spread through economics, political science, and the other social sciences, it ultimately convinced scholars that institutions shaped economic growth, the distribution of income, and political development. North's message in turn drew considerable attention to economic history, and it is no doubt the reason why his publications are widely cited: more frequently in fact than the work of Robert Fogel – the co-winner of the Nobel Prize with North – and even more often than the writings of Kenneth Arrow, one of the most influential Nobel Laureates in economics.[2]

The debate over institutions bears closer examination, because it has implications for future research. It turns on the question of measuring the economic effect of institutions – a difficult task since institutions themselves are endogenous – and it also involves the still unresolved issue of how institutions change. We will look at the debate, beginning with how institutions are defined, and pay close attention to the critics who argue that the role of institutions has been exaggerated. When their criticisms are on target, they reveal what future research needs to be done. So does recent work on institutions in fields outside of economic history – in behavioral and experimental economics, in evolutionary anthropology, and in political science. That future research is the last topic we will take up.

[1]For further evidence, see the case study in Acemoglu et al. 2005.

[2]North's most cited article (according to Google Scholar consulted on April 12, 2018) was his 1991 essay on institutions (North 1991), which had 54,008 citations. Fogel's most cited work was his coauthored book on slavery, *Time on the Cross* (Fogel and Engerman 1995), which had 1806 citations. As for Arrow, his most referenced publication was his book on his impossibility theorem (Arrow 2012), with 17,983 citations. The citation counts here include references to earlier editions of *Time on the Cross* and Arrow's book.

What Are Institutions?

Discussion of institutions abounds in the social sciences, but often it is not clear precisely what an institution is. In sociology, an institution is typically a "complex social form" that reproduces itself – for instance, "governments, the family, ..., business corporations, and legal systems" (Miller 2014). That definition includes groups and organizations such as the family, the government, or corporations, alongside the laws and courts that make up the legal system. North's definition is narrower and more precise:

> Institutions are the humanly devised constraints that structure political, economic and social interaction. They consist of both informal constraints (sanctions, taboos, customs, traditions, and codes of conduct), and formal rules. (constitutions, laws, property rights) (North 1991, 97)

So for North, institutions are human constraints and they are distinct from organizations such as the government or the family. As in sociology, North's institutions change slowly. In his view, humans devise institutions "to create order and reduce uncertainty in exchange" but their effects need not be beneficial, for they can push economic change toward "growth, stagnation, or decline" (North 1991, 97).

North came to this definition via his research for two innovative coauthored books, one on the role of institutions in the economic history of the United States (Davis et al. 1971) and the other on the part they played in medieval and early modern Europe (North and Thomas 1973). Both works argued that economic theory could not explain economic growth and that the explanation had to involve "institutional arrangements." Both also pointed to how new institutional arrangements could foster increased efficiency or come to the rescue when markets failed. For example, the creation of a new corporate form – the corporation – would allow firms to realize economies of scale. Similarly, the establishment of insurance companies would help individuals cope with risk when markets were incomplete (North and Thomas 1973; Davis and North).

The unspoken assumption in this work from the early 1970s was that individuals create institutions to foster economic growth or move the economy toward a Pareto superior outcome when the first welfare theorem of economic theory fails to apply. Sociologists have criticized that assumption (Granovetter 1992), as have economic historians (Ogilvie 2007). But North's ultimate definition of institutions – humanly devised constraints – explicitly abandons any such premise (North 1991). For North, institutions could easily harm the economy, and subsequent research in economic history has made abundantly clear the damage bad institutions could do.[3] North's

[3]Guilds in medieval and early modern Europe provide a striking example of the damage institutions could do, by enforcing monopolies and limiting the supply of skilled workers. That is Sheilagh Ogilvie's argument (Ogilvie 2004), in response to earlier claims that guilds helped accumulate human capital (Epstein 1998). One could make a similar case for the effect of the institutions that shaped the development of health insurance in the United States, including laws that allowed the use

definition is also compatible with an analysis of social structure, which sociologists believe economists neglect. The social structure in North's view consists of organizations, such as firms, families, political coalitions, or social groups. They in turn can be studied using tools from political economy, the economics of the family, or the economics of networks.

The actual problem with North's definition is not any assumption that institutions are in any sense optimal or welfare improving. Rather, it is the risk of glossing over the question of how the humanly devised constraints are enforced. North himself recognizes the importance of enforcing rules and he acknowledges that enforcement may not be effective (North 1991). But his brief definition omits explicit mention of enforcement.

The problem of enforcement comes to the fore in Avner Greif's work on institutions, especially his 2006 book (Greif 1989, 1993, 2006a). For Greif, the key question is explaining why people follow rules. A law may outlaw theft, but why do people obey it? Saying that the threat of punishment makes people obey is insufficient, for what ensures that the police will catch the thieves and courts jail them? After all, there are clear examples – even in an orderly democracy such as the 1950s United States – of thieves operating with impunity at least in some places (Hoffman 2006). To explain that sort of outcome, Greif argues that a satisfactory definition of institutions has to incorporate beliefs and norms and organizations alongside the rules. A person will not steal, for example, if he has internalized the norm against theft or believes that he is likely to be caught and thrown in jail. That belief may in turn depend on the effectiveness of organizations (the police and courts) or on working of other norms and beliefs (for instance, the expectation that the judges and the police will not accept bribes). So for Greif, institutions end up being a system of rules, beliefs, norms, and organizations that generate regular social behavior (Greif 2006a). In practice, one could perhaps reduce his definition to rules with a means of enforcement (as for instance in Hoffman et al. 2000), but specifying why people heed the rules is essential, and the answer will involve beliefs, norms, or organizations.

The Effect of Institutions

There is abundant and persuasive qualitative evidence that institutions matter in North's early work on institutions (Davis et al. 1971; North and Thomas 1973) and in Greif's book (Greif 2006a). But critics who have doubts about the role of institutions want quantitative evidence.

Such evidence exists, and it too is persuasive, particularly microeconomic evidence concerning a portion of the economy or a particular locality. Perhaps the most convincing evidence comes from Jean-Laurent Rosenthal's study of drainage and

of fringe benefits to get around wartime wage controls and continued tax exemptions for employer provided health care (Thomasson 2003). They led to heavier spending on health care than in other developed economies for health outcomes that were often inferior.

irrigation in France (Rosenthal 1990, 1992). Before the French Revolution, there were a number of irrigation projects in southern France that were never undertaken even though they would have raised agricultural productivity and earned a return higher than that available from alternative investments. The same was true for drainage projects in northern France. The problem was not a lack of potential entrepreneurs, a failure of credit markets, or technological obstacles, because the technology (essentially unskilled labor with picks and shovels, plus some skilled work by surveyors, masons, and carpenters) was well known. Rather it was institutions. Property rights overlapped, and because the court system lacked a clear central authority that could deliver a final legal decision, property owners had an incentive to sue in order to hold water control projects up for ransom.

Profitable water control projects therefore failed, or were never started, until the French Revolution and Napoleon completely reformed the court system and property rights. The reforms halted the pattern of unending litigation over water projects and left the ultimate decision to a centralized authority with powers of eminent domain. The result was a burst of irrigation and drainage in France after 1820, even though the projects themselves were less profitable than they would have been before the Revolution's outbreak in 1789.

The obstacle blocking irrigation and drainage projects was institutional – in particular, overlapping property rights, a legal system with no finality, and no effective power of eminent domain. The root of the problem was the lack of a sovereign legislative or judicial authority that could wield effective powers of eminent domain and either resolve problems of overlapping property rights or keep them from arising in the first place. Institutions of that sort were politically impossible in pre-revolutionary France, even under a supposedly absolute monarchy. They would have violated the basic political equilibrium between the kings and elites, which rested on divided fiscal, legal, and political authority. Even changing rules of evidence in a way that would have favored drainage projects was impossible because it risked diminishing the king's tax income.

How much did that the institutional failure cost the French economy? In areas that would have benefitted the effect was large: in southern France, for example, the eighteenth-century irrigation projects would have boosted the total factor productivity of agriculture by 30–40% (Rosenthal 1992). Drainage might have had a similar effect. That is of course only agriculture, but similar problems likely prevented private entrepreneurs from building the sort of toll roads and transportation canals that proliferated in eighteenth-century England and helped the economy industrialize (Bogart 2005a, b, 2011; Bogart and Richardson 2011). The same problem plagued most of Western Europe (Epstein 2002). Only England escaped, because of its early political centralization.

Institutional failure also took a heavy toll on the textile industry in nineteenth-century Brazil and Mexico. The industry was one with no economies of scale, yet it was heavily concentrated in Mexico and Brazil. The reason was restricted access to capital markets in Mexico and Brazil. In Mexico, legal obstacles kept banks from forming and limited sales of equity to firms with connections to political leaders. Similar hurdles obstructed access to capital markets in Brazil, although they did not

last as long. The only textile firms that could form were therefore the one that could tap the wealth of the owners' families or play upon political connections. The number of such firms was small and the textile industry was therefore concentrated, in contrast to the United States, where capital markets were open and textiles firms were small (Haber 1991).

Institutions can impose costs even in wealthy democracies such as the United States. Consider, for instance, property rights to land in the United States. They are defined using two different surveying systems. One, the rectangular system, was based on a standardized rectangular grid and was imposed on new states by a 1785 Federal Land Law. Before then another system, the metes and bounds system, which is based on idiosyncratic descriptions of parcels of land, prevailed in most of the states. The state of Ohio ended up with both systems because part of Ohio was already using the metes and bounds for exogenous reasons before Ohio became a state in 1803. A careful analysis of adjacent areas employing the two systems shows that the rectangular system raised property values by up to 20–30%. Conflict over property rights was far less common with the rectangular system too. The long run consequences were large: population densities and land use patterns in areas that were otherwise similar ended up being radically different, depending on the surveying system (Libecap and Lueck 2011). The differences, in other words, seem to have been caused by the institutions that defined property rights.

The Impact of Institutions on Economic Growth

In these three examples, institutions clearly have an effect, but only on part of the economy – for instance, French agriculture in regions that would have benefitted from drainage or irrigation. What about the ramifications for the economy as a whole or for economic growth?

A seminal article by North and Barry Weingast suggested how institutions could affect economic growth for an entire economy, using the example of England's 1688 Glorious Revolution (North and Weingast 1989). By obliging the monarchy to get Parliament's assent to its actions, the Glorious Revolution constrained what English monarchs could do. The new constraint – a new institution – made credible the monarch's promise to repay loans, and as a result, government borrowing jumped by an order of magnitude. But the effects of the new institution extended well beyond the government debt market. It stimulated private capital markets too and paved the way for the British Industrial Revolution by securing all property rights, not just those of the government's debtors.

Although North and Weingast left the proof of this last assertion to other researchers, the institution that stimulated economic growth was clear. It was the constraint on a powerful ruler that made all property rights secure. Broader econometric evidence to support such a claim – evidence from well beyond seventeenth-century England – was then provided by a pair of influential articles, by Acemoglu et al. (2001, 2002). They examined countries that had once been European colonies, countries that range from ones that are rich today (as in the case of the United States)

to ones that are poor (for instance Haiti). By using evidence on urbanization rates and population densities as a proxy for real per-capita income in the past, they traced the difference in incomes today back to institutions established when the countries were colonized. Where the native population was small and incomes were initially low, Europeans settled in large numbers and established institutions that encouraged investment. Where there were a larger number of natives and incomes were initially high, the Europeans created institutions designed to extract rents, not encourage investment. The crucial feature of the institutions that encouraged investment was that they protected property rights by constraining rulers, and those institutions explain why once poor colonies like the United States ended up rich today, even when their low initial income and other factors affecting economic growth are taken into account.

Another seminal argument traced important differences in institutions back to yet another ultimate cause – factor endowments at the time of colonization (Engerman and Sokoloff 1997, Engerman et al. 2012). Like Acemoglu, Johnson, and Robinson, Engerman and Sokoloff examine colonies, this time in the Americas only. In some American colonies, factor endowments created extreme inequality; for instance, when natives could be forced to work in silver or mercury mines, as in parts of Spanish America, or when slaves could be imported to grow sugar, as in Haiti. In other colonies – Canada and what is now the northeastern United States – sugar could not be grown, and native populations were too small to exploit for forced labor. Inequality among a population that soon became overwhelmingly European was then relatively small.

Where inequality was extreme, the European settlers fashioned institutions that benefitted the wealthy elite and limited the poor's political influence and their economic opportunity. For example, the elite might require voters to be literate and then limit public funding for education. If inequality was high, the poor would be unable to borrow to finance their children's education and as a result, they would be disenfranchised. In addition, education levels would be low, and economic growth would suffer.

A final example of the impact institutions could have on economies as a whole comes from Nathan Nunn's work on the consequences of the African slave trade (Nunn 2008). Countries where large numbers of slaves were seized in the past turn out to be significantly poorer today, even when other factors affecting per-capita incomes are controlled for. A plausible instrumental variable suggests that the relationship was causal, and historical evidence points to two ways for the slave trade to have harmed the economy. The first was that it destroyed nascent states in Africa. The second was that it heightened ethnic fractionalization and hindered the formation of broader ethnic groups. The result was a prevailing norm of distrust of other ethnic groups in areas where slaves had been captured, and modern survey research supports that claim (Nunn and Wantchekon 2011). The norm of distrust was an institution that worked against long distance trade. It also hampered the formation of states, as did the destruction of early African states. So areas where slaves were taken would end up with weak states that could not protect trade or property rights or settle cross ethnic disputes, and they would end up much poorer.

Criticisms of the Claims for Institutions

The work on the effect of institutions is widely cited, but it has also been criticized, particularly when it comes to the impact on economies as a whole. The studies of particular regions or sectors of the economy are hard to attack. For example, once the French Revolution changed institutions, successful irrigation and drainage projects proliferated, even though rates of return had dropped. It is difficult to argue with that sort of evidence.

Assertions about the whole economy or about long-run economic growth, however, are more vulnerable to criticism, and some of the critics are right on the mark. Others, though, fail to hit the target.

Let us start with criticisms that fail. A number of them aim at North's and Weingast's claim about the Glorious Revolution. Greg Clark (1996), for instance, contested their argument that the Glorious Revolution made private capital markets secure. His evidence came from the rates of return on land and from loans backed by real estate as collateral. The returns did not rise during periods of political turmoil, as they presumably would if property rights were insecure, and although returns were dropping in England, the decline did not accelerate after the Glorious Revolution, as they would if North and Weingast were correct. For Clark, the implication is that property rights were not secured by the Glorious Revolution; they had in fact long been secure.

Upon closer inspection, though, Clark's evidence falls apart. His evidence comes from the safest capital market, the market for land and loans backed by real estate. That market had little or nothing to with the capital markets North and Weingast are concerned with, the markets for government debt and investment in private companies. More importantly enforcement of the relevant contracts in Clark's capital market – tenancy and mortgage contracts – had been settled in the Middle Ages. It was a matter for lawyers and common law courts, not the monarch, who had no incentive to interfere (Cox 2016). Clark's evidence, in short, is simply not relevant to the Glorious Revolution.

There is evidence about private rates of return, though, that is harder to dismiss, and evidence too that property rights in capital markets were not secured overnight in 1688 (Quinn 2001; Sussman and Yafeh 2006; Stasavage 2003, 2007; Pincus and Robinson 2011; Murphy 2013). Secure property rights in capital markets required the lobbying by creditors and a powerful Whig Party in Parliament, all of which took time to achieve. Gary Cox (2016) makes sense of the whole process in what is perhaps the ultimate word on the political economy of the Glorious Revolution. The issue, as in North and Weingast, was making sovereign promises credible. Doing that involved giving Parliament ultimate authority over the promises. That entailed establishing Parliament's exclusive right to determine who could arrange sales of these promises and limiting the authority of ministers and other royal officials so that they could not interfere or evade Parliamentary control. These changes took time, but they raised Britain's tax revenues dramatically (Dincecco 2009, 2011) and had a similar effect on her ability to borrow via long term debt.

That the Glorious Revolution boosted Britain's tax revenues (even when one controls for other characteristics of the British economy) also casts doubt on Robert Allen's criticism of North and Weingast (Allen 2009). Having gathered data on European economies from the late Middle Ages to the nineteenth century, Allen estimated a system of four linear equations to explain urbanization, real wages, agricultural productivity, and the amount of rural industry. Among his explanatory variables was an indicator variable that took the value 1 when the executive authority in a given economy (typically a monarch) was constrained by representative institutions, as in Britain after the Glorious Revolution. When Allen used the coefficients from the regression to gauge the effect of representative institutions, he found it had only a minimal effect on urbanization and real wages – both reasonable proxies for per-capita GDP that play a major role in Allen's explanation of the Industrial Revolution.

One problem with this test is that an indicator variable that suddenly takes the value 1 after a certain date (for instance after 1688 in Britain) does not capture all the changes involved in making sovereign promises credible, at least from what we know of the Glorious Revolution. Cox's research (2016) suggests that the process was not instantaneous elsewhere in Europe either. There is another serious problem with Allen's test as well. One of the variables that does have a big impact on urbanization and real wages is per-capita intercontinental trade. But Britain won a lion's share of intercontinental trade in the eighteenth century because of military victories, victories against France in particular. It won those wars because it could levy much heavier taxes than France – heavier even as a fraction of GDP. And it could impose such heavy taxes because of the political changes that gave ultimate power to Parliament; representative institutions clearly increased states' capacity to tax (Hoffman and Norberg 2002; Dincecco 2009, 2011; Hoffman 2015). Intercontinental trade and other explanatory variables in Allen's regressions are endogenous and clearly influenced by institutions. So institutions are one of the ultimate causes behind Britain's high wages and extensive urbanization, and hence part of Allen's explanation for the British Industrial Revolution.

Those are the unsuccessful criticisms of the claims about institutions. What about the successful ones? Some of the successful ones are simply telling case studies. North and Weingast, for instance, argued for a connection between public debt markets and capital markets in general. If a monarch's promises to repay are credible, then the rights of investors in private capital markets are secure too, and private capital markets will prosper. In the eighteenth century, though, France had a thriving market for private debt, even though its monarchy defaulted repeatedly (Hoffman et al. 2000). And nineteenth-century Brazil's constitutional monarchy borrowed extensively at home and abroad without defaulting. Nonetheless, the private capital market in Brazil failed to thrive (Summerhill 2015). These two counterexamples cast doubt on the connection that North and Weingast emphasized. Having a sovereign who is a credible borrower is, in short, neither a necessary nor a sufficient condition for a flourishing private capital market.

There are reasons to criticize other work on institutions as well. One problem is a tendency to generalize hastily from limited data. A clear example comes from the

allegations about the causal role of the so-called European Marriage Pattern in stimulating economic growth. In parts of Western Europe before the Industrial Revolution, families were nuclear, celibacy rates were high, and women married late. These demographic patterns – named the European Marriage Pattern – have been invoked to explain why Europe industrialized early.[4] The virtue of the argument was that it fit an important model of economic growth and demographic change: unified growth theory (Galor and Weil 1999; Galor 2005). Yet although the model was fine, the evidence used to link it to Europe's industrialization does not stand up to scrutiny (Dennison and Ogilvie 2014). Dennison and Ogilvie's analysis of data from 39 European countries shows that the clearest examples of the European marriage pattern are in fact correlated with economic stagnation, not growth. Economic historians had, in short, generalized from a tiny number of cases – a mistake that led them astray.

Another problem is a recurrent one: gaps in the evidence connecting an institutional cause in the past and an economic outcome today. Research that connects institutions to modern outcomes typically relies on regressions where one of the explanatory variables is a variable measured in the distant past. It might be a characteristic of past institutions or a variable whose past value shapes the sort of institutions that eventually emerge in a country. In Acemoglu et al. (2002), for example, low native population densities at the time of colonization made it easier for Europeans to settle in new colonies; the settlers would then lobby for institutions that protected their property rights. Higher native population densities made it easier to take over tax systems of existing native states or to force the natives to work. The colonists would then design institutions to extract resources from the colony, not to protect property rights. A regression of current per-capita income on correlates of economic growth and past population density should therefore yield a negative coefficient for past population density, because of the effect the past density had on the development of institutions.

The trouble is the lack of data to follow the institutions over time.[5] Without such data, it is impossible to tell whether the bad institutions, once they were created because of high population densities, ended up lasting past the end of the colonial regime and on into independence, even though newly independent colonies often received new constitutions modeled after those of wealthy democracies. And

[4]Voigtländer and Voth 2006, 2013; De Moor and van Zanden 2010; Foreman-Peck 2011 are the relevant papers here. All were criticized by Dennison and Ogilvie for basing an argument on a generalization that does not hold up to scrutiny. Dennison and Ogilvie also have concerns about Greif (2006b) and Greif and Tabellini (2010), which also mention the nuclear family. But Greif (2006b) links the nuclear family to the corporation, a more limited and defensible claim, and Greif and Tabellini (2010) takes up a different topic – the contrasting way in which cooperation was achieved in China (via clans) and Europe (via cities).

[5]There are other worries as well, both for this particular example and for other articles linking past institutions to modern outcomes. First of all, the data (typically urbanization or population densities) is often suspect outside of Europe. Second, the regressions typically involve instruments because institutions are endogenous; the instruments, though, may be problematic as well. See, for example, Albouy 2012.

institutions in ex colonies did change after independence, in a way that might be consistent with a different argument, namely, that increases in human capital caused both economic growth and improvement in institutions (Glaeser et al. 2004).

The criticisms here are not peculiar to the influential 2002 paper by Acemoglu et al. Other work on institutions is vulnerable to similar attacks. To take an important example, consider Dell's impressive article (2010) on the effects of forced labor in colonial Latin America. She aimed to show what effect a bad institution – a colonial forced labor requirement – had on modern outcomes, and also to explain why this effect persisted. To do so, she contrasted outcomes in an area of Bolivia and Peru that had to provide labor for silver and mercury mines with an adjacent area that was exempt from the labor exactions. By using a regression discontinuity design and colonial evidence that the two areas were similar before just the labor requirement was imposed, she isolated the effect of the forced labor requirement, which was large: it lowered household consumption by 25%.

As to why the effect persisted after the forced labor requirement was abolished in 1812, Dell points to a colonial policy that restricted the formation of *haciendas* (large rural estates worked with forced labor) in areas subject to the labor requirement. The policy aimed to minimize competition with the authorities who sought coerced native labor for the mines. In the areas exempt from the labor requirement, elites formed haciendas and got secure property rights. They also lobbied for public goods such as roads. By contrast, in the areas that had to furnish mine labor, there was no one to lobby for roads, and the prevailing property rights were traditional communal land tenures that were abolished after the labor requirements ended. Property rights were therefore insecure. The result would be that the area with haciendas and rich elite would end up with higher incomes – a sharp contrast to Engerman and Sokoloff's argument.

The virtue of Dell's article is that it does lay out an explanation for why bad institutions persisted. But there are still gaps in the quantitative data, in particular between the end of the labor requirement in 1812 and the modern era. Before 1812, there were penalties for moving, but once the penalties disappeared in 1812 why did people not abandon the region with no roads and insecure property rights? Movement of individuals is the bane of regression discontinuity design when the discontinuity follows a geographic boundary. If only the poor or the uneducated stayed behind in the labor requirement area, then we might have a very different explanation for its low income today. Only more historical data could tell for sure and determine whether her argument holds up.

Another example of a gap in the data between a current outcome and a cause in the past comes from the influential literature on legal origins (La Porta et al. 1997, 1998). As La Porta and his coauthors have demonstrated, the size of financial markets today is correlated with the sort of legal system a country uses, and the correlation persists even after controlling for per-capita income and other variables. Legal systems based on British common law, which prevails in Britain and in former British colonies, such as the United States, favor the development of financial markets, apparently because they do more to protect investors. The other great family of legal systems – civil law, which is used in continental Europe, in the

ex-colonies of continental European powers, and in countries such as Japan – is not as effective at defending investors, and it leads to smaller financial markets. These legal systems were determined in the past – for instance, during colonization – but their effects survive today.

Implicit here is the assumption that the effect of the legal systems persist, so that if the civil law weakens protection for investors, it should do so in the past as well as today. But Aldo Musacchio's (2008, 2009) careful historical study of one civil law country – Brazil – suggests that is not true. He gathered data on investor protection in the past to fill in the gap between the current outcome and the past cause and found that Brazil did defend investors in the late nineteenth and early twentieth centuries, contrary to what the legal origins literature assumes. Brazilian creditors had strong legal rights, and the Brazilian bond market grew. Brazilian shareholders ended up being protected too, through corporate bylaws; Brazil's stock market boomed too. And Brazil, as Musacchio and Rajan and Zingales (2003) have shown, was not an exception. Other civil law countries had thriving financial markets in 1900 too, suggesting at the very least that other causes have to intervene to explain why the protection that is possible with the civil law ended up failing after 1900.

What is needed here is better historical research to fill in the gaps between the distant causes and the current outcomes – more research, for instance, on institutional change and political economy of colonies after independence. For several topics that research is already underway – for instance, on business organizations that have been linked both to legal systems and to economic development. It has been argued that the corporation is, as an institution, the superior form of business organization for economic development and that the common law favored the establishment of corporations. Timothy Guinnane and his coauthors (Guinnane et al. 2007) demonstrate that the historical reality is more complex. The corporation did have virtues but it also had disadvantages, and another type of organization – the private limited liability company – was often better for small and medium sized firms. But the common law, so their evidence suggests, actually worked against creating private limited liability companies.

We also need better models of how political institutions foster economic growth. Both North and Weingast (1989) and Acemoglu et al. (2001, 2002) argue that institutions fostered growth, but the way that happens needs to be fleshed out, with more historical research and with models that can explain how institutions protect property rights or promote economic growth – ideally models that can be generalized.

Cox (2016) models what happened after the Glorious Revolution in Britain, and his model does generalize to the rest of western Europe, as his historical research demonstrates. North et al. (2009) lay out a more general conceptual framework to understand both political and economic development. In their framework, the fundamental problem before 1800 is controlling violence, and the solution to this problem is the same in most societies. It consists of having violence controlled by a powerful coalition of elites held together by economic privileges that elites enjoy and that they would lose if coalition members split apart and began fighting with one another. Economic development requires both a political and an economic transition,

and the political transition is fundamental. It happens when the elite is opened up to both political and economic competition. Their framework could certainly be formalized and tested with quantitative data.

Acemoglu et al. (2005) have devised a similar argument about both political and economic development. For them, the fundamental causes of economic growth are political institutions and the distribution of resources. Political institutions determine de jure political power (the political power enshrined in laws and constitutions); the distribution of resources determines de facto political power (the unwritten power of the wealthy). Together, these two forms of power give rise to both current day economic institutions and future political institutions. The economic institutions then dictate economic performance today and the future distribution of resources. They illustrate this verbal framework with case studies and references to research that supports their claims or elaborates on them. Their framework could be formalized too, and the research they refer to shows how, with Acemoglu and Robinson (2005) being a particularly good example.

To improve our understanding of how institutions promote growth, researchers should also move beyond the fixation on protecting property rights, because growth may demand more than just safety for one's possessions and investments. Personal security is important too, as is access to a predictable and unbiased means of settling disputes. To assure all these things, the state will have to be powerful enough to settle disputes and protect lives and property; it should also be able to intervene when property rights overlap (for instance, for the construction of infrastructure) by using eminent domain. All of these powers will necessitate a state strong enough to impose taxation, and yet the state will have to wield all these powers without threating property or people, and it will have to use its powers in a way that encourages cooperation. So far the only study that begins to explain in detail how all this happens is Cox's (2016) study of the Glorious Revolution.

Explaining Institutional Change

One issue common to most of these criticisms is the question of explaining institutional change. If bad institutions in the past yield poverty or autocracy today, what has kept those institutions from changing? If good institutions arise and then produce wealth and democracy, what gave rise to the good institutions in the first place? What, in short makes institutions change and what locks them into place, even when they make people worse off?

For Avner Greif (2006a), the tools needed to answer these questions are game theory and careful historical analysis. Both are necessary: the game theory because institutions involve interactions among individuals where beliefs and regularities of behavior are important; the detailed historical research because institutions arise, change, and survive in particular societies, where historical details wield enormous power. The importance of history makes it difficult to generalize about institutional change. Only careful historical research will explain why institutions are born or persist even when the consequences are bad. But some institutions, Greif argues

(Greif 2006a) will be self-reinforcing in the sense that more individuals will find themselves in situations where they want to behave in the regular way that is associated with the institution. That sort of institution will persist; in a similar way, other institutions can actually undermine themselves and disappear.

Greif himself analyzes specific examples of how institutions arise, persist, or fall – institutions such as the community responsibility for debt that was common in medieval Europe (Greif 2006a). Community responsibility made whole groups responsible for an individual member's bad debts, particularly when long distance trade was involved. All Flemish merchants in England might be liable, for instance, if one of them had left England without paying his creditors; similar rules could apply even to merchants from other towns in the same country. But by facilitating interactions between an increasing number of communities, the institution of community responsibility lost its effectiveness. It became harder to verify that a merchant really was a member of a known community and easier to falsify a community affiliation. The institution dug its own grave and disappeared in the late thirteenth century.

Another example comes from eighteenth and early nineteenth-century France, where mortgages all paid one interest rate – 5%. Eighteenth and nineteenth-century France had a thriving mortgage market (Hoffman et al. 2019). In 1740, it allowed a third of French families to borrow, and in 1840 it was mobilizing as much credit for mortgages (relative to GDP) as the United States banking system did in the 1950s. But for most of the two centuries, the market was not cleared by prices. The 5% rate was common to all mortgages.

That regularity of behavior was an institution, one that had arisen in the 1660s, when the government lowered the maximum legal interest rate from 6.3% to 5% on what was the most common mortgage loan at the time – perpetual annuities. With the 6.3% legal limit, interest rates on the annuities had varied between 5% and 6.3%. But once the 5% maximum was in force, interest rate variation disappeared for two reasons. One, clearly, was the 5% maximum rate. The other was a serious problem of asymmetric information. Lenders did not necessarily know what collateral was worth or whether borrowers would repay their loans. In such a market, price competition may disappear, and credit will be rationed on the basis of creditworthiness and the value of collateral. Borrowers who had good collateral and seemed likely to repay would get loans at 5%; those who did not measure up would not. In France, there were mortgage brokers who had information about collateral and creditworthiness, and they solved the information problem by matching up lenders with reliable borrowers, often by referring a trustworthy borrower to another broker. That made all the lending possible. And they had no incentive to deviate from the 5% equilibrium rate because it would raise questions about the reliability of their borrowers and their referrals.

The institution was, in short, self-reinforcing, and it only disappeared at the end of the nineteenth century for several reasons – all of them exogenous. First, the government created a mortgage bank, granted it a monopoly on the issue of mortgage backed securities, and gave those securities implicit government backing. The mortgage bank could draw upon publicly available information about collateral and past mortgages that grew more plentiful in the nineteenth century, so it could do without the mortgage brokers' information, siphon off the best borrowers, and then

offer them loans at below 5% by raising money via its government-backed securities. Second, an agricultural depression in the 1880s cut demand for mortgages in the countryside and strengthened the hand of the best borrowers in cities, who could demand interest rates below 5% from mortgage brokers. Third, by 1899, returns on liquid government bonds had fallen to 3.5%; the low rate on government bonds made riskier 5% loans to less creditworthy borrowers attractive investments. Fourth, in the early twentieth century, the government began to intervene directly in the mortgage market to provide subsidized mortgages at below 5% to selected borrowers. All four exogenous factors made the 5% equilibrium unravel, and the institution disappeared.

Religion can also give rise to institutions by establishing organizations, rules and norms of behavior, and beliefs about how others will act. Recent work on the Islamic world offers two examples. For Timur Kuran (2012), Islamic commercial law blocked the establishment of large joint stock companies, making it harder for Muslims to take advantage of economies of scale. The law could not simply be changed, because it was the accidental result of inheritance rules spelled out in the Koran. Jared Rubin (2017) has pointed to a different institutional contrast between western Europe and the Islamic world. In his view, Islamic rulers tended to rely more heavily on religious authorities to establish their legitimacy than Christian rulers did. The reasons, again, were largely accidental: from the outset, Christianity distinguished between secular and religious powers, and the Reformation ended up diminishing the independent political power of the Christian clergy, even in Catholic lands. The consequences, Rubin argues, were large: religious authorities were generally conservative and they prohibited new ideas or technologies that threaten their authority. In the Islamic world, for instance, they banned the printing press. In the West, they simply had less power to block innovation.

New directions

There is a great deal of research on institutions left to do. Among the urgent tasks is to answer the critics of the claims for institutions. That will entail extending the analysis of the long-run impact of institutions by formalizing models of why they persist or change, and by undertaking careful historical research to fill in the gaps between the institution established in the past and the current day outcome. Both types of research are necessary to measure the true causal role of institutions and to understand why the effects of institutions are not diluted by other forces. Why bad colonial institutions survive past independence is one topic that obviously deserves study. Another is the persistence of institutions with bad outcomes, such as the United States health care system.

A third promising avenue for research is to take up the issue of culture. Economic historians such as Joel Mokyr and Avner Greif have long argued for the role that culture plays in changing institutions or locking them into place (Mokyr 2017; Greif 2006a; Greif and Tabellini 2010). Culture may also shed light on one of the fundamentals in the working of institutions: making sense of why people cooperate

when pure self-interest would seem to rule out such behavior. People may, for instance, contribute to a public good when shirking would seem to be the dominant strategy, and they may do so not just in laboratory experiments but in the real world when their lives are at stake. Contributing to the public good may in turn establish norms or beliefs about behavior – an institution.[6] One clear example comes from Dora Costa and Matthew Kahn's illuminating analysis of desertions during the Civil War: despite high mortality rates and minimal penalties for desertion, many Union army soldiers did not desert. Why they risked their lives – even though others did desert – was linked to the social homogeneity of a unit, which created a norm of honorable service and a fear of shame that helped soldiers to serve honorably (Costa and Kahn 2003a, b, 2010).

Research on culture in behavioral and experimental economics offers tools for understanding this sort of behavior; so does parallel research in cultural anthropology (Bowles and Gintis 2011; Boyd and Richerson 1988; Henrich et al. 2001; Camerer 2011). By using this literature and related work in experimental economics, Hoffman (2015) has explained how warrior leaders came to dominate Western Europe after the collapse of the Roman Empire and how these leaders could wage war despite having no system of permanent taxation – in other words, how the institution of "feudalism" originated. In a different vein, Marco Casari has employed his own work in experimental economics (Casari and Plott 2003) and his own detailed historical research (Casari 2007; Casari and Tagliapietra 2018) to lay bare the origins and working of the decentralized institutions that for centuries governed communal property rights to forests and pasture in communities in northern Italy. Users with rights could, at their own expense, report infringements on the commons, and collect a fine if the infringement was unjustified. The working of the institutions required group decisions, and the groups worked best when they remained a bit below 200 individuals. When they grew too large, they tended to divide to facilitate future decision making.

Besides culture and behavioral economics, cliometricians would also profit by cooperating with researchers in political science. The relevant political scientists are trained in economics and use econometrics and models from economics. They also do original historical research, some of it with large, original data sets. Cox (2016) is a model here of combining models with careful historical research. Other examples include David Stasavage's excellent study (2011) of how the size of states affected the development of representative institutions and the ability of states to issue sovereign debt.

As for political scientists' relevant work with large historical data sets, Stasavage has also done important research on how progressive taxation derived not from the extension of the suffrage to lower income voters (an institutional change that models of the median voter would emphasize), but rather from mass mobilization warfare (Scheve and Stasavage 2010). An even more exciting political science project with large historical data sets is Steve Haber's research (see Elis et al. 2017) linking political and economic development to natural endowments. The connection

[6]For historical and modern examples of this sort of behavior and a discussion of the relevant literature in experimental and behavioral economics and cultural anthropology, see Hoffman 2015.

suggested by their research runs through institutions, but it was not deterministic. The development of institutions favoring democracy and economic growth would be more likely with the right endowments (a climate that produced large storable crop surplus without large scale floods or droughts; level terrain and access to water transport) at the right time (circa 1800). Democracy and high incomes would then be more likely too, but they would not be inevitable. The relationship would be complex and probabilistic.

Conclusion

Despite all the criticism, institutions clearly play a major role in economic growth and political development. But much more needs to be done to verify and to clarify their role, and to show that it is causal, and not the result of other factors. The necessary work will involve careful historical research, the assembly of large data sets, and careful econometrics and formal modeling. And it should also involve cooperation with other social scientists, from experimental economics to anthropology and political science.

Abstract

This chapter surveys research on political economy in economic history. It discusses the integration of the public choice/political economy approaches with economic history. It provides a thematic survey of topics such as the origins of the state, different regime types, labor coercion, warfare, religion, and state capacity. The chapter also provides detailed illustrations of how economic historians have investigated specific historical episodes such as the Glorious Revolution, French Revolution, the consequences of European empires, and the rise of democracy.

Keywords

Political economy · Public choice · State capacity · Conflict

Introduction

Economic historians have always been interested in political economy. However, for a long time, political economy was resistant to cliometric approaches. In the work of Frederick Lane (1958) and John Hicks (1969), economic theory was a metaphor to illuminate topics such as conflict, war, and state development. This approach was insightful, but it stopped short of the aim of cliometrics: to derive predictions from theory that can be tested using historical evidence.

To summarize progress since Lane and Hicks, I first consider the relationship between cliometrics and political economy, before providing a thematic survey of how cliometrics has advanced our understanding of state formation, warfare, public debt, the state, and religion. The final part of the chapter considers some case studies, including the Glorious Revolution, French Revolution, the political economy of empire, and the rise of democracy.

Early cliometric work focused on employing neoclassical economics to understanding historical questions. These included the productivity of the slave economy in the American South or contributions to US growth in the late nineteenth century. This work is well represented by the research which won Robert Fogel and Douglass North their Nobel prizes.[1]

At the same time as economic history was revolutionized by cliometrics, the field of political economy was reborn in the hands of public choice scholars in Chicago, Rochester, and Virginia. This work was, by and large, abstract, theoretical, and ahistorical, as exemplified by classics such as *The Calculus of Consent* (Buchanan and Tullock 1962), *The Theory of Political Coalitions* (Riker 1962), *The Logic of Collective Action* (Olson 1965), and *The Theory of Economic Regulation* (Stigler 1971). Empirical work inspired by Buchanan, Tullock, Riker, Olson, and Stigler

[1]The Nobel Prize was awarded to Fogel and North for pioneering cliometrics, specifically, "research that combines economic theory, quantitative methods, hypothesis testing, counterfactual alternatives and traditional techniques of economic history, to explain economic growth and decline" (*The Prize in Economics 1993 – Press Release* 1993).

followed, but, initially focused on elections, voting systems, and regulation, it was somewhat removed from the concerns of most economic historians.

Public choice contrasts with conventional public finance exemplified by Musgrave (1959). The pioneers of postwar public finance explicitly differentiated it from older work which "proceeded in a historical and institutional context" (Musgrave 1959, v). Public finance began with the assumption that the optimal policy can be implemented by a social planner. It is normative rather than positive, focusing on what policies should be followed to maximize a social welfare function.

Public finance does not explicitly model government agents as rational actors. Such institutional-free analysis had little role for history. Public choice, in contrast, imposes behavioral symmetry. Its predictions are made on the basis of the self-interested behavior of politicians, bureaucrats, and voters. In the 1980s and 1990s, this public choice approach integrated into mainstream political science and economics, acquiring the label, political economy.[2]

The Introduction of Political Economy into Cliometrics

The influence of North, and the new institutional economics, was crucial to the integration of political economy into economic history.[3] North helped introduce cliometric approaches to economic history, both in his own research and through his editorship of the *Journal of Economic History*. Then, beginning in the late 1960s and early 1970s, North began to focus on institutional economics. Initially, he worked under the assumption that institutions were efficient (North and Thomas 1973). Recognition that this was not necessarily the case turned North's attentions toward political economy (see North 1981).

Through his status as a leading cliometrician, North bridged the historical literature and public choice and political economy scholarship. His influence did not stem from the fact that his writings were particularly quantitative. They were not. North framed his arguments in a way that was attractive to more quantitatively orientated scholars and suggested ways that it *could* be tested. North's work inspired other scholars to build on his arguments or to challenge them.

Following North, interest in political economy topics among economic historians blossomed. Many strands of research employ the Northian emphasis on "rules of the game" and take into account the self-interested behavior of politicians, elites, voters, and bureaucrats. Engerman and Sokoloff (1994, 2000) traced the connection between factor endowments, institutions, and differential economic development in the Americas. Stephen Haber and coauthors applied institutional arguments to the complex political economy environment that is Latin America (Haber 1997; Haber

[2]The political economy label is particularly associated with the works of Persson and Tabellini (2000), Alberto Alesina, and Dani Rodrik.

[3]See discussion in Diebolt and Haupert (2018) of the impact of Fogel and North on economic history.

et al. 2003). North himself revised his institutional framework throughout his career; the final iteration was the natural states to open-access framework of North et al. (2009).

The first generation of research relied on a combination of theory and analytical narratives (Bates and Lien 1985; Levi 1988; North and Weingast 1989; Greif et al. 1994; Bates et al. 1998). Since the seminal attempt to measure the impact of colonial institutions (Acemoglu et al. 2001), this line of research has fused with empirical research that attempts to identify the impact of institutions.[4]

Two approaches to research design have become particularly influential, instrumental variables (IV) and regression discontinuity design (RDD), in part because economic historians can rarely run experiments and often lack the panel data required for a difference-in-differences approach (DID).

Melissa Dell's (2010) influential study of the long-run effects of Peruvian Mita, for example, popularized the use of RDD. Recent papers that employ IV approaches include Dippel (2014) who instruments for the forced integration of Native American communities by using data on historical mining rushes.

Not all topics in political economy are amenable to causal methods. In politics few things are truly exogenous. Instruments that satisfy the exclusion restriction are difficult to come by. Political borders often arise endogenously making RDD designs challenging. Therefore, it is important that economic historians studying political economy employ mixed methods. Formal models (as in the analytical narrative tradition), qualitative evidence, and descriptive econometrics all have a place in improving our understanding of the interaction of politics and economics. In political economy, perhaps more than in other fields, understanding the historical context and the data generating process remains of paramount importance.

In his presidential address to the Economic History Association, Hoffman (2015, 305) argued that "we still know too little about what determines the laws, regulations, and policies that states adopt or what goods and services they provided … Worse yet, we do not even understand how states arise in the first place or how they gain the ability to tax." I will take a different view and argue that progress has been made in understanding both the rise of states and the development of modern welfare states. To substantiate this, the next section provides a thematic approach to major cliometric contributions to political economy.

[4]The current state of the field is influenced by Acemoglu et al. (2001, 2005a) who took Northian arguments and tested them econometrically using innovative empirical methods. Following the success of Acemoglu et al. (2001), this approach has bloomed both within economic history and in the related fields of growth economics, development and political economy. Other important publications by Acemoglu and Robinson and their coauthors include Acemoglu et al. (2005b); Acemoglu (2006).

A Thematic Overview

Origins of the State

In contrast to the assumption of a benevolent social planner maximizing a social welfare function, political economy begins by considering states as they actually are – i.e., organizations that are made up of the same individuals who populate private firms. Rather than taking the economy as its starting point (and treating it as an autonomous segment of society that can be analyzed independently of politics), political economy concerns itself with the interaction between the state and the economy. A natural starting point is the origins of the state.

Speculation about the emergence of states goes back millennia. But while it is possible to begin with Aristotle or Hobbes, modern social scientific analysis can be traced to Oppenheim (1922) and Carneiro (1970). In economics, Brennan and Buchanan (1980) developed a simple model of a revenue-maximizing leviathan state. These ideas were combined in Mancur Olson's stationary bandit model (1993). For Olson, organized states arise from violence and disorder. The presence of competing warlords or roving bandits causes poverty, as each warlord robs without taking into account the damage he causes. However, if a single bandit establishes a monopoly of violence, such a stationary bandit will have a more encompassing interest in the society that he now "governs." Olson's story is both a parable and a model with testable predictions.

A key problem for such a stationary bandit is that mobile populations cannot be compelled to pay taxes; they can move to avoid fiscal extraction. Allen (1997) applied these ideas to ancient Egypt. Egypt developed a stable and long-lasting state because its geography made it easy for rulers to corral tax payers. Geographical circumscription was possible earlier than elsewhere because agriculture first developed along the fertile Nile valley, and this area of lush farmland was surrounded by inhospitable desert. Early statehood brought stability, but may have made the average Egyptian worse off, as the surplus created by agriculture could be extracted by the political elite.

For both Olson and Carneiro, agriculture was a precondition for statehood because farming produces a storable food surplus. Mayshar et al. (2017), however, note that a slow rise in productivity alone could not have generated a surplus, since in a Malthusian environment, population size adjusts to prevent the creation of such a surplus. Only where output was transparent and storable could states emerge. Mayshar et al. (2017) contrast the pattern of state development between Egypt and ancient Mesopotamia. Nile agriculture relies on flooding. How much the Nile flooded was public information, transparent to the Pharaoh. Hence the Egyptian state could extract all the surplus. Egyptian peasants were tenant-serfs; elites were dependent on the Pharaoh. In Mesopotamia, however, agricultural productivity, while transparent to local elites, was opaque to a centralized state. Hence, authority tended to be organized at the city level. Consistent with this prediction, states were less stable in Mesopotamia than in Egypt.

City-States and Republics

The earliest large states that we know about were autocracies. Wittfogel (1957) ascribed the prevalence and resilience of autocracy in much of Asia to the demands of irrigation-based agriculture. He argued that such systems of irrigation required strong, centralized state control. Where agriculture was heavily dependent on river water, rather than being rainfed, strong and centralized autocratic states were likely to arise, such as the Pharaohs of Egypt, the Assyrian, Babylonian, Persian Emperors of Iraq and Iran, and the Emperors of China. Wittfogel's original hypothesis has been widely criticized. Recent empirical work suggests some support for it. Bentzen et al. (2017) find that irrigation-based agriculture is more likely to be associated with autocratic rule. Elis et al. (2018) argue that there are optimal climatic conditions for the emergence of participatory democracy.

An alternative political organization to autocracies was the city-state. The best known city-states were the *poleis* of classical Greece. In comparison to the ancient empires, these were egalitarian. They permitted self-government among strata of the population, either wealthy landowners in oligarchies or free males in democracies.

To understand how democracies emerged in ancient Greece, Fleck and Hanssen (2006) develop a model based on a time inconsistency problem. According to their account, democracy came about when and where there were productive opportunities for investment for the demos.[5] Democratic rights ensured that these investments would not be expropriated by a ruler or an elite. Another hypothesis for why democracy emerged in ancient Greece is that ecological conditions produced a relatively egalitarian distribution of income and a large population of smallholder farmers. The development of the hoplite military formation also empowered these smallholders and necessitated their political representation. In Athens, the rise of a navy was crucial in cementing the power of the demos (Kyriazis and Zouboulakis 2004).

Classical Greek *polis* witnessed an economic, cultural, and intellectual flourishing (Ober 2015). But they were limited in size and scope – unable to integrate outsiders – and in a state of constant hostility with one another. Inter-polis conflict was responsible for the catastrophic Peloponnesian War. The rise of Rome led to the establishment of an imperial monarchy, and monarchy was the main way subsequent European states organized themselves into the modern period.

The medieval period saw the revival of the city-state, especially in Italy and the Low Countries (Pirenne 1925). These city-states evolved institutions that sought to limit social conflict, as analyzed in the Genoese case by Greif (1998, 2006). But like their ancient counterparts, most medieval city-states were limited in size.

Medieval city-states are often viewed as economic success stories (Cipolla 1976). Their institutions were indeed conducive to initial economic growth, but as Stasavage (2014) documents, the constitutions of medieval city-states became

[5]Fleck and Hanssen (2013) discuss how the institution of tyranny – stable autocratic rule – helped to pave the way for democratization.

more oligarchic over time. As this occurred, the growth advantage enjoyed by city-states declined. Using city population as a proxy for economic development, Stasavage finds that overall autonomous city-states did not grow faster than other cities on average. City-states that had been independent for less than 200 years grew faster; then, after 200 years of independence, they grew more slowly than other cities.

Stasavage interprets this in terms of a model of oligarchies proposed by Acemoglu (2008). In this model, as oligarchic societies represent the interests of producers, they tend to protect property rights and to impose low taxes. But they also erect barriers to entry which can result in sluggish growth in the long run. In contrast, democracies impose higher taxes, redistribute more, but also tend to allow free entry. Oligarchic societies, therefore, tend to experience initially rapid growth followed by stagnation.

An example of this process is Venice, where the prosperity associated with trade made merchants politically powerful. They ended the hereditary rule of the Doge in 1032, which became an elected office, and, in 1172, established a Grand Council to further constrain executive authority. Tracing family names of the Council members, Puga and Trefler (2014) show that there was considerable mobility into and out of the Council, suggesting that membership of the political elite was fluid. However, this mobility threatened the profits of established merchants. This led to a period known as the Serrata ("closure") in which the established merchants used their power in the Council to pass laws to close entrance. A law in 1297 restricted new entrants in the Council, and one in 1323 restricted entry into long-distance trade. This speaks to the general trend: city-states were associated with impressive but transitory prosperity.

Medieval States and Feudal Institutions

An alternative to large empires or city-states were territorial states. Huning and Wahl (2016) argue that more observable agricultural output is associated with the emergence of larger territorial states. Testing this model using the Holy Roman Empire, they find higher observability leads to larger and longer-lasting states.

The larger territorial states that emerged in medieval Europe were feudal. Feudalism has a bad reputation among economic historians. It represented the dispersal of coercive power to such an extent that some historians deny that feudal polities were "states" (Strayer 1965). Blaydes and Chaney (2013) find that feudalism led to greater political stability in Western Europe. Under feudalism, rulers relied on powerful nobles for military support, and in return for their support, they granted these nobles privileges and political power. These bargains helped to solidify the nascent polities of Western Europe. After 900 CE, Blaydes and Chaney (2013) find a divergence in the duration of Christian and Muslim rulers, in favor of the former (Fig. 1).

Greater economic opportunities and constraints on the executive accompanied the increased stability of European monarchies. This more stable environment promoted urbanization and a Commercial Revolution. Feudalism ensured that monarchical

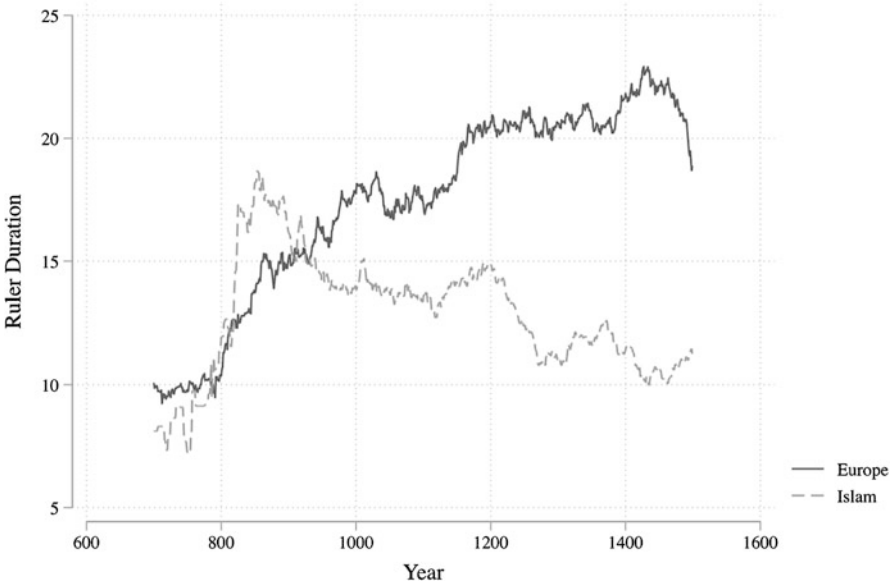

Fig. 1 100-year moving average for ruler duration in Europe and the Islamic world. (Data from Blaydes and Chaney 2013)

abuses were self-limiting. Political elites had the military power to stand up to overbearing monarchs (Blaydes and Chaney 2013). Perhaps the most well-known instance of this was the ability of the English barons to force King John to sign the Magna Carta (Koyama 2016).

Salter and Young (2018) argue that medieval polities were successful because they aligned the incentives of landowning elites. Political rights in medieval societies were bundled with property rights. According to this view, medieval lords were incentivized to pursue policies that were beneficial to development because they had economic property rights in their realms. And unlike satraps or appointed governors in centralized empires, they had the right to bargain with their sovereigns and to hold them to account.

For Blaydes and Chaney (2013), the rise of feudalism has implications for the divergence between Europe and the Middle East. In contrast to Western Europe, Islamic states came to rely on slave soldiers. Landlords were alienated from political power. Levels of political stability in these two regions of the world thus diverged centuries prior to the divergence in per capita income (Blaydes 2017).

Acharya and Lee (2018) point to the role of economic development in the formation of the European state system. They argue that when trade and commerce are underdeveloped, and hence the value of governance is low, there is no incentive for territorial states to emerge. In this world, there will be pockets of state authority but no territoriality. Territoriality emergences when there are overlapping markets for protection.

Labor Coercion

Feudal societies relied on labor coercion. North and Thomas (1971) hypothesized that serfdom arose as a quasi-voluntary institutional response to the frequent conflict and invasions that characterized the early Middle Ages. Domar (1970) argued that serfdom emerged where and when labor was scarce. This prediction can help to explain the emergence of serfdom in early medieval Europe and in Eastern Europe after c. 1600. Brenner (1976) noted that a purely demographic model was insufficient to explain the *decline* of serfdom in Western Europe following the Black Death; this phenomenon required studying political power and class relations. Labor scarcity increased the bargaining power of laborers contributing to a crisis of surplus extraction, in Marxian terminology.

These explanations can be reconciled. Wolitzky and Acemoglu (2011) build a principal-agent model to study the relationship between labor scarcity, outside options, and labor coercion. In this framework, coercion and effort are complements. Hence, when labor is scarce, there is a stronger incentive to employ coercion. However, labor scarcity also improves workers' outside options, which reduces the incentive to use coercion.

What were the economic consequences of labor coercion? Studying early modern Bohemia, Klein and Ogilvie (2016) show how coercive labor market institutions shaped economic incentives. In particular, under serfdom, landlords suppressed activities from which they could not extract rent. Close to urban centers, landlords were more likely to enforce coercive restrictions on labor. These findings suggest that the power of landlords to coerce labor in Central and Eastern Europe helps to explain their relative economic underdevelopment relative to Western Europe in the centuries leading up to the Industrial Revolution.

Serfdom persisted in Eastern Europe until the nineteenth century. Even in England, master and servant laws continued to be used to keep wages low in Industrial Revolution England (Naidu and Yuchtman 2013). Ashraf et al. (2017) explain the decline of serfdom in the early nineteenth-century Prussia in terms of the economic incentives facing landowners. They hypothesize that as skilled labor became more important in the production process, elites had an incentive to emancipate serfs in order to encourage them to invest in broad-based human capital. They find empirical support for this hypothesis using data on county-level emancipations from the nineteenth-century Prussia.

Conflict and Consensus

Politics involves competition over resources. Economics views efficiency as its central concern; the allocation of resources is determined by the price mechanism according to their highest-valued use. Political economy is concerned about the distribution of resources, in the absence of prices and in the presence of political power. Ogilvie (2007) discusses how paying attention to political power undermines the conclusion that whatever institutions exist are efficient. Institutions result from

sociopolitical conflicts over resources, and the absence of a political Coase Theorem means that conflicts often result in inefficiency (Acemoglu 2003). Existing institutions need not be efficient.[6]

Institutions shaped by those with political power may be inimical to economic growth. The importance of political power can explain the attention that economic historians have devoted to understanding institutions that constrain the powers of rulers and represent the interests of non-elites. In European history, the most important such institutions are the parliaments, which emerged in the twelfth and thirteenth centuries.

De Long and Shleifer (1993) provide evidence that representative institutions were associated with economic growth in medieval Europe. Van Zanden et al. (2012) measure the frequency that parliaments or estates met across Europe. They document the rise and spread of parliaments and then their decline after 1500, outside England and the Netherlands. The underlying argument is that parliaments enabled merchants and the owners of capital to limit predation by rulers or landowning elites.

While parliaments contained rulers, recent research stresses that parliaments emerged out of councils that rulers called (Congleton 2010). Rulers recognized that parliaments could increase their ability to raise taxes and legitimize their rule. Boucoyannis (2015) discusses how the power of English kings, like Edward I, to compel attendance in Parliament ensured that it was a representative body. This perspective suggests that parliaments enabled, as well as constrained, premodern states.

A complementary hypothesis is offered by Leon (2018), who argues that the gradual expansion of the elite in medieval England helped lay the conditions for the peaceful transition to democracy. He develops a model in which the king expands the size of the elite to gain support against barons. Once this elite reaches a certain size, it becomes cheaper for the king to compensate them with rights rather than pay them directly, and this can make the rise of more representative institutions self-reinforcing.

The view that representative institutions were necessarily good for economic development has been challenged. Taking the examples of Poland and Wüttemberg, Ogilvie and Carus (2014) argue that parliaments which only represented landed interests tended to grant legal monopolies to elites at the expense of broad-based economic growth. The Dutch Republic too, they argue, stagnated after 1670 due to entrenched power of established business interests.

Under what conditions, then, are parliaments likely to produce conditions favorable to economic development? Acemoglu et al. (2005b) study how the rise of Atlantic trade interacted with institutional developments in northwestern Europe. According to this argument, the opportunities for trade and commerce that opened up

[6]For a contrary perspective on institutions, see Doug Allen (2011) or Peter Leeson (2017). My understanding of their argument is that existing power relationships should be viewed as constraints. Hence existing institutions can be viewed as efficient relative to the appropriately defined set of constraints.

after 1500 strengthened the nascent merchant class in societies like England and the Dutch Republic where the state was not too strong, but reinforced the positions of absolutist monarchs in Spain and Portugal.[7]

Another perspective is provided by Cox (2017b) who argues that independent city-states and national parliaments together provided the economic liberty that unleashed faster urban growth in the premodern period. Before 1100 inter-city urban growth rates were uncorrelated, but after 1100 urban growth rates in Western Europe – but not elsewhere – began to move together. In other words, economic liberty promoted growth clusters. Cox argues that political fragmentation could lead to competitive pressures, which could force rulers to charge lower tax rates on commerce and trade. The effects of political fragmentation were largest, he suggests, in the presence of parliaments in which merchants were represented. But what factors led to the representation of merchants in parliaments? And what ensured that merchants did not use their power to erect barriers to entry?

Warfare

Military competition played an important role in ensuring institutional innovation and openness. States like Poland and Wüttemberg that erected barriers to economic development and did not invest in state-building efforts were eventually subordinated by their rivals.

The role of warfare in state formation was stressed by Hintze (1906) and Tilly (1975, 1990). Economic historians have shown how frequent warfare led to investments in state capacity and to improvements in military technology. Hoffman (2011, 2015) documents how after 1500 technological innovations brought down the unit costs of guns and cannons in Western Europe. The military sector was one of the most innovative in the European economy in the period before the industrial revolution. Handguns, in particular, became both more effective and cheaper, lowering the costs of employing violence.

A theoretical perspective is required to understand why warfare promoted state development in some instances and state collapse in others. Gennaioli and Voth (2015) build a model that integrates insights from the Military Revolution literature (Parker 1976, 1988). In their model, the incentive to invest in fiscal capacity depends on the chances a state has of defeating its rivals. Increased military competition provides incentives for some (initially more homogenous) states to invest in standardizing their fiscal systems, in order to invest in more capital-intensive means of waging war. But other states (which may be initially more heterogeneous and hence have higher costs of centralizing) may not find this worthwhile and hence may end

[7]Economic historians have rightly criticized the coding and the depiction of Spain and France as governed by overly powerful absolutist monarchs as out of date. But this research showed what was possible with historical data.

up losing out as a result of this intensified military competition. This model is consistent with the observation that the pressures of military competition led the most advanced and centralized European states to invest even more in state capacity, while it led to the destruction of others.

War and state-building went together in Europe's most advanced states. What role did intensified military competition play in explaining patterns of economic development in Europe? Dincecco and Prado (2012) estimate the impact of fiscal capacity on modern development. Instrumenting for fiscal capacity with causalities in premodern wars, they argue that this relationship reflects the effect of premodern fiscal innovations on current fiscal institutions, and these current institutions have a positive impact on economic growth.

Another possible channel was via urbanization. Dincecco and Onorato (2016) argue that frequent warfare in medieval and early modern Europe led to urbanization and economic development. Cities acted as safe harbors from conflict. Conflict exposure was associated with between a 6% and a 11% increase in urban population over the course of a century. Dincecco and Onorato (2017) argue that this effect has persisted and explains regional level variation in economic development in Europe today.

Other authors push back on this bellicose hypothesis, however. For one, frequent warfare did not promote urbanization, economic development, or the rise of more inclusive institutions in other parts of the world (Centeno 1997). When population density is low, warfare may promote slave raiding rather than state-building (Herbst 2000). Warfare alone seems insufficient as an explanation.

Patterns of Political Fragmentation and Political Centralization

One reason why military intensification led to investment in fiscal capacity in Europe was the competitive European state system (Fig. 2). What then accounts for this competitive state system?[8]

Geography was an important factor. Diamond (1997) provided geographical hypotheses for why Europe tended to be politically fragmented, while China tended toward unification. Europe's mountain ranges and fractured coastline promoted fragmentation. Hoffman (2015) criticized this hypothesis on the grounds that China was more, not less, mountainous than Western Europe. Recent research does suggest that European geography helps to explain its political fragmentation (Fernandez-Villaverde et al. 2019).

Certainly, geographical factors intersect with political economic considerations. Ko et al. (2018) build on the research of historians of Central Asia and theoretical models of state size such as (Alesina and Spolaore 1997). They argue

[8]A literature extending back to Montesquieu and Hume argues that Europe's political fragmentation was key to its eventual rise and to modern economic growth (Baechler 1975; Jones 1981; Hall 1985; Rosenberg and Birdzell 1986).

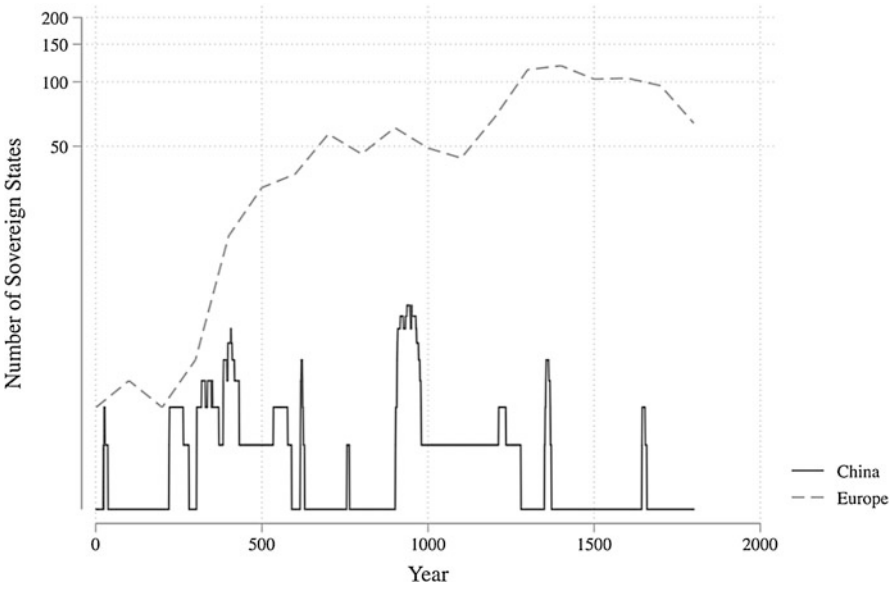

Fig. 2 Number of states in China and Europe, AD 0–1800. (Adapted from Ko et al. 2018)

that in comparison to China, Europe faced invasion threats from multiple directions, impeding the growth of a single European-wide hegemon. In contrast, China faced a single threat from the nomadic steppe. As a result, throughout Chinese history, a strong state tended to emerge in Northern China, and this state tended to be strong enough to establish an empire over the rest of the region. Ko et al. (2018) test their model using a combination of historical evidence and time-series analysis of the impact of nomadic invasions on political centralization in China.

What about the consequences of political fragmentation? Karayalcin (2008) introduced a model that predicts that fragmentation should have led to lower taxes in Europe. This is not what we observe, however. Taxes were higher in late medieval and early modern Europe than in either the Ottoman Empire or China. Ko et al. (2018) show that it might be in the interest of rulers of large empires to levy comparatively low taxes to reduce the probability of rebellion, but that this incentive is absent or much weaker in a competitive state system.

One insight from research is that political fragmentation was not an unambiguously positive factor in Europe's economic development. It imposed static costs and resulted in the multiplication of trade barriers and in an over investment in military power that was itself a cause of internecine warfare. In this respect, more centralized empires such as Qing China provided a potentially more fruitful environment for Smithian economic growth (as argued by Bin Wong (1997) and Rosenthal and Wong (2011)). There were, however, important *dynamic* benefits associated with political fragmentation and competition.

State Finances

One example of the institutional innovations associated with warfare is in the area of state finances. The Italian city-states were almost continuously at war. Venice and Florence pioneered institutional innovations like public debt, which enabled them to compete with much larger states and raise ever greater revenues to pay for their mercenary armies. The annual revenue of Florence in the fourteenth century varied between 250,000 and 350,000 florins, but historians estimate the direct cost of the 3-year war between Florence and the Papacy in 1375–1378 exceeded 2.5 million florins (Caferro 2008). To meet this shortfall, Italian city-states developed impersonal systems of public debt and permanent systems of taxation (Epstein 2000).

Epstein (2000) documents that throughout the late medieval and early modern periods, city-states and republics paid less interest on their debts than did territorial monarchies. Stasavage (2011, 2016) shows that representative institutions enabled city-states to borrow earlier and at lower cost. In city-states, the holders of capital were represented in government, ensuring that the promise to repay was credible. Figure 3, adapted from Stasavage (2011), is consistent with this argument (see also Chilosi 2014). Only in the seventeenth century did larger states, first the Dutch Republic and then England, develop institutions, such as the Bank of Amsterdam and the Bank of England, which replicated the success of smaller city-states (see section "The Glorious Revolution").

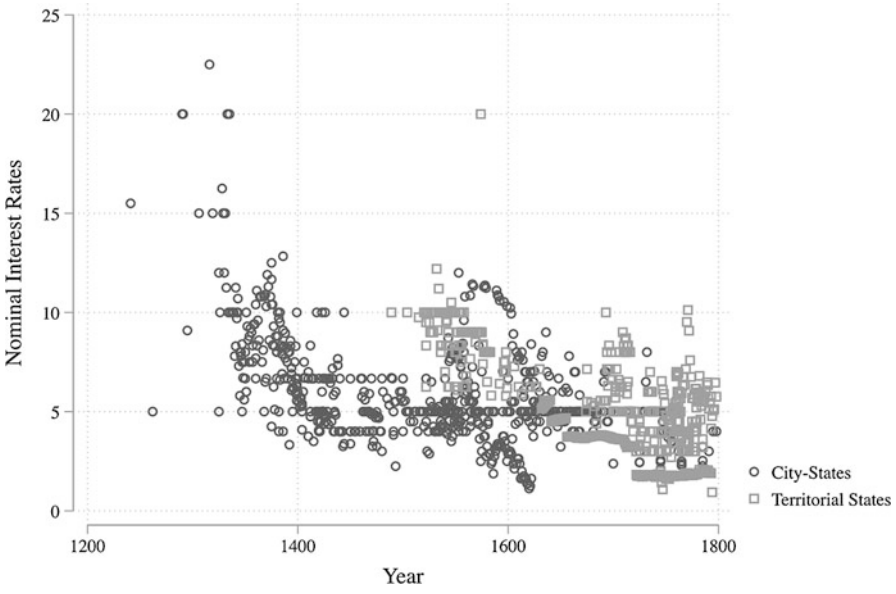

Fig. 3 Interest rates in city-states and territorial states. (Data from Stasavage 2016)

Religion

Despite the important role religion occupied in the studies of Weber (1922, 1930) and Tawney (1926), religion was neglected by cliometric historians until recently. A recent literature specifically focuses on the intersection of religion and political economy.

Kuran (2010) drew attention to the important role Islam played in shaping economic opportunities in the Middle East. He shows that Islam infused both the law and politics of Middle Eastern countries with important consequences for the formation of long-lasting business organizations and corporate institutions independent of the state, such as universities. Recent studies of the Reformation have moved away from studying the direct effects of religious change on economic growth toward discussing the institutional consequences of the Reformation (see Becker et al. 2016; Cantoni et al. 2018).

One area where the study of religion overlaps most significantly with political economy is in the relationship between the Church and the state. Throughout history, religion has played a key role in legitimizing political authority (Coşgel et al. 2012; Greif and Rubin 2015; Rubin 2017). Coşgel and Miceli (2009), for instance, develop a model of how a religious authority can lower the costs of taxation for the political authorities, the logic of which can be applied to numerous settings.

Chaney (2013) uses variation in the flooding of the River Nile in medieval Egypt to explore the relationship between religious and secular authorities. He finds that Nile shocks increased the political power of religious leaders. Nile shocks resulted in great potential for unrest, and this improved the bargaining power of religious authorities with respect to secular leaders. To neglect religion is to fail to understand many aspects of premodern political economy. In a recent contribution, Coşgel et al. (2018) compile a dataset of state religions going back to the year 1000 CE, which will prove usual for scholars working on these questions.

Rubin (2017) builds on these arguments to develop a novel account of the divergence that opened up between northwestern Europe and the Middle East after 1500. The greater power of religion to legitimize political authorities in the Middle East constrained the development of institutions and the adoption of new technologies such as the printing press. The comparative weakness of the religious authorities in northwestern Europe, however, set in motion institutional developments that helped limit government and provide the institutional preconditions for sustained growth.

Finally, Johnson and Koyama (2019) examine the rise of religious freedom from the medieval ages to the twentieth century. Given the centrality of religion to providing political legitimacy and enforcing institutional arrangements, they argue that the importance of religion to premodern polities meant that full religious freedom was inconceivable. Drawing attention to the various institutional arrangements premodern states used to deal with religious diversity, they point out their economic costs and the fragility of the resulting "conditional toleration" that resulted. In sum, religion cannot be ignored in studying the political economy of premodern states.

State Capacity

State capacity refers to the ability of the states to enforce property rights, implement policies, and provide public goods (Besley and Persson 2011; Johnson and Koyama 2017). It can be broken down into administrative capacity, legal capacity, and fiscal capacity. One challenge has been obtaining accurate measures of these concepts. Fiscal data now exists for a number of European countries from around 1650 onward (Dincecco 2009; Karaman and Pamuk 2013). But we lack comparable measures of other aspects of state behavior.

Preindustrial states were usually small and fiscally and legally fragmented. Fiscally fragmented regimes suffered from local tax free-riding. Fiscal centralization thus enabled states to increase revenues and often complemented the expansion of markets and the division of labor. This made it easier for responsible governments to follow sound fiscal policies and thus lowered credit risk. However, there was always the chance that rulers would waste the new funds on reckless wars. Thus, it was only the conjunction of limitations on the discretionary authority of government with centralized fiscal systems that enabled states to borrow at low cost.

Fiscal centralization was accompanied by legal centralization. Old Regime France was legally fragmented: customary law and the interpretation of Roman and canon law varied from place to place. During the seventeenth to eighteenth centuries, there was an effort to achieve some legal centralization. Johnson and Koyama (2014b) document how legal centralization and investment in state capacity was accompanied by a decline in witchcraft trials, in which obtaining convictions required a departure of standard legal procedures. Crettez et al. (2019) model the transition from legal decentralization to legal centralization in terms of a trade-off between allowing each region to choose its own idiosyncratic legal system and imposing legal centralization. The former allows a region to adopt rules closer to the preferences of its inhabitants; the latter eliminates legal disparities across regions. They apply this model to explain why the French Revolution was accompanied by a sharp move toward legal centralization.

Centralized fiscal systems were established comparably late in European history. Most European states achieved fiscal centralization and limited governments only after 1800. Dincecco (2009) dates the establishment of a centralized tax system in France and the Netherlands to the French Revolution. Centralized and limited regimes were only established in the Netherlands after 1848, in France after 1870, and in Spain after 1876. Only once European states established centralized tax systems, and limited government, did yields on public debt fall.

This account is consistent with the data provided by Karaman and Pamuk (2013), which depict marked increases in fiscal capacity in England, France, the Dutch Republic, Prussia, and Habsburg Austria after 1700, but no corresponding increase in fiscal capacity in the Ottoman Empire, Poland-Lithuania, Russia, or Sweden. Much of this increase in state capacity was associated with an intensification of interstate conflict. Karaman and Pamuk (2013) find that in states with representative institutions, such as parliaments, this increase in fiscal capacity was most pronounced. In contrast, in absolutist states, formal tax revenues were low. This was true of both the Ottoman Empire and Qing China. Due to a combination of economic growth and investment in

state capacity and military technology, by the mid-nineteenth century a large gap in state power had opened up between Western European states and the states of Asia.

Why did Asian states fail to keep up with Western Europe? Fiscal centralization was a gradual process in Europe. State tax collection emerged out of private tax farming. Tax farmers organized in order to discipline and bind monarchs who had an incentive to expropriate tax collects when in need of revenue (Johnson 2006; Johnson and Koyama 2014a). Balla and Johnson (2009) discuss how the inability of tax farmers to organize in the Ottoman Empire meant that they were unable to constrain the Ottoman state. To explain why tax rates were low in Qing China, Sng (2014) argues that a severe principal-agent problem meant tax collectors could embezzle revenues and extort taxpayers. In response, the ruler had to keep taxes low to minimize the threat of revolt. Ma and Rubin (2019) build on this argument by highlighting the commitment problem autocrats face vis-a-vis their own tax collectors. In times of crisis or war, autocratic rules cannot credibly commit not to expropriate tax collectors and administrators. One way to overcome this problem is to pay tax collectors very low formal salaries but also to turn a blind eye to the private exactions of tax collectors by not investing in monitoring technology. This results in an equilibrium where formal tax collected by the center is low and informal corruption is high. But it precludes investment in administrative capacity.

What accounts for the relative failure of Qing China to deal with new political threats after 1800? As Ma and Rubin (2019) discuss, whether states invested in fiscal capacity was a political decision. Koyama et al. (2017) study patterns of state development in East Asia after 1850. They examine why Japan embarked on political centralization and reforms following the intrusion of geopolitical threats from the Western powers after 1850, but why in China political authority was decentralized and modernization efforts failed. They point to how geographical size constrained the options of political actors. In China, the conjunction of threats from both the north and the south necessitated decentralization, and, as a consequence, the Chinese state lacked the capacity to ensure that modernization could be forced through successfully.

In summary, recent work in economic history has greatly improved our understanding of the political economy of preindustrial states. As a result of this body of research, which draws on the work of economists, political scientists, and historians, we have better explanations of the determinants and consequences of regime type. We also have new theories about the causes and consequences of political centralization and fragmentation. Our understanding of the relationship between religious and secular authority in the premodern period has also been greatly enhanced. The next section considers several important areas of research in political economy.

Case Studies

The Glorious Revolution

An important case study is England in the centuries leading up to the Industrial Revolution. The Glorious Revolution represents a widely studied critical juncture in English institutional history (North and Weingast 1989; Pincus 2009; Pincus and

Robinson 2014; Acemoglu and Robinson 2012). It involved England in a global war against France and led to the foundation of the Bank of England in 1694. By making England a constitutional monarchy, it laid the foundations of the party system and cabinet government (Stasavage 2002, 2003; Cox 2016).

The roots of this institutional transformation go further back in English history. One critical juncture was the English Civil War (1642–1651). Building on a hypothesis advanced by Brenner (1993) on the role merchants played in the first English revolution, Jha (2015) uses novel data on individual MPs to explore how emerging economic opportunities overseas helped the formation of a coalition in favor of constraining the crown. He finds that MPs with financial interests in overseas trade were more likely to support Parliament in the conflict with the crown. Shares aligned the interests of non-merchants, who otherwise would have lacked exposure to lucrative trading opportunities and hence expropriation risks overseas, with merchants. Ownership of shares in overseas trade shifted the views of non-merchants, helping to consolidate support for reformers in Parliament.

Fiscal centralization also began before the Glorious Revolution. The previous "bureaucratic patchwork of authorities subject to uniform surveillance or direction" (Brewer 1988, 91) and private tax farming began to change during the Civil War. Parliament raised new taxes, including the excise tax, to fund a new professional army and navy (O'Brien 2011). Taxes and expenditure fell in the 1660s, but lessons about how to modernize England's fiscal system were learned. Tax farming of the customs and then the excise was slowly dismantled, and the Treasury was given oversight over revenues (Johnson and Koyama 2014a).

The increase in taxes after 1688 was important, however. There was greater reliance on indirect taxation – in particular the excise – collected by a professional bureaucracy. The customs, excise, and land tax accounted for 90% of revenue. From 1720 onward, these revenues enabled the British state to secure its debt at low rates of interest – a key development in the formation of a modern state.

Other aspects of state administration remained dominated by patronage and cronyism. Cox (2017a) highlights the importance of the civil list in the political economy of the Hanoverian state. After 1689, while Parliament controlled taxation and the military budget, civil positions remained controlled by the crown. This resulted in a commitment problem. Because MPs did not have control over the civil administration, they were reluctant to fund it, impeding the development of a civilian bureaucracy. Reform only came in 1831 with the Civil List Act, which established full parliamentary control over the civilian budget and made it feasible for the state to invest in a modern bureaucracy.

North and Weingast (1989) argued that the credibility of the English monarchy to repay its debts after 1688 translated into more secure property rights in general. While this claim has not survived subsequent scrutiny, in other respects there was an improvement in institutional quality after 1688. It became easier to reorder property rights in order to exploit new investment opportunities. Parliament became a forum where land could be reallocated toward more productive uses (Bogart and Richardson 2009, 2011). As a consequence, investment in road and river transport dramatically improved, with important consequences for subsequent economic growth (Bogart 2011). Prior to the

Glorious Revolution, estate bills often failed due to political conflict. As a consequence, investment in road and river transport dramatically improved, with important consequences for subsequent economic growth (Bogart 2011). Dimitruk (2018) finds that political and constitutional changes after 1688 resolved or changed the nature of many of the conflicts in government. After the king became dependent on Parliament, sudden closures of Parliament were less likely.

The English/British case study is illuminating because it points to the importance of doing serious historical work rather than relying on proxies for institutional quality, as in common in many areas of economics. For instance, according to standard measures, institutional quality was constant in England between 1689 and 1830. Maden and Murtin (2017), for instance, claim that institutions did not drive British growth because they were unchanged in this period. But this conclusion is unwarranted; this is precisely the period that economic historians have found marked improvement in actual institutional performance.

Interest groups continued to push for rent-seeking legislation and to block potentially productive improvements. North et al. (2009) use the term "open access" to describe modern, liberal, market economies in which entry is not controlled by political elites. One sign that eighteenth-century England was not yet an open-access economy is that political parties made a difference for investments in infrastructure. Bogart (2018) finds that periods of Whig dominance were associated with investments in productive infrastructure, particularly river projects.

Parliament did become less rent-seeking over time. Early eighteenth-century parliaments were notoriously venal, passing numerous acts that benefitted specific interests – most notably the Calico Act of 1721 – at the expense of the larger public. Members of Parliament were expected to look out for their own material interests and pursued what to modern eyes looks like corruption and venality (Root 1991). Over the course of the eighteenth century, this changed. Mokyr and Nye (2007, 58) note that "[p]urely redistributional actions, however, began losing their appeal. Many special interest groups' legislated privileges, monopolies, exclusions, limitations on labor mobility, occupational choice, and technological innovation found themselves on the defensive as the 18th century wore on."

Consider the position taken by Edmund Burke as an MP for Bristol. Bristol was a port that benefited from mercantilist policies, notably protective tariffs on Irish goods. In 1778, however, Burke argued in favor of free trade with Ireland. This motion was successful, but Burke was attacked by his constituents. He was unwilling to be bought off by his prosperous constituents and instead argued for the policies that he believed would benefit the country as a whole (see Prior 1878).

This process of institutional change can be understood through Olson's distinction between decentralized and centralized rent-seeking. Britain moved from decentralized to centralized rent-seeking (Ekelund and Tollison 1981). This was associated with a lot of competition over rents in Parliament, but the elimination or streamlining of local rent-seeking. By the nineteenth century, it became evident that the growth of the British economy as a whole was the surest way for elites to gain materially and to retain their status. The British landowning elite were not replaced; they came to benefit from the growth of a commercialized economy.

An important historical topic that has not yet received attention from cliometricians is the retrenchment of the fiscal-military state undertaken after 1815. While authors such as O'Brien (2011), Vries (2015), and Ashworth (2017) make strong claims about the economic benefits of the mercantilist policies pursued by the British state, the period in which economic growth was strongest and which saw substantive gains in real wages for ordinary works was the period during which the fiscal-military state was being dismantled by Peel and Gladstone. Gladstone's success in reducing the fiscal burden of the state was remarkable. But this period of British history has yet to receive as much attention from economic historians as that before 1815.

The Political Economy of Empire

Concern with the economic costs of empire extends back to Adam Smith, a sharp critic of British imperialism. An extensive scholarship studies the costs and benefits of colonial empire. Historians influenced by either Marxism or world-systems theory place tremendous explanatory weight on imperialism to explain sustained economic growth in Europe and North America.

This work was largely based on impressionist evidence, however, and the Hobson-Leninist theory of imperialism. No doubt Atlantic and colonial trade stimulated urbanization and economic growth, particularly in cities like Bristol, Liverpool, Bordeaux, and Glasgow. But these accounts are apt to neglect the importance of domestic over international commerce. As a proportion of GDP, trade with the imperial periphery was small (O'Brien 1982). Imperialism is ancient; sustained economic growth is not. Moreover, the development of overseas empires, first in Asia and then Brazil, did not prompt industrialization in Portugal. Spain was "cursed" by the abundance of silver, obtained during its imperial heyday (Drelichman 2005).[9]

Nevertheless, in the case of Britain, O'Brien and Escosura (1998) argue that the "mercantile and mercantilist matrix dominated by colonialization and commerce with continents beyond Europe" was important though not necessarily crucial for Britain's long-run economic success. As the argument cannot rely on the share of trade in GDP, which O'Brien himself established was small, it hinges on the importance of overseas markets as a source of demand for British products and on increasing returns associated with the Atlantic trading nexus. Allen (2009), for instance, pointed out a role for colonization in boosting British wages, especially in trading entrepôts like London. These high real wages then provided the incentive for labor-saving technological change. Findlay and O'Rourke (2007) also make the

[9]Note that the most recent research on the Spanish economy, for instance, points to domestic factors such as the absence of integrated markets or a standardized fiscal system (Grafe 2012; Álvarez Nogal and de la Escosura 2013). Many of the bolder claims made on the behalf of the importance of empire to the origins of growth in Europe are ably dismissed by McCloskey (2010).

case that colonial trade played a critical role in the British Industrial Revolution. But, without a model or explicit theory, it is all but impossible to quantify these external benefits or linkages; hence this is a topic that needs further research.

The impact of colonial institutions on colonized counties, in contrast, was of critical importance. This was because it not only changed the economy of colonized countries, but their political economy as well. Building on Sokoloff and Engerman (2000) and Acemoglu et al. (2001), a large literature finds that extractive colonial institutions can explain the persistence of poverty in developing countries today. Acemoglu et al. (2001, 2002) argued that the colonial period saw a reversal in economic fortunes. The most developed parts of the Americas and Africa attracted the attentions of European colonial powers and, as a result, were among the least developed parts of the world by 1900.

In a seminal contribution, Nunn (2008) showed that the transatlantic slave trade left a lasting negative impact on economic development in Africa. The slave trade also lowered population density, impeded the formation of states, and left a legacy of mistrust (Nunn and Wantchekon 2011). Other research has found long-lasting negative effects of the colonial rubber industry in the Congo (Lowes and Montero 2018). There was some investment in colonial empires, particularly in the form of railroads (see Jedwab and Moradi 2016). But in general the burden of empire was borne by the colonized (see Huillery 2014).

The impact of colonial rule on African society should not lead one to believe that Africa was a tabula rasa prior to the arrival of the Europeans. Gennaioli and Rainer (2007) and Michalopoulos and Papaioannou (2013, 2016) point to the importance of pre-colonial African states. Michalopoulos and Papaioannou (2013) find that the complexity of pre-colonial institutions is associated with economic development as measured by light density. This confirms the hypothesis of political scientists that a history of statehood is important in explaining outcomes today.[10]

The political economy of colonial India has also been subjected to cliometric scrutiny. Banerjee and Iyer (2005) find that under British ruler landlords given proprietary rights in land were unequal in the post-colonial period, spent less on development and public goods, and have experienced less of a decline in poverty. Iyer (2010) exploits a British colonial policy, whereby the territories of rulers of native states who died without a natural heir were absorbed into the British Empire, in order to generate exogenous variation in whether an Indian state received direct or indirect colonial rule. She finds that direct British rule was associated with less public goods provision in the post-colonial period: low availability of schools, health centers, and roads. This translates into higher levels of poverty and infant mortality. At the same time, British railroad investments played a crucial role in decreasing trade costs and raising incomes in colonial India (Donaldson 2018) and reduced the incidence of famine (Burgess and Donaldson 2017).

[10]This leads one to ask what determines patterns of pre-colonial state development in Africa. According to Fenske (2014), pre-colonial African states emerged in more ecologically diverse environments where the returns to trade were greater.

In India, the impact of colonial rule interacted with preexisting state structures and distributions of political and social power. Chaudhary (2009) finds that primary education in British India was particularly low in areas that were religiously diverse and which had greater caste differences. Chaudhary and Rubin (2016) find that literacy was lower in Muslim states than Hindu states. They interpret this finding in the context of a model in which rulers have a greater incentive to provide public goods where a higher proportion of the population is coreligionists.

Besides this discussion of imperialism, the state, and economic growth, other aspects of the political economy of European and American empires have also come under scrutiny by cliometricians. Mitchener and Weidenmier (2005) provide evidence that the implicit American empire in Latin America, associated with Theodore Roosevelt's Corollary to the Monroe Doctrine in 1904, brought economic benefits, as reflected in the price of Latin American sovereign bonds. Roosevelt made the US's threat to intervene in South America credible. US hegemony, they suggest, provided the public goods of peace and security in the region. Ferguson and Schularick (2006) similarly find evidence for a positive empire effect, which enabled countries on the poor periphery to benefit from cheaper capital. The mechanisms behind the empire effect were institutional: a common legal framework protected investor rights (Ferguson and Schularick 2006). Formal and informal empire reduced default risk.

Looking at the period between 1870 and 1914, Mitchener and Weidenmier (2008) find that belonging to an empire doubled trade relative to countries that were not empires or colonies. Important channels for this effect include trade policy and transaction costs. Empires were trading blocks, within which there was often a fixed exchange and free trade with the metropole.[11] Another approach is by Accominotti et al. (2010). Looking within the British Empire, they note that whereas the white dominions were able to benefit from the lower borrowing costs associated with empire, the crown colonies were not able to do so, as their fiscal policy was determined in London. Crown dependencies had very small levels of government debt, and hence did not benefit from the empire, as the white dominions were able to.

The Consequences of the French Revolution

While the French Revolution is the subject of a vast historical literature, it has not been intensively studied by economic historians. Until recently, research focused on the importance of government debt in prompting the crisis of 1789, the inflation that followed the Revolution, and the role that the Revolution played in the nineteenth-century economic divergence that took place between Britain and France.

Recent scholarship explore the political economy consequences of the Revolution. Acemoglu et al. (2011) discuss how the invading French armies dismantled the institutions of the Old Regime that had prevailed for centuries, abolishing serfdom

[11]These articles have come under criticism for not taking into account the full cost of empire (see Coyne and Davies 2007).

and guilds, emancipating Jews, and replacing existing elites. They find that cities in territories that happened to be invaded by the French then grew more rapidly in the following century.

What about the economic consequences of the Revolution in France itself? Rosenthal (1992) argued that Old Regime property rights impeded investment in irrigation and that the Revolution permitted the reallocation of these rights. The French Revolution was also characterized by the massive redistribution of Church property. Finley et al. (2017) exploit the extensive spatial variation in confiscations of Church property to investigate the importance of the initial allocation of property rights for the success of institutional reform. Church property was confiscated and redistributed by auction. Combining disaggregated data on revolutionary confiscations of Church lands with data from agricultural surveys between 1841 and 1929, Finley et al. (2017) find that in regions where more Church land was auctioned off, land inequality was higher in the nineteenth century. This wealth imbalance was associated with higher levels of agricultural productivity and agricultural investments by the mid-nineteenth century. The effects of revolutionary land redistribution on agricultural productivity declined over the nineteenth century as other areas gradually overcame the transaction costs associated with reallocating feudal property rights.

Political Repression

Another side of the state that is worthy of consideration is political repression. Premodern states frequently purged political enemies and scapegoated religious or ethnic minorities – the most frequent victims of this in European history were Jews (Anderson et al. 2017). But in general, they lacked the capacity to conduct political repression on a large scale and for prolonged periods. Society-wide repression and violence occurred, but it was highly destabilizing. Johnson and Koyama (2019) discuss how the extremely costly disruptions associated with the Reformation led European states to reduce their reliance on religion as a source of political legitimacy.

One important premodern example of sustained political repression was the Spanish Inquisition. Rather than being subject to the Pope, the Spanish inquisition was a tool of the Spanish monarchy. Vidal-Robert (2013) argues that the Inquisition was used to suppress domestic opposition when the crown was committed to overseas war. Using data from Catalonia, Vidal-Robert (2014) finds that inquisitional trials reduced population growth during the early modern period. Even today Vidal-Roberts finds people living in areas with historically more intense levels of inquisitorial activity are more likely to think that new technologies will harm them.

Qing China conducted a fierce suppression of "'word crimes" through so-called literary inquisition. Xue and Koyama (2017) study the long-lasting consequences of this political repression. The persecution of intellectuals for their speech and writing led to a fall in social capital – as measured by the formation of local charities – in the decades following a persecution. Over the longer run, areas affected by the literary inquisitions display lower levels of trust, greater political apathy, and worse provision of basic education during episodes of decentralization.

The most widely studied modern episodes of political repression are Nazi Germany and the Soviet Union (Gregory et al. 2011; Harrison 2013). Nazi Germany provides an important setting for investigating the consequences of political repression. More than 1000 academics lost their jobs between 1933 and 1934 because they were of non-Aryan descent (Waldinger 2012). Many were at the pinnacle of their relative fields and would go on to win Noble prizes. The emigration of prominent scientists had both a negative direct effect on scientific output and a negative indirect effect via collaborations and partnerships, worse outcomes for PhD students, and other peer effects.

Revolution, Democracy, Public Goods

Prior to the modern era, states provided few services beyond defense and law and order. The rise of states that provide a broad range of public goods and insurance services is a phenomenon of the last two centuries.

Lindert (2004) documents the gradual rise of public provision from the late eighteenth century onward. Large-scale investment in public education began in Prussia. The French state created a system of secular and compulsory education after 1870. In Britain, investments in public education were slower than elsewhere in Europe. In America, investments in schooling were more decentralized, but by the early twentieth century, the high school movement was giving ordinary Americans access to the best broad-based system of education in the world (Katz and Goldin 2008).

Social insurance and pensions were likewise introduced in Prussia first before spreading to other developed countries. In the United Kingdom, the foundations of the welfare state were laid by liberal government before World War I. In the United States the size and activism of the federal government remained constrained until the Great Depression, but state governments played an important role in providing public goods at the local level.

These investments were driven by political considerations. One influential way to think about these developments is through the threat of revolution. In Acemoglu and Robinson (2000, 2006) the masses threaten revolution to obtain redistribution. If this threat is permanent, elites have an incentive to extend the franchise to make credible their promise to redistribute in the future. Aidt and Franck (2015) find that mobilization, in the form of the Swing Riots, increased the vote share of pro-reform politicians in Parliament before the Great Reform Act.[12]

[12]Dower et al. (2018) address the relationship between the threat of revolution and the emergence of representative institutions using data from Russia during the Great Reforms that abolished serfdom. They find that peasants received less representation in local assemblies (zemstvo) in districts that experienced more frequent peasant unrest in the years preceding 1864. This result is consistent with Acemoglu and Robinson (2000), who predict that political reforms are most likely to be offered when the poor posed only a temporary threat to the establish order. When the poor pose a permanent threat, however, democratization is no longer the sole way the elite can credibly commit to future redistribution.

The revolutionary threat hypothesis is not the only explanation for the transition to democracy. Political scientists have focused on inter-elite bargains and the role played by conservative political parties (Dasgupta and Ziblatt 2015; Ziblatt 2017). Galor and Moav (2006) discuss how the growing importance of human capital in the economy undermined the incentives of workers to overthrow the capitalist system. Galor et al. (2009) argue that while landowning elites had an incentive to oppose the granting of compulsory education, industrialists could actually benefit from this, as the basic skills learnt at schools were complements to industrial production. This helps explain why a political base supportive of compulsory education emerged in the late nineteenth century.

Not all societies experienced a smooth transition to democracy in the nineteenth and twentieth centuries. Carvalho and Dippel (2018) study transitions in power from white planters to colored merchants in the Caribbean. Even though colored merchants were more politically accountable to the citizenry, political outcomes did not improve as much as one might expect. They identify three mechanisms by which an "iron law of oligarchy" persists even in an electoral setting. The legacy of oligarchy, ethnic fractionalization, and weak institutions play an important role in accounting for the relative underdevelopment of many countries in sub-Saharan Africa and the Middle East today as discussed in section "The Political Economy of Empire."

The rise of democracy did not necessarily have a monotonic effect on public good provision. Chapman (2016) argues that the expansion of the franchise in Britain was initially associated with increased public goods spending. However, as voting rights were granted to poorer citizens, spending on public goods and infrastructure actually decreased.

The United States established democratic institutions before any major Western European nation but lagged behind in terms of government investment in public goods. Troesken (2015) discusses the trade-offs faced by authorities in the United States in deciding whether to invest in public health improvements. The decentralized federalist structure of the United States allowed individual states to adopt different public health policies. This facilitated jurisdictional sorting and allowed states to respond to local epidemics. But it was not suitable for coordinating responses to diseases that cross state boundaries. Using the example of small pox, Troesken shows that federalism impeded the introduction of measures such as vaccination against small pox that were crucial for lowering mortality rates. He argues that this same federalist structure ensured greater protection for individual liberty and spurred economic growth, but it came at a cost in terms of public health.

Concluding Comments

Cliometrics is based on the application of economic methods to historical questions. Economic theory can clarify questions and crystalize them in the form of testable predictions that can be taken to the historical evidence. As this evidence is often quantitative, cliometric economic historians have been at the forefront of introducing more formal econometric and statistical methods to the study of history.

Political economy also involves the application of economic models to nonstandard settings. In its modern form, it also stresses the importance of using economic theory to guide the empirical analysis of political questions. Its practitioners likewise need to have command over both economic theory and econometric techniques and knowledge of institutional details and particularities. Cliometrics and modern political economy can thus be viewed as two closely related and complementary fields within economics.

In addition to those topics discussed in this chapter, many other subjects could have been touched upon. Studies of the development of banking institutions in the nineteenth-century United States, for instance, increasingly consider questions of political economy. To what extent did local elites dominate and control banking institutions and to what extent were these institutions characterized by limited versus open access (Bodenhorn 2017)? The topic of trade and tariffs also raises questions of power and the extent to which particular interests are represented politically (Irwin 2017). This chapter has surveyed some prominent topics in the literature from the emergence of the state, the rise of state capacity, the political economy of empire, and the consequences of revolution. Political economy questions intrude on almost all aspects of economic history, leaving much fertile ground for future research.

Merchant Empires

Claudia Rei

Contents

Abstract

The Age of Merchant Empires started with the implementation of the Cape Route in 1498 and ended in 1874 with the extinction of the English East India Company. Europeans engaged in the business pursued trade (therefore merchant) and maintained their overseas possessions by force (therefore empires), but population density and established state hierarchies in Asia prevented them from engaging in full-fledged colonialism from the outset. By settling trade outposts in port cities around the Indian Ocean and the Far East, Europeans acquired the necessary network for the supply of a continuous stream of spices, and other Asian goods, to be loaded on ships sailing to Europe. Maintaining an empire required a steady supply of Eastern products implying necessarily the availability of capital and the development of capable shipping technology. But the longevity

of merchant empires also depended on a sophisticated administration of trade and personnel in Asia and the defense of trade interests. These multi-stranded enterprises were controlled by merchants and/or kings, to whom the prerogative of international trade belonged in early modern Europe. Organizational control had considerable implications on the way merchant empires were run as well as their long-term commercial success. The Asian territorial expansion that some merchant empires pursued reached colonial proportions even before the official start of colonialism in Asia when the administration of overseas territories was formally assumed by governments in Europe.

Introduction

Following the Great Maritime Discoveries of the fifteenth century, the Age of Merchant Empires marked the period when several European countries established direct trade connections with Africa, Asia, and the Americas. Based on all-sea routes, post-1500 trade broke the centuries old pattern of long-distance trade dominated by Venice and other Italian city states, who controlled Eastern trade coming through the Levant and arriving in the Eastern Mediterranean via land while relying on multiple intermediaries. Merchant companies, on the other hand, gathered investments from multiple agents, developed elaborate organizational structures headquartered in Europe and directly engaged with the distant locations producing exotic products, on which they based their trade. Not only were these the first joint-stock companies in history, they were also the first multinational structures carrying out activities on multiple continents. Regardless of the country they belonged to, these enterprises indelibly marked the histories of the regions where they operated and affected the power structure of the world.

It is often difficult to separate the Age of Merchant Empires from Colonialism, especially in South America where the arrival of European traders in the early sixteenth century occurred hand in hand with territorial encroachment. A combination of low population density, tropical conditions ideal for the production of cash crops, and the availability of precious metals precipitated the rapid conquest and colonization of that particular region. In Africa and especially in Asia, higher population densities and state hierarchies in place led European settlers to secure agreements with local sovereigns allowing for the establishment of coastal warehouses and fortresses to conduct trade on their shores. Such agreements were most often granted under coercion due to the military advantage of Europeans, who would (and non-rarely did) threaten to destroy cities, forge alliances with neighboring rulers, and eventually annihilate entire kingdoms. Reproachable as they were, these strategies resulted in the establishment of trade channels separate from formal territorial control, which was delayed to a later stage.

This chapter focuses on the merchant companies of early modern Europe that conducted trade across wide regions of the globe and not on the formal colonial rule that ensued. Started upon arrival of the Portuguese in India in 1498, England, the Dutch Republic, Denmark, France, and Sweden all established trading companies in the East, which endured until the dissolution of the last East India Company in 1874. Even though this chapter concentrates on merchant operations in Asia, the main focus relies on the European companies.

International Trade in Early Modern Europe

In the sixteenth century, international trade was a royal prerogative. Monarchs could lawfully exert their right of exploration of distant trade sources themselves (as it was the case with the Portuguese king after Vasco da Gama's arrival in India in 1498), or they could instead grant exploration rights to a subject or group of subjects in their realm. Whether owned by kings or merchants, these merchant companies were typically granted exclusive rights within the home country to conduct trade in specific areas for a given time period, both of which were clearly defined in the company's charter. In 1600 Elizabeth I issued the first charter of the English East India Company granting a group of London merchants the exclusive privilege within England, of conducting trade and traffic across sea or land (already known or yet to be discovered) in the area between the Cape of Good Hope and the Strait of Magellan for 15 years. Subsequent renovations of the charter extended the company's privileges for longer periods of time.

These companies operated therefore in very large portions of the world in the absence of a legal international framework to regulate or monitor their activities. They were subject to the set of norms in their charters, specifically designed to fit their novel forms of operation overseas. The charters allowed them to pursue, defend and protect their trade, and exert jurisdiction wherever they conducted business. The formidable power granted to these companies indelibly associates the trade they pursued with the military and political dominance they exerted outside their countries of origin (Findlay and O'Rourke 2007). To understand the various activities carried by these multinational ventures, this section focuses on three main areas of operation of these companies: trade, administration, and defense.

Trade

The prime *raison d'être* of these enterprises was trade in merchandise that was not produced in Europe but where it was in high demand and thus expensive. Asian products, especially spices, had reached Europe centuries before the emergence of merchant companies. Known to make food palatable, spices were also useful food preservatives, especially when appropriate food storage was not an option. Spices were gathered in the producing regions around the Indian Ocean by multiple Muslim traders, who then transported them in caravans through Central Asia and the Levant

until Constantinople or Cairo. From the Eastern Mediterranean, spices were brought by ship to Genoa or Venice and from there distributed to other markets in continental Europe. The many intermediaries of this process and the crossing of various, and not always peaceful, territories made spices in Europe limited and expensive.

Throughout the fifteenth century, Portugal's exploration voyages down the African coast resulted from investments in cartography, navigational instruments, and sailing ships fit for open-sea rather than coastal navigation. The technological prowess of Portugal and her propitious geography outside of the Mediterranean – and thus away from the influence of the Italian City states – facilitated the search for alternative routes to bring spices from Asia into Europe. The discovery of the Eastern passage around the southern tip of Africa in 1487 added to the contemporaneous geographic knowledge that the Atlantic and Indian oceans were linked and provided an early signal of the physical viability of an all-sea route to Asia.

Da Gama's first voyage to India in 1498 was a commercial failure, but subsequent voyages were not. In spite of the volatility of profits of early voyages, the commercial exploration of the Cape Route had substantial implications on European spice markets from the start. After 1503, real pepper prices declined in many European cities, as did the prices of other fine spices, suggesting serious disruptions to the Silk Route (O'Rourke and Williamson 2009). These traditional routes, however, would only be displaced a century later upon arrival of the Dutch in Asia (Steensgaard 1974). Caravan intermediaries gave way to perils in the high seas where storms and pirates could loom with more or less predictability. But the rising importance of the Cape Route in the sixteenth century went beyond the merchants' economic incentive of undercutting European spice prices. It depended heavily on the successful transportation of merchandise from Asia to Europe, implying therefore developments of the sailing ship, the workhorse of merchant empires (Unger 2011).

The sailing ship was the dominant technology for the time period of interest, as it evolved slowly from the year 1000 until the last quarter of the nineteenth century when steamers finally replaced it in long-distance routes (Graham 1956). Countries that were able to innovate and improve the sailing ship to serve their best purposes at any given time period achieved a prominent position in discovery and trade (Rei 2016).

Venice's early technological edge used a combination of oars and sails, allowing for the control of navigation in the Mediterranean roughly from the eighth to the fourteenth centuries. By the fifteenth century, Portugal's exploration voyages required small and easily maneuverable lateen sailed ships appropriate for the exploration of unknown coasts in unchartered waters. After 1498, however, the rising volume of trade increased capacity needs and replaced the earlier light and swift vessels by much larger square-sailed ships, such as galleons and carracks. In Lisbon, the shipbuilding industry grew rapidly and quickly specialized in the production of these very large vessels (Costa 1997). Ultimately, these heavily armed vessels proved inefficient as they were slower and more vulnerable to storms or attacks by foreign vessels. The foundation of the Dutch East India Company (VOC) in 1602 came after a century of Dutch experience in the shipping of bulk goods around Europe, from Portugal to the Baltic (Israel 1989). By the mid-sixteenth

century, the Dutch shipping expertise produced the *fluit*, a relatively small and light cargo vessel with modified sails and hull allowing for relatively larger cargo capacity and no added vulnerability (Eriksson 2014). Though better suited for safe routes in northern Europe or within Asia, *fluits* were not uncommon on the Cape Route and were also exported to most other merchant empires (Barbour 1930). The Dutch competitiveness in shipping stopped after 1650, halting the rapid growth of the Dutch Republic in the eighteenth century (van Zanden et al. 2009). By that time Britain had consolidated her power in the Indian Ocean and had a more powerful navy than any other empire. Long-distance trade leadership therefore cannot be dissociated from technological dominance in shipping.

Administration

The multinational nature of merchant empires required a sophisticated administration spanning across territories under different jurisdictions. Headquartered in Europe, companies faced the challenging task of managing trade operations through a network of overseas ports that could potentially extend from the Cape of Good Hope to Japan. Trade networks differed across empires. Portugal and the Dutch Republic centralized operations in a main port city (Goa and Batavia, respectively), from where they coordinated communications with Europe as well as with other port cities in Asia. England had a more flexible network of outposts, arguably more easily adaptable to changing market conditions (Erikson 2014). Denmark, France, and Sweden had much more limited areas of operation concentrated in specific subregions of Asia. Adding to the geographic complexity, the slow intercontinental communication depended not only on distance but also on the monsoon and the non-negligible risk of loss at sea. Depending on the European country of departure, the voyage from Europe to Asia took some 9 months for vessels departing in the spring, and the return trip from Asia was usually delayed until March of the next year to avoid the stormy season. Arrival in Europe by the end of the year made for an 18- to 24-month commercial cycle, imposing a lag in the implementation of decisions coming from Europe and implying a large degree of autonomy of workers in Asia, especially those in high-rank positions. These features affected the companies' administration of trade, of their own personnel, and also the administration of justice as the resolution of conflicts could not depend on European judicial structures.

Successful trade depended on the timely arrival of vessels and the ready supply of merchandise to be loaded and shipped. These demands required the procurement of goods from local producers (often selling exclusively to the companies in imposed monopsony schemes), to be weighted, valued, and stored in local warehouses until the arrival of company vessels. Coordination of these activities involved vessels arriving from and departing to Europe but also vessels engaged in intra-Asian routes. For instance, Europeans engaged in the very lucrative Japan and China trades, acting as intermediaries between the two Asian powers who had severed contact due to earlier conflicts, while widening the spectrum of Asian products arriving in Europe.

The bureaucratic administration to maintain operations in Asia involved locally hired labor, mostly for unskilled jobs (e.g., loading and unloading ships), but also labor hired in Europe to work in Asia whether in low-rank positions of trust (e.g., guarding warehouses), low-rank skilled positions (such as bookkeeper), or high-rank supervisory positions (such as director of operations in Japan). Hiring people in Europe to work in Asia constituted a classic moral hazard problem. Overseas jobs were attractive as they offered nonseasonal wages, unlike most jobs in Europe, and the potential to make a fortune (Marshall 1976). But these jobs were also notoriously risky: the trip to Asia was perilous, tropical port cities in Asia were stricken by disease, and military conflict could often emerge. From the companies' perspective, the choice of compensation should take into account the job's risks and uncertainties but also elicit honest behavior from agents directly dealing with highly valuable merchandise in distant locations.

Economic theory has long dealt with incentives to induce workers' effort in imperfect monitoring situations (Lazear 1995). In the context of merchant empires, economic historians in this line of work have studied wage structures, private trade, and career progression as mechanisms to deal with the inherent moral hazard problem. Rei (2013) uses a principal-agent model yielding different pay schemes in companies controlled by different parties, which correspond to different monitoring abilities. The model's implications are then illustrated with archival data on labor compensation of Portuguese and Dutch overseas workers. The latter were paid a larger fraction of total compensation in the form of wages when compared to their Portuguese counterparts, which is consistent with Dutch merchants controlling the VOC and, as such, implementing a monitoring structure providing better information on workers than merchants working for the king of Portugal. Hejeebu (2005) focuses on compensation beyond wages and argues that private trade in the English East India Company was complementary to the company's trade. Allowing workers to use the company's resources and enjoy its protection while conducting trade in their own account encouraged workers to fulfill the company's orders so to keep the opportunity of making a fortune of their own. The combination of private trade and a dismissal policy for workers who failed to meet the company's objectives in a given position ensured worker's effort and the pursuit of the company's goals. Rei (2014) uses data on Dutch overseas workers to illustrate the internal career and wage structures of the VOC. There were stable career paths, on-the-job training, fast tracks in promotions largely from within the company's ranks and sizeable returns to tenure. All these papers show that the personnel policies of merchant empires were designed to hire and retain workers, foreshadowing the practices of modern multinational companies.

Other than trade and personnel, merchant companies also administered justice in their geographic areas of action. As empire workers moved to overseas territories where the European court system did not reach, companies were granted judicial authority on behalf of the home countries courts, which constituted a delegation of an important state prerogative. Initially, the administration of the law was aimed at the resolution of conflicts within the community of European settlers, soldiers, privateers, and company officials. But the divide between these subjects and the

indigenous population was not always clear, especially in the Portuguese empire where the policy of intermarriage with locals and the Church's active proselytism extended jurisdictional claims to a growing Christian population (Benton 2002). Other empires may not have followed these same policies, but they faced similar challenges, especially with the expansion of territorial control, which encompassed larger indigenous populations, particularly in the English case.

Like other Europeans, the English encountered pre-existing local legal arrangements in Asia, so they implemented a parallel judicial system where local rulers could still conduct justice independently from the company's courts. The 1661 charter conferred judicial authority in civil and criminal matters directly on the Governor and Council, the only court of law in India until 1683 when the Courts of Admiralty were established (Fawcett 1934). The company's legal control expanded gradually with the company's territorial expansion. The concession of Bombay as a royal dowry of Catherine of Braganza upon her marriage to Charles II in 1661 transferred the city from Portuguese to English hands, but only in 1668 was it transferred to the East India Company, as it became too heavy expense for the English crown. Bombay became one of the main settlements of the company in India, together with Madras and Calcutta, which came under the company's control in 1698. As the company expanded its reach in the subcontinent, it developed a judicial hierarchy resembling that of England, with judges appointed to criminal and civil courts from the ranks of company employees. By 1726 such authority moved to the king marking a turning point in the judicial policy, mainly to avoid litigation against the company in England (Fawcett 1934). Continued attention to the company's affairs led to the Regulating Act of 1773, which was intended to bring profound reform of the company's administration in India.

Defense

The last major area of activity of merchant empires entailed military defense, due to the valuable nature of Asian goods. This scope of activity involved four main aspects that made it necessary. First, trade agreements with local Asian rulers were largely attained under coercion of the non-European party, whose lower military capacity made it impossible to refuse such agreements. Second, these valuable products, transported across the oceans, were coveted by several European countries engaged in long-distance trade and also by pirates in the high seas. Third, all merchant companies were granted monopolies within the home country but competed with each other in Asia for the best locations to establish settlements and acquire a steady supply of goods; very often such commercial activities led to bitter territorial disputes lasting several years, as in the case of the four installments of the Anglo-Dutch Wars. Lastly, as competition between England and the Dutch Republic intensified over the years, so did the urge of the corresponding companies to control larger portions of territory in India and Southeast Asia, some of which were managed as spice-growing plantations using locally enslaved labor, which required coercion power. Moreover, these plantations could themselves be targets of foreign interests and thus had to be defended.

From the early charters, all companies were given exclusive rights of trade and conquest in vast areas of the globe. This opened the door to diplomatic agreements but also to the protection and defense of their trade interests. The conflicting nature of merchant empire operations at multiple levels led, from the very beginning, to the investment in armed ships, resorting to travel in convoys to protect cargo, and the employment of labor exclusively dedicated to military defense. Vessels on the Cape Route carried not only spices but also soldiers who were initially bound to the protection of the companies' fortified settlements but were later involved in key battles with local kingdoms for vast portions of territory.

Portugal's military edge over local sovereigns was very visible upon arrival in Asia in the late fifteenth century, and it was only challenged by the Dutch who, nearly a century later, were able to displace the Portuguese from a large number of ports, especially in the spice-producing regions of Southeast Asia. The English, on the other hand, challenged and displaced the Portuguese from many outposts in the spice-producing region of Malabar in the West Indian coast. With the Portuguese out of the key areas of interest, the seventeenth century was marked by the stark commercial rivalry over trade and territories around the Indian Ocean, yielding to fierce confrontation of the English and the Dutch East India Companies. The Dutch were more successful in the 1600s, but British naval superiority and the decline of the Dutch Republic after the 1730s allowed the English East India Company to control larger portions of territory than any other empire. The decisive battles of Plassey (1757) and Buxar (1764) against Indian powers gave the English East India Company full control of Bengal, thus becoming the major political and military actor in the region.

The control of Bengal catapulted the company to a new level of influence: the original venture of London merchants now commanded a larger army, ruled over a greater number of subjects, and controlled a wider territory than the United Kingdom itself (Mcaulay 1877). Administering justice and having its own army were not unusual for early modern merchant companies, but the East India Company's power reached such unprecedented levels that it effectively became a state within the state. The company's growing authority in India and the consolidation of its commercial position could no longer be dissociated from its military strength. As such, the company came under thorough scrutiny, especially from parliament. Though in favor of maintaining the empire, prominent statesman Edmund Burke denounced the company as "a state in the disguise of a merchant" (Burke 1870: 23). Adam Smith, who mostly argued for the end of the empire and the development of a free-trade relationship with the independent colonies, characterized the East India Company as the "'strange absurdity' of a company state" (Stern 2011: 3). The ensuing imperial debates throughout the nineteenth century resulted in the gradual incorporation of the company into the British state and empire.

International trade in early modern Europe was a risky and expensive venture that went well beyond the pursuit of distantly produced exotic goods. Merchant empires did primarily pursue trade, which depended on the efficient administration of operations in the East and the defense of their interests against rival empires. The monopoly nature of merchant companies operating on multiple continents made

them necessarily large, at a time when high operational costs would advise a smaller optimal firm size (Anderson et al. 1982). Such high costs derived from the multivariate nature of challenges faced by merchant companies in a context of slow communications, constant development of competitive shipping technology, unpredictable dangers associated with weather *en route*, tropical climates prone to disease in Asian destinations, and complexities inherent to the administration of trade, personnel, and justice. These constraints led countries to the use of similar means to explore trade in distant locations. All countries pursued spices in Asia, all used the sailing ship on the Cape Route, and all mounted elaborate operations in search of profit. Yet, countries organized overseas operations very differently. The next section focuses on these differences and the economic incentives behind them.

Contrasting Empires

From the sixteenth to the nineteenth centuries, the expansion of European operations in Asia did not follow a uniform pattern despite sharing similar challenges and objectives. On the one hand, the variety of locations in Asia demanded adjustments to each company's settler strategy. For example, the Dutch settlement in Malacca – a renowned emporium of trade on the strait of the same name, linking the Bay of Bengal and the South China Sea – was necessarily very different from the Dutch settlement at the Cape of Good Hope, the main port of call of the VOC with the prime role of supplying victuals to calling vessels. On the other hand, European countries could have concentrated operations in Asia in a single city to which all other (minor) trade outposts would report and from where all communications to Europe departed and arrived (such was the case of the Portuguese and Dutch empires). Alternatively, they could have chosen a small number of main cities in their trade network to concentrate to serve as regional centers of operation (such was the case of England).

As many of the business decisions in merchant empires, the choice of how to geographically organize operations in Asia derived directly from the strategies devised by the owners of the enterprise located in Europe. If we understand merchant empires as partnerships between kings who had the prerogative of international trade and merchants who effectively conducted and managed trade, organizational control conforms to three distinct possibilities: king/government control (as in the case of Portugal), merchant control (observed in England, the Dutch Republic, and Sweden), and mixed control between king and merchants (as in Denmark and France). The theory of the firm shows that property rights of ownership matter as they determine the ultimate residual claimant of the firm, who controls inalienable business decisions that directly affect the firm's efficiency and success (Grossman and Hart 1986). In the context of merchant empires, the divergent long-term performances highlight the importance of company ownership.

Figure 1 shows the relative shipping of merchant empires to Asia as a percentage of total tonnage per decade in the sixteenth and seventeenth centuries. Alone in the long-distance trade market, Portugal held to her full share of the market until the

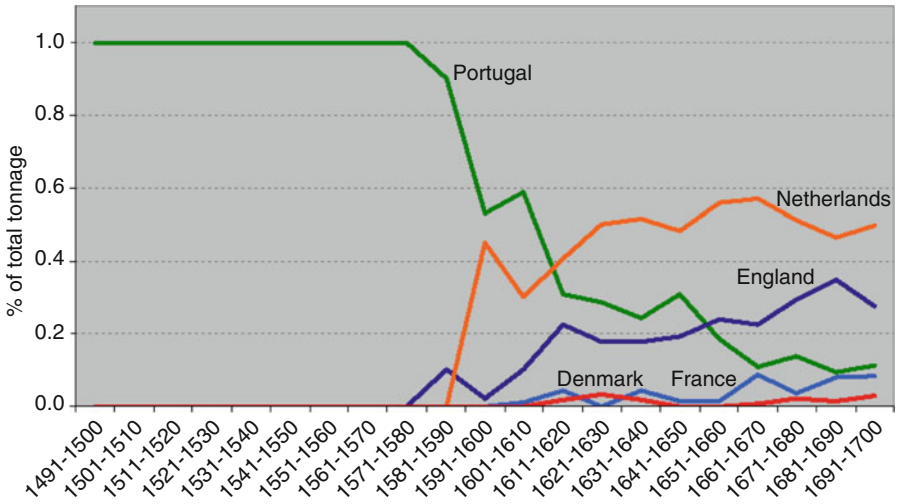

Fig. 1 European shipping to Asia (Source: Rei 2011: 117)

1590s when English and Dutch vessels began competing on the Cape Route shortly before the foundation of their respective trade companies in 1600 and 1602. The continued and marked decline of Portugal's market share throughout the seventeenth century suggests an inability to cope with competition when it arrived. Portugal, lost most of her trade posts in Asia to England and the Dutch Republic, and as such was unable to sustain trade volume at sixteenth century levels, since the decline is also visible in absolute terms. By the end of the 1700s, Portugal was as small a player in the long-distance trade market as were the Danish and French companies that never shipped much to Asia.

If firm ownership is indeed a factor affecting the long-term performance of merchant empires in Asia, it becomes imperative to understand why some kings chose to control the monopoly of trade while others chose instead to charter monopoly rights to private agents. Was Elizabeth I, the English monarch chartering the East India Company in 1600, more farsighted than her distant cousin Manuel I of Portugal in 1498? Were Portuguese merchants less entrepreneurial than English merchants, leaving the king of Portugal no alternative but to control the monopoly of trade himself? Why would the French king share the control of empire with merchants?

This Section is organized in three parts. The first, provides answers to all the above stated questions with a simple version of the model of organizational choice in Rei (2011). The model relies not on differences between monarchs, or merchants in different countries, but on differences between monarchs and merchants in any country. The second part, provides an interpretation of historical events at the emergence of merchant empires in light of the simplified model. The third part, provides evidence on the observed historical differences across merchant empires with different control structures.

A Model of Organizational Choice

Long-distance trade in a given country results from the cooperation between king and merchants. The king can either award the monopoly of trade to private merchants or keep it to himself. Merchants contribute with management skills in the form of effort either in a merchant-controlled firm or as royal employees in a king-controlled firm. King and merchants own cash, which they can either invest in long-distance trade or in other alternatives assumed to yield a lower return, which is consistent with historical evidence on the profits of the East India Companies (Chaudhuri 1965). As such, provided they have cash to spare, king and merchants will invest in long-distance trade.

In the context of uncertainty and incomplete contracts, the probability of success of long-distance trade depends on merchants' effort, non-contractible business decisions by the controlling party, and the realization of uncertainty after the contract is signed.

Preferences of king and merchants are similar with respect to profit that they both want to maximize, but differ substantially in two other aspects. First, merchants effort is costly. Adding a similar term to the king's utility function does not change the result, so this case is ignored for simplicity. Second, the king values being in charge of non-contractible decisions, which enter separately in the king's utility function but not in the merchants'. Adding a similar preference in the merchants' utility function does not change the result so long as merchants care less for business decisions than the king. Again, for the sake of simplicity, this case is ignored. This last characteristic fundamentally distinguishes king and merchants. Even though they both care for trade, which itself is affected by effort and business decisions, the king cares for being in charge of the enterprise, which implies not only the choice of non-contractible business decisions but also ruling over a larger number of people, controlling a vast amount of territory, and spreading his religion and culture, among other features.

The timing of the model develops in three sequential stages. First, merchants and king negotiate over the firm's control structure and the sharing rule of profits to be divided among them; both of these decisions are contractible. Second, after the contract is signed, uncertainty is realized, eliciting the choice of business decisions by the controlling party. Finally, merchants choose the level of effort based on the previously determined uncertainty and business decisions.

Figure 2 shows the graphic solution of the model. Utilities of king (v) and merchants (u) are measured in the yy- and xx-axes, respectively. When king and merchants cooperate, they get utility pairs represented by the higher curved frontiers upon variation of the sharing rule: KC for king control and MC for merchant control. The line closer to the origin represents the set of disagreement points from where king and merchants start the negotiation stage. In the absence of cooperation, these utility pairs represent the king and merchant's outside options given by their alternative choices in the use of cash (c), assumed to have a lower return (λ). This frontier also represents each party's relative bargaining power: moving toward the yy-axis has the king's outside option rising (and the merchants' decreasing) in the no

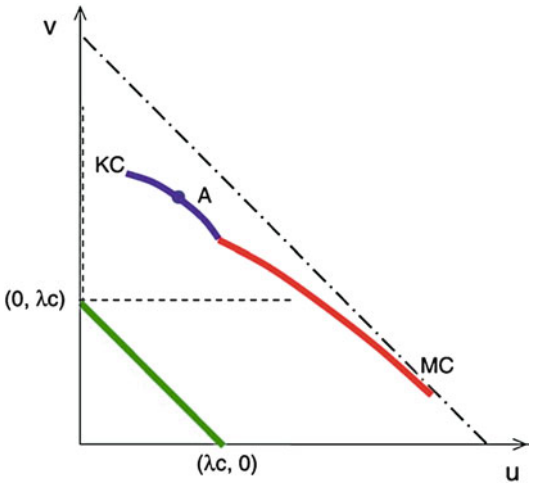

Fig. 2 Graphic solution of the model (Source: Rei 2011: 119)

cooperation case, so the king has a stronger bargaining position than the merchants. The reverse is true for the merchants. In the limit, when the king owns all the cash in the economy, the outside option is (0, λc), from where both parties negotiate, ending up in the KC frontier, say point A, where both parties are better off relative to the case of no cooperation. The reasoning is symmetric for merchants: the more bargaining power they have, the closer they are to (λc, 0), and the negotiation will yield a point in MC. A non-extreme disagreement point could lead to a mixed solution where the control of the enterprise alternates between king and merchants.

In this model, whether the solution lies on MC or KC depends on the relative bargaining power of negotiating parties, which results directly from the firm's financial structure. Thus, institutions emerge because they satisfy the incentives of those in charge, not because they are efficient or socially optimal. An example of a social utility function is the linear sum of king and merchants' utilities. The benevolent social planner would maximize the sum of utilities at the highest indifference curve of slope − 1, which touches the MC frontier closest to the xx-axis yielding very high utility for the merchants and very low utility for the king. Since there is no social planner, both parties maximize their own utility function according to their relative bargaining positions, so we may never attain the socially optimal solution. Either party is strictly better off when in control, that is, KC strictly dominates MC for the king, and the reverse is true for the merchants. Thus, when a party has the bargaining power to control the enterprise, it will never give up on such control.

The implications of the model are very clear: a cash-constrained monarch charters monopoly rights to merchants who control the enterprise, whereas a cash-flush monarch retains ownership of the venture and hires merchants as royal servants to manage the company. The control structure has stark implications on the model's choice variables: merchants work harder in a firm they control, and business decisions differ greatly whether they are made by the king or the merchants. The different choice variables in turn imply different probabilities of success under king

or merchant control, with the latter being larger. The model's implications suggest companies should differ greatly according to the control structure, which provides a vindication of the theory of the firm in the context of merchant empires, but also illustrates the historical differences empirically observed.

Historical Context of the Emergence of Merchant Empires

In light of the model's implications, this section focuses on the historical context of the emergence of merchant empires so as to infer the relative bargaining power of king and merchants in different countries from the surviving evidence on their relative financial endowments.

Vasco Da Gama's arrival in India in 1498 came after nearly a century of crown-sponsored naval expeditions down the African Coast and into the Atlantic in search of the Eastern passage to India. Some of these expeditions were military ventures, mostly in Northern Africa. Others reached uninhabited regions, such as the Atlantic islands of the Azores. Still others reached populated areas with potential for trade in gold, slaves, and Guinean pepper, mostly located in the Gulf of Guinea. This trade started in the late 1430s, giving the crown a comfortable fiscal position, which can be inferred from the frequency of *cortes* – meetings between the king and representatives of the clergy, the nobility, and the general estates with the main purpose of raising taxes. Before the start of the expansion in 1415, *cortes* occurred every one and a half years; from then until 1498, the average time between meetings doubled to 3 years, and after 1498 it tripled to 9.1 years (Rei 2011). This evidence suggests the king of Portugal had strong bargaining power to keep the control of the monopoly of trade in his hands after 1498. Estimates of the labor and capital costs of Portugal's exploration voyages show variable but very high returns on investment for the Portuguese king, further confirming the reinforcement of his strong financial status pre-1498 (Rei 2011). In light of the model, the Portuguese monarch had the financial leverage to keep the ownership of the monopoly of Asian trade, so this is a case of king control.

The chartering of the English East India Company in 1600 came at the end of Elizabeth I's long reign (1558–1603), which was marked by internal and external conflicts. The dispute of the throne by Mary Queen of Scots, the Nine Years' War with Ireland (1594–1603), and the Anglo-Spanish War (1585–1604) all contributed to this turbulent period of English history and added to the crown's financial distress. The pressing financial needs on account of war could not be met by government revenues: from a surplus in 1583–1585, the government balance turned into a deficit by 1597–1600 (Goldsmith 1987). The absence of formal capital markets before the 1688 Glorious Revolution led English monarchs to engage in confiscatory practices by the name of forced loans (North and Weingast 1989). This unpopular form of raising crown revenue hurt the monarch's credibility of repayment and added to the general dissatisfaction that, in time, resulted in the fall of the monarchy. The crown had plenty of pressing needs for the money raised by forced loans, but had the decision been to invest that capital in long-distance trade, it would not have been

enough to cover the costs of the East India Company's voyages in the first 15 years of the charter (Rei 2011). In the context of the model, England's precarious financial situation by 1600 rendered little or no bargaining power to the crown, who chose instead to allocate property rights of trade to the group of merchants who formally requested it, in exchange for customs duties. This is a clear case of merchant control.

From 1595, multiple companies of Dutch merchants sent ships to Asia on the Cape Route to take part in long-distance trade. Competition among these small companies increased spice prices in Asia but lowered prices in Europe as more quantity became available for sale. Encouraged by the Dutch government (not a king in this case), these companies reached an agreement to merge, and the United Dutch East India Company was born in 1602. The early companies had varying degrees of success, but their emergence in the late sixteenth century shows that merchants in the Dutch Republic had the necessary funds to engage in the expensive business of long distance trade, which, in the context of the model, would imply stronger bargaininng power in the negotiation for control. The degree of involvement of the government in the VOC was greater than that of the English crown in the English East India Company. Not only did the government initiate efforts to encourage the merger, it also provided convoy protection to the company's ships in times of war, for which it received an annual payment. The waiving of the first such payment can be seen as a contribution by the Dutch government to the assets of the VOC in the amount of 25,000 fl. corresponding only to 0.4% of the original capital stock of the company (Glamann 1981). As such, the Dutch government seems to have had some degree of bargaining power, since it was able to place the country in better competitive standing relative to other European rivals. But its bargaining power was probably not that great or we would have seen a larger initial investment in the Dutch company. This small initial contribution is suggestive of a cash-constrained Dutch government, still actively involved in the Eighty Years' War (1568–1648) in the first decades of VOC operations. The resulting control structure of the VOC is a clear case of merchant control, but the government had more of a say in the company than in the English case.

Denmark's East India Company, chartered in 1616, had a limited scope of operation in the Indian Ocean, locating mostly on the southern coast of India and in Ceylon. Like the English and the Dutch companies, it was a joint stock, but in many other aspects, it differed greatly from those other companies. The initiative to file the petition of monopoly rights for royal approval came from two Dutch citizens living in Copenhagen and not from Danish nationals, directly contrasting with England and the Dutch Republic. Additionally, Christian IV had a far more active role in the foundation of the company than his English counterpart or the Dutch government. The company faced capital shortages from the beginning, prompting the monarch to force contributions from private investors. The crown itself contributed 12.5% of the necessary capital, the nobility 15.5%, another 35% from citizens of Copenhagen and the university, 29.5% from other towns in Denmark, and 7.5% of the capital from abroad – 2.5% from Hamburg and 5% from the Dutch Republic (Feldbaek 1981). The king again played a decisive role in sponsoring the company through the Thirty Years' War (1618–1648), which was ruinous for Denmark. By

1630, the king had become the owner of half the company's shares, effectively controlling the enterprise. As such, Denmark offers a case of mixed control: the king was never fully able to carry out trade on his own and needed to rely on (or at times force) merchants to participate with part of the necessary capital. The reorganization of the company in 1670 proved similar in terms of bargaining power balance, with the king insisting on the financial support of Copenhagen merchants (Furber 1976). In the context of the model, Denmark's king and merchants would be located in an intermediate disagreement point, thus sharing or alternating control of the company.

The French East India Company was chartered in 1664 and designed by Jean-Baptiste Colbert, the long-time minister of Louis XIV, which denotes a stronger involvement of the king in the enterprise, as in the case of Denmark. This centrally planned company followed a series of unsuccessful companies since the early 1600s, dictating the late arrival of the French in India. The company was conceived to be similar to the VOC, but the lack of interest of French merchants in a company they could not control was evident early on (Manning 1996). Of the original 15 million livres in stock, the crown's subscription of three million forced subscriptions by the royal court, great financiers, and several French cities. Even so, subscriptions totaled only a little over eight million livres, with merchants becoming only a small minority of the shareholders (Furber 1976). From the start the company was plagued with capital problems that worsened with France's involvement in the War of Spanish Succession (1701–1714). As the company turned to the crown for a loan to which the king agreed so long as the directors and stockholders also contributed with given amounts. Barring the Portuguese in India, in no other empire was the involvement of the state more dominant. Still, the forcing of stockholders to engage in further investments shows the king alone was incapable of assuming sole control of the enterprise. Moreover, the incomplete subscription of the company's original capital stock is evidence of the merchants' bargaining power shown in their reluctance to participate in the state company. France, therefore, offers another case of mixed control in light of the model of organizational choice, where the balance of bargaining power probably favored the king a little more than in the case of Denmark.

In 1731 Frederick I chartered the Swedish East India Company after several merchant petitions for a company to engage in Eastern trade. Rather than competing directly with the bigger empires, Sweden specialized in Far Eastern trade with China, notably in tea and porcelain. The late chartering of this company owed to both internal and external factors. On the one hand, Sweden had a belligerent seventeenth century, draining capital to alternatives other than long-distance trade (Hermansson 2004). On the other hand, the suspension and subsequent failure of the short-lived Ostend Company, in 1727 and 1731, created a vacuum of investment opportunities for shareholders in that joint stock, favoring both the already existing Danish company and the newly created Swedish company (Koninckx 1993). The timeliness of the latter event suggests that merchant capital circulated in eighteenth-century Europe but also that kings willing to charter trade companies were relatively more abundant. The end of the Ostend Company resulted from pressure by the British and Dutch governments on Charles VI, the Holy Roman Emperor, to suspend the

company or they would not recognize his daughter Maria Theresa as his rightful successor (Furber 1976). Merchants petitioning the king of Sweden for the company in 1731 further requested the monarch to activate the necessary diplomatic efforts so that the company was recognized by other maritime powers in order to prevent a fate similar to that of the Ostend Company. These additional merchant demands and the late entry of Sweden into the long-distance market suggest the king had little influence in the company and thus no bargaining power beyond that of chartering the monopoly of trade. In the context of the model of organizational choice, Sweden is therefore a clear case of merchant control.

Different Firms

At the foundation of merchant empires, king and merchants' negotiating positions were central to determine the control structure of the enterprises. But the control structure itself implied fundamentally different firms. This section discusses just three areas where these differences were particularly visible.

First, merchant empires were faced with classic agency problems resulting from the nature of long-distance trade. Organizational control led to different incentive structures within the firm, which resulted not only in different pay schemes for personnel hired in Europe to work in Asia but also in different incentives at the upper levels of management. Irwin (1991) argues the Anglo-Dutch commercial rivalry of the early seventeenth century can be understood in light of the subtle institutional differences deriving from the English and Dutch India Companies' charters. At a time when both empires were establishing their foothold in Asia, the Dutch Republic was far more successful at eliminating competitors and gaining territorial control of key ports around the Indian Ocean. As a result, quantities and profits of the Dutch company were substantially greater than those of the English Company. This differential success, Irwin argues, is consistent with a strategic trade policy where the board of directors of the English company maximized profits to please shareholders, while in the Dutch company, they maximized a mix of profits and turnover. Since the English company was controlled by merchants alone, managers only served shareholder interests. But the Dutch company resulted from the government push for the merger of the small pre-companies, and thus, shareholder interests were eroded in favor of the government's. Irwin further calibrates the model with 1622 data evaluating the implications of alternative trade policies.

A second area where organizational differences were manifested was the shipping technology of merchant empires. Even though all empires used the sailing ship on the Cape Route, vessel size differed across empires controlled by different parties. The increasing size of Portuguese vessels on the Cape Route in the sixteenth century was a natural result of the rising trade volume as the all-sea route to Asia was opened. Portugal's ships, however, reached larger sizes than any other vessels on the Cape Route (Boxer 1948), fitting a king-controlled organization: large vessels carried more merchandise and were more fitting of the monarch's strategy of empire that valued glory and prestige, which the very large ships could project in distant

locations (Rei 2016). The problem with these very large vessels was the increased vulnerability in the event of storms or enemy attack, which resulted in higher loss rates. From the early seventeenth century, the Dutch specialized in the construction of smaller and more seaworthy vessels, which they exported to several other empires but never to Portugal, who kept invested in very large vessels well into the first half of the seventeenth century. Portugal's loss rates reflected the trend in ship size increasing from one loss in 10 ships between 1497 and 1550, to nearly one in every five a century later, or one in every seven after dropping losses due to enemy attack resulting from competition on the Cape Route (Rei 2016). The Dutch Republic on the other hand conducted far more voyages than Portugal, at a much lower loss rate of 3%, between 1602 and 1794 (Bruijn et al. 1987). Portugal's relatively higher loss rates could result from aspects beyond vessel size, such as worse shipping quality, or poorer shipping practices, such as travelling outside of convoys or overloading vessels. All these alternative explanations are associated with a poor organizational structure, but they are either unverifiable (shipping quality) or associated with ship size. For example, Portugal also used convoys, but larger vessels were slower and often sailed solo, thus becoming even more vulnerable (Solis 1955). Larger vessels also encouraged the bad practice of overloading, a well-known problem in the Portuguese empire mentioned repeatedly in secondary sources (Guinote et al. 1998). All these variations highlight the impacts of differential organizational control.

Finally, one of the most striking differences between Portugal's royally controlled empire and all other empires was the preoccupation with religion. From the early days, Portuguese ships on the Cape Route carried spices, soldiers, and priests. Trade and defense were common activities of all merchant empires, but only the Portuguese proved to be fervent converters of souls. A naïve approach could potentially see religious interests detracting from the purpose of trade and thus being at the origin of Portugal's decline and relative lack of commercial success in the long run. In merchant empires, the interest in religion (or the lack of thereof) can, however, also be interpreted as a manifestation of organizational control. In the context of the model, monarchs care for being in charge of the enterprise as they retain control over multiple decisions or factors that enter directly in their utility function. A prime example of these factors would be for the king to rule over a large number of people in distant locations, where he could spread his religion and way of life. These concerns were well beyond the scope of trade and touched the domain of colonialism. Kings cared for religion in all countries, but since they had less bargaining power than the king of Portugal in the negotiation for control, we do not see religion take a prime role in any of the merchant or mixed control empires.

The case of England is a very clear example of the monarchs' religious concerns, as the crown itself became the head of the Church in England after 1534 in the context of the English Reformation. Even though the East India Company chose not to interfere with religious beliefs and practices in India, as it would be counterproductive to the successful conduction of business, it could not avoid religious matters altogether. The company employed Christian servants in distant lands and thus allowed for the provision of religious services to them. Moreover, the increasing

scrutiny of parliament over the company's affairs after the Glorious Revolution slowly changed the balance of power between the government (parliament in this case) and merchants, which became clearly visible in the company's attitude toward religion. By 1813, the renewal of the charter required the company to provide for the "'religious and moral improvement' of its Indian subjects" (Carson 2012: 3). The incorporation of the company into the British state was merely 45 years away.

The Demise of the Companies and the Rise of Colonialism

Through their operations in Asia, East India Companies adapted to different market conditions and competitive scenarios. Their fate varied in terms of commercial success and duration of operations. This section focuses on the later life of merchant companies, which laid the ground for the ensuing stage of colonialism when countries took up efforts to establish an official presence in Asia beyond the original trade motives that brought their servants there.

Portugal's case is different from the other empires because the control of the king already implied colonial rule, even though Portugal's policy in Asia never entailed territorial encroachment beyond port cities. The demise of the empire was neither easy nor fast. The arrival of competition in the Indian Ocean saw Portugal's role in the Asian market decline substantially as most of her trade outposts in the Indian subcontinent and Southeast Asia either fell to rivals or were conceded in diplomatic agreements that recognized Portugal's restored independence from Spain in 1640. By the early eighteenth century, Portugal's minimal presence in Asia included three port cities on the west coast of India (Goa, Daman, and Diu) and also East Timor and Macau in the Far East. At this time, the Portuguese contribution to Eastern trade was negligible with Lisbon purely maintaining annual communication with the East and allowing returning ships to participate in the Brazil trade, where Portugal had redirected her colonial efforts. Despite not serving trade purposes anymore, the rusty structure of Portugal's empire in Asia endured long after the peaceful independence of Brazil in 1822. The slow death is consistent with the preferences of the party in control that encompassed more than trade objectives. The empire outlived Portugal's monarchy (which fell in 1910), the first republic (which collapsed in 1926), and was cherished by the fascist dictatorship that ensued. The start of the Colonial War in Africa in early 1961 precipitated events in Portuguese India, which fell in December 1961 with the Annexation of Goa, Daman, and Diu into the Republic of India, itself independent from the United Kingdom in 1947. The fall of Portugal's dictatorship in 1974 ended Portugal's Colonial War and started the clumsy decolonization process concluded in 1975. East Timor was abandoned that same year and subsequently invaded and occupied by Indonesia, her much larger neighbor. Macau remained a territory under Portuguese administration until its agreed transfer to China in 1999.

At the time of its demise in 1874, the English East India Company was a very different entity from the one chartered by Elizabeth I in 1600. The rebound from fierce competition by the Dutch in the seventeenth century and the subsequent

consolidation of territorial control resulting from the Napoleonic Wars saw the company strengthen its establishment in Asia in the eighteenth and nineteenth centuries. The battles of Plassey and Buxar marked the clear expansion of the company's territorial reach, strengthened by the favorable outcome of the fourth (and last) Anglo-Dutch War (1780–1784), which further consolidated the company's territory. The rising importance of nation states in the eighteenth century meant closer examination of the company's activities due to conflicting sovereignty of overseas territories and necessarily implied the decline of the company as a trade body, as it was incompatible with the state (Hejeebu 2016). Successive acts of parliament since 1773 curbed the powers of the company in a series of attempts to create the legal framework for the scope of its international operations. The 1813 Act was especially relevant, as it opened India to missionaries, for the first time raising concerns of religion in the context of a merchant company whose control was no longer purely merchant. The 1833 Act, on the other hand, removed all remaining trade monopolies from the company, officially relegating its commercial interests to second order, while renewing the company's political and administrative authority in India on behalf of the crown. The gradual transformation of the company into a branch of the British administration came to a conclusion with the 1858 Act that nationalized the company in the sequence of the Indian Rebellion of 1857. The company continued to manage the tea trade on behalf of the government until its stock was formally dissolved in 1874, making it the longest-lived merchant India Company. Formal colonial rule in British India started then.

The astounding success of the VOC in the seventeenth century was not replicated in the second century of operation of the company. The decline of the Japan and the China trades, especially after the loss of Formosa in 1662, led to a reorientation of the VOC toward Bengal, though the main strongholds of the Dutch were still in the Southeast Asian archipelago. In the long run, the geographic concentration of the VOC became a disadvantage as European consumption patterns began shifting away from spices and toward Indian textiles, raw silk, tea, and coffee, starting in the late seventeenth century (Chaudhuri 1978). The long decades of hostilities between the Dutch and English companies came to an end after the Glorious Revolution, which placed William of Orange, the Dutch head of state, on the English throne. This major shift in the balance of power between the Dutch and the English saw the Dutch drop their policy of ruthless elimination of all European competitors toward England (Chaudhuri and Israel 1991). Barred from fighting the English, who benefited from the break strengthening their positions in the Malabar coast, Bengal, and the Persian Gulf, the Dutch singlehandedly pursued fight with the French in southern India. The concentration of efforts in this area in the 1690s weakened the VOC's overall position in Asia. From the 1730s, the gradual exclusion of the VOC from various areas of commercial interest, and the symmetric rise of the English company, led to the steady decline of the VOC's revenue. Peace with the British came to an end when the Dutch began supporting the rebels, who had revolted against the British in the American Revolutionary War (1775–1783), quickly leading the way to the Fourth Anglo-Dutch War. The beleaguered Dutch Republic fell in 1795 in the context of the French Revolutionary Wars (1792–1802), bringing major disruption to the United Provinces that were only to regain independence in 1813. The VOC

was nationalized and its charter revoked in 1800. The territories of the VOC came under the administration of the Dutch government, starting a period of formal colonial rule in the Dutch East Indies.

Repeated financial problems of the French company led to multiple reorganizations throughout the company's history. Despite its smaller role on Asian trade, the French company showed territorial aspirations early. Successive attempts to establish a colony in Madagascar from the early days proved fruitless until the company finally gave it up in 1685, transferring it back to the royal domain. The decline of the Mughal Empire on the other hand led the French company to intervene in order to protect and expand its territorial interests in southeast India, implementing a policy of alliances with local rulers in the 1740s. These ambitions confronted directly with British interests in the region and confrontation between the two companies ensued in 1744. Though tempting, given the local conditions in India, the expansionary policy proved disastrous to the company's finances, bringing substantial reductions in the company's dividends (Boulle 1981). The situation was further aggravated by the Seven Years' War (1756–1763), which opposed Britain and France in Europe and rekindled the old conflict between the two East India companies in Asia. By 1769, the French company was no longer able to support its debts and was abolished by the crown, which took over the administration of French India, starting a period of formal colonial rule.

Though the Danish and the Swedish East India Companies had different control structures and different starting times, they were both dissolved in the early 1800s. Denmark had a more eventful history in Asia than its Scandinavian counterpart, due largely to the initial capital difficulties that were recurrent and resulted in the bankruptcy of the first two Danish companies in 1650 and 1728, respectively. The third Danish company also resulted from the cooperation of king and merchants in the initial capital stock. Upon dissolution of the French East India Company in 1769, Copenhagen merchants argued for the liberalization of the India trade, and, when renewing the 1772 charter, the state kept the monopoly of China trade but gave up the monopoly of India trade, allowing private merchants to compete directly with the company for a fee. At the same time, the company retained the administration of territories in India, giving rise to conflicts with private merchants (Feldbaek 1981). War with Britain in the context of the Napoleonic Wars (1803–1815) with the attack on Copenhagen in 1807 led to the end of operations of the company, while the remaining Danish settlements in India were sold to Britain in 1845. The Swedish company also succumbed at British hands, but differently. The company's charters were renewed in succession for periods of 20 years, but the 1784 Commutation Act enacted by the British parliament dropped the tea tax from 119% to 12.5%, effectively ending the smuggling of tea into Britain and putting the Swedish company's activity in jeopardy. Profits fell sharply, and by 1811 the Swedish company declared bankruptcy. Both the Danish and Swedish companies had small impact on Asian trade, in part because neither of them controlled much territory in Asia. The impossibility of victualing vessels en route, or the dependence on trade adversaries, hindered trade prospects of these smaller companies. Nevertheless, participation in Asian trade proved rather meaningful for the small Nordic countries, none of which engaged in subsequent colonial efforts.

Conclusion

The emergence of the Cape Route in 1498 opened Asian trade to countries with sufficiently developed shipping technology and enough capital to invest in long-distance trade, in the pursuit of notable arbitrage opportunities. Mounting expeditions involved producing ships, fitting and victualing them, as well as paying sailors, merchants and soldiers. Such expensive tasks led to innovative forms of pooling capital in the form of joint-stock companies, mostly participated by merchants but also by monarchs who held the royal prerogative of international trade in early modern Europe. The relative contributions of king and merchants led to varying control structures, with relevant implications on the organization's incentive structure. In Portugal, the king was wealthy enough to fund trade operations and thus retained control of the enterprise, effectively starting colonialism though without territorial expansion beyond port cities. In England, the Dutch Republic, and Sweden, merchants had stronger bargaining power than the monarch (or the government in the Dutch case) and controlled their respective merchant companies. In the case of Denmark and France, organizational control was shared between merchants and king, who retained considerable influence in the companies' decisions, especially in France.

Maintaining empires involved more than merchant initiative; it also required a powerful army and navy as well as the administration of operations in Asia coordinated from Europe, leading to a classic moral hazard scenario. Companies dealt with these administrative problems in ways resembling modern corporate practices, but they could not avoid the belligerent nature of operations in Asia, where the defense of trade interests often originated conflicts between competing parties. Additionally, events in Europe impacted operations in Asia, notably various wars but also the Glorious Revolution and the French Revolution. Finally, the waging of war against local powers also led companies to act well beyond the commercial objectives that led Europeans to Asia in the first place. From merchant entities, companies gradually transformed into political and military units, laying the ground for formal colonialism, which ensued after the demise of the companies, except in the case of the Danish and Swedish East India Companies.

The demise of the companies revealed a very different world than the one that had seen them emerge. Country monopolies were contested as more subjects wanted to take part in Eastern trade. The companies' sovereignty over distant territories and subjects raised legal and moral concerns that the companies were never designed to address. In the end, companies that were able to adapt to changing circumstances in Asia fared better in the long run.

Colonial America

Joshua L. Rosenbloom

Contents

Abstract

The first permanent British settlement in what became the United States was established in 1607, nearly 170 years prior to the American declaration of independence. This chapter examines the economic development of the British North American colonies that became the United States. As it describes,

abundant natural resources contributed to the remarkable growth in the size of the colonial economy and allowed the free white colonial population to enjoy a standard of living among the highest in the world at that time. While living standards were comparatively high, there was not much improvement over time. Scarce labor and capital, the corollary of abundant resources, also played an important role in shaping colonial institutions, encouraging reliance on indentured and enslaved labor and influencing the development of representative governmental institutions. The colonial period ended with the American declaration of independence in 1776. For most of the colonial era, the colonists had happily accepted their relationship to Britain. Changes in British policies following the end of the Seven Years War in 1763, however, created tensions between Britain and the colonies that ultimately led to the colonies to declare their independence.

Economic growth · North America · Mercantilism · Slavery · Institutions · Colonics

Introduction

Reflecting the dominant themes in the cliometric literature, this chapter is concerned with the economic history of those British mainland North American colonies that became the United States in 1776. It is important at the outset to acknowledge the backward-looking nature of this selection criterion. During the seventeenth and eighteenth centuries, Britain established a number of other colonies in the Americas, including parts of coastal Canada and the West Indies. At the same time, other European nations were also engaged in colonization efforts in North America. The Spanish had established colonies in parts of the Southwest and Florida, France had colonized Quebec, and until the 1660s, the Netherlands controlled parts of what would become New York and New Jersey.

Focusing on European colonization also diverts attention from the experience of the indigenous peoples who had occupied North America for millennia prior to the arrival of European explorers. For this latter group, European colonization proved profoundly destructive. Exposure to European diseases, such as smallpox, decimated native populations. Natives were exposed to these diseases through contact with European fishing expeditions even before permanent European settlements were established. Thus, when the first permanent European settlements were established, they encountered indigenous communities that were already disrupted, faced less resistance than might otherwise have been the case, and were often able to occupy lands that had been cleared by native inhabitants.

Despite the merits of these different perspectives in informing historical understanding of the colonial era, the cliometric literature has mostly adopted a vantage point that casts the history of this phase of American economic development as background for the subsequent development of the United States, asking how

developments in the years leading up to American independence from Britain shaped the subsequent evolution of the US economy. This chapter will largely follow this approach.

Economic Performance and Living Standards

Income at the End of the Colonial Period

Quantitative data on which to base measurements of income in the colonial period are quite limited. Nonetheless, recent scholarship has shed additional light on incomes near the end of the colonial period, suggesting that by this time, free white residents of North America enjoyed living standards that compared favorably with Britain, which, according to Maddison's estimates (Bolt and van Zanden 2013), had the highest per capita income in the world at the time.

Allen et al. (2012) have gathered time series of unskilled wages and the cost of living for workers in three British North American colonies as well as in a number of other locations around the world. Converting nominal wages in each location into their equivalent in grams of silver and then deflating these by the cost of subsistence, they have computed comparative welfare ratios for each location. These comparisons are depicted in Fig. 1. By the time of the American Revolution, laborers in Philadelphia had the highest earnings of any location represented in their data, roughly 25% higher than laborers in London. Laborers in Boston and Maryland,

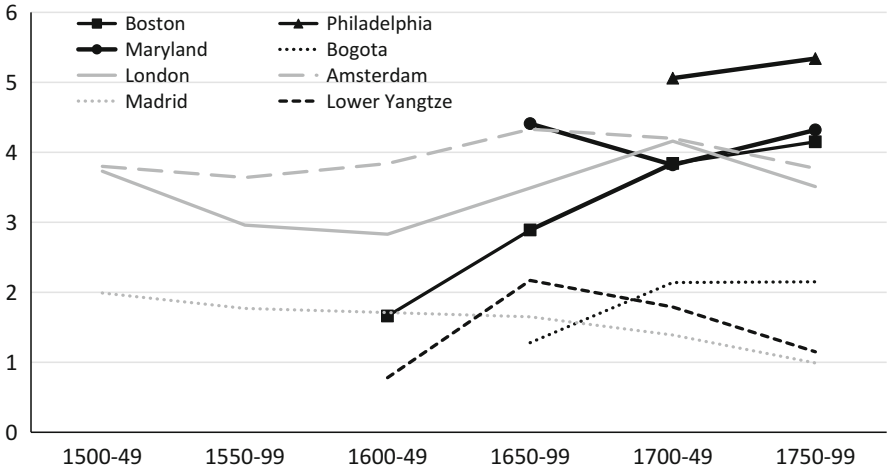

Fig. 1 Subsistence ratios (wages/cost of subsistence), by location, 1500–1799. (Source: Robert C. Allen, Tommy E. Murphy and Eric B. Schneider, "The Colonial Origins of the Divergence in the America: A Labour Market Approach," IGIER- Universita Bocconi, Working Paper no. 402 (July 2011), Table 4, p. 45)

which had lagged behind London, were by the 1770s quite close to London and well ahead of their counterparts in South America and China.

Peter Lindert and Jeffery Williamson (2016a) have undertaken the more ambitious task of constructing estimates of national income by combining social tables, describing the occupational and class structure of the population, with estimates of labor and property income for each group. Their approach allows them to construct aggregate per capita income estimates in 1774 for the colonies as well as examine the distribution of income within the colonies. Their estimates show that per capita incomes were higher in America than England by 1774 and much more equally distributed. According to their estimates, the Gini for free American colonists was 0.4, well below the average of 0.57 calculated for four Northwest European countries at the time. Even including the enslaved, their North America Gini rises only to 0.44. Adjusting for exchange rates and cost of living differences is challenging, as they acknowledge, but what seems clear is that while incomes at the top of the distribution remained higher in England, the colonies offered considerable economic opportunity for those further down the income distribution, a fact consistent with the rising tide of British immigration to North America in the decades before the Revolution.

Economic Growth

Estimating longer run trends in colonial incomes is more difficult. Demographic evidence attests to the robust extensive growth that characterized the colonial era. The first permanent British settlement in colonial America was established in 1607, at Jamestown, in what is now Virginia. A second settlement was established in Massachusetts in 1621. By the time the American colonies declared their independence in 1776, the population of colonial America had increased from a few hundred settlers to approximately 2.5 million. Nonetheless, this population remained confined primarily to a relatively narrow strip of land along the Atlantic seaboard stretching from present-day Georgia, in the South, to what is now Maine, in the North.

The growth of the European and African populations in colonial America was accompanied by a decline in the indigenous population. Estimates of the size of the precontact indigenous population vary considerably, but there is little question that smallpox and other European diseases hit the native population quite hard. Ubelaker (1988) estimates that the indigenous population east of the Mississippi River fell from about half a million in 1600 to 254,485 in 1700 and 177,630 in 1800.

Relying on a variety of censuses, tax rolls, and other documents, historical demographers have been able to work out reasonably detailed estimates of the growth of European-American and African-American populations. High rates of fertility, early marriage, and relatively small numbers never married combined to produce rapid rates of natural increase throughout the colonies. Voluntary migration and the importation of slaves further increased population growth rates. Together these factors contributed to population growth rates close to 2.8% per year, on

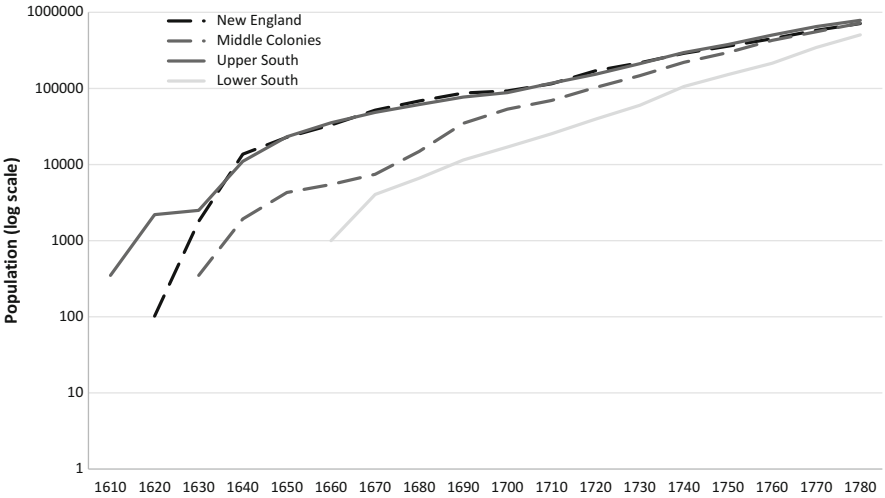

Fig. 2 Regional population growth, 1600–1780. (Source: Carter et al. (2006), series Eg1–59)

average, for most of the colonial period. This rate was sufficient to produce a doubling of population every generation. One contemporary observer, Thomas Malthus, characterized the rate of increase as "probably without parallel in history" and used it as support for his contention that in the absence of constraints, population would increase at a geometric rate (Galenson 1996, p. 169).

Figure 2 plots regional growth in population numbers on a semilog scale. Growth rates in the first few decades of settlement were quite rapid, reflecting the contributions of immigration to an initially small base, but then slowed as natural increase became the dominant source of growth. As the regions of earliest settlement, the Chesapeake and New England accounted for virtually all of the colonial population through the end of the seventeenth century. After 1680, however, the Middle Atlantic colonies (New York, New Jersey, and Pennsylvania) attracted growing numbers of immigrants and expanded rapidly. Settlement of the Lower South (the Carolinas and Georgia) did not begin in earnest until nearly 1700, but thereafter the region grew quite quickly, though the population of this region remained much smaller than the other colonial regions.

The early colonists experienced extreme hardships as they adjusted to a new land. Shortages of food, the challenges of adapting to conditions, and the disease environment all contributed to initial high rates of mortality (Perkins 1988, p. 6). As colonial settlements became more established, however, living conditions improved and mortality rates declined.

Quantifying early living standards has, however, proved difficult. Based on the robust growth of colonial population and the diversifying economy it supported, early accounts assumed that per capita incomes must have been rising in the colonial period. McCusker and Menard (1985), for example, in their influential assessment of the state of colonial economic history, suggested that per capita incomes in the

eighteenth century must have grown at least as fast as British per capita income and might have grown twice as fast – leading them to suggest that per capita income growth was in the range of 0.3 to 0.6% per year.

More recent scholarship has argued, however, on the basis of new data and more refined analytical techniques, that after overcoming the initial challenges of settlement, the pace of aggregate economic growth was quite small. In view of the limited quantitative data available for the colonial period, these estimates rely largely on backcasting income levels using indices for a few key indicators. Mancall and Weiss (1999), for example, applied the method of controlled conjectures to construct per capita GDP estimates for the period 1700–1800. They began with the identity that per capita GDP is equal to output per worker times the labor force participation rate. That is:

$$Q/P = (L/P) * (Q/L) \tag{1}$$

where Q is GDP, P is population, L is the labor force, L/P is labor force participation, and Q/L is output per worker.

Output per worker can then be decomposed into a weighted sum of per worker productivity in different economic sectors:

$$\begin{aligned} Q/P &= (L/P) * \left[(1 - S_a) * (Q/L)_n + S_a(Q/L)_a\right] \\ &= (L/P) * (Q/L)_a[(1 - S_a)k + S_a] \end{aligned} \tag{2}$$

where the subscripts a and n denote agriculture and nonagriculture, respectively, S_a is the share of the labor force employed in agriculture, Q/L is average output per worker, and k is the ratio of output per worker in nonagriculture to agriculture.

Beginning with known values of per capita GDP in 1800 and assuming that relative labor productivity, k, was constant at its 1800 level, it is possible to project backward per capita income on the basis of estimates of just three series: labor force participation, the sectoral distribution of labor, and labor productivity in agriculture. The first two series can be derived primarily from available demographic data and rest on a relatively sound quantitative base, but measuring labor productivity is more challenging. To derive estimates of agricultural labor productivity, Mancall and Weiss first computed total food production by aggregating estimates of consumption by different demographic groups (e.g., children, adult males, adult females, and slaves) and adding net exports. Dividing total food production by the aggregate labor force results in a measure of average labor productivity.

In the absence of firm evidence about trends in food consumption, their baseline case assumed constant levels of consumption of agricultural products over time, an assumption they justified based on the constancy of military rations over time. Combining all of the evidence, they calculated that per capita income (expressed in 1840 prices) increased only from $64 in 1700 to $68 in 1770 and then fell to $67 in 1800. This is a growth rate of just 0.08% per year for the shorter period and 0.04% per year for the entire century.

Mancall and Weiss explicitly acknowledged that they could not definitively measure agricultural production; nonetheless they noted that their estimates of per

capita GDP were constrained by the range of plausible values for domestic agricultural production. Assuming a more rapid rate of growth of agricultural productivity, for example, would result in higher rates of per capita GDP growth, but even assuming that agricultural productivity grew as fast as it did in the first half of the nineteenth century would result in a growth rate of per capita GDP of only about 0.2% per year, well below the range posited by McCusker and Menard. Yet, assuming this rate of growth, and accepting the levels of GDP in 1800, implies that the value of food consumed by free colonists in 1700 would have been lower than the value of the diet consumed by slaves in 1800. Mancall and Weiss argued that this implication seemed implausible and so concluded that likely rates of per capita GDP growth could not have been higher than 0.1% per year and were likely closer to zero.

In subsequent work, Mancall et al. (2004) and Rosenbloom and Weiss (2014) have constructed similar estimates for the colonies and states of the Lower South and the Middle Atlantic regions, respectively. Applying the method of controlled conjectures at a regional level allowed them to incorporate additional, region-specific evidence about agricultural productivity and exports and reinforced the finding that there was little if any growth in GDP per capita during the eighteenth century. Lindert and Williamson (2016b) have also attempted to backcast their estimates of colonial incomes. Their estimates rely in part on the regional estimates of Mancall, Rosenbloom, and Weiss, but the independent evidence they present is consistent with the view that economic growth was quite slow during the eighteenth century.

Wealth Accumulation

One of the richest sources of information about colonial living standards is provided by probate inventories. In one of the first studies to utilize these data, Jones (1980) drew a sample of 899 inventories from randomly selected counties in each region of the colonies in 1774. After adjusting the age distribution to reflect that of the population and reweighting observations to reflect the fact that wealthier decendants had a higher probability of entering probate, she was able to construct estimates of per capita wealth holding by region. These are summarized in Table 1.

The first column of Table 1 shows average total net worth per free capita by region. On this basis, there appears to be a wide gap in wealth accumulation between

Table 1 Probate wealth per capita, by region, 1774

	Per free capita			Per capita
	Net worth	Slaves and servants	Nonhuman	Nonhuman
New England	38.2	0.2	38.0	36.4
Middle colonies	45.8	1.7	44.1	40.2
South	92.7	31.1	61.6	36.4
All colonies	60.2	11.8	48.4	37.4

Source: Alice Hanson Jones (1980), pages 54, 58

colonial regions: residents of the southern colonies had accumulated nearly twice as much wealth as residents of the Middle Atlantic colonies and almost 2.5 times as much as residents of New England. This difference, however, reflects almost entirely the effects of slavery on the distribution of wealth. As the second and third columns show, most slave wealth was concentrated in the South, and regional differences narrow considerably if attention is confined to nonhuman wealth. When the definition of the population is broadened to include the enslaved as well as free residents, as shown in column 4, regional differences in nonhuman wealth per capita are nearly equalized. Thus, one can conclude that while slavery allowed the free residents of the southern colonies to amass a greater concentration of wealth, much of it in the form of property rights in labor, physical capital accumulation was remarkably similar regardless of region.

While Jones was able to provide a detailed cross-sectional snapshot at the end of the colonial period, several other studies have sought to use probate inventories to illuminate trends over time. The results of these studies largely support the picture of a relatively static standard of living. Main and Main (1988) analyzed the economic growth and development of southern New England using a sample of over 16,000 inventories from 1640 to 1774. Figure 3 plots the evolution of estate values and their major components in constant prices. There was, as they concluded, "no doubt that wealth in southern New England was growing in real terms, and the principal category in which that growth occurred was in land and buildings" (Main and Main 1988, p. 36). Indeed, the per capita value of many other categories of wealth was actually declining over time. Thus, while New Englanders cleared land and invested in additional improvements to this land, there was little growth in other markers of material well-being. Lindert and Williamson's (2016b) recent reanalysis

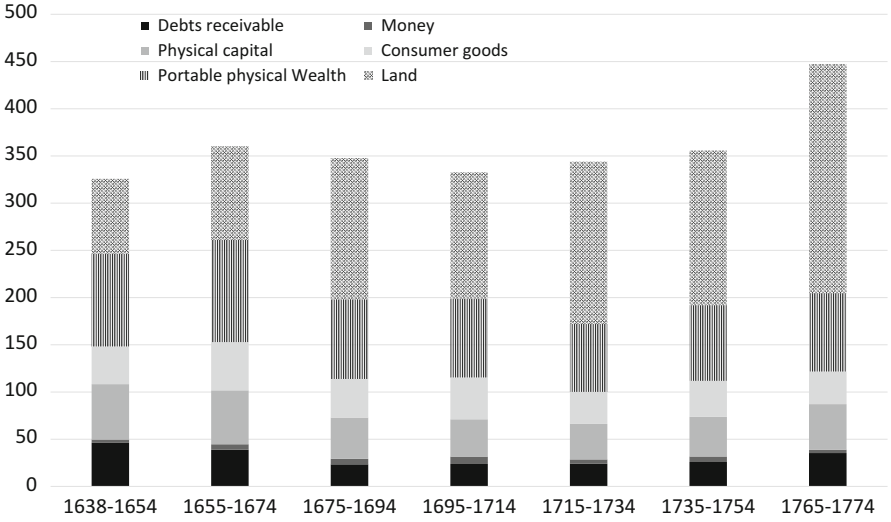

Fig. 3 Probate wealth in southern New England, 1640–1774 (constant sterling). (Source: Main and Main (1988), p. 36)

of these probate data further reinforces the impression of a relatively static economy. Using regression techniques to control for age, location, and occupation, they conclude that only farmers in the later-settled hinterland regions experienced significant gains in wealth over time as they continued to add to their improved land and accumulate additional livestock.

Ball and Walton (1976) made use of inventories from Chester County, Pennsylvania, to measure changes in agricultural productivity over the majority of the eighteenth century. To estimate productivity growth, they constructed indexes of outputs (grain and livestock) and inputs of land and capital from probate inventories and combined these with estimates of labor input from other sources. Setting productivity to 100 in 1714–1731, they found that it had increased to 108 by 1750–1770 but fell back to 105 in 1775–1790 (Table 6, p. 110).

The Colonial Economy

Economic historians have tended to view the colonial economy through one of two lenses. The first approach focuses primarily on the high ratio of land and natural resource to labor that European colonists encountered in North America. According to this "demographic" model, natural resource abundance raised labor productivity, especially in agriculture, contributing to the colonists' high standard of living and removing the demographic constraints that limited population growth in Europe (Smith 1980). Unchecked natural increase combined with migration, both voluntary and forced, to produce the economy's rapid extensive growth. The second view of the colonial economy focuses on the role played by key exports as drivers of economic growth. This "staple exports" thesis emphasizes European demand for tobacco, rice, indigo, and other exports as a major determinant of the size and structure of the colonial economy (McCusker and Menard 1985).

The truth, as is often the case, lies somewhere between these two views. There is no question that land abundance made entry into farming relatively easy, thus encouraging early marriage and high rates of marital fertility. At the same time, mortality was low because abundant food and forest products contributed to a better nourished, better housed, and healthier population, while low population density discouraged the transmission of diseases. Quantitatively, the production of food and fuel for domestic, and mostly local, consumption dominated the economy. Mancall and Weiss (1999), for example, estimated that colonial exports amounted to only about 10% of economic activity across the eighteenth century. Even in a highly export-dependent region, such as the Lower South, Mancall et al. (2008) estimated that foreign exports amounted to only 20–25% of GDP and were declining in importance over time.

Yet, exports were essential to colonial economic survival. The potential contribution of colonial exports to the larger empire was one of the primary motivations for colonization, and export earnings were crucial to the colonies' ability to pay for imports of manufactures and other goods that could not be produced domestically. Differences in export crops also resulted in the emergence of distinctive patterns of

economic organization across the colonies, as reflected in the distribution of wealth noted earlier. Moreover, volatility in international trade played a role in contributing to short-run fluctuations within the colonial economy, although it seems likely that these effects were concentrated in the commercially oriented port cities and did not greatly affect hinterland farmers.

Regional Differentiation in the Colonial Economy

In the Southern colonies, climatic conditions were conducive to the cultivation of crops that found lucrative markets in Europe. In Virginia, Maryland, and parts of coastal North Carolina, tobacco cultivation spread widely, stimulating demand for labor and encouraging immigration. Tobacco did not require major capital investments and was characterized by few economies of scale, leading to a society dominated by small holders working their land with family labor and possibly the assistance of a few servants. By the late 1600s, however, planters in the upper South had begun to import slaves, allowing some producers to expand the scale of production.

Further south, in the low country of South Carolina and Coastal Georgia, early colonists discovered that conditions were favorable for the cultivation of rice. In contrast to tobacco, rice cultivation relied on relatively large capital investments to control irrigation. As a result, rice was grown mainly on relatively large plantations, and colonists in coastal South Carolina and Georgia relied heavily on slave labor to provide an adequate work force. Interestingly, at its founding, Georgia was intended to be a free colony and slavery was prohibited. Settlement proceeded slowly, however, until its founders realized that the prohibition on slavery was discouraging commercial development and allowed the use of enslaved workers. Beyond the narrow coastal region, rice was not a viable crop, and the interior of both colonies was settled primarily by small holders and independent farmers.

The climate of the northern colonies more closely resembled that of northwest Europe, limiting export opportunities. Pennsylvania, New Jersey, and New York nonetheless supported the development of small farms raising livestock and growing wheat and other grains. Flour produced in the region found markets in Southern Europe and the West Indies. Conditions in New England were not as favorable for producing agricultural surpluses, but the region did develop markets supplying food to the West Indies, where intensive sugar cultivation squeezed out local food crops.

Reflecting the greater complexity of regional trading relationships, the northern colonies developed dense and relatively sophisticated merchant communities that helped to organize and finance regional and international trade and provide shipping services. By the late colonial period, Boston, New York, and Philadelphia had become bustling urban centers. The largest, Philadelphia had over 30,000 residents in 1775, while New York had 25,000, and Boston 16,000. In comparison, Charleston, the only significant urban center in the South, had a population of just 12,000.

Free and Unfree Labor in the Colonies

Regional differences in export crop production correlated closely with the use of enslaved labor. Although slavery was legal throughout the colonies, and there were slaves everywhere in British North America, by the 1770s over 90% of the slave population was concentrated in the colonies from Maryland to Georgia. It is tempting to explain the regional distribution of slavery in terms of the distribution of export staples, but the linkage between labor institutions and crops was mostly indirect. While investments in tidal irrigation needed to cultivate rice encouraged large-scale production, tobacco could be cultivated profitably on a small scale and was subject to no economies of scale (Wright 2006).

Because of land abundance, entry into agriculture was relatively easy, and few free men in the colonies were willing to work for wages rather than operating their own farm. As a result, planters who wished to expand the scale of production beyond what could be cultivate with family labor were required to turn to bound labor. As Evsey Domar (1970) has famously observed, it is not possible to simultaneously have free labor, free land, and large-scale production. The availability of unfree labor created the potential for planters to expand production, and the value of export crops provided the means to acquire unfree labor for this purpose.

During the initial tobacco boom in the Chesapeake, the high price of African slaves, which was determined by their productivity in West Indian sugar cultivation, discouraged planters from the use of enslaved labor. Instead, planters who wished to expand production relied largely on indentured servants from Europe. During the seventeenth century, indentured servitude emerged as the primary mechanism to finance the migration of labor to the Americas. Although the high returns to labor in North America made immigration an attractive prospect of English laborers, the high cost of trans-Atlantic passage (In excess of half a year's income) posed a significant obstacle (Grubb 1985). Indenture contracts provided a mechanism by which prospective immigrants could finance their passage.

Indenture contracts entered into with ship captains sailing to North America committed immigrants to work for a specified term (typically 3–4 years) in exchange for passage to the colonies. Once they arrived in America, their contract would be sold to a planter seeking to hire additional labor. At the end of their service, indentured laborers would receive a small payment from their employer and would be able to set out as independent farmers. Other migrants came as "redemptioners," committing to repay ships captains once they arrived in America by selling themselves into servitude to an American master to obtain the funds needed to pay for their passage (Grubb 1986).

Data on immigration in the colonial period are scattered and incomplete, but several scholars have ventured estimates that between half and three quarters of European immigrants arriving in the colonies came as indentured servants or redemptioners. Grubb (1985) found that at the end of the colonial period, close to three-quarters of English immigrants to Pennsylvania and nearly three-fifths of German immigrants arrived as servants. Galenson (1981) has examined the terms of several large samples of indenture contracts and concluded that the length of

service required to repay the cost of passage varied with characteristics likely to be associated with differences in individual productivity. He also concluded that over time, contract terms varied in response to larger supply and demand forces in a manner consistent with the operation of a highly efficient market.

In the 1680s, tobacco planters in the Chesapeake began to shift away from indentured servants toward reliance on enslaved Africans. Galenson (1984) attributes this transition to the falling price of African slaves and improvements in the market for labor in England that made indentured servants more expensive. At first, servants continued to be used to fill positions requiring more skill, but as the number of slaves increased and slave owners expanded their land holdings making it more difficult for new arrivals to gain a foothold as independent farmers, migration to the Chesapeake became less attractive to potential migrants. By the early 1700s, the bulk of indentured servants preferred to migrate to the Middle Atlantic region, and tobacco cultivation became inextricably linked to slave labor. In South Carolina, which was settled only beginning in the 1690s, planters relied from the outset on slave labor to establish commercial rice production. Consistent with the close connection between export-oriented agricultural production and the use of slaves, Mancall et al. (2008) document a strong positive correlation between slave imports to the Lower South by decade and changes in export values.

Figure 4 shows the rapid rise in the slave share of the population in both regions after 1680. Because the mainland colonies were relatively small importers in the larger Atlantic slave market, they faced what was effectively a perfectly elastic supply of slave labor at the world price, which was determined largely by supply and demand conditions in Africa and the West Indies. Consistent with this view, Mancall et al. (2001) show that between 1720 and 1800, long-run movements in

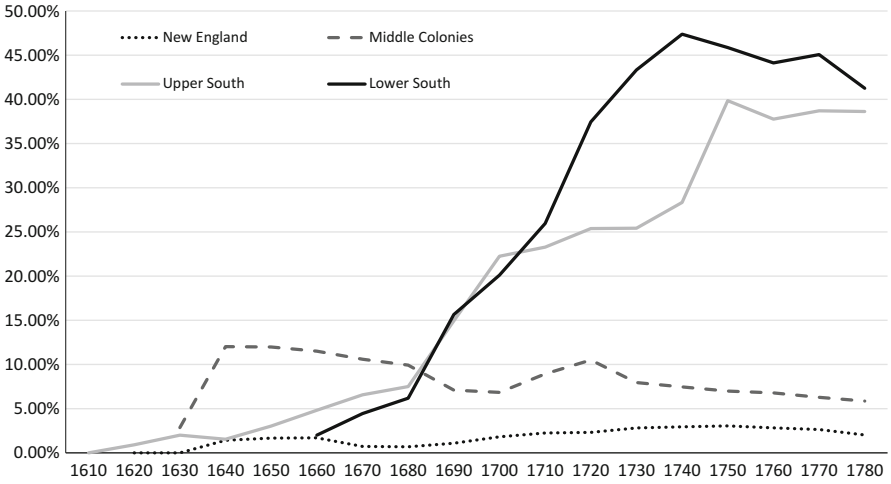

Fig. 4 Black population as percentage of total population, by region, 1610–1780. (Source: Carter et al. (2006), series Eg1–59)

South Carolina slave prices paralleled those in the West Indies and that in the short run, when demand for labor drove up local slave prices, the volume of imports increased and prices ultimately fell.

Institutions and Colonial Economic Development

Institutions and Economic Development

Influenced by North (1990), cliometricians and, more generally, economists have come to see institutions as one of the primary determinants of economic development. According to North, institutions are "the rules of the game" and their means of enforcement. In this definition, they encompass both formal structures of law and governance and informal structures, such as social norms and conventions. For the most part, economists have argued that institutions that provide relatively secure property rights and promote more democratic forms of governance encourage growth by creating conditions conducive to private investment and innovation. If institutions account for differences in economic performance, however, the question becomes why do some societies have institutions better adapted to promote growth than others?

Several recent and influential articles have sought to answer this question by arguing that variation in contemporary institutions, and hence economic development in the Americas, is explained by the interaction between European colonization and the initial conditions that European colonizers encountered in different parts of the world (Engerman and Sokoloff 2012; Acemoglu et al. 2002). The mechanisms identified differ somewhat, but both arguments emphasize a "reversal of fortune," through which conditions that were initially conducive to economic prosperity led to the development of institutions that discouraged subsequent growth, while conditions that were initially less favorable led to development of institutions more conductive to growth.

Engerman and Sokoloff, concentrating on Spanish and British colonization in the Americas, argued that differences in climate, geography, and natural endowments created opportunities for the extraction of precious metals (Latin America) or concentration in production of export staples (the West Indies) that caused them to develop highly unequal societies in which a small European elite exploited a large enslaved population. The resulting legal and political regimes produced high per capita incomes initially but proved poorly adapted to exploiting the opportunities for modern economic growth that emerged during the Industrial Revolution. In contrast, they argue that the absence of a substantial indigenous population in North America, and the fact that soil and climate resulted in limited opportunities to produce crops characterized by major economies of scale, led to the development of relatively egalitarian and representative societies in the mainland colonies. This more egalitarian social structure facilitated the transition in the nineteenth century to modern economic growth.

Acemoglu et al. (2002) adopt a broader perspective, seeking to explain global variations in modern economic performance in terms of the density of population and the corresponding complexity of the societies that European colonizers encountered. Where Europeans encountered (and took over) existing extractive institutions, as in Mexico, India, and Peru, they perpetuated extractive institutions founded on exploitation and inequality. In more sparsely settled and less prosperous areas of the world, such as North America, Australia, and New Zealand, they established institutions of private property and political equality that were better suited to promoting growth in the long run.

Institutions in Colonial America

For both Engerman and Sokoloff and Acemoglu, Johnson, and Robinson, colonial America is reduced in essence to a single data point. Such broad-brush theorizing helps to establish a broader context, but risks missing important local variations and the historical contingencies that underlie the development of American institutions. As we have seen, the economic and social structure of the British colonies that became the United States varied quite substantially, producing a highly unequal distribution of the slave population and wealth holding across the colonies. Yet, all followed similar paths in terms of political structure and long-run economic development.

An important commonality across colonial America was the shared influence of British institutions that the colonists brought with them (Jones 1996). In comparison to other European nations in the seventeenth century, Britain was characterized by a relatively weak monarch, who was obliged to negotiate collectively with quasi-independent local leaders in parliament (Elliot 1992). In comparison, in Spain, where the monarchy was relatively strong, individual notables negotiated directly with the King, resulting in a patchwork of agreements, all dependent on individual relationships (Irigoin and Graf 2008). When early colonists created institutions of local governance, they followed the template provided by the relationship between parliament and the King, establishing bodies to represent their collective interests vis-a-vis the empire, rather than seeking to negotiate individual arrangements.

Another manifestation of the English King's weakness was the limited resources available to devote to the project of American exploration and colonization. Instead of directly financing voyages of exploration, the King encouraged exploration by granting corporate charters or monopolies to private investors who undertook the expense and risk on their own account. Meanwhile, conditions in America encouraged the early development of relatively robust and egalitarian forms of self-government within the colonies.

The first colonial charter for a mainland colony was granted to the Virginia Company in 1606. It gave investors in the company the right to establish a colony and claim the protection of the King. Importantly, the charter established the precedent of private land ownership, specifying that land was to be held in free and common socage, a form of tenure that established secure property rights and made the land fully alienable and inheritable.

Organized as a joint-stock company with the aim of earning profits for its investors, the Virginia Company initially adopted a hierarchical model of control in which the early colonists were housed in communal barracks and farmed the company's land. This top-down organization was poorly adapted, however, to the conditions of land abundance that the early settlers encountered. As Morgan (1971) describes, the company found it nearly impossible to compel the colonists to work on the company's behalf. As a result, the early colonists devoted little effort to food production, and the early years of the colony were characterized by food shortages, epidemic disease, and hardship.

The problem of incentives was resolved when the company opted to grant each settler title to his own parcel of land and allowed them to farm on their own account. Tensions between settlers in America and investors in England and the long delays in communication across the Atlantic further obliged the Company to allow the colonists to establish a representative assembly to make the colony's laws. When the company's charter was revoked in 1624 and Virginia became a crown colony administered directly by the king, the settlers were successful in retaining self-government through the representative assembly, subject to the right of the royally appointed governor's veto.

The Virginia Colony was followed in 1629 by the granting of a charter to the Massachusetts Bay Company, which was also organized as a joint-stock company. Like the Pilgrims who settled at Plymouth in 1620, the Puritan founders of the Massachusetts Bay Company were religious dissenters, and in 1630 the leaders of the Company migrated to New England, taking the charter with them. With the investors in the company present in Massachusetts, tensions between settlers and investors in England were reduced, and the company evolved into a colonial government.

Several more efforts at colonization, including the grant of Maryland to Lord Baltimore, New York to the Duke of York, and Pennsylvania to William Penn, followed a model of proprietorial land grants. The charters granted these proprietors broad powers to govern their new territories and to distribute land within them. However, as in Virginia, land abundance and distance favored the development of local assemblies to represent the settlers and a shift toward local self-governance.

The development of colonial self-government was no doubt facilitated by the limited value of colonial exports. Because of this, the English government largely adopted a policy of benign neglect toward the colonies, exercising quite limited supervision. Political turmoil in England resulting from the English Civil War also diverted attention from the colonies during the middle years of the seventeenth century, allowing traditions of local governance checked only by the veto power of the royally appointed governor to become established.

In sum, while factor endowments and distance played a role in encouraging the colonies to develop mechanisms of self-government, political norms that promoted representation through an elected assembly that represented a unified set of colonial interests to the King were also important. By the late 1600s, when South Carolina was settled, these models were adopted even in an environment characterized from the outset by large-scale plantation agriculture and a heavy reliance on slave labor.

The Colonial Monetary System

At the outset, the colonies were primitive agricultural economies with limited international trading relationships. In the approximately 170 years from the first settlements to American independence, the American economy grew substantially in scale and developed more complex and sophisticated international trading and financial relations with England and other foreign countries. To support the growing scale and complexity of economic transactions, the financial system had to evolve. Among the notable innovations that the colonists introduced was the widespread use of paper money as a medium of exchange (Grubb 2016; Perkins 1988; West 1978).

For the colonists, specie (gold and silver coins) constituted the basis of the monetary system. The colonies did not produce gold or silver, however, and were prohibited from minting their own coins. Specie had to be acquired by selling exports, and the bulk of the specie in use in America came from exports to Spanish America. Exports to England also allowed the colonists to acquire pound sterling credits in the form of bills of exchange drawn on accounts in England. These foreign exchange earnings were used primarily to pay for colonial imports and little specie circulated within the colonies to facilitate domestic commerce.

In lieu of specie, the colonists relied heavily on barter for local exchange. In the Chesapeake transactions were often denominated in weights of tobacco. However, tobacco was not used as a medium of exchange. Rather merchants might advance credit to planters for the purchase of imported items, to be repaid at harvest with the specified quantity of tobacco. Elsewhere book credit accounts helped to facilitate transactions and reduce the need for currency. The colonists regularly complained about the shortage of specie, but as Perkins (1988) observed, the long-run history of prices does not suggest any tendency of prices to fall, as would be expected if the money supply was too small.

While English merchants provided commercial credit to finance international trade, there were no banks or credit institutions to which colonial legislatures could turn when confronted with extraordinary expenses. In 1690, Massachusetts issued £7000 in paper bills of credit to pay wages promised to soldiers who had participated in a military campaign against French Quebec and made the bills legal tender in the payment of colonial taxes. As the bills were returned to the treasury, they were to be retired from circulation. The experiment was a success and was soon followed by most other colonies, mostly in connection with large military expenditures. Details of these monetary emissions varied in terms of maturity, whether interest was paid and whether the bills were made legal tender or not (Grubb 2016). In most cases, however, bills were linked explicitly to future redemption through taxes to be collected or repayment of loans.

With only a few exceptions, the colonies' issuance of these notes did not give rise to inflationary pressures. There is by now a large literature that has analyzed the relationship between note issuance and prices and finds little evidence of any correlation between the series (Weiss 1970; Wicker 1985; Smith 1985; Grubb 2016). As Grubb (2016) has argued, this suggests that while the circulation of bills

of credit may have facilitated exchange by substituting for book credit or other forms of barter, they did not assume the role of currency.

Despite the colonies' history of limited currency depreciation, by the early 1750s, English merchants had begun to express concern that loans they had extended to the colonists might be repaid in depreciated colonial currencies rather than in pound sterling. In 1751, under pressure from these trading interests, Parliament intervened in colonial note issue, passing an act aimed at the New England colonies, restricting the maturity of new issues in Rhode Island, Connecticut, and Massachusetts to 2 years and prohibiting their designation as legal tender in private transactions. This was followed in 1764 by a second act applying to the remaining colonies and prohibiting legal-tender provisions both for private debts and for public obligations as well. A number of colonies, including New York and Pennsylvania, defied these prohibitions, however, and continued to issue new notes (Perkins 1988). Lobbying by colonial representatives was ultimately successful in winning a relaxation of these restrictions, allowing notes to be designated as legal tender for public debts.

The Colonies Within the British Empire

For most of the nearly 170 years between the founding of the Jamestown colony and the American declaration of independence, there was little tension between Britain's mainland North American colonies and the home country. The colonists identified as British subjects and thrived within the context of the expanding Atlantic economy that British policies supported. As Benjamin Franklin observed in 1775, "I never had heard in any Conversation from any Person drunk or sober, the least Expression of a Wish for a Separation, or Hint that such a Thing would be advantageous to America" (Quoted in Taylor 2016, p. 4). From a few small, isolated outposts on the edge of a largely unknown continent, they had grown by the 1750s into a well-established set of communities with a population close to 40% the size of the home country, enjoying relatively high living standards and supporting a complex set of international trading relationships. The context within which this growth occurred is usually termed "mercantilism."

Mercantilism

The key tenet of mercantilism was that national strength was enhanced through an inflow of specie that was achieved by maintaining a positive balance of trade with other nations. Colonies could contribute to these goals by producing specie directly (as was true of Spanish colonies in the Americas), by producing crops that were valued in export markets, or by acting as a source of goods that would otherwise have to be imported from outside the empire. At the same time, colonies could contribute as markets for manufactured goods produced at home.

The Navigation Acts, first passed by Parliament in 1651, were an attempt to achieve these ends by establishing the legal parameters for colonial trading relations.

Their key provisions were (1) vessels registered in foreign countries were excluded from carrying goods between ports within the empire; (2) goods manufactured on the European continent could not be directly imported into the colonies but had instead to pass through England; (3) certain valuable colonial exports, "enumerated goods," could be exported only to ports in Great Britain; and (4) bounties were authorized for highly valued colonial products. Among the enumerated goods were furs, ship masts, rice, indigo, and tobacco. Importantly, ships registered in the colonies were allowed to carry trade within the empire. Although subsequent acts modified bounties and adjusted the list of enumerated goods, the basic outlines remained consistent until American independence (Perkins 1988).

The requirement that major colonial exports pass through England on their way to continental markets and that manufactures be imported from England was the equivalent of imposing a tax on this trade. The resulting price wedge reduced the volume of trade and shifted some of the producer and consumer surplus to the providers of shipping and merchant services. A number of cliometric studies have attempted to estimate the magnitude of these effects to determine whether they played a role in encouraging the movement for independence (Harper 1939; Thomas 1965; Ransom 1968; McClelland 1969). The major difference in these studies arises from different approaches to formulating a counterfactual estimate of how large trade would have been in the absence of the Navigation Acts. In general, the estimates suggest that the cost to the colonists was relatively modest, in the range of 1–3% of annual income. Moreover, this figure needs to be set against the benefits of membership in the empire, which included the protection the British Navy afforded colonial merchants and military protection from hostile natives and other European powers.

Regional Variation Within the Colonies

Despite the common context created by membership in the British Empire, differences in climate and soil created varied economic opportunities in the American colonies that translated into significantly different patterns of economic development across the colonies. With a relatively short growing season and rocky, infertile soil, the New England colonies were poorly endowed to produce agricultural exports. During the initial years of settlement, the colonists participated in the fur trade, acquiring beaver pelts in trade with the indigenous population, until local supplies of beaver were decimated by over hunting. Northern forests also yielded tall trees that could be used as ships masts. Potash, used in making soap and gunpowder and a by-product of clearing fields by burning trees, also found an overseas market. But the value of these exports fell far short of the region's imports of textiles, hardware, and other manufactured goods. To make up this difference, New England merchants developed markets in the West Indies, supplying fish, grain, and livestock to support the intensive cultivation of sugar in these colonies. Boston merchants also earned considerable sums carrying goods within the empire (Walton and Shepherd 1979).

The Middle Atlantic colonies of New York, Pennsylvania, and New Jersey, settled later in the 1600s, emerged as a major source of food exports in the eighteenth century. Possessing better soil, a more favorable climate and excellent natural harbors in New York and Philadelphia, they became major exporters of bread, flour, wheat, and salted beef and pork for both the West Indies and southern Europe. As in New England, earnings from shipping services became a major source of export earnings in the Middle Atlantic region (McCusker and Menard 1985; Perkins 1988).

Although British policy officially discouraged colonial manufacturing enterprises, New England and the Middle Atlantic colonies also developed ship building and iron refining industries that benefitted from access to plentiful supplies of timber. Deforestation in England was a significant constraint on iron manufactures, and imports of pig and bar iron from the colonies were preferred to increasing dependence on European sources. By the late 1700s, the colonies accounted for 15% of world output of iron, ranking third behind Russia and Sweden (Perkins 1988).

The southern colonies conformed much more closely with mercantilist expectations than did the New England and Middle Atlantic colonies. The Chesapeake colonies of Virginia and Maryland, along with parts of North Carolina, became major producers of tobacco, which was in high demand, especially on the European continent. Exports of tobacco were the single largest source of export earnings for the mainland colonies. In the late colonial era, these colonies also began to export wheat and flour in response to rising world prices for food (McCusker and Menard 1985; Egnal 1998). Further South, in South Carolina and Georgia, rice provided a major source of export earnings. The region was also well adapted to the production of indigo, and production of this valuable dyestuff increased in the 1740s when Britain began to offer significant bounties for its production.

Table 2 provides a snapshot of colonial exports by region near the end of the colonial period. Tobacco, grain, rice, fish, and livestock made up close to 75% of the value of colonial exports, with the first two accounting for nearly half of total exports. By virtue of its role in the tobacco trade, the Upper South produced over 40% of all colonial exports, followed by the Lower South, and the Middle Atlantic colonies. New England produced the smallest value of exports and did so with a much more diverse trade than the other regions.

Economics, Politics, and Revolution

After nearly a century and a half of relatively harmonious development, relations between Britain and its North American colonies shifted radically after the conclusion of the Seven Years' War (often referred to in the American context as the French and Indian War) in 1763. Over the next 13 years, the colonists discovered a common identity in opposition to the British Empire, and in 1776 they declared independence. One important consequence of the Seven Years' War had been to largely eliminate France and Spain as rivals for control of North America and as potential allies for the indigenous peoples. As a result of the peace settlement reached in 1763, France had

Table 2 Annual average value of commodity exports from American Colonies, 1768–1772 (pound sterling)

Commodity	New England	Middle Atlantic	Upper South	Lower South	Total
Tobacco			756,128		756,128
Grains, grain products	19,902	379,380	199,485	13,152	611,919

Source: McCusker and Menard (1985, pp. 108, 130, 172, 199)

ceded Quebec and most of its North American territories to Britain. Spain, which had also entered the conflict, gave up Florida (which included territories along the Gulf Coast as far west as the Mississippi River) but acquired New Orleans from the French. Now, essentially all of North America east of the Mississippi river was under British dominion.

In the absence of significant European competitors, British attitudes toward colonial territorial expansion shifted dramatically. So long as Britain was in competition with France for control of the North American interior, colonial efforts to secure new land were consistent with imperial goals. But, after 1763, this competition was eliminated, and Britain sought to slow expansion and avoid provoking renewed conflict with the indigenous population. In the colonies, the rapid pace of population growth created an insatiable demand for new land on which to farm; thus obtaining title to western lands became an important source of wealth for leading colonists (Egnal 1980; Egnal and Ernst 1972). British efforts to restrain colonial expansion thus placed them in direct conflict with influential colonists who hoped to profit through development of western lands.

At the same time that British leaders sought to restrain colonial expansion, they were struggling with the challenges of paying the costs of the recently concluded conflict. Defending their North American possessions had been a major expense, and the colonists were lightly taxed relative to citizens at home. It seemed natural that colonists should contribute to paying wartime debts through higher taxes. To the

colonists, however, these measures helped create a perception that Parliament was favoring British interests at colonial expense and provoked a growing resistance movement centered among the mercantile and trading elite in New England and Middle Atlantic port cities (Taylor 2016).

Beginning in 1764 with the Sugar Act, Parliament sought to increase revenues from its colonial possessions. The Sugar Act actually lowered duties on colonial sugar imports from the French West Indies from the prohibitive levels that had previously prevailed, but British officials expected that lower duties would reduce smuggling and increase tax revenues. The Act also provided for increased enforcement, cracking down on a large and illicit trade between New England and sugar producers in the French West Indies. And because colonial courts could not be relied upon to enforce these laws, jurisdiction was moved to British Admiralty courts.

The Sugar Act was followed in 1765 by passage of the Stamp Act, which imposed a tax on a broad range of legal documents and newspapers. To colonists, this effort to tax domestic commerce appeared to be a significant departure from previous acts that had focused on external trade. And it evoked a strong negative reaction from influential members of the colonial elite. Colonists threatened or intimidated the appointed tax collectors and forced many of them to resign from their positions or to agree to not enforce the tax. They also sought to organize a collective response, calling on colonial governments to send representatives to a Stamp Act Congress in New York. As the first such meeting of representatives from the different colonies, the Congress was an important step in the emergence of a sense of national identity. The boycott of British goods the Congress organized led British merchants to join the colonists in urging Parliament to rescind the tax. In 1766, Parliament backed down and repealed the tax.

Britain's need for revenue remained, however, and in 1767 the Townshend Act imposed a new set of duties on the colonists. Believing that taxes on external trade would not meet with resistance, the Townshend Act imposed duties on imports of glass, paint lead, paper, and tea. The tax was coupled, however, with plans to use part of the revenue it generated to pay the salaries of colonial governors, who until then were supported by locally collected taxes, a change that would have made them less dependent on colonial legislatures. The colonists objected to this interference, however, and newly emboldened by the success of their resistance to the Stamp Act, they launched another boycott. As the volume of business lost by British merchants mounted, so did pressure to repeal the Townshend Act taxes. In 1770 Parliament dropped all of the taxes except that on tea.

The final provocation came in 1773 in the form of the Tea Act. Seeking to aid the East India Company, which found itself in significant financial difficulties, Parliament granted the company a monopoly on the sale of tea in the American market. Taxes on tea were actually adjusted, so that the price colonists would pay fell. Yet, local merchants, angered by their exclusion from a lucrative trade and seeing Parliament favoring a British company at their expense, organized protests. In Boston on December 16, 1773, a group of colonists boarded several vessels carrying East India tea and dumped it in Boston Harbor. In response to the so-called Boston Tea Party, Britain ordered the complete closure of Boston Harbor and dispatched a

large military force to enforce this action. Responding to these actions, the colonists convened the first Continental Congress in Philadelphia in 1774, and by early 1775, the tensions had devolved into an armed conflict precipitated by the British march on Lexington and Concord.

After the Revolution: American Independence

Looking backward it is easy to view the success of the American Revolution as inevitable. It was, however, anything but that. Residents of the colonies were deeply divided about independence: loyalists, who favored remaining part of the empire, were probably almost as numerous as revolutionaries, and a large part of the rural population remained uncommitted to either side. The Revolution thus entailed significant internal conflicts. Moreover, the revolutionaries confronted practical challenges in taking on the much larger and better-supported British Army (Taylor 2016).

The armed conflict dragged on for 7 years, ending only in 1782. The colonists faced a more numerous, better equipped and better trained military force; but the British had to contend with the logistical challenges created by distance and slow communication. For the most part, British forces were content to occupy a few major ports and exert pressure by attempting to blockade trade at sea. Unable to defeat the British, the colonists were ultimately successful in outlasting them as the costs of the war mounted.

For colonists outside contested areas, the impact of the conflict was relatively light. For those closer to the fighting, the effects were mixed. On the one hand, increased demand for food and supplies caused by British occupation may have raised incomes. On the other hand, some colonists saw crops seized or destroyed, and in the South, British forces confiscated slaves and encouraged others to defect.

Most accounts suggest that independence was a negative shock to the colonial economy but have differed in their assessment of the magnitude of the effect. After the disruption of the war, the newly independent country was largely excluded from the trading networks it had participated in prior to independence, and under the Articles of Confederation, Congress lacked authority to establish tariffs and consequently lacked the bargaining leverage necessary to negotiate access to European markets. Some of these difficulties were removed with the ratification of the Constitution in 1787, and the outbreak of hostilities between the French and British after 1793 created new trading opportunities for American merchants.

Bjork (1964) has argued that the effects of the disruption in international trade were short-lived and relatively mild, as resources were diverted toward westward expansion and import-competing production. Lindert and Williamson (2013), on the other hand, offer the most pessimistic estimates of the decline in incomes after the Revolution. Weiss (2017), however, offers reasons to be skeptical of their estimates. Expressed in prices of 1840, Lindert and Williamson (2013) estimate that per capita income fell from $74 in 1774 to $59 in 1800, a drop of 20%. Since incomes are generally thought to have begun to recover after the early 1790s, this suggests that

the trough in incomes must have been even larger. Mancall and Weiss (1999) argued that between 1770 and 1800, incomes were relatively flat but inferred that there must have been some decline in incomes between 1770 and 1790 that was erased by the subsequent recovery of the 1790s. Rosenbloom and Weiss (2014) estimate that in the Middle Atlantic, per capita income fell from $78.70 to $65.50 in 1791, before recovering to $78 by 1800 (all quantities in constant 1840 prices).

Conclusion

Between 1607 and 1776, the 13 British North American colonies that became the United States were transformed from small isolated outposts of European settlement to a thriving economy with a population almost 40% the size of Britain. After overcoming the initial hardships of establishing the colonies, per capita incomes grew slowly (if at all). But the remarkable feature of this history is that the colonies were able to sustain rapid extensive growth for nearly two centuries without a reduction in living standards.

Writ large, the story is fundamentally one of resource abundance relative to labor and capital. When North American land was combined with European agricultural technologies and European institutions of private property, resource abundance created high returns to mobile resources. The result was a flow of trans-Atlantic migration and investment. This response required a variety of institutional innovations. To facilitate the movement of European laborers, indentured servitude was developed as a mechanism to finance profitable migration. Yet the resulting labor response was not sufficient to meet the labor needs of the colonies, and colonists resorted as well to the involuntary transportation of thousands of enslaved Africans to perform less desirable work in less attractive locations. Among both European- and African-American populations, rates of natural increase were relatively high. Abundant food and fuel contributed to a relatively healthy population and allowed earlier marriage and high rates of marital fertility. As a result, populations doubled roughly every 20–25 years.

Of course, European and African settlers did not arrive in an empty land. Their success coincided with the displacement of aboriginal peoples. Early European settlers encountered natives whose populations had already been disrupted by European diseases spread by early contacts with fishermen and explorers, thus facilitating settlement. The trade in furs (beaver in the North and deerskins in the South) was an important component of European economies in the early years of settlement, and both trade and conflict with native populations remained an important element throughout the colonial period.

In much the same way that institutions adapted to promote migration, the colonists adapted mechanisms of self-governance to their new conditions. Abundant land made it difficult for the early Virginia Company to maintain top-down discipline in its settlement. Only when land was distributed to the colonists and they were allowed to retain the profits from their effort did production begin to grow. Dealing with distant masters, separated by a month-long trans-Atlantic voyage, the colonists

asserted their rights to establish local governments empowered to make collective choices for most local decisions. Local assemblies developed strong traditions that provided a foundation for local rule when the colonists declared independence.

Nonetheless, for most of the colonial period, there was little thought of seeking independence. The colonies thrived within the imperial trading relationships that the British created. Under the Navigation Acts, American merchants enjoyed the same access to this trade as British merchants, and the protection of the British Navy on the seas, and the British military on land, provided important benefits to the colonists. After 1763, however, the dynamics of colonial relations shifted. Having largely eliminated the competition of French and Spanish colonies for control of North America, Britain wished to restrain the spread of American population and avoid provoking conflicts with native populations. The colonists saw opportunities to expand. At the same time, new taxes and new policies led colonists to question whether the British government was committed to their interests. The result was a rapidly growing movement of resistance that culminated in a formal declaration of independence in 1776.

Property Rights to Frontier Land and Minerals: US Exceptionalism

Gary D. Libecap

Contents

Abstract

Property rights are the most fundamental institution in any society. They determine who has decision-making authority over assets and who bears the costs and benefits of those decisions. They assign ownership, wealth, political influence, and social standing. They make markets possible, define timelines, and provide incentives for investment, innovation, and trade. They mitigate the losses of open access and provide the basis for long-term economic growth. Economists and

economic historians have long recognized the importance of secure property rights for economic outcomes. Other political economy, philosophy, and historical and legal literatures emphasize different, but critical, attributes based on *how* property rights are allocated and to whom. The linkages among the social, political, and economic effects are examined here with respect to US and Latin American frontier land and minerals. Property rights were sharply different across the two frontiers with apparent long-term consequences for economic growth, innovation, wealth distribution, private investment in public goods, as well as social and political stability. The distinct assignment of property rights to land and minerals is likely a basis for long-term US exceptionalism in economic performance, individualism, mobility, and optimism. The mechanisms through which property rights to land in a frontier society affect outcomes in a contemporary, highly urban one are complex. Because property rights to land were broadly distributed, Americans could participate in capital markets using land as collateral. This ability shaped opinions regarding markets, capitalism, and individual opportunity. In the twenty-first century, these critical attributes may be eroding, inviting more analysis from economists and economic historians.

Property rights · Frontiers · Incentives

If a man owns a little property, that property is him.. . .it is part of him. . ..in some ways he's bigger because he owns it. John Steinbeck, *The Grapes of Wrath* (1939, 1976, 48)

Introduction

The above quotation points to attributes of property rights that are more individualistic, social, and political than are those emphasized in most economic discussions. Nevertheless, there are direct linkages across these characteristics, and emphasizing the relationships is the focus of this chapter. Attention is directed to frontiers in North and South America where property rights were distributed to land and minerals in very dissimilar ways, seemingly leading to starkly different consequences – economic, political, and social. These varying frontier experiences appear to have had long-term consequences. Frontiers provide a natural experiment because, by definition, they are areas where new rights to resources are emerging. The discussion is based on the existing literature and does not provide tests of hypotheses regarding property rights and various outcomes. Causality between property rights structures and observed variation in immigration patterns, middle-class development, innovation, social and political cohesion, individualism, reduced reliance upon the state, private investment in public goods, and long-term economic growth seems, however, to be supported by available research.

Property rights are the most fundamental institution in any economy and society. The economics and economic history literatures explore the role of secure property rights in mitigating the losses of the common pool, in promoting markets and

exchange, and in encouraging investment. These facilitate long-term economic growth and welfare. Older political economy, philosophy, and history literatures, as well as growing legal scholarship, point to widespread ownership of land and related resources in molding social, economic, and political relationships and the role of individuals relative to the state. In those literatures, the existence of secure private property rights leads to more independent, self-reliant, and individualistic citizens. They innovate, are politically conservative, and invest in local public goods. They rely on rents they discover and generate. The state is less important than the market, and the economy in turn is less centralized, more atomistic, market-based, and supportive of entrepreneurship.

For the USA, the frontier is defined according to the US Census as an unsettled region where population density was less than two persons/mile^2 (U.S. Census Bureau 2012). In Latin America, frontier regions were new to Europeans, but often had denser native occupation, and there were multiple frontiers. Nevertheless, for land and minerals, the definition of the frontier is used here for European settlers in the region. The settlement of temperate North America by European migrants, molded in part by the English common law of property and contract, along with the actions of colonial and US courts and legislatures, granted access to and ultimate ownership of unimaginable riches to common individuals in a piecemeal fashion. In Latin America, land and mineral ownership was retained by the sovereign with use rights to large tracts of land granted to political and economic elites. Mineral rents largely were reserved by the crown. In the postcolonial period, hierarchical, centralized control continued, although individuals could obtain title to their land. Minerals remained owned by the state. These differences in the property rights to land and minerals allocated to individuals by the state between North and South America appear to have had long-lasting, important economic, political, and social effects that are collected from the relevant literatures and described below. The outcomes underscore the perhaps underappreciated, far-reaching, and enduring impact of the nature of property rights to fundamental resources that exist in any society. They go far in offering an explanation for contemporary differences observed across nations and across times in development, equity, opportunity, entrepreneurship, and social and political stability.

The Economic Institutions of Property Rights

Property rights critically shape economic behavior by fixing incentives for resource use, investment, exchange, and inheritance. They set time frames and define the decision-makers for such actions. They determine flows of associated benefits and costs and designate who will receive or bear them. Externalities arise from incomplete property rights, when decision-makers do not internalize the full benefits and costs of their actions. Depending on the size of the imprecision in definition of property rights, incentives are distorted, leading to losses in potential resource value and welfare. Property rights can be informal (implicitly recognized) or formal (legally documented) and can range from state ownership to group rights to private

property rights. In all cases to be stable, they must be socially sanctioned and often are enshrined in an established law.

Property rights can exist with almost any imaginable array of attributes. They may (a) be held by a single party or be divided with one party having use rights and another actual ownership; (b) be permanent or short-term; (c) have comprehensive or restricted authority over use, exchange, investment, and assignment to heirs; (d) completely direct costs and benefits to rights holders or split costs and benefits among multiple entities, including users, sovereign rulers, politicians, and bureaucrats; (e) be well-defined or imprecise; and (f) be secure or insecure. This assortment of possible attributes leads to a similar multiplicity of economic outcomes for the same resources and decision-makers.

Economists and economic historians have long recognized the critical role of property rights in determining economic performance. North and Thomas (1973) emphasize the emergence of different freehold rights between England and Holland and France and Spain as a key source in differential patterns of economic growth. When reasonably well-defined and durable, private property rights critically contribute to economic growth (Davis and North 1971; North 1981, 1990; Acemoglu et al. 2001, 2005; Mehlum et al. 2006; Rodrik 2008; Dixit 2009; Besley and Ghatak 2010; North et al. 2009; Acemoglu and Robinson 2012; Alston et al. 2018). They facilitate greater investment when returns are uncertain or delayed (Besley 1995; Jacoby et al. 2002; Galiani and Schargrodsky 2010; Hornbeck 2010). They allow for the development of markets (Greif et al. 1994; Barzel 1997; Dixit 2009; Edwards and Ogilvie 2012). And finally, they reduce rent dissipation associated with common-pool resources (Gordon 1954; Scott 1955; Cheung 1970; Johnson and Libecap 1982; Wiggins and Libecap 1985; Grafton et al. 2000; Wilen 2005; Costello et al. 2008).

The principal long-term economic benefits of property, as an institution, arise from private property rights (Merrill and Smith 2010). Although group management of resource access and use has been effective in overcoming the losses of the common pool (Ostrom 1990), the conditions for successful collective action may be quite limited (Cox et al. 2010). Moreover, communal rights may not facilitate markets and asset trade outside the group nor risky, disruptive innovation within it. Finally, neither theory nor empirical evidence indicate success with state-owned rights or socialism in promoting long-term economic growth or in mitigating open-access losses (Barro 1991; Grafton et al. 2000; Costello et al. 2008).

The dominant performance of private property rights, relative to others, lies in the more complete alignment of private and social benefits and costs, lower transaction costs in decisions (initial assignment of rights may entail high transaction costs, Libecap 2008), market development, and incentives for value or rent creation (Ellickson 1993; Allen 2011). With state ownership or control, value may be lost, even if externalities are addressed. While private property rights assign ownership to individuals, group or state property rights *separate* ownership from actual decision-making, potentially generating distortions with possibly high welfare losses. There can be externalities associated with private ownership, and in that case, one question is why the property rights are incomplete in the first place, as compared to traditional

calls for state regulation or taxation (Pigou 1920; Coase 1960; Dahlman 1979). Externalities are far less likely for resources, such as land and minerals, where property rights can be defined and enforced at relatively low transaction costs. For other resources, such as air, water, or fish stocks, property rights are more difficult to define and enforce, and government ownership or regulation of access and use is more prevalent (Libecap 2008). For some resources, such as forestland and rangeland in the USA, political demand by advocacy groups, beginning in the late nineteenth century, led to their retention by the state, rather than assignment to private parties (Libecap 2007). The underlying arguments for retention by the state were not fundamentally due to an inability to define property rights effectively (Libecap 1981, 2007). The key problem for state regulation or ownership in either of these cases is that neither politicians nor bureaucrats are full residual claimants to the benefits and costs of their actions in the way that private owners are, so that incentives and outcomes differ, often creating other, and perhaps costlier, externalities (Libecap 2016).

Social and Political Institutions of Property Rights: Pre-frontier

Historically in Europe, ownership of land and all natural resources lays with the Creator, as represented on earth by the sovereign. The landed nobility had use rights that were held at the pleasure of the sovereign, and much of English and European history involved conflicts between the crown and the nobility over the extent and nature of those rights, their security, and taxation. Those who actually worked the land, thousands of serfs, peasants, and tenant farmers, had little or no authority over it and captured few of the benefits, with most rents taxed away by their feudal masters and passed on in part to the crown. Those who used the land were bound to it. This very centralized setting was static so as not to upset key relationships, and there was little incentive among tillers of the soil and grazers to innovate, and they had little political role in the society.

Political economists and philosophers during the European Enlightenment, including Adam Smith, John Locke, Jeremy Bentham, J.J. Rousseau, John Stuart Mill, David Ricardo, Edward Wakefield, and Robert Torrens (Winch 1965; Ellickson 1993; Linklater 2013; Priest 2019), debated the role of individuals in society, their potential for advancement, their relationship with the state, and the critical impact of widespread private ownership of land for advancing individual and resource potentials. The implications of land ownership as a threat for an authoritarian state also were clearly understood by Marx, Lenin, Stalin, and Mao Zedong. Land as a fundamental resource was key, and its ownership had contagious effects on the entire economic, social, and political orders in the short and long run.

The colonization of western hemisphere frontiers during the sixteenth and nineteenth centuries by England, Holland, France, Spain, and Portugal was molded by very different views of land and minerals distribution and ownership. In the Spanish, Portuguese, and French colonies, the process was controlled centrally by the crown. There was little emphasis on large-scale emigration with land being granted in large

tracts to political elites. Ownership remained with the crown, and those who received land grants held them at its pleasure. For English North America, the nature and distribution of property rights were in sharp contrast. Individuals, not the crown, were the ultimate owners of land, and for the most part, it was allocated in small plots. Vast numbers of immigrants were attracted by the opportunity to secure land, and their ability to own it had profound consequences in the development of English colonies and, subsequently, the USA.

The Magna Carta of 1215; the Glorious Revolution of 1688; land enclosures that broke up communal holdings, particularly in the eighteenth and nineteenth centuries; and the English agricultural and industrial revolutions ended the ultimate ownership of land by the crown as the representative of God on earth. Comparatively static, feudal, and communal obligations were broken. More materialistic economic and democratic political objectives became ascendant. The legal basis for alienable, private property in land became part of the common law. Ordinary individuals could own land and enjoy the benefits of using, investing, and trading it. William Blackstone commented in 1766 on the implications: "There is nothing which so generally strikes the imagination, and engages the affections of mankind, as the right of property; or that sole and despotic dominion which one man claims and exercises over the external things of the world, in total exclusion of the right of any other individual in the universe . . .." (quoted in Ellickson 1993, 1317). English colonization and migration to North America were driven by these ideals (Ely 2008). Those who migrated to and occupied frontier land eventually held it in fee simple as independent owners and not as a dependent peasantry (Story 1858).

Property Rights to Land on the US Frontier

Claire Priest (2019) summarizes much of the early literature and key elements of colonial and early federal land law. She argues that the colonists brought with them English laws, customs, and legal institutions and then modified them through the statutory enactments of local representative assemblies and rulings of common law courts. Gradually, colonial and early US property law became quite distinct from that in England, fundamentally transforming the economic, political, and social structure of the country (Priest 2019). Property rights in land became a liquid source of wealth, to be bought and sold and used to obtain credit. Because land was the most basic resource, its widespread ownership became the catalyst for colonial economic and political development. The ownership of property made individuals as special stakeholders in the society and dispersed political and economic power from elites in a manner that had not occurred in England. The easy circulation of land in the market facilitated extensive property ownership, undermining privileged inheritance and inalienability. Dynamic, open land markets became an essential ingredient for the credit system and its ability to support the growth of a middle class as well as to spur investment and innovation throughout the economy (Priest 2019).

There were many commentaries on the benefits of land ownership and exchange. Benjamin Franklin saw it as the way for ordinary persons to improve their position in

life and that of their children (Franklin 1751, quoted in McCulloch 1845). Thomas Jefferson saw a nation of numerous, small freeholders not only as good economics but good politics. The seemingly endless abundance of frontier land provided the perfect opportunity to create a society composed of small, independent, freeholding farmers that could support a republican form of government. Such citizens with an attachment to the land and to the country had virtue and a common interest in political stability and social cooperation. He notably stated that: "The earth is given as a common stock for man to labor and live on... The small landholders are the most precious part of a state" (quoted in Katz 1976, 480). Alexis de Tocqueville observed that being freeholders changed the way in which Americans thought of themselves and the political structure: "Why, in a quintessentially democratic country like America, does one hear no complaints about property in general such as those that often resound through Europe? Needless to say, it is because there are no proletarians in America. Since everyone has property of his own to defend, everyone recognizes property rights as a matter of principle" (de Tocqueville 1835, quoted in Goldhammer 2004, 273).

Later in the nineteenth century, as the frontier neared its end, the US Public Lands Commission endorsed the small-farm, homestead principle: "The maxim that He who tills the soil should own the soil is accepted as a fundamental principle of political economy... Small holdings distributed severally among the tillers of the soil is believed to be a fundamental condition for the prosperity and happiness of an agricultural population" (US Public Lands Commission 1880, xxii). Frederick Jackson Turner in 1893 in his famous thesis about the role of the frontier in US political and social development went further, claiming that America ultimately was shaped by small-farm frontier settlement as the underpinning for democracy, an independent citizenry, and generalized economic well-being (Turner 1893). This is the notion of US exceptionalism and its dependence on frontier resource ownership emphasized here.

Colonial Property Rights to Land

The English Crown granted colonial charters that conveyed land and lawmaking authority. Some colonies began as trading companies, such as the early Virginia, Plymouth, and Massachusetts Bay Companies, and the charters were to the owners of the corporation. Other colonies were proprietorships based on grants from the crown to an individual or a group of individuals, such as those to William Penn and Lord Baltimore, creating Pennsylvania and Maryland. A third type was the royal colony directly ruled by the crown, including New Hampshire, New York, New Jersey, Virginia, North Carolina, South Carolina, and Georgia. In all cases, a governor or proprietor served as the top official, and assemblies of elected representatives were authorized to enact legislation (Priest 2019).

Land sales were seen by the crown, proprietors, shareholders, and others as a major source of revenue, and accordingly, there was a need to attract immigrants to North America who would create small farms and cultivate the land. Large land

grants, in general, were not consistent with the policy. Especially in the Middle Atlantic and Southern colonies, a headright of 50 acres or more was given to those who would cover the transport costs of any immigrant. In repayment, the immigrant served an indenture period, 5 to 7 years, whereby they served their sponsor. Indenture contracts were supplemented later in the colonial period by redemptioners, who borrowed for their travel costs and were released from their indenture commitments upon paying off the loan (Ford 1910, 416; Grubb 1986; Abramitsky and Braggion 2006). The headright policy also encouraged the importation of slaves, but indentured servants had a future as freeholders with voting rights within the colonies. The headright/indentured servant system may have accounted for 50–66% of white male immigration to the American colonies between 1630 and 1776, or 300,000–400,000 people. Slave importation, primarily in the eighteenth century, was just over 255,000, largely to Bermuda, Barbados, and the southern US colonies (Priest 2019).

High-level colonial administrators were recruited with the promise of landed estates, and they expected to profit from rising land values and sales, stimulated by rapid new settlement by small holders. To quiet titles, attract settlers, and support land exchange, colonial administrators promised surveys of small parcels. Although most property boundaries followed natural terrain (metes and bounds), more systematic, rectangular survey of parcels was implemented in flat areas. Rectangular survey facilitated subdivision and sale (Ford 1910, 329–356; Libecap et al. 2011).

The extensive availability of fertile land to small holders, who could secure and cultivate freeholds, not only invited vast immigration but generated an egalitarian society with high levels of real per capita income. By 1751 the British North American colonies may have had 1 million inhabitants, compared to 52,000 or so in New France and a generally small number of immigrants to the Spanish and Portuguese colonies of South America (Linklater 2013). Lindert and Williamson (2013, 2014a, b) report that in 1774 the American colonies had the most equal distribution of income in the western world and per capita purchasing of income exceeded that in Great Britain. The process of distributing land on the frontier took time to sort out during the colonial period. Much of the political instability observed at the time, aside from opposition to English rule, came from frontier settlers against colonial proprietors and other administrators over issues of taxation of local production, protection against natives, and overall access to land (Bacon's Rebellion, 1676; Culpeper's Rebellion, 1677; Cary's Rebellion, 1711; Shay's Rebellion, 1786; and the Whiskey Rebellion, 1791–1794). During the postcolonial period, there was seemingly far less political volatility on the frontier. As described below, policies to grant land to migrants at low cost and to support their property rights and land markets became routine. The political coalition of small holders and would-be small holders, who also were land speculators and frontier territorial politicians who wanted their regions to have dense settlement so as to qualify for statehood, was a formidable one in Congress. At the same time, the federal government had no strong reason to hold on to frontier land. Until the rise of the conservation movement, there was no advocacy for maintaining federal ownership. For several reasons, land

policies promoted the distribution of frontier land to private claimants as quickly and at as low a cost as possible. As discussed below, political motives for land transfers were very different in Latin America.

Federal Property Rights Policies for Land

Following the end of the French and Indian War in 1763 and the Revolutionary War in 1783, frontier migrants began moving in large numbers beyond the Appalachian Mountains to the comparatively flat lands in the Ohio River Valley and elsewhere. Land in the vast new territory was distributed through direct sales from the federal government and from the issuance of military warrants, redeemable for small parcels, to compensate Revolutionary War soldiers (Ford 1910). Military warrants were bought and sold and were a major means of securing access to land by their ultimate holders. The Federal Land Ordinance of May 20, 1785, called for the survey of all lands ceded by the states to the federal government and all additional lands acquired through purchase from native tribes. It created the Public Land Survey System (PLSS) of grids of square townships of 6 miles square and 23,040 acres each, aligned along latitude and longitude. Each township was subdivided into 36 sections of land that could be further subdivided into half and quarter sections for purchase and sale. The survey made land a commodity with clearly defined parcel boundaries that were easily addressable (Libecap and Lueck 2011; Libecap et al. 2011). Libecap and Lueck (2011) estimate that the rectangular survey raised land values by 23% relative to the baseline alternative of metes and bounds, which invited boundary disputes and created irregular parcel sizes and shapes that hindered market exchange. The General Land Office was created in 1812 to administer and extend the survey across the continent and to distribute additional federal lands under land laws enacted by Congress (Table 1 below). The rectangular survey reduced gaps between properties and promoted dense, rapid settlement of the frontier. The federal government offered land at fixed prices, often $1.25/acre to raise revenue. This revenue objective ultimately was undermined by the inability to police squatting and occupancy and growing political demand for free land.

Figure 1 shows the movement of the frontier across the continent based on population density. In 100 years, the frontier went from the Atlantic seaboard to its announced end by the Census Bureau in 1890. As noted above, the Bureau defined the frontier as an area where population density was two persons/mile^2 or less, and in the figure the frontier is represented in the lightest yellow states. Land densities rose in established areas as the frontier progressed westward through time. Bazzi et al. (2017) provide a similar description of the frontier.

Table 1 lists the major federal land laws enacted by Congress that distributed property rights to land and minerals on the frontier. The demand for free small freeholds was incorporated into policy, beginning with the Preemption Act of 1830 and its many amendments (Kanazawa 1996) to accommodate and legally recognize squatter claims and on through the Homestead Act of 1862 and its adjustments. The Homestead Act effectively was ended by Congress in 1934. Under all laws, property

Table 1 Federal land distribution laws

Law	Date	Stated goal and brief impacts
Land Ordinance of 1785	May 20, 1785	Established the Public Land Survey System
Land Ordinance of 1787 (Northwest Ordinance)	July 13, 1787	Determined that the land south of Canada, north of Ohio, west of Pennsylvania, and east of the Mississippi River would be distributed by Congress and that Congress would institute governments and laws in this territory
Land Act of 1796	May 18, 1796	Made the rectangular system of 6 square mile townships permanent and determined the size of sections to be sold. Set minimum land prices
Preemption Act	May 29, 1830	Allowed settlers to occupy and purchase federal lands up to 160 acres at $1.25 an acre
Preemption Act	September 4, 1841	Permanently recognized preemption or squatter claims of land. Donaldson (1884) estimates around 175,000,000 acres were secured by individuals under the Preemption Acts
Graduation Act	August 3, 1854	Reduced the minimum prices of unsold federal government from $1.00/acre to $0.125/acre
Homestead Act	May 20, 1862	160 acres of federal land was made available to individual actual settlers after 5-year continuous residency
Coal Lands Act	July 1, 1864	Distributed coal lands at $20/acre and allowed individuals and associations to claim 160 acres and 320 acres, respectively
Timber Culture Act	March 3, 1877	Applied to 11 western semiarid states and territories to augment Homestead Act claims. Settlers paid $0.25/acre at filing and $1.00/acre when proving compliance
Desert Land Act	March 3, 1873	Authorized an additional 160 acres to Homestead claims if 40 acres of trees were grown
Timber and Stone Act	June 3, 1878	Authorized sale of land at $2.50/acre for land valuable for timber or stone in far western states and territories
Mining Lode Act	July 26, 1866	First major mining law, allowed individuals to claim ownership of ore veins
Mining Act	May 10, 1872	Second major mining law, added placer or shallow ore bodies; required a $100 investment in development to obtain title; procedure for obtaining title outlined
Oil Placer Act	1897	Recognized oil deposits as claimable as a placer ore deposit under the Mining Act of 1872
Stock- Raising Homestead Act	December 29, 1916	Authorized 640-acre homesteads to raise livestock

Sources: Material drawn from Donaldson (1884), Hibbard (1924), Robbins (1942), Gates (1968), and Lacy (1995)

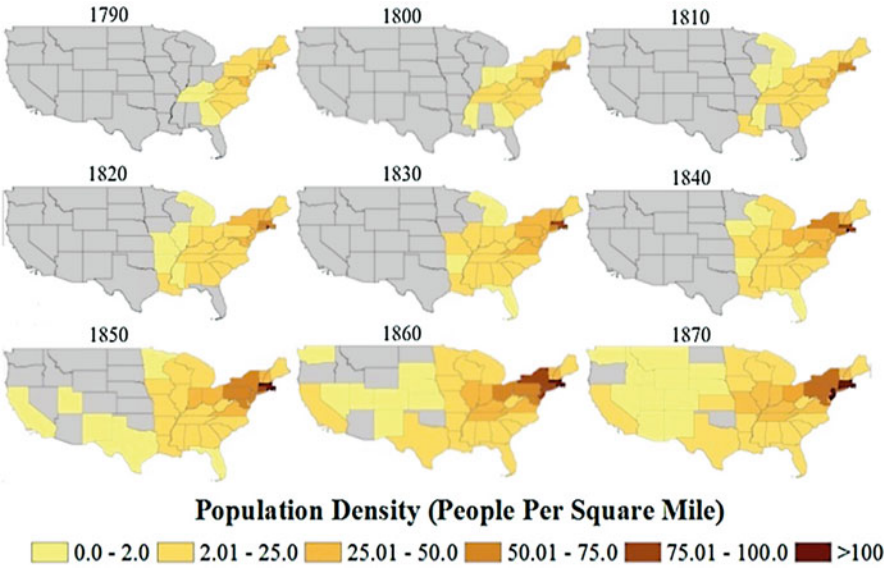

Fig. 1 The progression of the frontier. Notes: State population densities from 1790 to 1870 are from the US Census. Gray states are those with missing data. US Census Bureau (2012, September 6), retrieved from https://www.census.gov/dataviz/visualizations/001/. To construct the figure, population densities for each individual state were taken from the decennial censuses for the years 1790 to 1870. ArcGIS was used to create maps with contemporary state boundaries and their respective population densities for each census

rights to agricultural land were given out piecemeal in plots of 40 to 160 acres (later, up to 640 acres) with the requirement of occupancy and beneficial use (Hibbard 1924; Robbins 1942; Gates 1968). Through these land allocation laws, immense amounts were placed under private ownership. Under the Homestead Act, for example, some 2,758,818 original entries were made between 1863 and 1920 for 437,932,183 acres, an area larger than Alaska (Gates 1968).

There is an extensive literature on the wealth generated from migration to and along the frontier and associated capital gains from land sales. There were benefits from arriving early in a frontier region and obtaining, improving, and selling land. Relatively poorer migrants often benefitted disproportionately, and the rents generated led a more egalitarian wealth distribution than what was found in non-frontier areas. Major works include Lebergott (1985), Oberly (1986) for the period following the War of 1812, von Ende and Weiss (1993) for 1800–1860, Swierenga (1966) for 1840–1869, Kearl et al. (1980) for 1850–1870, Steckel (1989) for 1850–1860, Galenson and Pope (1989) for 1850–1870, Ferrie (1993) for 1850–1860, Stewart (2009) for 1860–1880, and Gregson (1996) for the latter part of the nineteenth century. Most of the studies examine the East and West North Central regions, where production conditions supported small-farm distribution. Easterlin (1960) reveals gradual convergence in per capita income and population patterns between 1840 and 1950 across the frontiers that are shown in Fig. 1.

The Private Provision of Public Goods by Land Owners

The hypothesis that small-farm distribution of property rights to land resulted in civic virtue among freeholders and political participation as suggested by Jefferson, de Tocqueville, and Fredrick Jackson Turner has not been tested. There naturally are measurement challenges, and within the USA there are no clear baselines for comparisons. The literature suggests such differences existed between US and Latin American frontiers as examined below. There are no comparative studies of political activity (voting participation rates, per capita involvement in political office, politician turnover rates) that might have varied with land allocation across and along the US frontier. There is, however, suggestive evidence for public goods investment in education in the USA that supports the relationship. Go and Lindert (2010) find that school enrollment and the number of teachers per capita were greater in the rural northern USA in the mid-nineteenth century, where small farms predominated, than in the South where there was a more heterogeneous mix of constituencies and farm sizes. They also find that student enrollments in the rural north were greater than in most of Europe by 1850. Northern schools relied more than elsewhere on local public money and governance. Go and Lindert (2010) credit the autonomy of local governments and the voting power of citizens in rural communities for this education achievement.

Goldin (1998, 2001) and Goldin and Katz (2010) explore the rise of high school or secondary education in the USA at the turn of the twentieth century that far outpaced that in Europe. Although the high school movement began in New England, it spread rapidly to the central Midwest and western USA that were dominantly rural, agricultural, and in the Midwest at least, characterized by small-farm ownership. The pedagogical focus was practical, pragmatic in emphasis, and egalitarian, aimed at understanding and using new technologies. Educated farmers and their children were more apt to adopt the new technologies and cropping changes underway at the time, and they needed high school education to be able to take advantage of the opportunities. Investment in general education, as compared to apprenticeships and firm (or farm)-specific training, was useful in a highly mobile society where labor would migrate to new locations and employment. School governance was decentralized with 130,000 independent school districts in America by the 1920s, locally supported and administered (Goldin 2001, 279). The demand for and local support of practical education in rural areas are consistent with the argument that small freeholders had incentives to innovate because they captured the rents from doing so and because they had strong ties to their communities. They were motivated to contribute financially and administratively to their schools. The school districts were small and homogenous with respect to citizen incomes and educational objectives. These conditions promoted local collective action to invest in schooling.

Related evidence for the impact of small-holder ownership on the frontier on democracy and individual initiative as claimed by Turner (1893) is provided by Bazzi et al. (2017). They map US frontiers and find that those who lived along them shared characteristics of rugged individualism, self-reliance, and opposition to government intervention and redistribution programs.

Property Rights to Minerals and Oil and Gas Deposits

Not only were frontier lands generally distributed in small parcels, but subsurface mineral deposits and oil and gas formations were secured initially by small holders. In most countries, the subsurface estate has been owned by the crown and later the state. In the USA, the Land Ordinance of 1785 included mineral lands that were to be sold to private bidders as surface lands, with reservation of 1/3 of the properties to the government. As it turns out, however, minerals were not prominent in the central and eastern USA, except for copper deposits in Michigan. Between 1776 and 1848, most mineral lands went to private ownership as agricultural lands, and the government did not claim the minerals below them (Lacy 1995). As the frontier moved into the far West, however, things changed. Rich gold and silver ore was found, beginning in California and then throughout the western region, and those individuals who discovered ore deposits claimed ownership as first possession even though minerals as separate resources from the surface land were not covered in the land laws until 1866. Eventually well over 600 mining camps were established throughout the West with bylaws regarding the requirements for defining, maintaining, and trading individual mining claims and arbitrating disputes over them. Figure 2 shows the range of mining camps in California in the late nineteenth century and the US West. Each camp had local mineral rights bylaws.

Libecap (1978) describes the institutional evolution of private property rights to ore on the Comstock Lode of Nevada from those defined by early mining camp rules to the actions of the territorial and state government and, ultimately, the federal government in the Mining Laws of 1866 and 1872. Mineral rights could be traded, and as surface ore was depleted, requiring more capital-intensive deep-vein mining, surface mining claims were sold and consolidated into new mining companies with their shares listed on the San Francisco Stock Exchange and other capital markets.

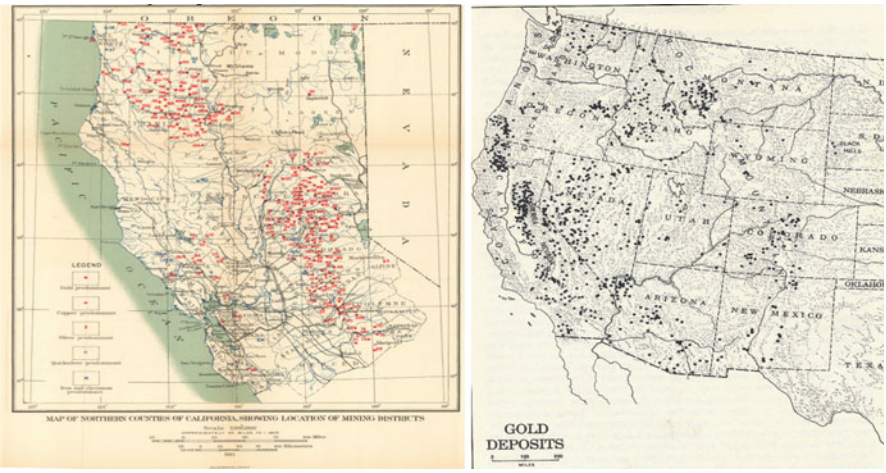

Fig. 2 Frontier mining camps in California and the far West. (Source: California, Hill (1912, 78) and gold deposits, Paul (1963, 4))

There is an extensive literature on mining camp rules, including that by Umbeck (1977), Clay and Wright (2005), and others noted by Libecap (2007). Drawing from public use samples from the 1850 to 1852 US Censuses for California, Clay and Jones (2008) analyze who went to the mining frontier in California and how they fared in their efforts to become rich. Most came from New York, Illinois, Michigan, and Wisconsin as well as Missouri, areas that once had been on the agricultural frontier. Clay and Jones find that this risky endeavor did not always pay. On average, migration may have lowered real earnings for many prospectors, relative to what they might have earned in their home locations. It was the promise of riches that drove migration and the ability to acquire individual ownership of ore in the quest for rents that drove migrants west. Overall, private property rights to minerals encouraged exploration, discovery, and production. As the mining industry developed, American mining engineering schools and technologies became world leaders. Human capital and physical technology investments in the USA led the country to produce beyond what its resource endowments would have otherwise suggested.

Ownership of major oil and gas deposits also went to private individuals. Oil discoveries in Pennsylvania in 1859 and in Oklahoma, Texas, Kansas, Illinois, and California in the late nineteenth century and into the twentieth century largely took place on private lands, and as noted above, surface owners held title to the minerals beneath their properties. As with minerals, private ownership and the potential to gain rents encouraged exploration and production. Those who specialized in search were called wildcatters, and they obtained leases from surface owners for exploration and later, if discoveries were made, for production. By the early twentieth century, prolific new oil fields were developed, particularly in the central and western USA. Fabled oil fields include Spindletop, Yates, Hendrick, East Texas in Texas, Oklahoma City and Seminole in Oklahoma, and Long Beach and Kern County in California. Given relatively low costs of locating, drilling, and producing in new fields, entry was easy, and production soared (Libecap and Wiggins 1984). The resulting output drove local economies; created local, self-reliant middle and upper classes, characteristic of Oklahoma and Texas today; and made the USA a major world producer.

There is nothing comparable in virtually all other countries, where minerals and oil and gas deposits are owned by the state. Surface property owners may or may not share in the rents generated from new discoveries, and they often resist exploration on their properties. Incentives for exploration and production are quite different. This explains why, for example, the current rapid adoption of nontraditional production techniques (fracking) is based on US innovation and occurs dominantly on private properties in the country, where surface property owners can anticipate a share in the returns.

Although private ownership of minerals and oil and gas encouraged exploration and discovery, competitive output may have been nonoptimal in an aggregate sense (Libecap and Wiggins 1984; Clay and Wright 2005). Figure 3 shows the many small mineral claims that often overlapped with unclear property rights, at least early in a mining camp. The rush to locate and prove or extract ore could have motivated excessive production. The figure also shows town lot drilling that was found where

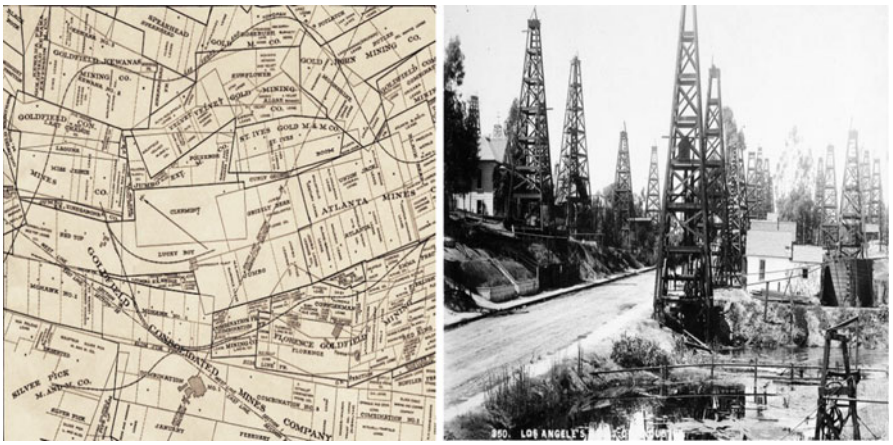

Fig. 3 Fragmented minerals and oil and gas ownership, Goldfield, Nevada, 1905, and Long Beach, California, 1920. (Source: https://www.mininghistoryassociation.org/Meetings/Tonopah/Goldfield%20Claims.jpg; http://texasalmanac.com/topics/business/history-oil-discoveries-texas, https://www.kcet.org/shows/lost-la/when-oil-derricks-ruled-the-la-landscape (2011))

surface ownership was extremely fragmented. With subterranean oil and gas deposits migratory, adjacent producers had an incentive to competitively drill and drain, generating classic common-pool resource losses.

It is difficult, however, to make strong welfare conclusions in either case. The trade-offs with more centralized, large minerals or oil and gas ownership, involving potentially less discovery and innovation, may offset the losses of rapid output. All in all, competitive output was mitigated by lease consolidation and large-scale hard-rock mining later in the life of most mineral regions and with the unitization of oil and gas fields that designated a single firm to develop a hydrocarbon formation (Wiggins and Libecap 1985).

Property Rights on Latin American Frontiers

Besides England of course, the western hemisphere was colonized by France (largely in Canada), Portugal (Brazil), and Spain (Central and South America) with limited colonization by Holland, Russia, and Sweden. Property rights to land and minerals were starkly different in Latin America, providing an opportunity to examine the consequences. The English language literature on frontier resource ownership is smaller, and only generalized conclusions are presented here. Nevertheless, the diverse patterns relative to the USA are quite clear (Alston et al. 2012). The differences in economic outcomes across the US and Latin American frontiers are in part attributable to the factors underscored by economists and economic historians on the clarity, enforcement, and durability of the property rights to land and minerals provided in the two regions. In Latin America, property

rights were ambiguously defined between the crown/state and private individuals, creating uncertainty as to decision-making, net rent capture, and durability. Short-term, extractive practices often were the result. Other differences in outcomes are attributable to the factors underscored in the political science, historical, legal, and other economics and economic history literatures. Property rights to land and minerals were distributed in a centralized way in large blocks to privileged parties, not in a decentralized manner to common people as in the USA. The political and social power structures that emerged in the two settings were, accordingly, very distinct, leading to lasting effects in political stability, social interactions, individual mobility and optimism, and economic growth.

Hennessy (1978) provides a summary of experiences on multiple frontiers in Latin America. Unlike the relatively orderly progression across North America shown in Fig. 1 above, Latin American frontiers varied within and across countries. Latin America was formed of generally extractive colonies (Acemoglu et al. 2001). The process of European migration and settlement was more centralized and limited, very different from English colonization in North America (Engerman and Sokoloff 1997; Acemoglu et al. 2001; Linklater 2013). Ownership of land and minerals was retained by the crown in the colonial period, and mineral ownership continued to be held by the state in postcolonial periods. In the colonies, use rights to land were granted by the Spanish and Portuguese crowns in large tracts to political elites who paid tithes or quit rent payments (Hennessy 1978; García-Jimeno and Robinson 2011). Large-scale immigration of the kind that occurred in the USA was both relatively unattractive because of limited access to desirable land and officially discouraged due to concerns in home countries of population shortages. The experience of common people on the land in Spain and Portugal was very different from their English counterparts who already had familiarity with broad private land ownership prior to emigration. Some 243,000 immigrants may have arrived in Latin America in the first 100 years of colonization along with perhaps 7 million more between 1820 and 1920, as compared to 34 million to the USA (Hennessy 1978).

Hennessy argues that long-term economic underperformance and political conflicts in Latin America have their origins in the initial land distribution (Hennessy 1978). It created enduring political and social elites and established internal country conditions that have influenced subsequent immigration, urbanization, and industrialization. Land grants – latifundia, encomienda, *sesmarias*, estancias, haciendas – not homesteads, were the typical rural institution. The estates often were near-feudal organizations with natives and immigrant farm laborers bound to the land and the patriarchal structure (Hennessy 1978). Others worked land in or near the grants as sharecroppers and tenants, with payments or crop shares to the large landholders (Leff 1997; Chowning 1997). Mandatory labor conscriptions were assessed in native communities for working the mines of Bolivia and Peru via the Mita (Arad 2013). There was little active smallholder participation in land or resource markets in the way that occurred in North America. Ownership and wealth were highly concentrated as were the political structures (Frank 2001; Arad 2013). Relative to the US frontier, a much smaller agricultural land or minerals-based middle class developed.

Privileged locals invested in agricultural export industries and may have neglected or resisted other development opportunities that could undermine their positions.

Engerman and Sokoloff (1997, 2012) and Acemoglu et al. (2001, 2002, 2005) point to factor endowments, climate and disease environments, and densities of native populations, along with general institutional differences emanating from the source countries. They argue that these factors explain the differential performance of North and South American colonial and postcolonial economies and for their unattractiveness for immigration. The underlying nature of the property rights granted to land and minerals, their distribution among the population, and associated incentives for innovation, market development, political participation, and social mobility also likely played critical roles. The US South had similar factor and environmental characteristics to much of Latin America, but small freehold farms did emerge alongside plantations (Engerman and Sokoloff 1997). Economic, social, and political outcomes there were more similar to the northern USA than to Latin America. Moreover, in temperate Argentina, Uruguay, Chile, and southeast Brazil, the best lands were often preempted by large grant holders, and small farmers had difficulties in obtaining title to their lands. Land conflicts due to incomplete property rights also occurred elsewhere in Latin America where small holdings otherwise would have been economically viable (Sanchez et al. 2010). The relatively fewer immigrants to these regions more easily became tenants or were employed as agricultural laborers or range riders, or gauchos, than small freeholders (Engerman and Sokoloff 1997; Garciá-Jimeno and Robinson 2011). In this regard, the Latin American frontier seems to have had an enduring impact, as F.J. Turner argued for the USA, but with very different consequences, because property rights were assigned to it in very different ways.

Conclusion

Property rights are the most fundamental institution in any society, an assessment recognized by early political economists and philosophers, as well as by later historians and legal scholars. Economists and economic historians have understood the direct economic importance of property rights, but the broader implications of the nature and distribution of the rights granted to land and minerals have not been central in recent research. Yet, these seem critical in explaining long-term differences in economic, political, and social performance. Property rights determine who has decision-making authority over assets and who bears the costs and benefits of those decisions. They make markets possible, define timelines, and provide incentives for investment, innovation, and trade. They mitigate the losses of open access and provide the basis for long-term economic growth. They assign ownership, wealth, political influence, and social standing. For these reasons, how property rights are defined and allocated to land and minerals determines who the players are and who has a lasting stake in the society and economy. The contrasting experiences of the North American and South American frontiers illustrate these arguments, and there likely are durable, path-dependent effects in the process of economic growth. The property rights distribution to land seems to have affected how citizens participated

in capital and other markets and how they assessed their ability to advance economically, socially, and politically through markets as compared to state intervention. Whether and how the effects of broad ownership of land are maintained in more urban, developed economies requires research attention.

Major Water Infrastructure and Institutions in the Development of the American West

Canals, Dams, and Hydropower

Zeynep K. Hansen and Scott E. Lowe

Contents

Abstract

In the history of western expansion in the United States, arguably no natural resource has impacted the economy of the American west more than water. As a consumptive natural resource, water is necessary for urban growth and development, industrial mining, and for irrigated agriculture. However, water resources also provide non-consumptive, in-stream benefits, by allowing for transportation, energy production, and recreation. This chapter addresses the roles that water resources played in enabling western expansion in the United States, first into the trans-Appalachian west, and later into the more arid western territories. We address the institutions that arose in tandem with the development of water resources, and the complexities that competing demands have introduced to the management of these (often) constrained water resources.

Introduction

Fresh water is a raw, consumptive natural resource, necessary for urban growth and development. However, fresh water is also an input to production that can be used to increase the productivity of mining and industrial processes and enable irrigated agriculture. In addition to its value as an input to production, water and water resources may offer transportation, energy, recreation, and environmental benefits, benefits that may be recognized in tandem with the consumptive or industrial uses and benefits that may in fact dominate the consumptive uses. In the history of western expansion in the United States, arguably no natural resource has impacted the economy of the American west more than water. However, for all of the benefits that they enable, water resources are not without costs and complexities. When scarce, water resources are virtually priceless but when abundant can be costly to restrain and even more costly when they generate damages via flooding. Unlike many of the in situ or sedentary natural resources, riparian water resources in the natural environment are transient and transboundary, crossing sociopolitical boundaries and meandering over time. Water resources are also fleeting – uncertain from day to day, month to month, and year to year, particularly in an age of heightened climate uncertainty and variability and even more so in the arid parts of the world in which water is *the* constraining input. Water resources are often of varying quality and can be rendered worthless due to degradation and pollution. Water is bulky and difficult to move but can be lost due to evaporation and groundwater recharge.

As much of the precipitation in the western United States falls in the high mountains and is stored in snowpack at a great distance from anthropogenic demand, humankind has been bequeathed with a natural, environmental buffer and storage service. However, the meting of water resources in the arid western United States rarely aligns with demand, so in order to overcome some of these complexities and uncertainties, humankind has developed great water works to store, pump, and move water and to put it toward beneficial uses. In tandem, water institutions and governance have evolved to regulate and distribute the vast water resources. Dams, canals, and aqueducts crisscross the American west, storing, elevating, and transporting water resources. Although effective and able to remove uncertainty from an otherwise exceedingly complex resource, major water infrastructure projects are costly and have often involved decades-long negotiations and politicking. This chapter addresses the role of major water infrastructure in the economic development of the American west.

Focusing first on western migration from the eastern seaboard to the trans-Appalachian west, we address the growth of the US canal system and the ways in which these canals enabled industrial growth, opened up new markets, and changed the composition of the Midwestern United States. Working in tandem with a growing rail industry, canals created a great commercial center in the Midwest. Contributions by Bogart (1913), Turner (1920), Rae (1944), North (1956), Cranmer (1960), and Ransom (1964), all addressed in this chapter, illuminate this epoch in the great American migration. This newfound access was not without cost – the

urbanization and industrialization that resulted had a deleterious impact on the quality of life, noted by Haines et al. (2003) and Chanda et al. (2008).

Following this great first migration into the trans-Appalachian west, we look to the second great migration westward, into the more arid territories. Perhaps based on prior experiences and the great wealth that was created in the Midwest, pioneers and pilgrims found new wealth in the arid west in the form of mining and agriculture. Unlike the east, where water supplies were plentiful, water in the new arid west was a constraining resource: water supplies were snowpack-determined, and often were not available for many months of the year. As such, major water works and infrastructure provided a man-made source of storage, allowed pioneers to reclaim the desert, lengthened the growing season, and enabled the planting of crops that were previously thought impossible to grow. Hydraulic mining for precious metals required the diversion of rivers and the development of high-pressure water extraction techniques. Pisani (1984) and Reisner (1986) provide insights into the mining and agricultural booms in western American history.

The growth of water infrastructure and storage in the arid western United States necessitated a new era of water governance. Federal legislation, including the Homestead and Reclamation Acts, facilitated the migration west but also introduced a number of issues and complications. Coman (1911), Libecap (1981, 2011), Libecap and Hansen (2002), Hansen and Libecap (2004a, b), McCool (1994), and Rhode (1995), among others, detail these issues and complications.

Hansen and Libecap (2004a) discuss US land policy and show that the Homestead Act of 1862 worked well initially in the northern plains while sufficient precipitation (precipitation without prolonged drought periods) allowed farmers to utilize familiar farming practices on small farms. Although there were warnings (e.g., Powell's call for a minimum of 2560-acre pastoral regions in the arid lands) and proposed bills to change federal policy, these were not considered, and strong sentiment for maintaining the emphasis on small farms remained. The prolonged drought during 1917–1921 was especially difficult for the homestead farmers of the northern plains, and as a result, many small farms failed. The prevalence of 160-acre and 320-acre farms in the region (and as a result a decline in average farm size) was due largely to the policy model and the restrictions imposed by the Homestead Act. Moreover, the prescribed dry farming techniques that called for intense cultivation of small farms (Libecap and Hansen 2002) produced further disastrous results for farmers in arid regions. Hansen and Libecap (2004b) address these externalities and analyze the origins of the great drought of the 1930s, linking the severe drought and wind erosion to the prevalence of small farms created by the Homestead Act (Hansen and Libecap 2004b). Farm size played a major role in contributing to severe wind erosion as well as inhibiting corrective action as most farmers were not operating at productively efficient sizes to adopt wind erosion controls, such as putting a part of their cropland to fallow.

Prior to the development of major water infrastructure in the arid western United States, conflicts between water users were particularly common, and given the limits of in-stream supplies, demand often outpaced supply (Coman 1911). Although the presence of large dams in the region, partially due to the Reclamation Act, enabled

the spatial and temporal transfer of water resources across seasons making agricultural production viable, there were many negative environmental impacts, including the major declines in wild fish stock due to very low water levels in many streams and rivers (Hansen et al. 2014).

As cities grew, urban demands increased, creating the need to move water from distant sources. Technological developments allowed for hydroelectric power. Vast amounts of hydroelectric power fueled an industrial renaissance and electrified the farm, thus allowing agriculture to thrive in areas where even canals and aqueducts could not reach. Erie and Joassart-Marcelli (2000), Libecap (2009), Kitchens and Fishback (2015), Kitchens (2014), Kline and Moretti (2014), Reisner (1986), and Pisani (1984) all reinforce the importance of major water infrastructure in the electrification of the farm and home.

Westward Expansion

Scholars note that many canal openings, such as the Erie Canal in 1825, were viewed as "epoch-making events" – allowing for the growth of many of the larger northwestern cities and their development into centers of global commerce (Turner 1920). With the Appalachian Mountains geographically dividing the Midwestern lands from markets on the eastern seaboard, canals such as the Erie "provided dramatic proof that a canal to the West was both technically feasible and economically profitable" (Ransom 1964, pp. 365). The canals served as the "highway for a new migration" and provided thoroughfares that moved people into the new west and in turn returned the surpluses of the American west – namely, agricultural commodities and raw natural resources – to the urban centers from which they fled (Turner 1920; Rae 1944). The opening of canals in Ohio had a profound (and predictable) impact on commodity prices. The availability of new markets in the east resulted in a two- or threefold increase in prices paid for western agricultural commodities such as timber, wool, pork, wheat, and corn. Nonagricultural mineral commodities such as coal, salt, pig iron, and stone found easy access to eastern market. Similarly, the access to commodities sold by eastern markets resulted in a decline in the cost of finished goods such as pins, coffee, and sugar, as purchased by Ohio residents (Bogart 1913). Some canals, such as the Wabash and Erie Canal in Indiana, stimulated so much migration that the populations of the counties that it served had quintupled in less than 10 years (Rae 1944). Political historians have identified the new American west, at this time, as holding the balance of power and setting the course for future national progress, particularly with regard to the public domain, tariff systems, banking and currency systems, and interstate commerce rules (Turner 1920).

The growing canal system, together with the related growth in railroad access, "gave birth to the cities of Chicago, Milwaukee, St. Paul, and Minneapolis, as well as to a multitude of lesser cities" (Turner 1920, pp. 137). The Sault Ste. Marie Canal in Canada, at that time representing a small fraction of the total distance of water-based and canal traffic for all of the Midwestern commerce, saw more tonnage than

the Suez Canal (Turner 1920). This Great Lakes traffic resulted in the development of several freshwater port cities, such as Chicago, Detroit, Cleveland, and Buffalo, with Chicago recognized by historians as the "metropolis of the Mississippi Valley" (Rae 1944). The growth resulted in a subsequent industrial and commercial revolution in the Great Lakes region after 1866 – "the tonnage doubled; wooden ships gave way to steel; sailing vessels yielded to steam; and huge docks, derricks and elevators, triumphs of mechanical skill, were constructed" (Turner 1920, pp. 150). Similarly, the economic and policy practices such as the fixation of rates by government officials – practices that would eventually be identified with railway management – had their genesis in early canal development and management (Bogart 1913).

Historically, there has been some debate regarding the overarching economic impact of canal investment. Ransom (1964) notes that many economists are quick to point out the indirect and induced effects of canal investments but ignore the fact that the returns from some canals were insufficient to justify the investments that were made in their construction. Cranmer (1960) identifies three distinct cycles in canal investment between 1815 and 1860: a first wave (1815–1831) noted by Cranmer as "canal mania," in which approximately $50 M was spent on both public and private canals that were viewed to be some of the most successful canals constructed in the United States; a second cycle (1832–1844) in which over $70 M was spent on largely public canals; and a third cycle (1845–1860) in which approximately $56 M was spent, ending precipitously at the outset of the Civil War. The first phase of development was intended to serve as main arteries of transportation, whereas the last wave was intended to improve navigation to and from the Great Lakes (Rae 1944).

Ransom (1964) notes that by 1860, approximately 4,250 miles of canal had been constructed in the United States, with a total capital investment of over $190 M, reflected by a number of "spectacular successes... and spectacular failures"(1964, pp. 366). Using benefits estimated based on canal traffic and revenues generated, Ransom identifies approximately 25 canal segments (located in New York, Ohio, Pennsylvania, Indiana, Illinois, Maryland, and Virginia,) representing $102 M in state investment, and divides them into "probably successful" and "probably not successful" in terms of their benefits being greater than the costs of construction. Of the $102 M in state investment, he notes that only $16.3 M of the total was spent on canals that he deemed to be "probably successful." Toward the end of the canal construction boom, he argues that it is undeniable that some canals were worthwhile investments that contributed considerable impetus to growth and increased the efficiency of the larger US economy. However, he is quick to note that in other cases, canal investments were unnecessary – there were too many canals that were competing with one another, perhaps replicating existing low-cost transportation opportunities such as rail, as opposed to opening new avenues of trade between regions. In many parts of the Midwest, freezing winters would shut down canal commerce and transit for many months of the year, making rail the only option for moving goods.

In support of the growing canal system, and to assist in their construction, the federal government provided aid in the form of land grants (Rae 1944). Unlike the development of the rail system, which received a substantial land grant allocation totaling over 130 M acres, the land grants earmarked toward canal development

totaled only about 4.5 M acres (Rae 1944). As the precursors to the rail land grants, canal land granting adopted an alternating section practice, so as to stimulate development along the length of the canal – a practice which was later successfully applied to rail-focused land grants. Given the shorter length and capital intensiveness of the canal system, relative to the rail system, the land grant was viewed as only part of the financial package necessary to fund the canals and was of "slight assistance" (Rae 1944). At the time, there was very little political opposition to the land grants, particularly given the "prudent proprietor" doctrine, which posited that "since completion of the canals would greatly increase the price of the adjoining public land, Congress would simply be making a sound investment if it gave part of its estate away for a purpose that would enhance the value of the remainder" (Rae 1944, pp. 169). In reality, the intent of the land grant was not to fully fund the canal, but rather to "give some aid and encouragement to enterprises that were considered to be of national importance" (Rae 1944, pp. 177).

Canals provided a direct connection between markets in the east and the raw material in the west, stimulated migration, and set the foundation for further western expansion. However, the presence of the canals also opened up existing nearby lands that were inaccessible and/or wilderness (Bogart 1913). In 1845, before the completion of the Miami and Erie Canal, "not a single bushel of grain nor a single barrel of flour or pork was exported," but by 1846, "over 125,000 barrels of flour and almost 2M bushels of grain were sent through the canal to the northern market" (Bogart 1913, pp. 58–59). The first-growth forests of the region were harvested for lumber and sold in eastern markets. Whereas previously wooded areas were cleared by burning, the presence of canal boats made clearing the land and selling the lumber in eastern markets more profitable. In general, however, the development of a canal or rail system did not open up new land, but rather made existing land available where it had been previously inaccessible for commercial production (North 1956).

The development of major water infrastructure energized the US economy, expanded agricultural outputs, increased urbanization and industrialization, and ultimately impacted the standard of living of all Americans (Haines et al. 2003; Chanda et al. 2008). The aggregate of the impacts resulted in a complex, often counterintuitive, outcome. Throughout the nineteenth century, as the major water infrastructure of the nation was being developed, the human health of the nation was at first heterogeneous but eventually became more homogeneous, converging toward a steady state. Access to clean water and improved sanitation eventually increased personal hygiene and thus the quality of life; access to more varied food sources, at a lower cost, of a higher quality and the ability to refrigerate foodstuffs increased the quality of life. However, urbanization and industrialization had negative impacts on the quality of life as well. Improved transportation served as a vector for disease transmission, and as cities grew, with their inhabitants often working long hours inside factories, people "lived closer together and were exposed to a larger set of diseases" (Chanda et al. 2008, pp. 23). Haines et al. (2003, pp. 409) find that "being born in a county with water transport connections in 1840 also is consistent with both a contagion and a commercialization view. The result that farmers were taller and that laborers were shorter is also supportive of these rural-urban effects."

The Development of the Urban West: Mining to Agriculture

By the middle of the nineteenth century, although the mining boom in California was in full swing, agricultural development was still in its infancy, with many agricultural commodities still being shipped in from Europe and Asia (Pisani 1984). This would not last for long, as the skills that the miners acquired in building the vast mining waterworks that were used to extract precious metals from the mountain were eventually applied to building agricultural and municipal water infrastructure. Pisani (1984) notes that by 1867, the mining industry had constructed over 300 individual ditch systems across a total of 6,000 miles. Although many of these systems still remain, it wasn't the infrastructure itself that would drive agricultural development in California, but rather the skills that were developed – the ability to design and construct irrigation works and water systems and the adaptation of mining tool fabrication processes to agricultural and industrial machinery.

Although the mining boom in California was fleeting, the growth of its agricultural industry would persist, starting with an agricultural boom in the 1860s and 1870s that mirrored the mining boom of the 1840s and 1850s. Pisani (1984) notes that by 1870 the number of miners in California had fallen from a peak of 83,000, 10 years earlier, to a mere 36,000. Conversely, over this same time span, the number of farmers more than doubled from 20,000 to 48,000, and the acreage of wheat farmland more than quadrupled. The growth in demand for agricultural products spurred a demand for the delivery of water resources. By the end of the 1860s, there was only a single canal, aqueduct, or dam in California; over the next decade, nearly two dozen more would be constructed (Pisani 1984). By the turn of the twenty-first century, California would be carpeted with over 1,200 major reservoirs, and almost every major river in the state would be dammed, some more than 14 times (Reisner 1986).

Migration west after the Civil War saw the number of farms, and the total population of California increase by nearly 50% throughout the 1870s. Whereas, in the early years of the agricultural boom, many farmers were planting forage crops and cereals, by the turn of the twentieth century, the plantings had changed – vegetables, grapes, citrus, and orchards were the norm, which in turn demanded additional water resources and infrastructure. By the late 1870s, only 200,000 acres of farmland in California were irrigated, but a mere 10 years later, the irrigated acreage had increased by 500% (Pisani 1984).

The Development of Agriculture and Water Infrastructure in the Arid West

Water rights laws and major water infrastructure in the arid western United States have long gone hand-in-hand and are reflective of the close relationship between the land and water. This land-water relationship has been an essential attribute of westward expansion since at least the middle of the nineteenth century, when most of the land in the western states and territories was still in the public domain and homesteading was a major policy emphasis (Hibbard 1924). Unfortunately, the

Homestead Act of 1862, which was well designed for the humid lands located east of the 100th meridian, did not fit well with the arid conditions of the west (Xu et al. 2014). The western agricultural landscape boasts some of the most arid and rugged terrain in the continental United States. Agricultural lands in the arid western United States exhibit tremendous heterogeneity in topography, climate, soil types, and water resources, and for much of the arid west, melting snowpack comprises a majority of the agricultural water supply that is available during the growing season (Brosnan 1918; Hansen et al. 2011, 2014). Unlike farming in the east, which could rely on rain-fed, seasonal irrigation, agriculture in the western United States is entirely reliant on man-made irrigation and therefore is much more subject to the influence of the water infrastructure and water rights institutions where it is located.

Thomas Jefferson defined the dominant focus of US land policy as small, family farms when he claimed: "The earth is given as a common stock for man to labor and live on...(T)he small landholders are the most precious part of the state" (Hibbard 1924). US land policy, which began with the Land Ordinances of 1785 and 1787 that called for the orderly, systematic distribution of federal property to private claimants, continued with the Homestead Acts and between 1862 and 1935 became a period of major federal land dispersal (Gates 1979; Robbins 1942). The Homestead Act of 1862 allowed any family head to claim federal land between 40 and 160 acres and to receive title after satisfying the continuous residence and improvement requirement. The Homestead Act was modified in 1909 to increase the claims of land to 320 acres and again in 1912 to change residency requirement to 3 years. Moreover, the required fees and commissions under the law were adjusted. Following the Homestead Act, the Timber Culture Act, which granted 160 acres if settlers planted 40 acres of trees, was repealed in 1891 (Gates 1979). Hansen and Libecap (2004a) argue that the Homestead Act, the most commonly used law to claim federal lands, worked well initially, east of the 98th meridian, as the "familiar conditions" in soil quality and sufficient precipitation allowed farmers to transplant existing farming practices and knowledge. However, conditions were quite different in the Great Plains (Hansen and Libecap 2004a). Although John Wesley Powell made a warning in his "Report on the Lands of the Arid Region of the United States" to Congress in 1879 that arid lands necessitated new agricultural methods and called for a minimum of 2,560-acre homesteads for "pastoral regions" and proposed bills to change federal policy, these were not considered, and no significant modifications to land policy were implemented. The strong sentiment for maintaining the emphasis on small farms remained as illustrated by the statement of Representative George W. Julian of Indiana:

> If our institutions are to be preserved, we must insist upon the policy of small farms, thrifty villages, compact settlements, free schools, and equality of political rights, instead of large estates, slovenly agriculture, wide-scattered settlements, popular ignorance and a pampered aristocracy lording it over the people. This is the overshadowing question of American politics. Worster (2002)

Libecap and Hansen (2002) explain that at the time, there wasn't any scientific or experiential knowledge to support Powell's claim. Their view is that the science

was inconclusive to support the politically controversial modifications in federal land policy. Thus, they analyze the weather information problem in the Great Plains and show that the absence of knowledge about the region's climate combined with the positive experience of homestead farms during wet periods, which corresponded with major settlement in the northern plains, led to optimism. The rise of folk theories to explain the weather "rain follows the plow," which held that precipitation would increase with cultivation, and the pseudoscientific prescriptions for farming practices "dry farming doctrine," which explained how the use of tillage would solve or alleviate the problems with drought, were readily accepted (Libecap and Hansen 2002).

A more accurate understanding of the region's climate and the implications for small farms only emerged when the 1917–1921 drought was particularly hard on farmers. Prior to the 1917–1921 drought, optimism among farmers and western politicians was common, and Powell's suggested distributions, which were 16 times the size of existing allocations, were considered extreme, and it was commonly believed that they would drastically reduce the number of farmers that could settle in the region. Politicians, however, wanted to increase the number of farmers (and hence the population) in their jurisdictions in order to encourage economic development and therefore supported the existing land policies. As Representative Thomas Patterson of Colorado explained: ". . .our agricultural lands. . . are limited, and the number of our population following agricultural pursuits must also be limited. But to have that number as great as possible, to swell it to its maximum," the 160-acre homestead must not be exceeded (Patterson 1879 as quoted in Hansen and Libecap 2004a). In addition, a greater population expedited the territorial progress to statehood and increased the chance of having more voting members in the US House of Representatives. Thus, western politicians, including the territorial delegates, strongly opposed any major changes in the size of plots, and the Homestead Act remained generally unmodified except for a few minor changes, including the 1909 Enlarged Homestead Act that increased the claims of land to 320 acres. These 320-acre plots were still far smaller than those suggested by Powell, and subsequent events would reveal that they also were too small for long-term survival on the Great Plains.

A more complete analysis of the origins of the Dust Bowl of the 1930s, one of the most severe environmental disasters in North America, links this severe drought and wind erosion to the prevalence of small farms created by the Homestead Act (Hansen and Libecap 2004b). This analysis emphasizes the important role that farm size played in contributing to severe wind erosion as well as inhibiting corrective action. Most farmers were not operating at productively efficient sizes to adopt wind erosion control, such as putting a part of cropland to fallow. Larger farms had greater shares of fallow, and erosion was more severe in those Great Plains counties where cultivation shares were greater (Hansen and Libecap 2004b). Soil conservation districts, which could be as large as 600,000 acres, helped coordinate erosion control as farmers within districts entered into regulatory contracts. These regulations, combined with the gradual consolidation of farms, led to changes in cultivation practices that better protected the soil. Thus, when droughts affected

the Great Plains in the 1950 and 1970s, the region was less vulnerable to wind erosion. Nace and Pluhowski (1965) report that while the 1950s drought was at least as severe as that of the 1930s, the wind erosion in the 1930s happened to be much more extensive and damaging.

The homesteading led to a decline in average farm size in the Great Plains as the settlers claimed and subdivided the land that had been previously occupied by very large ranches. Under the federal land laws, ranchers could not obtain title to these large plots, and many were broken up as the homesteaders arrived (Libecap 1981; Dennen 1976; Fletcher 1960). For example, in Fergus County, Montana, in 1904, prior to major homestead migration to the northern plains, there were 472 farms or ranches with an average size of 1,300 acres. By 1916, however, the number of farms had grown by over eightfold to 3,843, and average farm size had fallen to 322 acres, a decline of 75% (Libecap and Hansen 2002).

Indeed, homestead settlement led to the proliferation of small farms throughout the Great Plains. Over one million original homestead entries were filed for 202,298,425 acres in western Kansas, Nebraska, the Dakotas, eastern Colorado, and Montana between 1880 and 1925 (U.S. Department of Interior, General Land Office, Annual Reports of the Commissioner). Most farms were 160 acres, although the average homestead sizes larger than that were due to the 1909, 320-acre Homestead law. The prevalence of 160-acre and 320-acre farms was due largely to the model and restrictions of the Homestead Act. Indeed, the dry farming techniques prescribed by the USDA extension service and experiment stations from the region's land grant colleges prior to 1917 called for intense cultivation of small farms of 160 or 320 acres (Libecap and Hansen 2002).

As mining opportunities and homesteading opportunities drew settlers west, those same miners and the earlier Mormon settlers from Utah (Coman 1911; Xu et al. 2014) heavily influenced the agricultural landscape in much of the arid western United States. In the arid northwestern United States for much of the nineteenth century, the only convenient water sources were located in close proximity to the riparian corridors; therefore early settlements rarely veered far from the major waterways. With the development of the Oregon Short Line Railroad in the 1880s, and major water infrastructure developments in the early twentieth century, settlements began to extend further away from the riparian corridors (Brosnan 1918).

A number of federal laws including the Carey Act (1894) and the Reclamation Act (1902) promoted the major water infrastructure projects in the arid western United States. The Carey Act encouraged private investment in water infrastructure and allowed for the private capture of profits from water sales (Xu et al. 2014). Unlike the Carey Act, which focused on private investments in major water infrastructure, the Reclamation Act provided federally subsidized funding for major water infrastructure projects in the arid western states and required the establishment of local water supply organizations to govern the use and distribution of water resources. These major water infrastructure projects profoundly transformed the agricultural landscape of the western states (Coman 1911; Hansen et al. 2011).

All told, the Reclamation Act authorized the development of hundreds of major water infrastructure projects, which were spread across the seventeen western states. With tens of billions in federal investment, Reclamation Act projects provide water resources to industrial, agricultural, and domestic users and hydroelectric resources for millions of those same users (Pisani 2002; Hansen et al. 2011). One of the primary goals of reclamation was to transform water resources into commodities that could be bought and sold (Pisani 2002). While the primary motivation for the Reclamation Act was to provide agricultural water, the water infrastructure provided a number of secondary benefits, including flood, tailings and debris control, fire protection, recreation, and navigation, among others (Hansen et al. 2011). Many of the projects that the Reclamation Act funded were financed through a Reclamation Fund, which was in turn financed through a cost-sharing agreement between the federal government and the local water supply organizations and through the sale of public lands (Pisani 2002). Immediately after the passing of the Reclamation Act, the federal government set aside some 40 million acres of public lands from use – including 1.5 million acres in Colorado, 2.7 million acres in California, 3.7 million acres in Idaho, 4.4 million acres in Nevada, and 8.5 million acres in Montana (Pisani 2002). The land that was "locked up" by the federal government through the Reclamation Act included many of the best reservoir sites and much of the publicly owned acreage that adjoined streams (Pisani 2002).

Over time, Hansen et al. (2011) find that the investments made by the federal government in the arid western states produced dividends. Those arid western counties with major water infrastructure were better able to deal with climatic variability, having more predictable agricultural production and fewer crop failures. The presence of major water infrastructure was particularly valuable during the regular drought or flooding events, when farms with access to major water infrastructure planted more acreage, of a higher value, with a greater harvest and fewer losses, than farms without access to a stable supply of water (Hansen et al. 2011, 2014).

Prior to the development of major water infrastructure in the arid western United States, conflicts between water users were common, and given the limits of in-stream supplies, demand often outpaced supply (Coman 1911). The riparian-based water laws that worked in the humid east, where water supplies were more plentiful and rarely were a binding constraint, did not work in the arid west. As settlements increased, population levels expanded, and large-scale agricultural practices replaced subsistence farming, a different rule of water law was needed. At the state level, in much of the arid west, appropriative-based water laws and rights were developed in order to establish and enforce the general rules of water use and to provide a mechanism for water distribution and ownership (Xu et al. 2014). These state-level rules of water law, many of which were being established at the same time that the territories were transitioning into statehood, and at a time when much of the nonirrigated land was still in the public domain, were profoundly influenced by earlier legislation. For example, the Desert Land Act (1877) set the stage for the wording of future appropriation legislation by requiring the identification of beneficial use and the documentation of the first date of use or prior appropriation

(Xu et al. 2014). However, because of the nature of the water right, which often includes a place of use and a point of diversion from the riparian corridor, these water rights introduce barriers to trade that can limit the transferability of water and therefore may result in economic inefficiencies (Xu et al. 2014).

Water is a scarce resource in most regions, which is especially true in the western United States. The economic development of the west mostly followed the possession of and the ability to use water. Competition and conflict over water was common both for American Indians and non-Indian settlers (McCool 1994). Although the case of *Winters v. United States* (also known as the Reserved Rights Doctrine) of 1908 established that the federal government implicitly reserved the water rights of reservation lands, western states adopted water codes and policies that allocated water rights on the basis of priority of beneficial use (McCool 1994). Prior appropriation – first in time, first in right principle, which was also used to settle disputes in many natural resources, such as grazing rights and land use – became the legal principle applied to water use in the arid west, defining the development of the agriculture in the region (Pisani 1996). It has been argued that without prior appropriation, the capital needed to build dams and irrigation canals to transform the west into an agricultural region could not have been raised. Although the Reclamation Act of 1902 gave the authority and job of building irrigation projects to the federal government, private capital was used to reclaim most of the irrigated land in the west, and only about one in four irrigated acres used water provided by federally developed projects in the 1980s (Pisani 1996). Moreover, although westerners might have expected the federal government to foster the development of major irrigation projects, most (miners in California, western politicians, developers, and farmers) favored local control over water, where the administration of water rights were best left to individuals organized in irrigation districts (Pisani 1996; Worster 1985).

Utilization of prior appropriation in the western water allocation should not be considered only as a by-product, or the result, of its arid climate, as was first asserted by Walter Prescott Webb, since economic needs and conditions of the region were instrumental in shaping the water rights institutions in the western United States (Dunbar 1983; Webb 1931). Aridity in the west was a crucial limiting factor in the development of western agriculture, but the principle of prior appropriation was first considered in court cases regarding water use in mining in California. In mid-nineteenth-century California, prior appropriation allowed miners on the public lands to have the priority rights both in mineral claims and water with first possession or beneficial use (Pisani 1996). Thus, in some western states and territories, including California and Montana, the principle of prior appropriation was not intended to apply to agricultural lands initially. By the time the Desert Land Act was enacted in 1877, however, lawmakers formally recognized the rights of settlers to use water through the public lands for agriculture and other uses under the prior appropriation rules and procedures.

The Reclamation Act of 1902 was the culmination of a long political struggle to have the federal government help build major water infrastructures in the arid west. Although many westerners wanted federal funds for the irrigation projects, they did

not want the federal control. The result was an act that was a compromise of federal funds and state control with prior appropriation laws. The reclamation iron triangle began to develop in 1889 with the creation of the Committee on Irrigation of Arid Lands in both congress and the states, even before the Act of 1902 (McCool 1994). This committee was made up of mostly pro-irrigation westerners well known for their regional emphasis and bias. Reclamation interests were also successful in sponsoring legislation through the Appropriations Committee, especially due to the chairmanship of Senator Carl Hayden of Arizona, who began serving on the Committee in 1928, became the chair in 1953, and served as the chair until his retirement in 1969 (McCool 1994). Among the many reclamation projects that Senator Hayden won for the west was the Central Arizona Project.

The decision-making process explaining the background and building of the Teton Dam in Idaho is a memorable example of the iron triangle of stakeholders, including interest groups, congressmen, and agencies working together as described by Engstrom (1976) soon after its collapse. To gain support for the Teton Dam project, its major advocates (the Bureau of Reclamation and the Fremont-Madison Irrigation District, represented by Mr. Willis Walker,) provided a significant quantity of favorable expert testimony to Congress and congressional committees and pushed for the building of the dam. These advocates wanted a multipurpose dam with flood, irrigation, and hydroelectric power production purposes. Although flood control was not the major purpose of the dam, the floods in the spring of 1962 and 1963 helped establish the need for a dam on the Teton River. The Army Corps of Engineers, which was also interested in the construction of a dam on the river, however, ruled it out after studying the feasibility of a levee system to help control the spring floods in 1955 (Engstrom 1976).

Since many farmers had "natural flow" water rights on the Teton River, the upstream users could only divert the surplus water after priority water rights were used. Thus, when the dam was built, it could not legally be filled with water unless the runoff was high. Thus, a plan was developed to put in a system of underground wells and pump water from the ground to the surface and into the river to meet the downstream water requirements. The plan called for 100 wells, with an estimated cost of $3,680,000 (Engstrom 1976). The storage was to provide supplemental irrigation water for approximately 114,000 acres in the Fremont-Madison Irrigation District. Phase II of the project was to provide water to 37,000 new acres of land carried by a 30-mile pump canal and 28-mile gravity canal. However, these benefits likely were overestimates, since 3 to 3.5 acre-feet of water could be sufficient to produce crops in the region and 87,000 of 111,000 acres already received an average of 11 acre-feet of water per acre of irrigated land (Engstrom 1976). Unfortunately, after the construction of Phase I was completed early in 1976, the dam was about 70% filled when the north side ruptured and collapsed, flooding the valley all the way to the American Falls Reservoir, killing 11 people and injuring hundreds.

As major water storage infrastructure was developed in the arid west, the water rights institutions within which they operated, in some cases, exacerbated the water distribution situation. For example, many of the storage water rights that are maintained at a great distance from the farms that utilize the water resources utilize

existing riparian corridors to deliver the water resources. Therefore, a detailed knowledge of the river dynamics, taking into account losses from evaporation and groundwater recharge in addition to the ability to translate volumes of storage into dynamic flow measures, is necessary. Similarly, the electrification of the farm and the ability to tap into deepwater wells (which can be hydrologically connected to surface water sources) require a unified water rights system (Xu et al. 2014).

Although the direct (consumptive) impacts of the development of major water infrastructure in the arid western United States tended to be positive, the nonmarket impacts were most certainly negative. The presence of large storage dams, which enabled the spatial and temporal transfer of water resources across seasons, resulted in reductions in water available for ecosystem use and increased the intra-seasonal volatility in water deliveries (Hansen et al. 2014). Particularly in drought years, many streams and rivers in the arid western United States are dewatered for much of the year, reducing the opportunity for anadromous fish migration; this is particularly true for rivers in which the main channel is dammed. These rivers have seen major declines in wild fish stocks throughout the twentieth century (Hansen et al. 2014).

Rhode (1995) analyzes both the demand and supply forces that influenced the intensification of California agriculture from 1890 to 1914. There is a range of explanations for the transformation of California agriculture from extensive to intensive products, such as fruits. These explanations include improvements and changes in transportation with the completion of the transcontinental railroad, the spread of irrigation, and changes in labor market conditions with the increased availability of labor. Rhode, in his systematic investigation of economic forces to explain the shifts in California agriculture, finds that traditional literature overstates the relative importance of the transcontinental railroad in the transformation of California agriculture and instead finds falling interest rates due to decreasing scarcity of capital as well as advances in biological knowledge that resulted in increases in productivity to be relatively important supply-side forces in this transformation.

The Development of the Urban West: Agriculture to Urban Growth

Whereas canals and major water infrastructure in the eastern part of the United States used water resources as a capital input more akin to a technological input, for users in the arid west, water was a raw material input to production. In most cases, and in the whole of the arid western United States, water resources are the constraining input – there has always been far more land available to be irrigated than there is irrigation water available. Similarly, for many of the major metropolitan areas in the arid western United States, major water infrastructure enabled population growth and provides the water needed for urban, commercial, and industrial development. Examples include the greater Sacramento, Los Angeles, San Diego, Las Vegas, and

Phoenix areas, which are home to nearly 10% of the total US population, and all of which receive less than 15 in. of precipitation per year.

The practice of importing vast quantities of water from distant sources in order to meet the consumptive demands of a burgeoning urban population was pioneered several millennia earlier by the Romans. Even in the arid southwestern United States, as recently as 1400 AD, the Hohokam civilization moved water dozens of miles in order to irrigate the desert (Reisner 1986). However, unlike the Romans and Hohokam, who relied on gravity to move the water from a relatively nearby source to site, many of the aqueducts that supply water in the arid western United States rely on costly pumping plants and move the water resources across elevational gradients, over many hundreds of miles. The City of Los Angeles "pioneered" the practice of importing water from a great distance – drawing water from the Colorado River, San Joaquin Delta, and Owens Valley. The Metropolitan Water District of Southern California, founded in 1928, serves more people, over a broader area, than any other water district in the United States. Without the availability of imported water, the existing local sources would only meet the needs of a small fraction of the total population (Erie and Joassart-Marcelli 2000).

In September of 1905, the City of Los Angeles issued and approved a $23 M (approximately $500 M in 2018 dollars) bond to build an aqueduct to deliver water to Los Angeles from Owens Valley, some 223 miles away (Reisner 1986). At the time, Owens Valley, which was agriculturally dominated, had vast water resources but very little agricultural potential – the volume of arable land was limited, the soil quality was poor, the growing season was short, and the cost of transporting agricultural commodities to market was steep (Libecap 2009). The aqueduct itself would take 6 years and upward of 6,000 people to build and in the process would result in 53 miles of tunnels, 120 miles of railroad track, 170 miles of electric transmission lines, and 500 miles of roads and trails (Reisner 1986). Surprisingly, in the early years, the aqueduct produced very little water for Los Angeles, with the lion's share being delivered to higher-valued agricultural fields in the San Fernando Valley instead (Reisner 1986). In terms of total volume, by 1920 the Owens Valley watershed, via the Los Angeles Aqueduct, supplied four times as much water to Los Angeles as the Los Angeles River supplied (Libecap 2009). By 1930 (from 1900), property values in Los Angeles County had increased by 4408% but by only 917% in Inyo County, home to Owens Valley (Libecap 2009). This disparity is reflected in the current marginal value of water for agricultural uses ($15–$25 per acre-foot) when compared to urban uses (over $500 per acre-foot) (Libecap 2009).

Further north in the San Francisco Bay Area, the San Francisco Board of Supervisors, having already experienced a massive population surge during the mining boom of the mid-1800s, was interested in securing a long-range water source to meet the growing needs of the city (Starr 1996). This need was only amplified after the 1906 earthquake and major fire, which destroyed much of the city and led to calls for a high-pressure water system to prevent any future recurrences (Starr 1996). Over 150 miles away in the Sierra Nevada Mountains and, more significantly, entirely within the confines of Yosemite National Park, the supervisors identified the

Hetch Hetchy Valley as the best site to build a reservoir on the Tuolumne River. After years of politicking, in 1923 the O'Shaughnessy Dam was completed – the second highest dam in the United States. It required 500 men and 3 years to complete (Starr 1996). Eleven years and $100 M later, the Tuolumne River waters arrived in San Francisco. All told, the Hetch Hetchy complex would encompass five major reservoirs, four dams, several hydroelectric facilities, and hundreds of miles of tunnels and pipeline (Starr 1996).

Until 1941, the water resources delivered to Los Angeles from the Owens Valley were the only sources of imported water (Libecap 2009). With a growing population, alternative sources were needed. The Colorado River Aqueduct and Storage Project, a $220 M project funded largely by property taxes, was completed in 1941. It supplied the greater Los Angeles area with two thirds of the power that it produced and over four million acre-feet of water (Reisner 1986). Unlike the earlier Owens Valley project, which was gravity fed, Colorado River water brought with it costly pumping requirements due to the need to move the water over great mountain ranges and across great distances (Erie and Joassart-Marcelli 2000). Hoover Dam "had been built to safeguard the future of the entire Southwest" and served as an example to all of the other states and countries that aspired to build truly massive water storage dams. The Colorado River, which the Hoover impedes, is not a huge river, ranking just outside of the top 25 in the United States in terms of total flow (Reisner 1986, pp. 257).

The California Water Plan, which had its genesis in the 1950s, presented a proposal for what would become the largest water project ever built by a state or local government (Reisner 1986). Previous water systems, such as New York's Catskill Aqueduct or the Delaware Aqueduct System, which was completed during the Second World War and included 85 miles of underground tunnels, would be dwarfed in comparison with what was proposed in the California Water Plan. The California Plan, when compared to the Catskill Aqueduct that delivered water to New York City, would deliver four times the water over six times the distance (Reisner 1986). Unlike the Colorado River Aqueduct, the State Water Project, which includes the California Aqueduct and a number of smaller branch aqueducts and canals, was funded by water sales, as opposed to taxes (Erie and Joassart-Marcelli 2000). This is primarily because the water collection and distribution network is spread across the state, with dozens of dams and hundreds of miles of canals, tunnels, and pipelines.

The Electrification of the City and Farm

In the early 1930s, the Pacific Northwest region of the United States only had three million residents, over half of whom lived in rural communities. Of the rural population, over 70% had no access to electricity (Reisner 1986). Reisner (1986) notes that prior to 1933 the Columbia River didn't possess a single dam; by the mid-1970s, the main stem of the Columbia and its tributaries possessed 36 great dams, including 13 "tremendous dams" such as the Grand Coulee, Bonneville, John

Day, and Hells Canyon. As the Grand Coulee filled in the early 1930s, very little of its available hydroelectric power was utilized, which was due largely to the construction of the Bonneville Dam downriver (Reisner 1986). However, by the early 1940s, with wars raging in the Pacific and European theaters, over 90% of the hydroelectric power being produced by the Grand Coulee and Bonneville was going toward defense industries and processing the aluminum needed for weapons and airplanes (Reisner 1986). Reisner (1986, pp. 164) noted "the Axis powers were no match for two things: the Russian winters, and an American hydroelectric capacity that could turn out sixty thousand aircraft in four years." Later, the Grand Coulee would provide inexpensive power to the burgeoning aerospace industry and would help to provide the electricity that was needed to develop the Hanford nuclear production facilities. To say that the Grand Coulee was a large dam was off considerably; according to Reisner (1986, pp. 159) "Hoover was big; Shasta was half again as big; Grand Coulee was bigger than both of them together." The Grand Coulee was the largest dam in the world, both in the total mass of 10.5 million cubic yards of concrete and the crest length of nearly a mile, requiring 130 million board feet of lumber to build. The city that arose to support the workers had more bars and brothels within a 5-mile radius than any other area in the world (Reisner 1986).

The impact of the Rural Electrification Administration (REA), in tandem with the availability of relatively inexpensive hydroelectric power, brought electricity to rural farms and significantly increased crop productivity, output, and land values (Kitchens and Fishback 2015). The dams themselves not only provided flood control and water for irrigation but also increased the economic potential of farms at a distance from riparian water sources by providing electricity that could be used to pump groundwater and process agricultural commodities. Pisani (2002, pp. 204) estimates that the electrification of the farm "added 10 million acres of bench and mesa land into the West's supply of irrigable land." It is difficult to disentangle the REA benefits from the benefits that arose from the major water infrastructure complexes (Kitchens 2014). From the early years of the Reclamation Act, hydroelectric power was seen as a resource that would "revive and expand old industries as well as create new ones" (Pisani 2002, pp. 203). Given the sheer landmass of the arid west, its scattered population, and rugged terrain, a rail system built on electricity as opposed to coal made tremendous sense. Electric rail was believed to be "cheaper, faster, more efficient, and less vulnerable to cold weather and mechanical breakdown than steam-powered trains" (Pisani 2002, pp. 204).

By the early 1940s, many of the nation's largest hydroelectric dams and complexes were completed – including the Grand Coulee, Hoover, and the Wilson and Norris Dams under the Tennessee Valley Authority (TVA). In the early 1930s, farming accounted for only 2.6% of all electricity consumed; by 1940, rural farm electrification had increased by 230% (Kitchens and Fishback 2015). As with most hydroelectric projects, the areas that receive the hydroelectric-produced electricity have some of the lowest, if not the lowest, electricity rates in the country (Kitchens 2014). This is certainly true of the TVA, which included a series of canals, roads, flood control systems, reservoirs, and dams (currently 29 hydroelectric dams) that provided hydroelectricity to many farms and homes that previously didn't have

access to electricity, as well as a broad array of co-benefits such as flood control and navigation improvements (Kline and Moretti 2014; Kitchens 2014). The TVA provided electricity to seven southeastern states, and although the short-term, aggregate economic impacts from the electrification that the TVA did provide, relative to its costs, aren't substantial, the aggregate infrastructure investments, flood protection, and transportation safety resulted in "the model intervention for any nation that sought to develop its water resources" (Kitchens 2014, pp. 390). The fact that the TVA was a place-based investment raises the fear that any localized benefits may be offset by losses elsewhere in the United States (Kline and Moretti 2014). However, over the long run, Kline and Moretti (2014) found that the net present value of the benefits from the TVA is on the order of $6.5–19.2 billion, with notable industrialization and the creation of manufacturing employment opportunities and high-paying manufacturing jobs. Overall, there were minimal indirect effects from the TVA, but the lion's share of the national direct impact, which was an increase in productivity of the domestic manufacturing sector by a third of a percent between 1940 and 1960, came directly from the investments in public infrastructure (Kline and Moretti 2014).

Concluding Thoughts

Water and water management are complex economic resources that have resulted in equally complex physical infrastructure, institutions, and governance. In the history of the US west and western migration, we argue that no natural resource has impacted the economy more than water and the infrastructure and governance that it promoted. The major water infrastructures of the west – dams, canals, and aqueducts – that crisscross the arid land have facilitated this migration by storing, elevating, and transporting water resources. Water in the arid west is *the* constraining input to growth, so major water works and infrastructure were needed in order to provide storage and to allow humankind to reclaim the desert. Federal legislation, including the Homestead and Reclamation Acts, encouraged and facilitated this migration. The institutions that developed in tandem with mining, agricultural, and urban water demand in the arid west bore little resemblance to the riparian water governance of the east. As cities grew in the arid west, urban demands increased, and technological innovations allowed the vast stored water resources to simultaneously create hydroelectric power, which fueled an industrial renaissance and electrified the farm.

In the age of heightened climate variability, major water infrastructure continues to play an important role in mitigating the potential impacts of floods and droughts (Hansen et al. 2011). Greater historical perspective, strengthened by the quantitative approach to economic history, i.e., cliometric research, has been essential in providing insights for the current debate about the effects of climate change and climate variability and how best to respond to it. The expansion of agriculture west of the 100th meridian during nineteenth and twentieth centuries in North America encountered climatic variability that was not predicted or previously experienced

(Olmstead and Rhode 2008). Thus, historical analyses of how those variable climatic conditions were addressed in the past can and will provide valuable information for addressing heightened climatic variability and it impacts. For example, Hansen et al. (2011) show the significant impact of water infrastructure and water management on crop mixes, fallow practices, and agricultural production in the western United States using large-scale, comprehensive data, such as county-level water infrastructure data that is spatially linked to topographic characteristics, historical climate data, and historical agricultural data during the twentieth century. In addition to examining the agricultural land use and crop productivity benefits of water storage infrastructure, the literature has addressed some of the potential ecosystem impacts, such as low levels of stream flow and water supply variability that may have been exacerbated by the water supply infrastructure and water rights governance in Idaho using cliometric techniques and exploiting the long-term patterns of water transfers between cold and warm seasons (Hansen et al. 2014). This more comprehensive and quantitative way to evaluate the long-term impacts of water infrastructure development and its management on agriculture and natural ecosystems in the semiarid regions will continue to help illuminate the debate on the trade-off between the agricultural benefits and ecological impacts and lead to a set of more balanced policies in the future (Hansen et al. 2011). Comparative analyses of crop mixes and agricultural yields, hedonic analyses of the impact of water infrastructure on property values and recreational use values, and estimates of the value of the hydroelectric power that dams provide do not capture their true impacts, and such analyses require better understanding and the incorporation of institutional responses and more rigorous econometric analysis with a longer time frame (Libecap 2011; Hansen et al. 2011). The institutions that emerged in response to the agricultural needs in semiarid regions of the United States are still here today and play a key role in today's water markets by raising the costs of reallocating water to higher-valued uses (Libecap 2011). Prior appropriation and governance of water rights systems provided framework for water allocation, use, and investment, and this framework continues to impact the contemporary use and allocation of water in response to new urbanization and environmental, industrial, and agricultural demands (Leonard and Libecap 2017).

The hydroelectric power enabled by the major water infrastructure provides a renewable and sustainable, carbon-neutral, inexpensive electricity production technology when compared to nonrenewable coal- or natural gas-based electricity technologies. Over a third of the US population lives in states at, or west of, the 100th meridian that also comprise a majority of the food-producing capacity in the United States. However, whereas in the past the focus was on constructing major water storage and transportation infrastructure, looking forward, much of the focus has been on decommissioning and removing this same infrastructure. Environmental awareness and a returned focus on the in-stream values of wild-flowing water, including recreational uses, first foods, and the survival of endangered and threatened native species, have elevated this conversation. Far more dams have been decommissioned than constructed since the last major dams were proposed in the late 1960s and early 1970s (Pisani 2002). In fact, much of the new major water

infrastructure that has been proposed is focused more on rehabilitating the aging inventory of major dams, adding hydroelectric production capabilities to those that lack it, moving water resources away from the major dams, providing alternatives for migrating fish species, and raising the height of existing dams so as to provide storage for additional water resources. As climate-driven conversations emphasize the need for sustainable energy resources, and nonconsumptive uses exert more influence on water management decisions in the arid western United States, the contributions of cliometricians, in an attempt to better understand how we have arrived at the constrained situations that we find ourselves in today, are essential components of the discussion.

Early Capital Markets

Ann M. Carlos and Stephen Quinn

Contents

Abstract

Capital markets before 1750 created enduring ways to fund risky, long-term, large-scale investments. Demand for capital was driven by the expansion of long-distance trade and by conflict between fiscal states. Supply responded with experimentation in political structures, in legal environments, in how firms initially raised funds, and in how investors resold securities. Improvements in these structures allowed investors to better protect their claims against the information and incentive problems inherent in long-term commitments. As a result, more investors could and did participate. Notable innovations such as the

Dutch and English East India Companies and the British national debt had a strong influence on the subsequent era of industrialization by demonstrating how to arrange deep secondary markets for equities and bonds.

Keywords
Early modern capital markets · Equity and debt · Joint-Stock companies · Sovereign debt

Introduction

A capital market is a market where buyers and sellers trade in securities such as equities and bonds. Such markets help channel surplus funds from savers to institutions with a demand for long-term investment funds. The capital market consists of primary markets, which deal in the new issue of stocks and bonds, and secondary markets, which provide liquidity for those holding securities through the resale of existing securities. In this chapter we lay out the foundation of this market. Most firms before 1800 were small, and most "early capital" was self-funded within those small firms, but there were major exceptions that drove a demand for external and long-term funding. Examples are long-distance trade, transportation, war, and the military.

This chapter focuses on the development into what we consider today as the modern capital market. The chapter proceeds by defining terms and setting out the basic challenges facing that development. Successes, and failures, are then considered. The chapter concludes by noting how this development created funding technologies put to great use during the nineteenth century.

Concepts

Businesses, even small businesses, need some combination of land, buildings, infrastructure, ships, equipment, and raw materials. Such expenditures commit large sums for long periods with uncertain returns. In the context discussed in this chapter, capital refers to a long-term investment in a business where profits often take years to arrive and at levels hard to foresee. The simplest example is the sole proprietor nurturing a fledgling business with her own time and money. She alone is balancing a variety of incentives because she has invested her own money; she controls decisions, and she will receive eventual profits or losses. As the sole proprietor, she internalizes the nexus of firm-specific trade-offs. At the same time, her entrepreneurial capacities limit the scale of operation. Even if she has the skills to expand, she may prefer not to concentrate too much of her wealth into one endeavor. Capital markets begin when she invites others to make a long-term commitment to her enterprise (Guinnane et al. 2007).

For outsiders, capital investment in someone else's enterprise is perilous. The incumbent owner obviously knows more about the firm than investors do, and her goal might be to take advantage of the less well informed. To paraphrase the famous lemons problem, if the entrepreneur knows the enterprise has poor prospects, she might want to sell out, and she might misrepresent to do so (Akerlof 1970). If such behavior is common, then investors will assume most opportunities are poor, and, as a result, quality opportunities struggle to find funding on agreeable terms. So to encourage a market for capital investment in situations rife with asymmetric information, owners need ways to signal quality, and investors need ways to screen prospects. One method is to share active ownership though partnerships. The new partners gain access to inside information and participate in governance, while the original owner remains invested in ongoing success. Another method is for the owner to borrow. Lenders gain a schedule of interest payments and principal repayment while the owner retains profits. If the debt is not repaid, the lenders gain priority in a bankruptcy. Borrowing can signal firm quality because owners expecting profits might favor debt more than do owners of unprofitable firms (Ross 1977). Debt, however, leaves substantial information asymmetries that lenders can ameliorate through a variety of stratagems: limiting the amount lent, demanding collateral, rolling over short maturities, covenants that limit additional borrowing, etc. To navigate these issues, equity and debt can be arranged and combined in a variety of ways. The point is that the structure of long-term funding is a fundamental way capitalists find imperfect solutions to information and incentive problems.

We can think of capital market development occurring when new structures result in investors having to make less effort to protect their claims. If the sole proprietorship is our benchmark, then a publicly traded, limited liability, joint-stock company has capital investors with much reduced information and control. At the same time, such companies can raise far greater sums than the wealthiest individual can supply. Capital markets developed to allow the paradoxical reduction of investor engagement to coincide with greater capital accumulation. The proximate cause of innovation was a larger demand for capital. For example, long-distance trade to Asia required more money for longer periods than did nearer trade. The innovation that allowed this to happen was the organization of the market such that an investor did not need to know or control what ships or agents did on the other side of the world while being liable for no more than the capital she alone invested. As such, capital market innovation can be thought of as learning to supply imperfect substitutes for investor engagement and knowledge acquisition. These substitutes range from accounting procedures to boards of directors and from limited liability to secondary market liquidity. This chapter is about how markets did this. Markets here mean not just the act of investing but all the institutions, arrangements, and structures supporting the process.

Before proceeding, we must clarify that short-term funding is a different story. Businesses have a persistent need for funding to cover payroll, suppliers, inventory, goods in transit, and customer credit. These needs usually resolve within months and can be covered by ledger credit, letters of credit, bills obligatory, bills of exchange, overdrafts, discounts, promissory notes, commercial paper, repurchase agreements, and the like (Puttevils 2015; Santarosa 2015). These types of instruments are supplied

by firms along an information spectrum. Members of the supply chain lend based on transaction-specific information and repeated interactions. Specialty lenders, like merchant banks and commercial banks, blend industry-specific information with funding from outside investors. Finally, the money market comprises lenders who supply funds while knowing few specifics; outsiders invest because insiders carefully arrange the debt into (secure) instruments insulated from privileged information. Short maturities are the most common way to reduce the need for information. Examples of short-maturity instruments favored by outside investors are bank accounts, bills with multiple endorsements, and repurchase agreements with government debt as collateral (Quinn 2001; Quinn and Roberds 2014).

Gorton (2017) defines such safe assets as giving investors little incentive to produce their own information about the circumstances behind the debt. For example, knowing that 30-day commercial paper is rated AAA is sufficient justification for a money market mutual fund to make a purchase. Similarly, Holmström (2015) defines safe assets as having the quality of no-questions-asked. This means, for example, that a merchant accepts bank money in payment without questioning the balance sheet of the bank. The goal is to make investors collectively ignorant of specifics but confident that others will not take advantage of such ignorance. The result is short-term debt that pays relatively low rates of return and varies little, if at all, in price. The process of risk/price discovery has been carefully and intentionally minimized.

In contrast, financial capital (large-scale funding for long periods) is rarely a safe asset. By definition, equity represents firm-specific risk. The underlying business model needs to be remarkably stable for equity investors to not ask questions. Long-term debt is easier to make safe because it can be insulated by equity, but it still requires firms of sufficient scale to be well known, and it requires the firm to have sufficiently limited leverage in order for equity to be a credible insulator. The more common example of safe long-term debt is the bond of credible governments. While not-for-profit enterprises, governments certainly need large-scale funding for long periods. Investors must consider the political willingness to repay in addition to the fiscal ability, but this is a distinction of degree because politics looms over most all large-scale companies in the early modern era. The Bank of Saint George in Genoa, the Dutch and English East India Companies, and the Bank of England were each intertwined with their respective states.

This chapter focuses on early (pre-1750) examples of how markets found ways to supply capital from increasingly anonymous investors. The examples discussed are not strictly the first example of a particular innovation but the example that has had a lasting impact. The first steps are in primary (initial) investment such as adding active partners, adding sleeping partners, and, eventually, the joint-stock company whose development required secondary (resale) markets, an expansion that brings with it price-based markets, dealers, exchanges, financial newspapers, etc. Finally, the particulars of how a capital market developed (or failed to develop) vary with the sector in question. The chapter will focus on two sectors where demand reached sufficient scale to encourage supply-side innovation: trade and the fiscal state.

Long-Distance Trade

Trade is ubiquitous. It takes place within families when members specialize by task. It happens within communities when some specialize in products for sale or barter with other members of the community and it takes place between communities. By long-distance trading we mean the movement of goods over considerable distances and thus long period of time. Long-distance trades go back millennia with evidence coming, for example, from stone tablets and pre-Columbian archaeological records. Our interest here is not in trade itself but the intersection between trade, especially over long distances, the financing of that trade, and the development of capital markets.

The volume and extent of trade depend on relative supplies and demands for particular commodities which, in turn, are shown by the relative prices in the sending and receiving regions and the transportation costs of moving goods from the lower-price region (higher relative supply) to the higher-priced region (higher relative demand). High unit costs of transportation will limit trade to commodities with higher market value in the importing region. Costs of transportation do not merely capture the physical movement of goods by horses, camels, wagons, or boats but also costs of transshipment, taxes, and tariffs as the goods cross political borders, banditry, theft, and holdup by varied authorities. Thus, independent of the physical costs of moving goods, the political environment and security of legal rights affect the volume of trade; the more uncertain that environment, the lower the volume of trade.

Long-distance trades changed in scope and scale in the fifteenth century with the ocean voyages of the Age of Exploration. Explorers, European and Asian, made amazing voyages of discovery circumventing known continents, reaching continents previously unknown by Europeans and creating new sea routes for regions previously connected by land. These ocean voyages created new opportunities and new markets and changed the financial requirements for these activities. Ocean-going vessels were larger and more expensive than those that traveled along the coast or through the Baltic or Mediterranean; they held more cargo; they had to be armed; and the total voyage time round-trip could take 2–3 years. Each of these characteristics increased the financial requirements. As a result, these changes in the spatial operation of trade led to changes in the financing of the trades and developments in the market for capital.

Precursor Solutions

Concurrent with the increasing financial requirements of long-distance trade, long-distance trade itself posed challenges for the operation of the firm and thus for the financing of the firm stemming from reallocation of risk (Goetzman 2016). To understand the nature of these challenges and the solutions that emerged, we first discuss some of the precursor solutions that allowed for the allocation and reallocation of risk between owners and investors prior to the joint-stock company

and the emergence of the early capital markets. Although the discussion following pertains to the operation of the firm, we are not interested in the firm per se but rather in the structures the firm used to manage its organization and how they reflect the issues of information, monitoring, control, and profits important to external investors.

The majority of firms, today and historically, are sole proprietorships. A sole proprietorship combines information about the firm, monitoring within the firm, control over decisions, and profit/losses from the firm into one capital investor. Thus the size of any such firm is determined by the ability of that single proprietor. As a firm grows, or when the activities of the firm take place in two different locations, the ability of the proprietor to monitor activities diminishes substantially. When a sole proprietorship engages in foreign trade, the owner can travel with his or her goods to one single destination, leaving activities in the home base unattended or the merchant can hire an agent to conduct her business in the foreign location.

Organizing business spatially is complex. When a merchant hires an agent to conduct business on his behalf in a foreign location, he is assigning authority to that person to handle his business activities in that foreign location. The problem facing the merchant/owner is whether the agent will honor the contract and work in the merchant's best interest or cheat the merchant (Greif 1993). Because the agent's activities are taking place in a location removed by time and distance, the merchant will have only incomplete information about the agent's conduct. How does the merchant know that the sale price was low as the agent attests? How can the merchant know if the goods were damaged in transit as the agent attests? Incomplete information and imperfect monitoring make it very difficult for a merchant to verify the extent to which an agent is behaving in the best interest of the owner/firm or behaving opportunistically, because such incomplete information and imperfect monitoring make it easier for an agent to cheat (Carlos and Nicholas 1988, 1990). Given this, a merchant should never hire an agent, and such arm's length activity should not take place. Attenuating an agent's ability to behave opportunistically, or to reduce moral hazard, is essential for any merchant who engages in long-distance trade.

Here we describe just a number of possible solutions.[1] A famous example of merchants' actions to attenuate opportunistic conduct of its agents is the case of the Maghribi traders. Greif (1993) argues that Maghribi traders, who operated across the Mediterranean, handled the agency problem through what he terms a coalition, which laid out the expectations of behavior for agents and the consequences of cheating. Information flowing within the coalition enabled monitoring and the existence of the coalition allowed for a coordinated punishment strategy. Agents who cheated any one merchant faced collective punishment by all members of the coalition, meaning that no members would hire that agent, and if a merchant

[1] An obvious mechanism is the legal system. If an agent defrauds a merchant or does not uphold the conditions of the contract, the merchant can sue in court. Historically, however, while a court system might sometimes be available, issues of locational, legal, and religious jurisdiction could apply.

cheated, all members of the coalition were free to cheat on that merchant. Although solving the agency problem, such a coalition structure depended on the ability to coordinate and to ostracize. As outside opportunities rose, such community-based structures would fail (Greif 2006).

More common than coalitions just described is the use of partnerships, whereby individuals invest jointly in the firm and are jointly liable for any obligations. Partnerships are agreements that generally cease upon the death of any one partner or if a partner wishes to exit. There are examples of this form from Greco-Roman times to the present. In the thirteenth century, a variant emerged in the Western Mediterranean port cities – *commenda* contracts – that encouraged greater trade and mitigated opportunism by overseas agents. Essentially, the *commenda* was a profit sharing contract that limited an investor's losses to the investment made by the investor at the same time as rewarding the overseas agent with a share of the profits and a cap on losses. What came to distinguish this contract form from a partnership was the limiting of liability for the investor, allowing merchants to mobilize capital from anyone within the community, and allowing those with savings to diversify by investing in multiple *commenda* contracts, with the downside risk limited to the investment made. A constraint on the firm, however, was that each trip required its own *commenda* contract, in which all profits were distributed at the conclusion of the voyage (Harris 2009). While *commenda* contracts were used extensively in the Western Mediterranean, salaried agents remained common in English and Baltic trade with the attendant agency issues.

Similar to but differing from a coalition, individual merchants could organize themselves in associations with obligations and benefits. The guild was one such association, often formed to protect the interests of the particular group and enjoying certain privileges granted to it by the authorities (Ogilvie 2014). Of importance is the legal development that saw the guild itself as a legal entity with a perpetual life, independent of the particular members at a point in time. In England, the guild structure and distance trade came together with the Merchant Staplers incorporated in 1319 and the Company of Merchant Adventures of London incorporated in 1407 with a Royal Charter. Another example is the Russia Company (1555). These companies received a set of privileges from the government that could include the rights to trade in certain locations or designation as the sole importer or exporter of a particular commodity. The Hanseatic League in northern Europe is another example of a formal association of merchant guilds and towns. Within these organizations, however, individual merchants operated on their own accounts but did so under the umbrella of the organization rules and obligations. What the institution provided was a trade-related infrastructure of ships, warehouses, lodging houses, and legal protection in the main ports of the trade, which were financed by the dues or payments owed by the members of the organization. While this did not solve the agency problem, it did enhance the flow of information. The umbrella term for these organizations is the regulated company. Thus, while the merchants themselves continued to be sole proprietors or partnerships, the association was infinitely lived and had privileges in its own name.

Joint-Stock Companies

The new long-distance sea routes to Asia, Africa, and the Americas opened new opportunities for both merchants and European governments. Although these sea routes were yet another example of water-based trade, the scale and scope of these new markets were challenging. Capital requirements for ships, cargoes, and crews were greater than more local trade, and for investors the risk was unknown. Additionally, Spanish and Portuguese first-mover advantage in these markets added an additional layer of political complexity and potential for conflict. The Spanish and Portuguese managed their trade as royal/state-run monopolies excluding investors from the market (Rei 2011).

The first challenge facing merchants was the need to mobilize capital to cover the costs of sending a ship to Asia, India, the Americas, or Africa. In the 1590s, both Dutch and English merchants began to organize trade to the East Indies. In 1599, a group of English merchants petitioned the Crown for a charter to trade in the East Indies (Scott 1910). Issued in 1600, the charter was along the lines of a regulated company. It gave a group of insiders, who would be called the East India Company, monopoly rights over English trade to the region (defined in the charter) and monopoly right to import products from that region into England. Of course, the English company was competing with all other European companies and countries and with other English groups that could also be chartered by the Crown (Scott 1910). The actual investment made by these EIC merchants was in the voyage/ship and its cargo (not in the company) with liability limited to the amount invested. Profits depended on the costs of the voyage (cargo, wages, supplies for the voyage), the return of the ship, and the sale of the commodities. What must be remembered is that these voyages to and from China could take 2 years, during which there would be minimal information on the likely success of the voyage. These shares in the voyage were tradeable, but not very liquid, and their price uncertain.

From 1600 to 1659 the English East India Company organized its trade both by selling shares in single voyages and sometimes for multiple sets of voyages, some of which were profitable and some not at all. Indeed, in some years, the company was close to, or actually, insolvent (Scott 1910). A shortcoming of this method of financing was that any net profits had to be fully dispersed to the investors, which left the "company" seeking new investment for each subsequent voyage. In other words, there could be no retained earnings. Whether formally realized or by happenstance, the re-chartering of the company in 1659 provided for a permanent joint stock such that investors owned a share in the company. Each investor's liability was known: limited basically to the equity investment made or requirements laid out in the charter. The ownership of shares also created a political constituency in support of corporate trade rights (Jha 2015).

In Holland, merchants faced the same issues of distance and cost. There, however, the first voyages were full liability partnerships. There too the first ships that returned in 1597 failed to cover the costs of the expedition. As in England, the belief in potential profits encouraged further voyages. Whereas in England, the trade was organized under the umbrella charter of 1600, in Holland, the first years of the trade

were carried out by competing sets of merchants from the major cities. The failure of attempts at local coordination led to coordination at the federal level with the chartering of a public monopoly in 1602, the *Vereenigde Oost-Indische Compagnie* (VOC), or the Dutch East India Company. It was to be managed by the six local chambers which, in turn, appointed a governing board of seventeen delegates (the *Heeren* XVII) to manage the business. Each of the major cities was represented, and the capital stock was specified in the charter. Shareholders committed capital for 10 years, but the initial charter (set for 21 years) required a full-distribution in 1612, at which time shareholders could decide to pull out or reinvest. In this first decade the company faced financial constraints, which the distribution of assets in 1612 made difficult to resolve. Unlike the East India Company of this period, the VOC played a role as an arm of the government with forts, factories, and Asian shipping assets. How these complexities would be realized in 1612 led to a decision to give the VOC an indefinite life, but with the same fixed capital stock. While the shares in the VOC were traded from its outset, the constraint on the size of the capital stock limited trading potential (Dari-Mattiacci et al. 2017).

From the mid-sixteenth century, there was experimentation in the organization of English trade to Africa. Starting from partnerships with exclusive grants to land areas, to constructing forts on the coast, various groups pursued the Africa trade, which focused on gold, ivory, pepper, and redwood with the slave trade as a smaller part of many of the early voyages. While the length of these voyages was shorter, the trade was volatile. Depending on the ability to acquire goods, to evade Portuguese and other European vessels and privateers, the outcome could be highly profitable or the investors could experience sizeable losses. The result, as described by Scott (1910), was a series of experiments prior to the chartering of the Governor and Company of the Royal Adventurers of England trading into Africa (1662–1672), which went bankrupt within 10 years. Its charter was ended and the debts taken over and written down by the newly chartered Royal African Company of England in 1672. This company was a joint-stock company with a perpetual life and capital stock of £100,000 sold in shares of £100 face value. The charter included limited liability for the investors. Two years earlier in 1670, a charter had been issued to the Governor and Company of Adventurers of England trading into Hudson's Bay, also with shares of £100 face value and limited liability for investors.

From the middle of the sixteenth century, merchants experimented with different ways to mobilize capital for the long(er) distance trades – private trade, partnerships, quasi-regulated companies, and the joint-stock company. The joint-stock company sold transferable shares in a perpetually lived company with locked-in capital. By the middle of the seventeenth century, the joint-stock structure, whereby investors purchased shares in the enterprise, was widely used in many countries in Europe. Scott, in his three-volume work, documents the range of these companies across multiple sectors in England, Scotland, and Ireland. Those companies with a royal, or after 1689 a parliamentary, charter generally had limited liability and tended to be larger in terms of their capital stock. The charters laid out the organization of the company, the face value of a stock, and the level of shareholding needed to be an officer or serve on the company board. These were modern joint-stock organizations.

Secondary Stock Markets

The existence of a joint-stock company does not imply the existence of a secondary stock market. If each initial investor was a long-term passive investor, there would be no stock market because no investor would be selling. Stock markets contribute to economic growth because they provide a mechanism to mobilize savings; they provide liquidity and risk diversification; they allow for the acquisition of information. The existence of a stock market eases the tension between the needs of the firm for long-run financing, especially in the case of high-return projects, and an investor's demands for liquidity (Levine and Zervos 1996). The difficulties the East India Company faced during its early decades in trying to finance individual voyages or sets of voyages (as did other such long-distance trades) speak to this tension.

For early capital markets there needed to be a place or person where trading could occur. In the last quarter of the seventeenth century a number of local but interrelated markets for shares arose in London and in Amsterdam. One location was the company head office, where potential buyers and sellers could locate one another. Coffee houses, located in Exchange Alley and Lombard Street close to the Royal Exchange in London, became another focal point, especially Jonathan's and Garraway's.[2] Social standing, gender, and living outside the metropole circumscribed access to company houses or coffee shops. Well described by Anne Murphy (2009), the market was quickly served by an array of middlemen, brokers, and solicitors willing to act on behalf of individuals. Some of these agents could themselves be women (Laurence 2008). Regardless of the location or entity involved in the transaction, the transfer of a share had to be documented at the company office to legalize the transfer of the property right and also to ensure that the company would know to whom to pay a dividend.

For a capital market to function efficiently, investors need information. To the extent that markets work efficiently, information will be revealed through price and price changes. In the aftermath of the Glorious Revolution and the loosening of restrictions on the press, financial broadsheets, such as John Castaing's *Course of the Exchange* (1689–1823), emerged (Neal 1991). Such broadsheets listed the market prices of various financial assets. The *Course of the Exchange* was published on Tuesday and Friday, listing the price for that day and for the preceding 2 days. The periods when trading was closed, such as Sundays or prior to making a dividend, were also noted. These financial broadsheets were widely distributed not just in London but also mailed to interested parties in England and elsewhere, in particular, Amsterdam (Koudijs 2016; Carlos and Neal 2011). Trading prices were also listed on boards in the various coffee houses along Exchange Alley and at the company headquarters.

Shares, trading locations, price information, financial broadsheets, property rights, and limited liability made it possible for the long-term opportunities in the

[2]Indeed, the London Stock Exchange would be built on the site of Jonathan's coffee house.

overseas trades to access capital. Market liquidity made it possible for investors to invest in a company because they knew they could "quickly, cheaply, and confidently sell their stake" when needed (Levine and Zervos 1996: 327). The confluence of these forces provided a mechanism through which firms/institutions could access large amounts of capital from multiple small investors.

Fiscal State

In the early modern era technological advancement and increasing scale caused military expenditure to rise relentlessly (Hoffman 2015a). To pay for these costs fiscal states had to navigate the politics of creating permanent taxation (Hoffman 2015b). To expand the tax base, fiscal states struggled to centralize and standardize revenue authority and create political mechanisms to monitor expenditure (Dincecco 2015). The slowly emerging result was an increasingly large and credible stream of future revenues, with states using capital markets to turn these future expected streams into money for current warfare. Substantial government spending on other public goods, such as education and sanitation, did not arise until well after the Napoleonic era (Hoffman 2015b).

It was not, however, simple to convert expected taxes into current funding. Like any enterprise, a government might lack the funds to repay, or it might decide not to repay. For capital investments by firms, reliable enforcement of contracts through courts of law can compel the unwilling to pay. Investors thus focus on the ability to repay either through expectations of profit or bankruptcy. A sovereign, however, lacks a third party who can coerce repayment, so investors must decide if they trust the state to repay. The longer the time to repayment, the more time there is for expectations or ability or willingness to degrade. Unlocking future tax revenue for current uses requires a sovereign to convince investors that the future revenues are secure and that the commitment to share them is credible. In short, the whole arrangement is as much political as economic. The political being the decisions to assess taxes and then redistribute the funds to creditors.

Monarchies

The interplay of ability and willingness is evident in monarchical efforts to secure multiyear borrowing. The monarchs of early modern France and England typically had the right to collect a set of ordinary taxes but had limited administrative capacity by which to do so. A tax farm is when a sovereign sells the right to collect one of those taxes. The tax farmer pays an amount certain to the monarch for an amount variable that s/he can seek to collect. The sovereign can use bidding to ascertain how much a tax could supply, and the resulting contract informs perspective lenders of fiscal ability. The sovereign can signal an enhanced willingness to repay by pledging the farmed revenues to repay specific loans. The pre-assignment of revenue streams reduces room for the monarch to overcommit collateral. It also makes default more

painful through injury of the monarch's general credibility. Modifying a sovereign's willingness to repay works on the margins, because a sovereign can only be induced to repay rather than compelled to repay.

To further signal ability and willingness, a sovereign can combine debt collection with tax collection: a syndicate buys collection rights and lends in anticipation of those collections. The disciplinary innovation here is that the combined creditor-farmers can disrupt or threaten to disrupt both revenue collection and credit supply should the government default, so they are willing to lend more than they would have otherwise (Johnson 2006). In the early modern era, the monarchs of France and England moved to such "cabal" tax farms to fund the increasing cost of warfare (Johnson and Koyama 2014). The monarchs had to use tax farm syndicates to gain multiyear credit because their unsecured pledges were insufficient; the alliance of tax collection and anticipatory lending eased the rationing of credit only as far as the threat could be maintained. And the threat was needed. For example, from 1598 to 1655, French kings broke the leases on two-thirds of tax farms (Johnson 2006). Moreover, the arrangement's capacity to lend increased with scale, so both France and England invested in the centralization of revenue administration. For example, Louis XIV merged tax farms into the General Farms in 1681, a quasi-corporation that routinely renegotiated terms with kings from a defendable bargaining position of being "too big to fail" (Johnson 2006).

In both nations farm syndicates were a result of monarchs doing their best to borrow independently of their representative bodies. For example, when French kings summoned the Estates General in 1576 and in 1789, the assemblies did not support new taxes because of opposition to redistribution and because giving the king what he wanted removed the need for the assembly (Stasavage 2015; White 1995; Hoffman et al. 2000). In contrast, with the restoration agreement of Charles II in 1660, parliament became willing to supply the monarch with extraordinary taxes for limited periods. As a result, Charles ended the two great farms in 1671 (customs) and 1683 (excise). The arrangement became more explicit after the Glorious Revolution of 1688. Among other issues, parliament agreed to fund the king's war in exchange for the powers of routine assembly and routine reauthorization of the king's power to collect taxes (North and Weingast 1989). In these negotiations, sovereign debt both redistributes from tax payers to creditors and is a key determinant of political power. In England, assemblies, and the Crown eventually found a compromise, and farm syndicates ended. In France, they did not.

Spain avoided tax farms becoming loan syndicates. When the kingdom's assembly (Cortes) agreed to make a tax permanent, the king could pledge the stream of revenue to fund an annuity. While sometimes tax farms did collect these taxes, the farms did not control lending on those revenues. Instead, the annuities were sold to the nobility, and the nobility formed the assembly, so repayment was credible. Also, the Cortes resisted creating new permanent taxes because withholding such authorization was the assembly's primary source of negotiation power (Drelichman and Voth 2014). Unlike other European monarchs, Spanish monarchs did have independent revenues, especially silver fleets from Latin America, and they did borrow in advance of those revenues, but they did so from Genoese bankers.

Although the Spanish king, Phillip II, repeatedly defaulted on such Crown loans, he eventually negotiated terms with the bankers. In the long term, the bankers did well because they could determine if Phillip's default was from a legitimate inability to pay, i.e., a silver fleet failed, versus a strategic unwillingness to pay (Drelichman and Voth 2014). Like farm syndicates, the Italian bankers could credibly threaten to disrupt future borrowing if the monarch was able but unwilling to repay. Spanish kings were, however, careful not to violate commitments sanctioned by the Cortes.

Republics

Centuries before the monarchs of England, France, and Spain learned to arrange multiyear borrowing, the city-republics of Italy unlocked the supply of long-term capital. Like for the monarchies, the critical source of domestic credit was the merchant class, because they had money and wanted to diversify their investment portfolio. Unlike the monarchies, merchants held substantial political power in cities like Florence, Genoa, and Venice, so political will was expected to remain focused on repayment (Stasavage 2015). Initially, this was done through substantial elite participation in loans, and "Citizens thus became true lender-taxpayers, rather than lender-investors" (Pezzolo 2007: 4).

For example, in 1262, the oligarchy running Venice compelled creditors to restructure and consolidate short-term debts into perpetual annuities backed by dedicated revenues managed by the city (Fratianni and Spinelli 2006). When subsequent wars created more fiscal need, additional compulsory loans were created. While such loans sound predatory, the elites of Venice used this instrument because it required their political consent, it limited the use of direct taxation that would fall on them, it avoided the domination of lending by a faction, and it created a useful demarcation of citizenship (Pezzolo 2007). As a result, most people of at least modest wealth held perpetual bonds in the form of a ledger entry at the state loan office. A local resale market developed. "Government credits could be transferred by sale, by testamentary bequest, or by contract of gift or dowry; they could be lent, pledged as surety for nearly any kind of transaction, including bank loans, or used as money in payment of obligations" (Mueller 1997: 458). This only made the credits more valuable, and that helped Venice borrow even more. By the mid-1400s, however, new compulsory loans began to exceed the elite's ability to supply. As a result, people had to sell old credits at diminished prices to pay for new credits and political support for compulsory loans dissolved. In 1528, Venice switched to voluntary loans.

The Republic of Genoa did not have as stable an oligarchy as did Venice. Noble factions quarreled with each other and with an ascendant merchant class, so maintaining the political will to repay creditors was less assured. To acquire long-term credibility for its compulsory annuities, Genoa conceded control of revenue collection to tax farms, whereas Venice maintained direct administration of its taxes. Also, Genoa hit the limits of its long-term borrowing a century before Venice did. In 1407 Genoa initiated a voluntary restructuring that swapped old annuities for

shares in a new holding company called the *Casa di San Giorgio* (Bank of St. George) by which the state got a reduction in interest rates. Creditors got a company that increased their bargaining power by consolidating negotiations, tax collection, and debt management into one entity. This super tax farm syndicate "reduced creditors' fears of government defaulting on its obligations, and ultimately lowered the cost of debt to Genoa" (Fratianni 2006: 487). It also deepened the resale market for sovereign debt by repackaging it as a homogeneous share of the company. In modern parlance, San Giorgio securitized Genoa's sovereign debt. The result was that capital investors needed to know little because the leadership of the company were political elites who collected information and negotiated terms on behalf of a board and the rest of the shareholders. Leadership even assessed when circumstances legitimately prevented repayment, in which case debt could be restructured or even forgiven (Fratianni 2006: 496). In total, individual investors in San Giorgio owned a liquid security about which they needed little information, a remarkable innovation for the 1400s. This security encouraged institutions like the church and charities to become substantial investors and resulted in Genoa, on a per capita basis, borrowing substantially more than any other Italian state (i.e., three times Venice) from 1500 to the French Revolution (Chilosi 2014).

The first republic to cover a territory encompassing competing cities was the Dutch Republic. During the early years of the revolt from Spain (1568–1648), individual Dutch cities continued the tradition of borrowing on annuities. As early as the thirteenth century, French cities such as Amiens, Rheims, Tournai, and Troyes had gained commune status from the French kings. Each used that corporate status to borrow in its town name. The status was credible because French lawyers agreed that the King had the authority to grant communal status, at the same time the King's authority to impose modifications to local arrangements was limited by tradition (Tracy 2003: 19). In exchange for communal status, the cities supplied military funding to the king. The commune-annuity arrangement spread into the cities of the Habsburg Low Countries, and later the northern cities issued annuities to fund their rebellion. The arrangement did not work in southern France because either the French king's "rights as suzerain were not so clearly defined" (Tracy 2003: 19) or the city was under English rule and suffered from political divisions.

During the revolt, the Dutch cities had to determine how to coordinate their fiscal efforts. In 1574 the cities decided to standardize taxation authority at the level of the province – the Dutch Republic being comprised of seven provinces (Fritschy 2003). In this way tax obligations were made uniform for those in cities and the countryside. The cities, however, did not centralize the collection and processing of taxes. Instead, they continued using local tax receivers to borrow advances on the local obligations to provincial taxes. The same receivers then later repaid those advances with locally collected funds. The cities controlled the provincial government; keeping taxes local assured urban citizens that rates were necessary, that funds were spent wisely, and that advances would be repaid (Gelderblom and Jonker 2011). The local sequestration of Holland's fiscal process had the intended effect of standardizing local rates while keeping local control of the flow of funds. The national government had only a minor fiscal role.

An unintended effect was to give localities freedom regarding how to supply long-term sovereign debt. While the province might favor annuities repayable at the government's discretion, locals preferred bills due within a year, partly because the transfer of annuities was cumbersome and paid a tax/duty while bill's matured quickly without a tax (Gelderblom and Jonker 2011). As a result, Holland's long-term capital debt became mostly a continuous rolling over of short-term bills.

Massive use of short-term debt had two related consequences. Borrowing rates were lower than annuities, but lenders might withdraw their support and not roll over their loans. This happened in 1672 when France coordinated a three-sided invasion of the Netherlands. Holland had to suspend conversions and impose forced loans (Gelderblom and Jonker 2011). The conclusion of that war in 1678 allowed the situation to restabilize. Holland successfully created safe sovereign debt that was functionally equivalent to a time deposit with the local tax receiver. Like a bank deposit, investors were largely ignorant of fiscal operations. "The Estates published no financial information whatsoever; only the receivers knew how much money was to be raised or still needed to be subscribed, so they could play investors against each other" (Gelderblom and Jonker 2011: 24). Like a bank, the "no-questions-asked" status of Holland's bills could suddenly collapse into a run if investors decided that their ignorance made them vulnerable.

As ever in the early modern era, the reliability of Holland's system depended on politics, and politics depended on war. The wars of 1687–1697 and 1701–1713 placed massive fiscal demands on Holland, and under this pressure the province turned on its bill creditors. In 1687 Holland began to tax interest payments on bills (Gelderblom and Jonker 2011). In effect, the tax used the amount owed on bills as a proxy for a person's wealth. At the same time, the province borrowed new funds that were not subject to the tax while limiting access to investors who held the old bills and paid the tax. All this was possible because local tax receivers controlled who had access to new debt issues. Receivers threatened to cut off access to any government debt to locals who cashed out old bills to avoid the tax. Receivers encouraged rollovers by controlling access to the new, more lucrative investment. Receivers could manipulate local investors precisely because the province did not have a centralized process.

Joint-Stock Sovereign Debt

While the Dutch manipulated illiquid forms of sovereign debt, their ally Britain experimented with melding the liquidity of trading companies with sovereign annuities. The proof of concept was the public offering for the Bank of England. With the defeat of allied forces by the French in 1690, the navy needed funds to rebuild, but trust in the government was such that borrowing at any reasonable interest rate was not possible. The limited liability, joint-stock company structure was used as the vehicle by which funds would be channeled to the government. The Bank of England, chartered in 1694, raised £1.2 million in only 12 days in a world in which the annual wage for a laborer was roughly £20. In simple

purchasing power, this is the equivalent of £160.1 million pounds in 2017 (Measuring Worth). Not only did the IPO demonstrate the wealth available in London but also the willingness of individuals to buy into the stock market (Carlos and Neal 2006; Murphy 2009).

Although called a bank, the initial Bank of England was, in effect, a pool of sovereign debt funded by securities: shares and bonds (Kleer 2017). The Bank of England only slowly learned to issue circulating banknotes. Additionally, the early Bank of England did not manage tax collections nor represent all sovereign creditors, so it had much less threat potential than Genoa's *Casa di San Giorgio*. However, the government did get to place long-term debt at a low rate. Investors got liquidity, and the collective political threat of upset shareholders should the state default (Murphy 2013). The Bank soon discovered the power of supplying currency and a trade-off evolved (Broz and Grossman 2004). In 1697, the Bank of England agreed to swap new shares in the bank for short-term sovereign debt held by savers that was in arrears. The debt was simultaneously converted into annuities. In return, the Bank of England was granted a monopoly over corporate banking in England. Five times over the next century the Bank of England absorbed new annuities in exchange for being allowed to keep its monopoly, and the amount of annuities tied to the Bank of England's charter grew tenfold from its origin. The Bank of England, however, never held more than a quarter of the national debt. But the model was one that was replicable. In exchange for corporate privileges, the New East India Company lent £2 million to the government in 1698, and the United East India company lent £1.2 million more in 1708 (Scott 1910). This is in contrast to the VOC, whose capital stock was fixed in perpetuity.

The path to the great financial bubbles of 1720 begins with the use of the corporate form to convert existing debt into shares (Neal 1991). In 1711 the Tory government chartered the South Sea Company (SSC) to rival the Whig's Bank of England. While not a bank, and hardly even a trading enterprise, based on the experiences of the Bank of England and the East India companies, the South Sea Company was able to undertake a very successful swap of £9.1 million worth of sovereign debt for new shares in the company because people wanted liquidity.[3] As a result, the SSC suddenly held more government annuities than the Bank of England and the East India Company combined. The Treasury, which was responsible for selling annuities to the public, decided to use these companies to restructure other annuities held by the public. Benefits accrued to all parties: the government paid the companies a lower rate of interest, companies received a stable flow of interest payments, and the shareholder now held a highly liquid asset.

[3]£9.1 million in 1711 is £1,219 million in 2018 in terms of purchasing power parity or $1,1618,868,570 at current exchange rates. Measuring Worth "How Much is That" accessed June 15, 2018.

The British experience showed the power of aligning long-term sovereign debt with corporations in exchange for various trade and banking privileges. The Scottish promoter John Law took the lessons to Paris and convinced the Regent to follow the example and then go one better. From 1717 to 1720 in France, Law monopolized currency (Bank Royale), the collection of taxes (Comptroller General), and foreign trade (Mississippi Company). He used the combination of powers to encourage people to swap sovereign debt for Mississippi Company shares.

This expanded concept jumped back to London where the treasury had the South Sea Company and the Bank of England bid for the right to absorb the half of the national debt still held directly by public investors through a giant debt-for-equity swap. The South Sea Company won the contract and was indebted to the government for over £7 million pounds (Scott 1910). South Sea Company share price rose dramatically because the company supplied subscription credit but also because investors expected that the successful company would dominate public finance like Law's system in Paris. Most of the available annuities were converted into shares as the South Sea Bubble inflated over the summer of 1720.

John Law's scheme in France began to implode in May of 1720. Law was printing so much currency to maintain a Mississippi Company share price floor that he suspended convertibility of currency into coins. The suspension, however, was politically unacceptable, with the result that Law had to revert to a policy that was unsustainable. In July his bank failed and the stock's value collapsed.

Meanwhile, in London, credit creation could not keep pace with subscription margin calls on earlier rounds of credit, and South Sea Company share prices began to fall in late August. But by then, the conversions were largely complete, so the Treasury did not suffer. However, many investors who had swapped government debt for equity were unable to repay credits. Personal failures increased for those who had purchased at the height of the market, leading to calls for government to take responsibility for these losses. Much has been made of these losses but not everyone lost; those who sold at the height of the market or gained over the Bubble period tended to be hidden (Carlos and Neal 2006). In 1723 the political calls for action resulted in a compromise in which half of the holdings of South Sea Company stock were split into two – one half to continue to be held as equity and the other half to convert to annuities to be housed in the Bank of England. Despite the Bubble, the capital market in London continued to grow through subsequent decades of the nineteenth century. Both debt and equity became a highly liquid and safe form of sovereign debt. In the decades to follow, the Treasury took the final step of routinely and directly issuing annuities that traded like stock. The annuities were recorded and transferred at the Bank of England using the same types of ledgers as equity shares. Indeed, people called these perpetual annuities stocks. This market provided the British government with a mechanism to meet the financial exigencies of war. But more importantly, the market was and continued to be available and accessible to even the smallest of investors. It was this accessibility that provided the liquidity not only for smoothing expenditure needs but also for companies making large capital investments in canals, railroads, and many other infrastructure projects.

Conclusion

Capital markets involved a great deal of experimentation, often in desperate times. By 1800, however, a replicable system of limited liability, long-term securities had been worked out. Investors needed neither to participate in management nor to closely monitor the firms. A great deal of useful information flowed through the prices of stocks and bonds on the secondary market. Indeed, one of the milestones in cliometric analysis was when Larry Neal (1991) showed that capital markets were highly correlated in the eighteenth century. A substantial literature has followed that uses statistical analysis to highlight the sophistication of information processing in early modern capital markets: some recent examples being Chilosi (2014), Petram (2014), Koudijs (2015), and Wandschneider (2015). In the modern era, the corporate securities technology developed by Dutch and English trading companies would jump sectors again and play an essential role in funding the large, industrial giants of railroads, steel, automobiles, etc. And the sovereign version of the corporate bond would go on to become the safe asset that anchors the financial system of the industrialized world.

A capital structure using corporations and securities, however, was limited in the early modern era and remains a questionable fit for smaller firms. For example, Hoffman et al. (2002) showed how Parisian notaries intermediated capital lending without secondary markets or even price competition. Again, a substantial literature has followed showing how capital could be created through personal connections and rolling over short-term loans. For example, see Temin and Voth (2013), Hoffman et al. (2015), and Gelderblom and Jonker (2016). While securities-based finance has become a massive industry, it is important to remember that a good deal of capital creation still occurs through more private networks.

Origins of the U.S. Financial System

Richard Sylla and Robert E. Wright

Contents

Abstract

Before the Revolution, British North American colonists generally circulated foreign specie (full-bodied silver and gold coins) rated in local monies of account and paper bills of credit to settle open account balances, but during monetary stringencies they resorted to country pay and other exigencies. Formal financial intermediaries were few, and for the most part urban and nonprofit.

During the Revolution, governments financed rebellion by issuing dollar-denominated Continentals and other fiat paper monies. Much more currency was emitted than demanded at the prewar price level, so the paper money depreciated until it became virtually worthless. Americans then reverted to specie, and the rebel governments turned to foreign loans and in 1782 to the nation's first joint-stock commercial bank, the Bank of North America.

Shortly after the Revolution, two more commercial banks appeared in seaport cities, and a few other business corporations formed, but generally entrepreneurs held back, fearful of the continuation of recession and the return of civil war. Only with the passage of the new Constitution and the installment of a new federal government, led by the venerable George Washington and financial reformer Alexander Hamilton, did the investment floodgates open. By 1795, the new nation had a fully formed modern financial system – including strong public finances and debt management, a uniform unit of account, a central bank, a commercial banking system, efficient securities markets, a network of insurance companies, and economic incentives and legal rights to innovate – that drove America's nineteenth century economic growth and development.

Introduction

Early U.S. economic history furnishes what is perhaps the best example of financial modernization leading to modern economic growth. When the members of the new federal government under the Constitution took office in 1789, the country had virtually none of the key components of modern financial systems. Half a decade later it had all of them. The term "financial revolution" is apt.

At roughly the same time, economic growth also accelerated to its modern rate, i.e., sustained increases in Gross Domestic Product (GDP) per person of 1% or more per year. The United States – not, as long assumed, Great Britain with its "first" industrial revolution – may have been the first country to benefit from modern growth rates (Lindert and Williamson 2016). After its financial revolution of the 1790s, it took the United States less than a century to succeed Great Britain as the richest and foremost industrial economy.

The United States was not the first or the last country to experience finance-led growth. The Dutch Republic at the turn of the seventeenth century experienced financial modernization and went on in that century to become the leading world economy. A century later, after its Glorious Revolution of 1688, Great Britain also had a financial revolution; it succeeded the Dutch Republic as the leading economy of the eighteenth century and the first part of the nineteenth. Perhaps the most interesting case, and a later one, is that of Japan, which after centuries of isolation, opened up to the world starting in the 1850s. During the 1870s and 1880s, the Japanese modernized their financial system as the Dutch, the British, and the Americans had done earlier. The growth of the Japanese economy then accelerated to modern levels and by the early twentieth century Japan far surpassed its Asian neighbors in economic development (Rousseau and Sylla 2003).

During their long colonial era from the early seventeenth century to the late eighteenth, Britain's North American colonies that became the United States experienced economic growth, but only at pre-modern rates. Living standards were high compared to the rest of the world because land and other natural resources abounded compared with the relatively small, though rapidly growing, population. But over time, living standards increased little if at all. Expansion resulted from a rapidly increasing population – the increase was about 3% per year – that maintained, not increased, its relatively high level of income. In other words, both the population and economic output expanded at roughly 3% per year, an exceptional rate in world history up to that time, but not growth in per capita (person) terms.

Pre-modern financial arrangements constrained colonial growth. Much of the specie that colonists earned from their exports of commodities and shipping services was expended on needed imports. The dearth of specie led to a search for innovative substitutes, but both economic realities and imperial regulations often frustrated their usefulness. British interference with colonial financial and monetary experiments and the resulting constraints on colonial economic growth, along with Britain's mercantilist trade policies and taxation without representation, became prime causes of the American revolt, which began in the wake of the long French and Indian War (1754–1763) and reached a world-altering climax in the 1770s.

Money and Banking in Colonial America

For legal and practical reasons, British North American colonists minted few coins themselves. Full-bodied foreign gold and silver coins (specie) generally did not abound in domestic circulation because colonists preferred consuming imported goods over maintaining copious cash balances (Michener 2003). A colonist about to part with a Portuguese gold coin (a Johannes, "Joe," or "Jo") penned a poem about the peripatetic nature of specie:

> We are come to the unhappy parting hour. Lately I received you into my house as a Traveller, and almost a Stranger; you was welcome. . . . I must tell you, I am now obliged to sell you to a Merchant, don't think I do it of choice. . . . I hoped you might have remained an inhabitant of the country, that I might have receiv'd some visits from you, but now I expect you will have a quick dispatch to Boston, or New York; immediately take ship and I shall see you no more. . . . Think not hard of me for putting you under this sentence of Banishment, necessity knows no Law. Farewell, my friend Jo ("The Following is a Speech, Made at the Delivery of a Gold Piece, Call'd a Johannes, to a Merchant for Debt," *Connecticut Gazette,* 23 January 1768).

Colonists chose to remit full-bodied coins (i.e., with precious metal content equal to the face value of the coin) to pay for imported goods because they possessed cash substitutes that were generally adequate to their needs. Contrary to myth, colonists rarely engaged in barter – the direct exchange of one nonmoney good for another, though final payments often consisted of goods or services. Under the "country pay" system, for example, colonial legislatures made baskets of local agricultural products

legal tender, sometimes only for public debts but sometimes for private debts as well, at specific specie prices. Single commodities, including tobacco, beaver skins, and wampum also served as money at various times and places, sometimes by fiat and sometimes by common consent. Tobacco also spurred the creation of a representative paper money known as tobacco notes, which provided holders with legal rights to specific amounts of inspected and warehoused tobacco (Michener 2003).

The open account system was much more flexible and honest than country pay, which could be used to trick unsuspecting or ignorant creditors. Sometimes called bookkeeping barter, the open account system, which lasted into the twentieth century in rural areas, entailed the exchange of goods, services, and money between economic entities over long periods, from months to years to decades (Flesher 1979). In essence, every household and business firm performed banking functions by keeping track of the market value in specie of purchases, sales, loans, and repayments over time, with periodic settlement with counterparties made in cash (coins, bills of credit, or tobacco notes) when a balance grew too large.

Colonists typically recorded economic values in terms of local pounds (£), shilling (s), and pence (d) with 12d to the s and 20s to the £. By rating foreign coins, especially the Spanish milled dollar, each colonial government or merchant association set the value of its local pound at some fraction of the Mother Country's pound sterling. New York eventually rated the dollar at 8 shillings New York money, so the New York pound was worth 2 and one half dollars (20s/8s = $2.50). Pennsylvania rated the dollar at 7 shillings and 6 pence Pennsylvania money, so the Pennsylvania pound was worth 2 and two-thirds dollars (20s/7.5s = $2.67). In late colonial New England, the dollar was rated at 6s (20s/6s = $3.33). In Britain, the dollar was worth about 4s 6d sterling, or $4.44 per pound sterling (20s/4.5s = $4.44) (Michener 2003).

The differences in local coin ratings were reflected in exchange rates, i.e., the prices of sterling-denominated bills of exchange. To purchase £100 sterling, New Yorkers in peacetime typically paid £174 to £182 New York currency, while Pennsylvanians typically paid £163 to £171 Pennsylvania currency, and late colonial New Englanders paid £127 to £133 Massachusetts currency. The intercolonial difference was due to the differential rating of the silver dollar in each colony compared to the sterling rating of 4 s 6d per dollar. The intracolonial range reflected the transaction costs inherent in shipping and insuring specie. When bills of exchange became too dear, colonists who owed debts in Britain shipped specie instead; when bills of exchange became too cheap, which occasionally happened, colonists with credit in Britain imported specie from abroad instead (Michener 2003).

Bills of exchange were short-term credit devices with a foreign exchange component, a sort of international paper check denominated in another currency, typically pounds sterling (but sometimes Dutch guilders or German marks). Typically, a drawer (or maker, an individual with funds or credit in England or elsewhere overseas) would sell the bill, which could be completely epistolary or a printed form with key blanks filled up by hand, to a purchaser, who remitted the bill to the payer (the banker/merchant) in London, Liverpool, Amsterdam, Hamburg, etc. in triplicate (or quadruplicate) via different ships. Only the first bill presented to the

payer was valid. Bills of exchange could be sold or otherwise transferred to another party only by endorsement (signing over ownership on the back) and the payer did not always honor (pay) them.

Bills of exchange provided a substitute to coin in international trade but not in domestic circulation. There, a very different paper instrument with a similar sounding name, bills of credit, substituted for cash money. Issued by colonial governments via mortgage loans or directly for goods and services, bills of credit were printed bearer instruments typically denominated in local pounds, shilling, and pence. Often, but not always, a legal tender for all debts public and private, bills of credit were typically backed by loose promises to redeem them for taxes in the future, not by specific mortgages, caches of specie, or other assets. Only Maryland backed an emission of bills of credit with tangible assets and a credible commitment to redeem them at a specific time. Everywhere else, bills were essentially unbacked, so their value in the marketplace was determined first by the local coin rating and second, if bills displaced all specie from domestic circulation, ostensibly by the quantity of bills circulating. Attempts to cliometrically test the quantity theory of money in the colonies, however, have been flummoxed by the cross-border circulation of bills, incorrect measurement of the total value of bills outstanding, and the difficulty of measuring specie flows (Michener 2003, 2015).

Writing after the Revolution about bills of credit in the Middle Colonies (New York, New Jersey, and Pennsylvania), "Eugenio" explained that they maintained their value because

> the people voluntarily and without the least compulsion threw all their gold and silver, not locking up a shilling, into circulation concurrently with the bills; . . . If any one doubted the validity or price of his bill, his neighbor immediately removed his doubts by exchanging it without loss into gold or silver. If any one for a particular purpose needed the precious metals, his bill procured them at the next door, without a moment's delay or a penny's diminution (*New Jersey Gazette,* 30 January 1786).

In other words, the inhabitants of the Middle Colonies, not formal financial institutions, maintained the convertibility of local bills of credit into specie and vice versa as part of their open account or bookkeeping barter system (Michener 2003). Such formal financial institutions that did exist in the Middle Colonies were charities or mutual insurers that made long-term investments in mortgages and ground rents (perpetual interest-only mortgages) (Roney 2014).

The monetary situation in early colonial South Carolina and mid-century New England was very different. In those places, military exigencies induced the colonial governments to issue far more bills than were needed for domestic circulation at prevailing prices, freeing all the coins in domestic circulation to be sent abroad in exchange for manufactured goods. While exchanging small pieces of metal for consumption goods and productivity-enhancing tools provided a temporary boon, with nothing to anchor the value of bills of credit they began to depreciate. Although it is tempting to call such episodes inflationary, that would be anachronistic and misleading because prices denominated in specie did not change appreciably.

Instead, bills of credit lost value vis-à-vis specie and goods until reforms were initiated. In South Carolina, that meant an exchange rate of about £700 South Carolina currency for £100 sterling. Nominal exchange rates in New England were also quite high until the region, led by Massachusetts, underwent a series of currency reforms in the early 1750s that essentially put the region back on a specie standard (Brock 1975).

The first attempts to create private forms of money took place in South Carolina and New England as entrepreneurs sought to create specie substitutes that held their value better than fiat bills of credit did. In the former, Sir Alexander Cumings ran a private bank that issued paper notes redeemable, at least at first, upon demand in specie. During a diplomatic mission among the Southeast's American Indians in 1729, Cumings, who had seen John Law's system in operation in France in 1719, issued his promissory notes via three different loan offices. After establishing his creditworthiness, he began to sell bills of exchange as well and when he left the colony, quite publicly, all seemed well. Three weeks later, however, the bills of exchange he had drawn came back protested (unpaid) due to the "Character of the Drawer." Noteholders busted into his "treasury" building only to find in it "some empty Boxes, old Iron, and other Rubbish." Contemporaries estimated Cumings' haul at £15,000 sterling (*Boston Weekly News Letter*, 30 July 1730; [London] *Echo*, 16 September 1730).

Ironically, Cumings' initial success spurred the creation of a competitor, a bank with 25 principals who each chipped in £2000 South Carolina currency (approximately £286 sterling). After a rocky start, the merchants lent £40,000 to £50,000 worth of their notes to the public and redeemed them on demand in South Carolina bills of credit. A third bank and several individual merchants also apparently were able to circulate private notes in 1730s South Carolina, but documentation remains thin (Michener 2017).

Also in response to the depreciation of fiat bills of credit, a group of Boston merchants in 1733 printed and lent at 6% interest £110,000 in private paper notes, redeemable in specie at 19 s an ounce of silver in three installments over the course of a decade. The action caused a stir, but the attorney general of Great Britain eventually ruled the notes were legal because the Bubble Act and other legal barriers did not (yet) apply to the colonies. Because Rhode Island successfully continued to pump new bills of credit into circulation throughout New England, the value of fiat money paper money dipped enough to induce people to hoard the merchants' notes, which soon disappeared from circulation (Michener 2017).

In Connecticut in 1732–1733, another group, styled the New London Society United for Trade and Commerce, tried and failed to get their paper notes to pass current, apparently because the projectors were not considered creditworthy. The legislature revoked its charter within a year. In New Hampshire in 1735, a group of prominent merchants copied the business plan that Boston merchants had used 2 years earlier to issue notes successfully. Merchants and lawmakers quickly agreed to make the New Hampshire notes illegal in Massachusetts, which soon killed the scheme, leaving the noteholders to bear the full loss (Michener 2017).

In 1740, two more private banking schemes were floated in Boston, one that would have issued notes backed by mortgages on real estate and another backed by deposits of silver. Political rivalries prevented either scheme from moving forward with much speed and the extension of the Bubble Act to the colonies in 1741, which made explicit reference to both the land and silver banks, effectively squelched both enterprises, along with two additional schemes, one established in April 1741 in Essex County and another in Middlesex County. Extension of the Bubble Act to the colonies also forced the South Carolina banks to wrap up their affairs, which by then apparently were negligible anyway (Michener 2017).

In the aftermath of the French and Indian War, British authorities outlawed the issuance of new, legal tender bills of credit, mandated high taxes that rapidly called in the bills of credit issued during the war, and placed colonial trade under very strict supervision. As a result, the colonial money supply (coins and bills of credit) dropped precipitously, causing a major macroeconomic disturbance tied directly to the agitation over the Stamp Act. Money became so scarce that interest rates soared, property values plummeted, and default rates on loans soared.

Desperate for some means of liquidating debts, the residents of Bucks County, Philadelphia, resorted to circulating squirrel scalp bounties, epistolary IOUs worth 1d each made out by justices of the peace to pay the bounty on squirrels, which colonists considered agricultural pests of the first order. Merchants in Philadelphia, where debts were larger and squirrels less numerous, opted instead to form a bank that would issue private, asset-backed notes. Jealousies at home and legal pressures from London, however, quickly killed the enterprise, along with a similar scheme floated in New York (Michener 2017).

Revolution

The postwar monetary stringency helped lead to the Revolution by inducing colonists to resist the Stamp Act. As an anonymous colonist explained to a correspondent in 1768:

> It is not the Stamp Act or New Duty Act alone that had put the Colonies so much out of humour tho the principal Clamour has been on that Head but their distressed Situation had prepared them so generally to lay hold of these Occasions. . . . money being plenty, both in Specie and Bills of Credit [during the war] People were not afraid of entering into deep Engagements equivalent to our Circulation. . . . [In addition to the use of warships to] cramp trade by stoping [sic] and detaining Merchant ships and pressing their Men . . . Another capital Greivance [sic] and Inconvenience to these middle Colonies is being restrained from issuing Notes or Bills of Credit, which is no other than a Bank held by the public who are engaged for the Credit of it and reap the Emoluments of it; to recount our Distress for want of this Medium were Endless or by what unaccountable Policy G. Britain acts in the Restriction ("New Jersey Currency Question," Record Group 23, Box 4, New Jersey Historical Society, Newark, N.J.).

Resistance to the Stamp Act set off a long chain of events that ended with the Declaration of Independence. At first, the rebel governments financed the

Revolution the same way that most had financed wars throughout the eighteenth century, by issuing fiat paper money. During the Revolution, that meant state-issued bills of credit and also dollar-denominated Continentals issued by Congress, the nascent national government. The paper money issues at first refreshed economies long desiccated of cash, but as the war dragged on and the unbacked money in circulation swelled in nominal value, depreciation soon set in. Inflation, i.e., a rise in the specie price of goods, also occurred but paled in comparison to the depreciation of paper monies, which is shown in Table 1, a "scale of depreciation":

While the war had the salubrious effect of reducing reliance on bookkeeping barter and inducing more Americans to reckon economic value in terms of dollars, the massive depreciation and repudiation of federal and state-issued bills of credit, the third instance of bills of credit losing almost all value in a generation (New England's currency reforms of 1750 and colonial bills were the first two), soured Americans on fiat paper money for the better part of a century. They could have reverted to the use of specie and open accounts but the government's need for revenue suggested the more fiscally-savvy approach of establishing a commercial bank that would issue bank notes and deposits convertible into specie and would make short-term loans to governments and businesses.

Credit for the nation's first commercial bank, the Bank of North America (BNA), must be shared between Alexander Hamilton, a financially precocious young officer on General Washington's staff, and Philadelphia merchants Robert Morris and Thomas Willing, two of the merchants behind the abortive 1760s bank scheme. Hamilton laid out the policy grounds for the bank in two letters in 1780 and 1781. In the first letter, written most likely in early 1780 to an unknown addressee who may have been a member of Congress, Hamilton developed a plan to restore confidence in American currency, which had been destroyed by excessive issues of fiat currency and the near hyperinflation that followed. His plan called for Congress to obtain a

large foreign specie loan and use the proceeds to capitalize, along with private investors, a bank – which he calls the Bank of the United States. The bank, by backing its notes and deposits with specie, would create a new and trusted form of money to replace the discredited fiat issues of state and national governments. It would be jointly owned by the national government and private investors, who would share in its profits, and would lend to businesses to promote commerce, and perhaps most importantly, to the national government so that it could carry on the War of Independence (Sylla and Cowen 2017, Chap. 1).

Over the course of following year, Congress sent John Laurens, a fellow army officer and close friend of Hamilton, to France to seek the loan. It also tried to reform its discredited fiat currency by trying to call in old bills and replacing them with new ones at a ratio of 40 old to one new. The reform proved ineffective, inducing a frustrated Congress in early 1781 to appoint Robert Morris to be its Superintendent of Finance, an appointment Hamilton had recommended to a congressman in September 1780.

Hamilton used the occasion of Morris's appointment to write him a long letter in April 1781. He told Morris, who likely needed no convincing, that bringing order to America's chaotic finances was more important than winning a few battles if the Americans were to prevail in their War of Independence. After making rough estimates of Congress's revenues and expenses, he calculated a large deficit that pointed to the need for the foreign loan he had called for a year earlier. He reiterated his earlier argument that the best use of such a loan was to capitalize a national bank. Hamilton cited historical examples of how such banks had strengthened governments that sponsored and used them in their public finances, while also promoting economic growth by furnishing credit to merchants and entrepreneurs. Now, however, he outlined in great detail what the charter of such a bank might contain. Hamilton concluded by saying that his proposed bank would enable the Americans to prevail over the British, who were tiring of the long and inconclusive war, and that the growth of the American economy after independence would make it relatively easy to manage the new nation's large war debts and even redeem them in a matter of decades (Sylla and Cowen 2018, Chap. 3).

Shortly after his letter to Robert Morris, Hamilton left Washington's staff to become a line infantry commander in the Continental Army. In October 1781, he led his troops on a daring nighttime assault on a British fortification at Yorktown. The operation's success made the British position untenable, leading British General Cornwallis to surrender his army. The Yorktown victory proved decisive. As Hamilton had predicted in the Morris letter, the British were tired of the war, and a new government in London entered upon the peace negotiations that recognized American independence in 1783.

While Hamilton was fighting in 1781, Morris told him that he shared his ideas on a national bank. The Superintendent of Finance persuaded Congress by the closing days of 1781 to charter the Bank of North America. Based in Philadelphia, it was on a smaller, more realistic scale than the bank envisioned in Hamilton's letter to Morris. Still, the BNA had trouble attracting sufficient subscriptions from private investors. To complete the bank's contemplated capitalization, Morris had to

purchase a majority of its shares for the national government. He was able to do that using the proceeds of a specie loan from France, which John Laurens successfully negotiated in 1781.

As Hamilton predicted, the new bank helped the nation to finance itself during the war's long closing period. By 1783, a return of confidence allowed Morris to sell the government's shares to private investors, and the BNA became an ordinary commercial bank.

Soon after peace became official in 1783, merchants in New York and Boston sought to reprise the success of the Bank of North America, which the government had granted a monopoly for the duration of the war. Hamilton, by 1784 a rising lawyer in New York, helped that year to draft the constitution of the Bank of New York, an institution in continuous operation ever since (but under the name Bank of New York Mellon since its 2007 merger). The three commercial banks of the 1780s in Philadelphia, New York, and Boston were a portent of what was to come, but their overall economic impact was limited. The Bank of New York was an especially conservative lender at first because the state of New York would not grant it a corporate charter, potentially rendering its stockholders open to unlimited liability if the institution failed. Moreover, the overall economy remained soft in the 1780s as it remained unclear if the new nation could remain united, independent, and solvent.

Constitution and Financial Revolution

Despite the achievement of independence, the 1780s unfolded the weakness of the U.S government under the Articles of Confederation became increasingly manifest. The national government lacked powers of taxation. Instead, it made requisitions of revenue from the states, which often failed to meet them. Lacking revenue, the Confederation Congress could not meet its large debt obligations incurred in the war, and was forced to meet interest payments with more debt.

States had taxing authority and hence were in better shape to meet their debt obligations, which some did. But the states also bickered with one another over trade and territorial claims, and some turned to fiat money in excess, in some cases to inflate away their debt burdens at the expense of creditors.

A taxpayers' revolt, Shays's Rebellion, arose in Massachusetts in 1786, indicating that the new nation, barely a decade old, might be coming apart. Looming over all this domestic dissention, fears that European powers would take advantage of American weakness to reassert their claims prompted nationalist leaders led by Washington, Hamilton, and James Madison to look for a better way.

Their solution was to replace the Articles of Confederation with a new Constitution that greatly expanded the powers of the new federal government it authorized, albeit with many built-in checks and balances designed to prevent abuse of the expanded powers. The Constitution created separate executive and judicial branches of the federal government; under the Confederation, these had been subsumed by the legislative branch: Congress.

The new government had taxing powers concurrent with those of the states along with exclusive powers to tax imports and ship tonnage. In the financial and monetary areas, the Constitution authorized Congress to use federal revenues to pay the debts of the nation, granted it authority to incur further debt on the credit of the United States, and gave it powers to coin money and regulate its value.

To address perceived problems and make its intent perfectly clear, the Constitution explicitly removed the power of states to coin money, issue bills of credit, make anything other than gold and silver a legal tender in debt payments, and pass any laws impairing the obligation of contracts.

Washington became the first president under the Constitution in April 1789. In September of that year, after Congress created the Treasury Department, he appointed Hamilton, his former principal aide-de-camp and comrade in arms, to be the first Secretary of the Treasury (i.e., finance minister). Hamilton, who had a modern understanding of finance and its possibilities far in advance of any other American of his era, proved to be the right man in the right place at the right time. Since his letters on finance of 1780 and 1781, Hamilton had spent a decade refining his plans to modernize America's financial system. As Treasury Secretary, he was in a position to implement the plans. He did so in a whirlwind series of reports – on public credit, on a national bank, on a mint, and on manufactures – prepared at the request of Congress, which then debated his proposals, accepted most of them, and enacted laws to implement them.

The first was the Report on Public Credit of January 1790. It called for federal assumption of the states' war debts into an enlarged national debt, and funding the entire debt including the large arrears of interest at par. "Funding" meant pledging specified tax revenues, mostly those derived from customs and tonnage duties, to servicing and eventually redeeming the debt. Under the plan, a variety of existing federal and state securities constituting the old domestic debt were to be voluntarily exchanged for a package of new Treasury bonds – a 6% bond, a 6% "deferred" bond that paid zero interest for 10 years and then became a 6% bond in 1801, and a 3% bond.

The reason for offering a package of bonds to holders of old debt was to reduce the effective interest rate on the debt from 6%, the original rate promised to investors, to about 4%. The Treasury was empty when Hamilton took office, and it would be several years before tax revenues would prove sufficient to service the debt and fund ordinary government operations. Offering debt holders a reduced rate of interest was effectively a "haircut" in modern terms, but Hamilton made a number of arguments in the Public Credit Report on why they should accept the lower interest payments. He hinted that raising taxes high enough to pay debt holders the 6% they thought they were owed could lead to more taxpayers' revolts like Shays's Rebellion, and that would not be in debt holders' interest. He also offered the debt holders some valuable considerations in return for their accepting the haircut, notably call protection. The deal included a provision that the government could redeem not more than 2% of its outstanding debt in any 1 year, meaning that debt holders were protected from the government taking advantage of lower market rates down the road to borrow at lower rates and redeem all or much of its 6% debt (Sylla 2011; Sylla and Cowen 2018, chap. 7).

Most of the 6% bonds were to pay the original principal of the old federal debt. Other 6 s, some of the deferred 6 s, and the 3% bonds were to cover the assumed state debts and the large arrears of interest on the entire debt that had accumulated since the war. Overall, after the assumption of state debts, the domestic debt of the country stood at some $63–64 million. The voluntary conversion of old debt to new was essentially accomplished by 1795 when Hamilton stepped down from his cabinet position.

The United States also had accumulated a large foreign debt of about $12 million, including arrears of interest, mostly as a result of loans from its ally, France, during the War of Independence. These were paid according to the terms of the original contracts, mostly by taking out new loans in Europe, chiefly Amsterdam, during Hamilton's tenure as Treasury Secretary, 1789–1795. By the time he stepped down, the entire French debt had been repaid, using the proceeds of Dutch loans that matured in the early nineteenth century (and were repaid then).

Congress, after much contentious debate and some notable side deals (Hamilton gained the support of southern-state congressmen for the assumption of state debts, to which most of them were opposed, by agreeing in June 1790 to locate the permanent national capital on the Potomac River, closer to their homes), Congress enacted the essence of Hamilton's debt restructuring plan in the summer of 1790. The three new bonds representing the national government's debt began to be issued in the fall of 1790, and quarterly interest on them commenced in January 1791. Interest on bonds issued to replace assumed state debts began a year later.

As the new bonds were issued, they immediately began to be traded in new and newly energized securities markets organized in Philadelphia, New York, Boston, and eventually other cities. They also began to serve as collateral for loans from banks, and even to pass as a form of near money among merchants, investors, and others. Hamilton had foreseen these developments in his Report, and no doubt was pleased to witness them. This was the birth of the U.S. Treasury debt market, which in time became the largest and most liquid market in the world (Sylla 1998).

Hamilton met the interest payments due on the enlarged national debt promptly, which quickly bolstered the formerly badly damaged credit of the United States government. It was not an easy task because tax revenues remained insufficient to cover the costs until 1793–1794. Hamilton met the deficiencies by borrowing from domestic banks (including, as of 1792, the newly established national bank, the Bank of the United States [BUS], which was a key element of his overall plan, as discussed below) and foreign bankers. Despite the dicey financial situation, Hamilton exuded competence, control, and confidence. This charmed public creditors, who experienced large capital gains. Before 1790, when the federal debt was essentially in default, old U.S. and state debts sold in sporadic markets for small fractions of their face value. By the summer of 1791, the 6% rose to par, with proportionate gains in value for the deferred and 3% bonds. But the new wealth seemingly created out of thin air and the speculation taking place in securities markets infuriated Hamilton's political opponents, who resented his ability to implement his program and assumed his true intentions were nefarious, if not corrupt. The national unity of 1789 would give way to political party formation and competition by 1791 (Sylla 2011).

Debt restructuring and the establishment of public credit was the first key element of Hamilton's plan. The second was the founding of a national bank, the BUS. Hamilton had called for such a bank in 1780 and 1781, and Robert Morris presided over the creation of a limited version of such an institution, the Bank of North America, in 1781–1782. Hamilton's proposal for a much larger national bank, the BUS, came in his Bank Report of December 1790. The report discussed at some length the pros and cons of banking in general, which was a new and controversial subject for most Americans, and referenced history to show that the leading nations of Europe had established such banks, and found that they became sources of government strength and economic prosperity. Among the advantages to the economy would be an augmentation of the money supply by the bank's issue of currency notes and deposits convertible into gold and silver, and an expansion of credit by the bank's lending to creditworthy private borrowers.

The Report touted the advantages of a national bank for aiding the Treasury's financial management and for supporting public credit. Much of the bank's initial capital would consist of recently issued public debt, which would support the government bond market, and the bank would be a source of loans to the Treasury, which very much needed them (although Hamilton did not emphasize this) given its limited revenues in relation to the large financial obligations it had taken on in restructuring the national debt (Sylla 2011).

The Bank Report went on to outline a constitution consisting of 24 articles for the bank, which became the basis of the charter Congress would enact in February 1791 for the first Bank of the United States. The bank would be a very large corporation (in comparison to the few existing banks and corporations then existing) with a capital of $10 million, divided into 25 thousand shares each with a par value of $400. The U.S. government would subscribe for a minority ownership position, 20% of the shares, paying for them with a loan from the bank that would be repaid over 10 years, and it would share in the bank's profits to the extent of its ownership stake. These design features ensured that the bank would get off to a fast start and indicate that it had some responsibilities to be the federal government's bank, although to maintain the bank's independence, the government was to have no role in its management. By having the federal government share in the bank's profits, Hamilton also sent a message to state legislatures: you too can profit by chartering banks and tying them to state public finance. That the states got the message quickly is evident in the rapid expansion of banks chartered by state governments, which both invested in banks and taxed them (Sylla et al. 1987; Sylla 1998).

Private investors would own 80% of the bank's shares, and their subscriptions could be paid one quarter in specie and three quarters in the 6% Treasury bonds recently issued. Hamilton cleverly designed the bank to support the national debt and the debt to capitalize the bank. The private shareholders would elect the bank's directors, who had to be U.S. citizens. Finally, the charter authorized the bank to open branches, called Offices of Discount and Deposit, throughout the United States. State-chartered banks were confined to operating in the states that chartered them, so this provision was important for giving the country a version of nationwide banking in its earliest decades.

Both houses of Congress quickly approved the bank. But a minority in opposition raised the issue of the bank's constitutionality. Among the opponents who deemed the bank to be unconstitutional was James Madison, and he was joined in that view by cabinet officers Thomas Jefferson and Edmund Randolph. President Washington, mulling over whether to sign or veto the bill, asked Hamilton to respond to the opponents, which he did in a powerful, far-ranging defense of the bank and its constitutionality. The president was persuaded by Hamilton's opinion, and signed the bill (Sylla and Cowen 2018).

The BUS's initial offering of shares (actually rights, called scripts, to buy shares in several later installments) took place in July 1791. It sold out quickly, and a speculative bubble and collapse in them occurred over the following weeks, but was contained with deft interventions by Hamilton (Sylla et al. 2009). In December 1791, the bank opened for business at its home office in Philadelphia, and it began to open branches in other cities and states a few months later.

The third key element of Hamilton's plan came in his Mint Report of January 1791. Its main purpose was to define the U.S. dollar as the unit of account and monetary base of the country. Before the Mint Report, the United States had virtually no coinage of its own. Instead it relied on a variety of foreign coins, the most common of which were Spanish-empire minted silver pesos, which Americans since colonial times accumulated in trade and called dollars (Michener and Wright 2005). Not all of these dollars contained the same amount of silver, a point Hamilton addressed in his report. To be a respectable nation, Hamilton argued, the United States needed to have its own unit of account and mint. Should it be based on gold or silver? Hamilton set forth the pros and cons of each metal, in the end opting for bimetallism and a dollar defined in terms of both silver and gold.

Well aware of Gresham's Law, which predicted that if the mint ratios of gold and silver differed from their ratio in markets, the one undervalued at the mint would not be minted, he reasoned that a fairly long-term stability of the market ratio of gold and silver of about 15 to 1 might allow bimetallism to work for the United States. He studied a variety of Spanish dollars to determine that on average they contained 371.25 grains of pure silver, which standard he adopted as the silver dollar of the United States. The 15 to 1 ratio therefore implied that the U.S. gold dollar would contain 24.75 grains (371.25/15) of pure gold. Underlying opting for bimetallism was Hamilton's hope that it would result in a larger money supply and offer more stimulation to economic growth. The rest of his report dealt with technical issues of coinage such as the names and denominations of coins, the amount of alloy in coins, and the organization of the mint and how it would be financed (Sylla and Cowen 2018, Chap. 11).

Congress adopted the essence of the Mint Report in 1792, and launched a mint in Philadelphia. Hamilton hoped that it would supply sufficient U.S. coins within a few years so that foreign coins would no longer need to be legal tender at U.S. ratings. In that he would be disappointed. The mint failed for decades to supply enough U.S. coins to dispense with the use of foreign ones. Only in the 1850s, after the major gold discoveries in California, would the United States end its reliance on foreign coins as legal tender. Until that time, the U.S. money supply would consist of

a few U.S. coins, a larger amount of foreign coins rated in dollar terms, and bank notes and deposits (Wright 2005).

The last of Hamilton's great state papers of 1790–1791 was the Report on Manufactures, delivered to Congress in December 1791. It was his longest report and perhaps in the long run his most influential effort because it mapped out the policies by means of which an undeveloped or underdeveloped economy with the support of enabling governmental policies might develop and grow. It said little about finance, other than to provide arguments and evidence that the restoration of public credit and the national bank resulting from the adoption of his policies were already working to alleviate the young nation's deficiencies of capital and credit that some considered reasons to avoid developing U.S. manufacturing. Congress took no direct action in response to the report, although less than a year later, for reasons unconnected to the report itself, it adopted most of the report's recommended revenue measures.

As Treasury Secretary, Hamilton had the direct authority to recommend and implement policies to establish public credit, launch a central bank, and define the U.S. dollar as the nation's monetary unit. He relied on others to implement the rest of his plan, which called for promoting the development of the U.S. banking system, its securities markets, and its corporations. But his policies induced them to do so.

The creation of $64 million of prime domestic federal debt securities and $8 million of Bank of United States shares in the hands of the public, for example, fostered the development of vibrant securities markets. They sprang up almost immediately in Philadelphia, New York, and Boston, and soon spread to other cities such as Baltimore and Charleston (Wright 2008). The three Treasury bonds and BUS shares became the national market securities in each city market, where they were later joined by the bonds of state governments, and the shares of state-chartered banks, insurance companies, and other corporations (Davis 1917; Wright 2014). Americans were not the only ones to use these markets. Foreign investors were large purchasers, such that by the first years of the nineteenth century they owned more than half of the U.S. national debt and more than half of the shares of the BUS (Sylla et al. 2006). This, too, was part of Hamilton's plan for attracting foreign capital to the United States. Cliometric investigations have uncovered the securities listings and price histories of these early markets, and documented that they grew over time (Rousseau and Sylla 2005; Sylla 2005).

Similarly, Hamilton's BUS, by far the largest corporation of the early United States, prompted states for a variety of reasons to charter an increasing number of banks of their own, as well as insurance companies and other corporations. The United States, which had only three state banks in operation in 1790, had 28 by 1800, more than a hundred by 1810, more than 300 by 1820, and nearly 600 by the mid-1830s (Sylla 1998). In total, some 300 corporations including banks were chartered in the 1790s, and that was just the beginning (Davis 1917). In subsequent decades, as again shown by cliometric research, thousands and tens of thousands more corporations were chartered by state legislatures, and eventually by administrative agencies of state governments (Sylla and Wright 2013; Wright 2014, 2015).

Hamilton's launch of the U.S. financial revolution was complete by 1795, the year he resigned as Treasury Secretary and returned to New York to practice law. His policies had given the country a modern, articulated financial system with several key institutional components, namely strong public finances and public debt management, a central bank (the BUS) with nationwide branches, the U.S. dollar as a new national currency, an expanding banking system, active securities markets and two nascent stock exchanges in Philadelphia and New York, and a growing number of corporations, both financial (e.g., banks and insurance companies) and nonfinancial (e.g., transportation and manufacturing companies). Virtually none of these components existed before 1790. The new financial system financed the country's territorial expansion (e.g., the Louisiana Purchase in 1803), its transportation and industrial revolutions of the early nineteenth century, and its wars. Financial development, as in other places and times, led U.S. economic development and growth.

There were, to be sure, bumps and setbacks. One came in 1792 in the form of the new nation's first financial crisis, which was intimately bound up with Hamilton's financial policies. Speculators fueled by expanding credit, including that of the brand-new BUS, attempted to corner the market in U.S. 6% bonds, which subscribers to BUS stock needed to complete their purchases of BUS shares. The bonds' prices rose well above par early in the year, only to come crashing down to below par in the early weeks of March after one notable speculator defaulted on his obligations, triggering other defaults and panic sales of securities. Hamilton sensed what was happening early in the year, and called for banks to gradually reduce their credit creation. Instead, banks, notably the BUS, stepped on the brakes, contributing to the panic and crisis.

At that point, Hamilton stepped in and managed the crisis much like a modern central banker would. He urged solvent banks to keep up their lending, and promised the banks that their loans to finance merchants' tax payments would not lead to Treasury withdrawals of cash. He organized open-market purchases of substantial amounts of government debt to inject liquidity. He hatched and saw implemented a plan whereby distressed securities dealers were encouraged to collateralize their holdings for bank loans at values Hamilton specified instead of dumping them on the market at fire-sale prices to obtain liquidity. He coupled the plan with a sort of repo guarantee, saying that if a bank making such loans got stuck with the collateral, he would take it off the bank's hands at the values he had specified. These and other measures alleviated the crisis, which blew over in a matter of months with minimal damage to the economy (Sylla et al. 2009).

A greater, if temporary, setback to the financial revolution came in 1811, when Congress failed to renew the 20-year charter of the BUS by the narrowest of margins. It was not because the central bank had failed to do its job of stabilizing the financial system and regulating the banks. All evidence points to it having done a good job of that. The problem was political, not financial or economic. By 1810, states had chartered more than a hundred banks, which both competed with the BUS in many markets and were regulated by it. Some of these banks and the state legislatures which chartered them and invested and taxed them, reasoned that if the BUS was not rechartered, they would get rid of a competitor and a regulator, and once it was gone

they would get the banking business of the federal government, which would no longer have its own bank. It was a win, win, win political opportunity, and it led to the defeat and demise of the first BUS in 1811 (Sylla 2008).

Hamilton was not there to fight this battle. He had died after a duel with Vice President Aaron Burr 7 years earlier, in 1804. It was left to new Treasury Secretary, Albert Gallatin, to fight the battle. Gallatin fought hard and gallantly to preserve the BUS, but in the end he failed.

War of 1812 and Advent of the Second Bank of the United States

The timing of the demise of the first BUS was unfortunate. In mid-1812, barely a year after the bank closed its doors and began to wind up its affairs, the United States declared war on Great Britain in response to Britain's continued predations on American shipping and impressments of crew members of American ships into the British navy. Without a central bank, the country embarked on a war with one arm (finance) tied behind its back. The war itself proved inconclusive; when it ended, the status quo ante bellum was simply restored. But as the war unfolded, financial embarrassments were as numerous as military failures. Even before the war ended in early 1815, national leaders realized that killing the first BUS had been a major mistake, and they moved to create a new version of it.

The absence of a central bank during the War of 1812 had two negative consequences for U.S. finance. First, the government could not borrow from a bank that did not exist. Treasury Secretary Albert Gallatin, anticipating war, had hoped up to 1811 to recharter an enlarged version of the first BUS, one with $30 million of capital instead of the first BUS's $10 million, and to obligate the new bank to lend half of its capital to the government on demand (Edling 2014). In the event of war, short-term loans from the central bank would facilitate a quick mobilization of military resources, just as in 1794, when a BUS loan of $1 million financed the mobilization of forces that put down the Whiskey Rebellion. Central bank loans could be repaid with the proceeds of long-term government borrowing via bond issues as a war continued and wartime finance became regularized. Congress rejected Gallatin's plan in 1811, complicating his task of financing the war a year later.

The second negative consequence of not having a central bank came in 1814 when banks outside New England suspended specie payments at the time of a British invasion of the Chesapeake. Instead of having one national currency managed by a central bank, which also transferred the government's funds throughout the nation (and even internationally) to places where they were needed to make payments, the country had multiple local currencies of varying rates of exchange with the specie dollar. Without BUS notes constituting a national currency, the government was forced to accept local bank notes of varying values in payment of taxes and as subscriptions to its debt issues. That sometimes meant that although the government had a surplus of local currencies in some places, it was short of acceptable means of payment in others. War finance became needlessly complicated and expensive (Edling 2014).

Without a central bank, and in the later stages of the war an inadequate national currency, the government relied heavily on issues of short-term Treasury notes to relieve the money shortage and pay war expenses. The notes bore interest, were payable to the bearer, and were to be redeemed 1 year later. They substituted for an absent national currency. More importantly, they became reserves for the state banks that proliferated during the war era, and served to stimulate an inflationary monetary expansion. The government issued a total of $37 million of Treasury notes during the war, but because of redemptions, the maximum outstanding at any one time was about half of that (Edling 2014).

Even more important than Treasury notes was the issue of long-term bonds. Five loan acts during the war authorized issues of bonds totaling $73 million at face value. But the bonds were not easily sold, and they brought in proceeds that were well below the face value of the bonds. Before the war began, the first loan act in March 1812 authorized $11 million of borrowing. Subscriptions from banks and individual investors totaled only $6 million. Another loan act of early 1813 fared even worse. The government asked for $16 million, but buyers initially took only $4 million. In response, the government reopened the books with a novel approach: the bonds would be auctioned to the highest bidders. That worked. The loan was over-subscribed, but the bonds sold at a discount, 88% of par value. Wealthy individuals acted as nascent investment bankers, purchasing large amounts of the bonds with the intention of reselling them at a profit to smaller investors. A few months after the $16 million loan, a third act authorizing $7.5 million achieved similar results, with investors paying 88.25% of par for the bonds (Edling 2014).

The year 1814 proved more difficult for Treasury finance. A $10 million loan in April filled at 88% of par, but only because a dubious investor made a large subscription on which he later partly defaulted. Around the same time, the British subdued Napoleon in Europe, increasing the chances that they would send more forces to America, prolong the war, make a favorable outcome for the United States less likely, and increase the likelihood that more loans would be needed. Fearing this, investors in the April loan forced Treasury Secretary George Campbell (Gallatin had stepped down to participate in peace negotiations with Britain in Europe) to agree that if another loan later in 1814 were sold below 88% of par, the price of their bonds would be similarly reduced. The investors were prescient. The Treasury requested a new loan of $6 million in August, at the very time British forces were invading the Chesapeake and burning U.S. government buildings in Washington, D.C. The bottom fell out of the bond market, and less than half of the loan was filled at a price of 80% of par. That meant the investors in the April loan had their price reduced from 88 to 80 (Edling 2014).

A new treasury secretary, Alexander Dallas, replaced Campbell. He called for tax increases to service old debts, and a new and vastly larger BUS, capitalized at $50 million, to be the principal source of new loans. In the interim, the Treasury relied on new issues of Treasury notes to pay most of its bills. Fortunately, the war ended at the start of 1815, leaving U.S. government finances in a mess, but relieving the pressures of financing a continuing war. Breathing sighs of relief, national leaders turned attention to undoing the mistake of 1811 by creating a new central bank.

Congress's bill to charter the second BUS became law in April 1816. The new bank, with a capital of $35 million, was essentially an enlarged version of the first BUS. Like its predecessor, its main office was in Philadelphia, and it could open branches throughout the nation. The government again took 20% ($7 million) of the bank's stock; the government had the right to appoint 20% of the directors, a privilege it did not have with the first BUS. Private investors could pay for their $28 million in shares in three installments by tendering 25% of the cost in specie and 75% in U.S. government securities, which were accepted at par even though selling at discounts from par in securities markets. The resulting demand for $21 million of government debt to pay for bank shares led to a rapid rise in federal bond prices, with yields falling from more than 7% to less than 6%. In effect, the second BUS as it was organized absorbed about a sixth of the outstanding U.S. public debt of more than $120 million, an amount greatly enlarged by the War of 1812 borrowing (Knodell 2017). The rapid restoration of the U.S. government's credit, which had become tattered in the war, was a principal achievement of the bank's founding.

The restoration of public credit, however, was not a main reason for founding the bank. Congressional leaders and the Treasury were more interested in restoring a national currency convertible into specie. Such a currency had been lost when, with the first BUS gone, banks outside of New England suspended specie payments in mid-1814. Convertibility was soon restored in the older Atlantic seaboard states, but the West was another story. There the wartime inflation gave way to a postwar boom in land sales, much of which was financed by the credit expansion of state banks, whose interest in, and capability of, maintaining convertibility was highly suspect. When the new BUS pressed western banks to convert their notes to specie by presenting them, it encountered resistance. So it stopped accepting them. That forced the Treasury to revive its wartime practice of selecting state banks to become depositories for Treasury receipts of tax payments and proceeds of land sales. In effect, the second BUS transferred currency risk to the Treasury (Knodell 2017). The Treasury was not happy about the BUS's lack of cooperation, and even unhappier when some of the banks it had selected as depositories for public funds in a form the BUS had declined to accept failed. The BUS had protected itself from those defaults, but by contracting credit in the western land boom it had paved the way for a financial panic in 1819. Westerners, including Andrew Jackson, would remember the Panic of 1819 and the BUS's role in leading up to it when the issue of renewing the BUS's 20-year charter came up in the early 1830s.

After this shaky start, the second BUS settled down to provide the nation with the currency and financial stability that its predecessor, the first BUS, provided from 1792 to 1811. That was particularly true after Nicholas Biddle, a Philadelphia patrician, became its president in 1823. Several notable achievements marked Biddle's presidency. One was establishing a large branch network throughout the country, which helped stabilize U.S. currency and credit everywhere, but especially in the West, where so many state bank failures occurred around the Panic of 1819. Besides smoothly transferring the government's money from where it was (mostly in established eastern financial centers) to where it was needed (often on the rapidly settling western frontier), Biddle's BUS promoted economic expansion and national

economic integration by operating an efficient system of domestic monetary exchanges. A western merchant, for example, could easily use BUS facilities to order goods from an eastern supplier by obtaining a credit from the local BUS branch in the West, and the money would be paid to the supplier by an eastern BUS branch. The goods would be shipped west and sold, allowing the western merchant to repay his credit from the local BUS branch. The entire transaction went smoothly and at a low cost. In the absence of the BUS, such transactions could have required more costly specie shipments or the facilities of private bankers who would have charged more because they lacked the economies of scale achieved by the BUS (Knodell 2017).

A second achievement of the BUS was increased confidence in the currency. The BUS became the principal repository of the nation's specie reserves. When more specie came into the country than went out, BUS reserves rose; when more went out than came in, they fell. In that way, the BUS cushioned a growing number of state banks from large fluctuations in their own reserves. With more stable reserves, the state banks could lend more and create more notes and deposits. Nevertheless, they were restrained from excessive expansion by the BUS, which received state bank liabilities (notes and checks written on deposits) and presented them to the state banks for payment. Banks and entrepreneurs could (and did) complain about BUS restraints on credit expansion, but Knodell (2017) finds no evidence that economic growth was constrained. A positive result was growing confidence in bank currency, for which there is substantial evidence. The money-holding public had a choice of forms in which to hold money, which could be divided between specie and bank liabilities. Over the course of the 1820s and early 1830s, the public chose to hold increasing amounts of money in the form of bank liabilities and to reduce holdings of specie. Americans economized on specie, an expensive form of money, in favor of the cheaper bank money (notes and deposits), in which the second BUS had fostered increased confidence (Engerman 1970; Knodell 2017).

The BUS managed the foreign monetary exchanges of the United States along with internal domestic exchanges. Large amounts of U.S. debt and equity securities were held in Europe, necessitating payments of interest and dividends in foreign financial centers. The BUS had business arrangements with foreign bankers that facilitated these payments. By the late 1820s, the principal of the U.S. national debt was being paid off as well, much of it to foreign investors. The BUS managed all these foreign payments without disrupting the domestic financial system. That, too, increased Americans' confidence in bank money.

In 1825, Britain suffered a major banking crisis with numerous failures of financial institutions. The United States, which had numerous trade and financial ties with Britain, escaped the crisis. Some financial historians credit the second BUS with taking actions to prevent the British crisis from spreading to the United States (Hammond 1957; Govan 1959); others point to instances in which the BUS appeared to be looking out for itself instead of taking actions to stabilize the U.S. financial system (Temin 1969; Knodell 2017). The telling fact in these disputes would seem to be that the U.S. avoided a serious crisis and a long period of stable economic expansion continued (Sylla 2013). On balance, therefore, the BUS acted as a stabilizer.

Despite its economic and financial successes, the second BUS, like the first, became a victim of banking politics. Whig politicians, seeking to embarrass the populist Democrat president Andrew Jackson in 1832, an election year, introduced a bill to recharter the second BUS early, 4 years before the bank's federal charter expired in 1836. The bill passed both houses of Congress, but was vetoed by Jackson, and the bank's backers could not muster the supermajorities needed to override the veto. The bank hoped for a reversal of veto, but when it contracted credit in response to the government's diversion of deposits of revenues to other banks, it lost favor with the public. On the expiration of its federal charter in 1836, the BUS reconstituted itself as a Pennsylvania state bank with a charter that cost it dearly. A few years later, after forays into investment banking, it failed.

The United States would be without a central bank for seven decades, from 1836 to 1914. The price was not reduced economic growth, but decreased economic and financial stability. Financial crises and economic downturns became more frequent during the seven decades without a central bank (Sylla 2013). European nations in those decades introduced new central banks and converted old national banks to central banks. As a result, Europe had far fewer crises. The panic of 1907, which afflicted the United States but largely bypassed Europe, was the last straw. Congress responded with authorizations for emergency currency issues and the creation of a National Monetary Commission, which recommended a new central bank. It came in 1914, in the form of the Federal Reserve System, which now has lasted for more than a century.

Financial Sector Development and Growth to 1836

As Fig. 1 shows, despite the trials and travails of U.S. central banking, the number of commercial banks in operation grew quickly in the first decades of the nation's existence. New entrants vastly outnumbered exits, the first of which occurred with the bankruptcy of three banks controlled by Boston speculator Andrew Dexter in early 1809 (Kamensky 2008). Some early exits were due to voluntary liquidation rather than outright failure; mergers came later.

Early commercial banks had three major sources of funds (types of liabilities): notes, deposits, and owner equity (capital). Occasionally, a troubled bank borrowed from another bank or a rich individual, but such instances were rare. Uses of funds (types of assets) included specie reserves, secondary reserves (generally government bonds), notes of and deposits in other banks, physical property (banking house; land seized for debt), and short-term loans, known as discounts, wherein the bank literally purchased a promissory note, bill of exchange, or other short-term evidence of business debt for its discounted present value. At 6% annual interest, for example, a bank would pay $94.34 today for a $100 note with exactly a year to run ($PV = FV/(1 + i)^n$, where PV = present value or price; FV = future, face, or principal value; i = interest rate; n = number of compounding periods. So in this case, PV = 100/1.06 or $94.34 rounded up to the nearest penny) (Bodenhorn 2000, 2003).

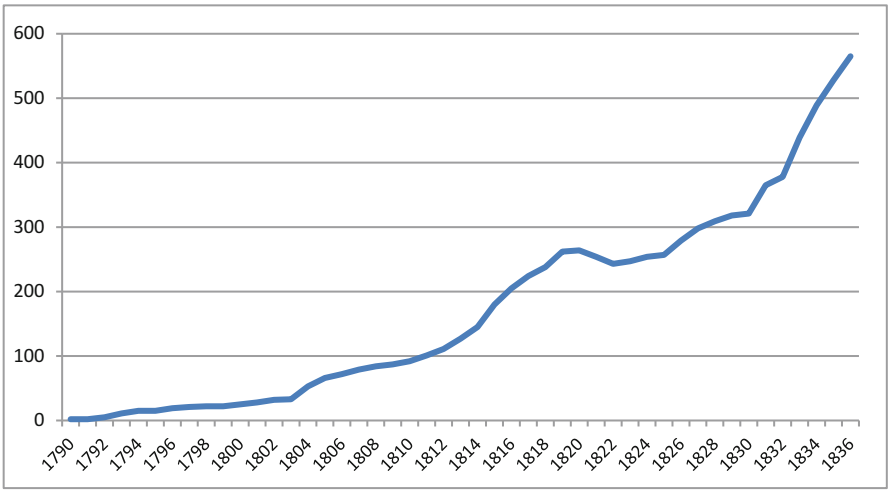

Fig. 1 Number of U.S. Commercial Banks in Operation, 1790–1836. (Source: Weber 2005)

Like banks today, early commercial banks faced interest rate, credit, liquidity, and capital adequacy risks. If interest rates increased, the market value of their secondary reserves dropped. If they discounted notes willy-nilly, defaults cut directly into capital, which, if insufficient to cover losses, meant bankruptcy. Bankers also had to keep sufficient specie reserves on hand to meet depositor withdrawals and noteholder redemptions, so instead of lending money that would fall due in a few, large globs, banks tried to spread repayments out evenly over time so they always had new cash flowing in. They also held liquid assets like government bonds as secondary reserves that could be quickly and easily sold should they need cash to meet unexpected exigencies (Bodenhorn 2000, 2003).

Political opponents and groups that wanted to charter new banks sometimes portrayed early commercial banks as the exclusive clubs of a few wealthy merchants or, in New England, related industrialists (Lamoreaux 1994). Many early commercial banks, though, lent to significant numbers of artisans, farmers, retailers, and manufacturers as well as to large wholesalers. That said, commercial banks were generally not open to consumers, i.e., small depositors and individual borrowers, especially those seeking mortgages. Their needs were met by person-to-person markets, like those for mortgages and ground rents, or new forms of financial intermediaries including lombards, mutual savings banks, joint-stock savings banks, building and loans, and marine, fire, and life insurers (Perkins 1994; Murphy 2010).

Lombards were for-profit financial intermediaries that lent small sums to consumers. The first, the New York Lombard Association, formed in April 1824. Before the end of 1836, eight lombards had formed, two in Pennsylvania and the rest in New York. Their total legally authorized capital ranged from a minimum of $1.5 million to a maximum of $2.6 million (Wright 2015).

The first mutual savings bank formed in the United States was organized in Philadelphia in December 1816 and was quickly emulated in Boston and elsewhere. The first incorporated joint-stock savings bank, the New Orleans Savings Bank, received its charter from Louisiana in March 1827. By the end of 1836, 151 savings banks had formed across the nation, 26 joint-stock, 3 hybrid (a mix of mutual and joint-stock), and the balance mutual. Regardless of their ownership structure, all accepted small deposits, made large mortgage loans, and bought public securities. The joint-stock and hybrid savings banks had a cushion of equity capital that averaged about $75,000 but paid for the privilege in the form of stockholder dividends. Mutuals built up cushions over time out of accrued profits (Wright 2015, 2017).

Fire, marine, and life insurers also invested in mortgages and public securities, including government bonds and corporate stocks and bonds. There were 620 insurance companies incorporated nationwide by the end of 1836. Most were joint-stock, but 103 were mutuals and 39 took a hybrid mutual-joint-stock form. Insurers aided businesses by spreading and pooling risks like shipwrecks and warehouse fires, but also by inducing insureds to mitigate risks through the adoption of best practices, like fire drills, and technologies like fire-resistant construction and reinforced hulls (Wright 2015, 2017).

All the individual lenders, savings banks, and insurers could not satiate the demand for mortgages, so in 1831 the first building and loan association in the United States appeared in Frankford, just north of Philadelphia (Rilling 2001). Building and loans dominated the residential mortgage business throughout much of the country in the late nineteenth and early twentieth centuries before being replaced by savings and loans during the Great Depression (Mason 2004).

Conclusion

From its humble colonial origins, where most households provided basic banking services, to the horrors of wartime hyperinflation, the U.S. financial system emerged in modern form soon after ratification of the Constitution in 1788, thanks in large part to the policies of Treasury Secretary Alexander Hamilton, who unleashed the power of private investors by restoring their confidence in the national currency (a specie-defined dollar) as well as in public credit. From the solid foundation established in the early 1790s, which included a central bank that on occasion acted as a lender of last resort and helped to maintain the national government's credit, financial innovators built a system of commercial, investment, private, and savings banks and fire, marine, and life insurers.

Although imperfect, the system was far from primitive. It did much to supply the money and credit that stimulated rapid U.S. economic growth and development in the nineteenth century, including the agricultural, market, transportation, and industrial revolutions (Rousseau and Sylla 2005; Wright 2017). A detailed, quantitative comparison of the U.S. and British systems as they developed over the four decades from 1790 to 1830 concludes that the United States had the better, more modern system overall (Sylla 2009). Britain's deserved reputation as the financial leader of

the nineteenth century came because its system improved after 1825, while the U.S. system retreated after Jackson's veto of the bill to recharter the second BUS (Sylla 2008).

Cliometrics and Antebellum Banking

Hugh Rockoff

Contents

Abstract

The three decades before the Civil War in the United States provides a remarkably rich source of informative experiences for the student of banking and finance. The Second Bank of the United States was wound up after the famous "Bank War." Inflows of gold and silver and banking panics disrupted the financial system. And the states followed a wide array of models when they chartered and regulated banks including the famous free banking laws. This paper describes the evolution of scholarly thinking about this era and the many contributions made by cliometricians.

Introduction

This paper reviews the work by cliometricians on banking in the United States during the 30 years before the Civil War. I have used the term antebellum to describe this period, although the term is somewhat flexible. Sometimes it is used to refer to the whole period from the War of 1812 to the Civil War, and at other times to just the two decades before the Civil War. One reason for limiting the coverage of the essay to this period is pragmatic: another essay in this volume will cover banking up to 1830. But 1830 to 1860 also forms a coherent historical epoch. The demise of the Second Bank of the United States in the mid-1830s led to a wide variety of experiments with banking systems. Cliometricians have therefore found this period to be especially fertile for testing ideas about the effects of alternative banking arrangements.

Although monetary economics has long been quantitative, banking history, to a surprising extent, has not. American economic historians have often written about banking history while making very little use of quantitative data or methods. Fritz Redlich's (1947) *The Molding of American Banking: Men and Ideas* is still required reading for anyone who wants to understand the history of banking during the antebellum era. But it contains no charts, tables, or equations. Bray Hammond's (1957) brilliant *Banks and Politics in America from the Revolution to the Civil War* was awarded the Pulitzer Prize for History in 1958. It is still one of the key texts on antebellum banking, yet it also contains no charts, tables, or equations. Clearly, there was room for studies that made more use of the quantitative record. Here I will describe how a generation of cliometricians enriched the work of these pioneers. First, however, we need to be clear about what a bank was and how it functioned during the antebellum era.

The Antebellum Bank Balance Sheet

Banks are financial intermediaries that issue short-term liabilities and invest in longer-term assets. The customers of banks gain because they value the liquidity from holding an asset that can be quickly turned into cash. The price they pay for liquidity is the low rate of interest they receive. The bank profits from creating liquidity because the longer-term assets they buy pay a higher rate of interest than the short-term liabilities they issue. Table 1 shows a stylized balance sheet of an antebellum bank.

Most items will be familiar to someone familiar with modern bank balance sheets. Deposits were subject to check, although to make a long-distance payment a depositor would have to purchase a draft on a bank familiar to his or her counterparty (James and Weiman 2010). For example, someone living in Springfield, Ohio, would not normally be able to make a payment in New York by drawing a check on our hypothetical Springfield bank. Instead, they would purchase a draft on a New York bank. The capital, surplus, and loan loss reserve accounts were also similar to accounts on a modern balance sheet. In some dodgy cases, the capital would be "paid" with loans from the bank itself, so that the true amount of capital invested in the enterprise was exaggerated.

Table 1 Balance sheet of the first cliometric bank of Springfield, Ohio, July 4, 1840

Assets		Liabilities and capital	
Reserves	$10	Notes	$100
Loans	$200	Deposits	$100
Securities	$100	Loan loss reserves	$50
Real estate	$50	Surplus	$50
Bank building and furnishings	$40	Capital	$100
Total	$400	Total	$400

Banking theory at the time held that ideally these loans should be short-term bills that originated in "real" transactions. The famous "real bills doctrine" can be traced back at least to Adam Smith who gave the idea its name. For example, a miller draws a 90 day bill to buy wheat from a farmer; and the farmer discounts the bill at a local bank. The bill is a safe investment for the bank because it is "two-name" paper and because it had originated in a real transaction – a sale of wheat – so that the miller would be able to pay the bill when the flour made from the wheat was sold. It was liquid because it would be paid in 90 days. These bills, however, because of their safety and liquidity, often paid low rates of interest and banks frequently made longer-term loans. And of course, nominally short-term loans could be renewed again and again, in effect becoming long-term loans. Many of these loans in the antebellum era, as Lamoreaux (1994) showed, were "insider loans." The bank would make loans to shareholders who often were trustees or administrators of the bank. Obviously there was a danger that insiders would exploit and weaken the bank by making excessive loans to themselves at unrealistic rates. But Lamoreaux shows that the system often worked surprisingly well: by lending to insiders the bank solved the problem of securing adequate information about the worth of the borrower.

The securities of the banks would normally be government bonds, often bonds issued by the state or municipality where the bank was located. Under the free banking laws, discussed in more detail below, banks were required to hold bonds to protect the value of the notes they issued. The reserves of the bank were, first of all, specie (gold and silver coins). For the first part of our period, they were usually silver, but gold became important after gold was discovered in California. Banks also considered deposits in other banks to be part of their reserves.

Bank Notes

Bank notes are the least familiar and the most controversial item on the antebellum balance sheet. Private Banks at that time issued paper currency that circulated from hand to hand like modern Federal Reserve notes. This was true not only in the United States but around the world. Today, only a few privately owned banks still issue notes intended to circulate from hand to hand. Typically, these notes promised to pay legal tender on demand when presented at the bank's office. In New England, as will be discussed below, country bank notes could be redeemed at the Suffolk Bank in Boston.

Many economic historians have condemned private note issues. Why? For one thing, banks sometimes failed and people who held the notes were left holding notes of little or no value. Some of the note holders may have accepted notes passively as part of a minor transaction. In situations of this sort, looking into the condition of the bank and deciding whether or not to accept a note would have been impractical. Moreover, with so many banks issuing large numbers of notes, it has been claimed that counterfeiting was made easy. If someone offered a note, how was the poor merchant to know whether it had been issued by a strong bank, a weak bank, a bank that had already failed, or whether, indeed, it was a counterfeit? Mihm (2007), consistent with much earlier writing, maintains that this was a disastrous state of affairs curable only by the nationalization of the currency. Bank note reporters that listed discounts to be applied to notes from distant banks as well as descriptions of the many altered (10s changed to 100 s) and counterfeit notes circulating were regularly published. The Bank note reporter certainly helped the merchant in deciding whether a note should be accepted in payment. But using them took time, and in the nature of things the information they provided was imperfect. It was indeed a strange state of affairs to someone familiar with today's safe and universally accepted notes. But at the same time the cost of using the currency for most users is easily exaggerated. In Chicago, one would typically use Chicago notes. If someone arrived with New Orleans notes they could exchange them, although the New Orleans notes would be discounted by 2% or 3%. It was a fee on the same order of magnitude that one might pay today at an ATM machine. There were many counterfeits and altered notes one had to be wary of, but not very long ago merchants kept lists of phony credit card numbers. It was an inconvenience, but in my judgment the social costs were limited.

The lists of discounts in the bank note reporters have provided grist for the cliometrican's mill. In one of the first studies, Gary Gorton (1996) showed that the discounts on notes issued by newly established banks were high, but that they then declined as note brokers gained confidence in the soundness of the bank. Gorton argued that this seasoning of notes was an important factor discouraging bad banking; wildcat banking as it was known. Bodenhorn (1998) reinforced Gorton's point by showing that the notes of banks that were about to fail went to high discounts. Jaremski (2011) continued the study of the discounts showing, among other findings, that the discounts reflected evaluations of the stability of state banking systems. All in all, these studies show that the banknote discount market was much like modern markets for other types of financial assets.

The requirement that notes and deposits be redeemable in specie set limits on how much exchange rates could vary between regions. For example, if a $1 note issued by a Louisiana bank found its way to Chicago, it would be discounted. It might sell, for example, for $0.97 in notes issued by Chicago banks, "current money" as it was called, but the price would be unlikely to fall, say, to $0.50 because anyone could buy the note and send it to New Orleans where it could be redeemed (exchanged) for $1.00 coin. A profit opportunity of that magnitude would not last for long. The price of the bank note would rise. Nevertheless, Shambaugh (2006) shows that there was enough flexibility in interregional exchange rates that some states could and did follow somewhat independent monetary policies.

The United States became a true multiple currency area with flexible rates during the Civil War. The South, as is well known, had a separate currency; and during the War and after until 1879, the Eastern part of the United States was on the greenback standard while the Pacific Coast remained on gold, and the rate of exchange between the two regions varied. National Banks in the two regions even issued different types of bank notes. Notes of National Banks in the East were redeemable in Greenbacks; Notes of National Banks on the Pacific Coast were redeemable in gold (Greenfield and Rockoff 1996).

The Structure of the Banking System in the Antebellum Era

The banking system during the antebellum era was fragmented into a wide variety of institutional and regulatory regimes. At the beginning of the period, the United States had a "central bank," the Second Bank of the United States. Central bank is in quotes because there is some debate about the extent to which it resembled a modern central bank. It was a reincarnation on a larger scale of the First Bank of the United States. Like its predecessor, it was modeled to some extent on the Bank of England and the large Scottish banks, the Bank of Scotland, and the Royal Bank of Scotland. It had branches throughout the country, and a dominant role in the payments system. But it is not clear that it ever operated as a lender of last resort or that it took responsibility for macro-economic variables such as the price level or rate of exchange. The Second Bank of the United States was forced to give up its federal charter in 1836, a loser in the great "Bank War" between President Andrew Jackson and Nicholas Biddle, the president of the Second Bank. Jackson led the Democratic Party which was strongly supported on this issue by state banks angered by competition from the Second Bank, and by Western entrepreneurs and farmers hoping for lower interest rates. Biddle was backed by the Whigs who were strongly supported by Eastern commercial interests. Politics, of course, is always complicated. Frontiersman Davy Crockett broke with Jackson on the Bank and other issues; no doubt from principle, although there were also his difficulties in repaying a loan from the Bank which was ultimately forgiven (Catterall 1903). The Second Bank struggled on for a short time under a charter issued by Pennsylvania, but failed in 1841.

The establishment and regulation of banks then fell to the states. They followed a surprisingly diverse range of models. Some states continued chartering banks one by one through legislative acts, some created publicly owned monopolies, some allowed free banking (more on this below), and some even prohibited banking. Indiana created a system of independent but mutually cooperative banks that has been praised as a model for achieving stability (Calomiris 1990). There were also savings banks, mutual savings banks, private banks of various sorts, and trust companies. Hammond (1948) and Bodenhorn (2003) survey the landscape. All of these institutions deserve study, but for the most part, cliometricians have focused on the travails of the commercial banks and the Second Bank of the United States.

The End of the Second Bank and the Jacksonian Inflation

The First Bank of the United States, like other central banks in that era, had a renewal provision in its charter. The renewal provision served several purposes: it assured critics of the Bank that they would have a chance to get rid of the bank if it did not live up to the claims of its advocates, and it provided an occasion for extracting some money from the Bank in exchange for renewal. In 1811, when the renewal date was reached, the charter, after a bitter controversy, was not renewed. The United States was left during the War of 1812 without a central bank. After the War, the deranged state of the currency led to calls for a Second Bank of the United States. And in February 1816, a Second Bank of the United States was established, in many respects simply a larger version of the First Bank.

Many traditional banking historians praised the Second Bank for its management of the financial system. Jane Knodell (2017) used cliometric methods to reinforce the traditionally favorable view while arguing that at points the traditional historians went too far. Knodell found that the Second Bank had indeed played an important role in reducing the costs of interregional payments, and that the demise of the bank was a backward step in this regard. After its demise, the financial system had to wait until the issue of the greenbacks and the establishment of the National Banking System during the Civil War to achieve a low uniform price for domestic exchange (Weiman and James 2007). While the costs of making interregional payments remained high after the demise of the Second Bank, it does appear that regional interest rates converged, leading to the conclusion that over the long run the capital market was integrated during the late antebellum era (Bodenhorn and Rockoff 1992; Bodenhorn 1992). Despite some earlier claims, however, Knodell shows that the Second Bank differed in important ways from a modern central bank. It did not act as lender of last resort or set monetary policy to maximize macro-economic variables.

The most important question concerning the Second Bank, at least from the point of view of political history, was whether Andrew Jackson's successful attack on the Second Bank produced a bank-driven inflation. The argument was that the demise of the Second Bank allowed banks to increase their lending, creating a flood of paper money and deposits that produced rising prices and speculative excesses, particularly real estate speculation. And that in turn led ultimately to the revulsion and inevitable collapse: the Panic of 1837, and the depression that followed. In terms of the balance sheet shown in Table 1, the argument was that banks had been constrained by fear of attacks by the Second Bank. The Second Bank, it was claimed, would collect the notes of banks that lent too much given their resources and present the notes for redemption. Fear of this kind of attack kept the banks in line. Freed of this constraint, banks issued notes and created deposits in order to make more interest-earning loans.

The first cliometrician to challenge this view was George Macesich (1960). Macesich's paper began life in Milton Friedman's famous Workshop on Money and Banking at the University of Chicago. Macesich compiled data on the stock of money, the monetary base (gold and silver coins held by banks or in general circulation), price indices, exchange rates, and imports and exports for the period

1834–1845. His main findings were that changes in the stock of money were produced mainly by fluctuations in the balance of payments, and that changes in money were highly correlated with changes in prices, confirming the quantity-theory explanation of the inflation.

Peter Temin (1968) built on Macesich's study. Then, in *The Jacksonian Economy* (1969), a book that became one of the classic texts of the "New Economic History," he offered a new interpretation of the underlying causes of the increase in the stock of money; an interpretation that he showed had many important implications for political as well as economic history. Some of the monetary data that Temin (who used a somewhat different methodology from Macesich) put together as well as data on prices and output are shown in Table 2. Temin's construction of the antebellum stock of money, I should note, built on the pioneering work of Fenstermaker (1965). I have made the table easier to read by dividing each observation by the value of the series in 1829 and multiplying each resulting observation by 100.

It is obvious that there was a very rapid increase in the stock of money shown in the first column of data. The stock of money rose a remarkable 13.8% per year between 1829 and the peak in 1836. The second column shows the ratio of the total stock of money to the amount of coin in the economy, what is commonly known as the "money multiplier." The money multiplier is determined by the extent to which the public trusts the banks and holds notes and deposits rather than coin and the extent to which the banks create notes and deposits from their reserves. The more notes and deposits banks create for each dollar of reserves, other things equal, the higher is the money multiplier. As can be seen in Table 2, the multiplier did rise from 1829 to 1831; but then it declined. If we look at the whole period from 1829 to 1836, the behavior of the money multiplier suggests, and an examination of bank reserve ratios confirms, that the increase in the stock of money was not fueled by the willingness of banks to create more notes and deposits for each dollar of coins held in reserve. The explanation for the increase in the stock of money then is that it was fueled by an increase in the

Table 2 Money, prices, and output in the 1830s

Year	Money	The ratio of money to coin (the money multiplier)	Prices (the GDP deflator)	Real GDP
1829	100	100	100	100
1830	109	112	98	110
1831	148	162	97	121
1832	143	152	99	129
1833	160	129	98	137
1834	164	106	98	135
1835	234	119	104	144
1836	263	119	111	150
1837	221	83	112	150
1838	229	87	110	152
1839	205	81	113	164

amount of coin in the economy. The finding that increases in the money multiplier did not explain the increase in the stock of money, Temin pointed out, contradicted the traditional story that the banks had run wild once they were freed from the watchful eye of the Second bank. Temin then looked at where the additional coin was coming from, and showed that part of the story was an influx from Mexico and a decrease in the traditional outflow to China. The decreased flow to China in turn, Temin contended, was a consequence of the deterioration of the Chinese balance of payments resulting from the expansion of the opium trade. In a related paper, Rockoff (1971) argued that the Mexican influx was the result of capital flight. To economic historians this was exciting stuff. Traditional US-centric stories proved to be mistaken. And the key to overturning the traditional interpretation was to look at the numbers. Previous generations of historians, the cliometricians claimed, had found lots of stories that seemed to support the case against Jackson and his attack on the Bank of the United States, but they had missed the key underlying forces.

The third column of Table 2 shows the GDP deflator. Evidently, inflation during the Jacksonian inflation was rather moderate by today's standard, averaging less than 2% per year between 1829 and 1836. Inflation may have seemed worse to the Jacksonian generation than it would to ours because it followed a decade of moderate deflation. It is also possible that in talking about inflation contemporaries had asset prices in mind, such as the prices of land and slaves – the latter rising about 9% per year (Carter et al. 2006, series Bb210) between 1829 and 1836 – that we donot include in GDP. The last column of Table 2 shows that while inflation was moderate by modern standards, real output rose rapidly, averaging an increase of more than 5% per year from 1829 to 1836.

Temin also reexamined the Panic of 1837, which brought the Jacksonian inflation to a close. Again, he stressed the role of international developments, in this case the decision by the Bank of England to raise its policy lending rate. The Bank of England had not been ignored in traditional accounts, but those accounts had focused on American developments: real estate speculation, President Jackson's "specie circular" (an order requiring payment for public land in specie), and the spectacular failures in March 1837 of Hermann, Briggs, & Co., a cotton broker in New Orleans, and J.L. and S. Joseph, an investment house in New York. Subsequently, Rousseau (2002), based on a careful review of regional bank reserves and specie flows, showed that the distribution of the federal budget surplus to the states had a far larger impact than historians had previously thought.

The Panic of 1837 was followed by further panics in 1839, 1854, and 1857. The Panic of 1839 appears to have been triggered by the suspension of specie payments by the United States Bank of Pennsylvania, the successor to the Second Bank of the United States, in October 1839. John Wallis (2001) showed that the Second Bank had gone overboard funding infrastructure improvements, mainly canals, which proved unprofitable.

The Panic of 1854 was mainly a regional disturbance. Banks in Cincinnati were badly hit, and national financial markets were disturbed, but the financial system recovered quickly. The Panic of 1857, however, was another story. This panic was triggered by the failure of the Ohio Life Insurance and Trust Company in August.

Bank runs and suspensions throughout the country followed. The economy slowed and there appears to have been severe distress among some groups, although judgments must be tentative because statistics on unemployment, national income, and so on, despite heroic efforts by cliometricians, are subject to substantial margins of error. The available statistics show that real GDP per capita fell about 0.2% between 1853 and 1854, but fell 2.3% between 1856 and 1857. An index of industrial production rose 1.94% between 1853 and 1854 and another 0.50% between 1854 and 1855, but fell 2.21% between 1856 and 1857, and fell another 6.09% between 1857 and 1858.

Despite the lack of data on a modern scale, cliometricians have made considerable progress in understanding the panic. Calomiris and Schweikart (1991) examined the spread of the crisis and showed that states that permitted branch banking or other forms of cooperative banking systems did better than states with unit banking systems. Kelly and Ó'Gráda (2000) and ÓGráda and White (2003) analyzed the records of the Emigrant Industrial Savings Bank in New York, where Irish immigrants saved, and showed that the response of these immigrants to panics reflected their financial sophistication and social ties that in some cases stretched back to Ireland.

The Panic of 1857 had political as well as economic consequences (Huston 1987). In the North, the Panic strengthened the hand of the newly formed Republican Party. The Panic, Republicans claimed, was the fault of the established parties. Their policies, such as a high tariff, would help to restore prosperity. In the South, the Panic strengthened the hand of the radicals who wanted to secede from the Union. After all, the secessionists said, the recession was less severe in the South than in the North because of the South's near monopoly of cotton production. Whatever suffering the South felt was the result of being tied to the North and its Wall Street speculators. We would be better off if we separated from those people.

Free Banking and Wildcat Banking

With the Second Bank gone after its defeat in the Bank War, it was left, as noted above, to the states to regulate banking. Many plans were tried, but the "free banking law" was the plan for establishing and regulating banks that has attracted the most attention from cliometricians. Under a free banking law, anyone could establish a bank anywhere within the boundaries of the state provided the bank met certain basic requirements, such as capital, note issue, and reporting. The most important of these requirements was that any notes that were issued by the bank had to be backed by government bonds. The exact rules about the backing for notes varied from state to state. Typically, there was a designated list of eligible bonds that included, understandably, the bonds of the state issuing the free bank charter but that often included municipal bonds, bonds of other states, and federal bonds as well. The laws also described how the bonds were to be valued for the purpose of issuing notes. The bonds backing the notes were held by a state official. If the bank issuing the notes went bankrupt, the state was required to sell the bonds and reimburse the holders

of the notes. Thus the system, it was hoped, would provide both the benefits of competition to borrowers and depositors while providing for the safety of noteholders. Note holders, it was thought, were different from other bank creditors because they were passive creditors of a bank. A depositor chose to put their funds into a particular bank, and so if the bank failed, it could be said that they had not done proper diligence and should suffer the loss. On the other hand, a noteholder may have simply accepted the note in as part of a small transaction and could not be expected to investigate the character of the bank issuing the note. The baker can decide where to deposit his money. But whether to accept a bill in the course of selling a loaf of bread is another matter. The baker could consult a "bank note reporter" to see if the note was on a list of bad notes, but the time and inconvenience of doing thorough diligence for currency used in small transactions was prohibitive.

Under the traditional system of chartering, promoters had to get a charter from the state government as a specific legislative act. The traditional system had obvious weaknesses. There was an incentive for would-be bankers to bribe legislators to get the charter they wanted; and an incentive for existing banks to lobby against the issue of new charters. Anna Schwartz (1947), in the first published paper in her distinguished career, explored how these incentives played out in Pennsylvania at the end of the eighteenth and beginning of the nineteenth centuries. Bodenhorn (2006, 2008) explored corruption and politics in bank chartering as they evolved in New York during the antebellum era. Calomiris and Haber (2014) view the free banking law, more generally, as the product of what they dub the "game of bank bargains," in which bankers bargain with the state for privileges. In this case would be bankers won some important privileges, for example, the right to enter new markets as they saw fit, but in exchange the state got a stronger market for its bonds, created by the requirement that free bank notes be backed by bonds. States, of course, had many other ways of extracting resources from banks. Sylla et al. (1987) show that levies on banks became a major source of revenue for state governments before the Civil War. Free banking laws, it should be noted, were also part of a larger movement toward free incorporation of all types of businesses. Indeed, free banking, for all that it reflected the interests of bankers and the governments that created and regulated banks, also reflected the spirit of an age that emphasized opening political and economic opportunities traditionally reserved for the rich and well-connected to the common man. Free banking was especially attractive in regions of new settlement. These states and territories were filled with new, small towns that hoped to grow into great metropolises, and they badly wanted banks because they believed that banks would be engines of growth.

Something called free banking – sometimes similar to the U.S. model, sometimes very different – was adopted in many other countries in the nineteenth century. The Scottish case in particular has often been explored in part because it was celebrated by Adam Smith in the *Wealth of Nations*. Space does not permit an examination of those cases here. Selgin and White (1994) provide a good guide to the literature available when they wrote and put it within the context of the long debate about the appropriate role of competition in banking. Briones and Rockoff (2005) also summarize a good chunk of the historical record.

The free banking laws have been of great interest to cliometricians. In several states, the passage of a free banking law produced a rash of new banks and often, not long after, many of those banks failed. The phenomenon was dubbed "wildcat banking." The origins of the term are uncertain. One interesting although possibly apocryphal story is that the banks were located in remote areas to forestall attempts to redeem their notes – wildcat country. In other words, the banks appeared to be simply note-issuing machines set up to buy eligible bonds rather than intermediaries intended to provide credit for the local community. The story about free banking producing wildcat banking has been important for economists because of the lesson it might hold for the more general question of the limits of *laisse-faire* as a policy for banking. For example, David Alhadeff (1962) claimed that entry into banking, historically, was restricted in the United States because of the danger of overbanking if entry was easy; with some of the worst abuses happening during, as he (1962, 248) put it, in "the 'wildcat banking' period." An exchange in the *Journal of Political Economy* is of special interest because it reveals the opinions of two of the leading monetary economists of the era. Allan Meltzer (1967), a leader of the monetarist school, proposed reducing regulation of banks to increase competition and improve their performance. In commenting on Meltzer's proposal James Tobin (1967, 508), a leader of the Keynesian school of macroeconomics who received the Nobel Prize in 1981, answered Meltzer in part by pointing out that "The United States had a history of wildcat banking that no one would wish to repeat."

Perhaps I am taking too much credit for myself, but I believe that Rockoff (1974, 1975a) inaugurated the cliometric study and revision of the traditional view of wildcat banking. I argued that, first, wildcat banking consisting of a rash of banks that simply bought bonds and issued notes was a relatively rare phenomenon that afflicted only some of the states that adopted free banking laws, and that in other states, where the law was more carefully drawn, notably New York, it had worked well. Indeed, in some cases, such as Massachusetts, where the bond requirements for issuing notes were very demanding, little banking was done under the law. Second, that it was usually a failure to require adequate security for notes that led to a rash of wildcat banks; for example, a decision to accept bonds at par when they were selling below par. And third, that the overall losses from wildcat banking were small. I had expected to be criticized by defenders of the traditional view that free banking had been a disaster. For that reason, following the lead of Robert Fogel (1964), I tried to make sure that my estimates of the amount of wildcat banking, and the resulting losses were upper bound estimates. Surprisingly, most of the subsequent literature criticized me from the other side by arguing that the incidence of wildcat banking and the resulting losses were even lower than I had suggested. Thus, most of the subsequent literature, although critical of my work, strengthened the case for believing that most wildcat banking was a minor phenomenon. I summarized my reaction to the literature that emerged in the decade and a half after my papers in Rockoff (1991).

Arthur Rolnick and Warren Weber were among the first to collect additional evidence and present a view of free banking and its troubles that was more sanguine than mine. In important papers in the Federal Reserve Bank of Minneapolis

Quarterly Review and the *American Economic Review,* Rolnick and Weber (1982, 1983) examined data for four free banking states – New York, Indiana, Wisconsin, and Minnesota – and showed that while those free banking systems "had a significant number of problem banks," they also had a large number of successful banks. They argued that it was misleading "to characterize the overall free banking experience as a failure of *laisse-faire* banking" (Rolnick and Weber 1983, 1090). In a subsequent paper in the *Journal of Monetary Economics* (1984), they provided more evidence and argued that most of the problems faced by the free banking systems were due simply to shocks that reduced the value of the bonds that the free banks held, rather than any inherent instability produced by free entry. Kahn (1985), however, re-examined the methods employed by Rolnick and Weber and concluded that free banks, especially in their first years of operation, had suffered higher rates of failure than Rolnick and Weber had calculated.

Economopoulos's (1988, 1990) studies of Illinois, New York, and Wisconsin provided additional evidence supporting the claim that wildcat banking was rare. He found that few free banks entered when profit opportunities were exceptionally high. He did find, however, that in Illinois free bank losses were high, even if they were not due to wildcat banking. Hasan and Dwyer (1994) took another look at some of the free banking states and argued that sometimes bank runs that undermined free banking systems were ignited by shocks that originated outside the state where the banks were located. Dwyer (1996) summarized much of the earlier literature, added some new facts of his own, and reinforced the view that whatever the problems experienced by antebellum banks, the incidence of wildcat banking was rare.

A more skeptical note about the experience in the free banking states was sounded by Jaremski (2010). Using a large data set created by Rolnick and Weber and made available on the Internet (a model contribution to the discipline), Jaremski argued that it was the undiversified portfolios of the free banks that caused their problems rather than bond price declines, because banks in chartered-banking states did not fail in the same numbers as banks in free banking states as a result of the decline in bond prices. To be sure, regulation left many would-be bankers in free banking states with little chance of getting into the game except by purchasing bonds and issuing notes. But they could have chosen not to take such a risky course. Lehman Brothers was hurt by a fall in the value of subprime mortgages beyond its control, but they can still be castigated because they chose to invest a large part of their portfolio in assets ultimately backed by subprime mortgages.

Two states, New York and Michigan, represent the extremes under free banking. In New York the banking system flourished and New York City continued its march to its preeminent place in world finance; in Michigan, free banking got off to a disastrous start and proved to be the source of many of the famous stories, real and apocryphal, about wildcat banking. Although Kahn (1985) had emphasized the high rate of bank failure in some free banking states; he also drew attention to the success of free banking in New York. Haupert (1991, 1994) explored the New York system in detail and argued that one reason for its success was the efforts banks made to establish a reputation for soundness, for example, by holding large amounts of reserves. Bodenhorn and Haupert (1995, 1996) explored another aspect of the New York experience: the "note issue

paradox." After the Civil War, it appears, at least according to some straightforward calculations, that National Banks did not take full advantage of the profit opportunities made possible by their privilege of issuing bank notes. This paradox – that they left money on the table – was made famous by Friedman and Schwartz (1963) and explored by a number of economic historians. Bodenhorn and Haupert (1995, 1996) made similar calculations for the antebellum free banks in New York. They concluded that various legal restrictions meant that at the margin it paid for these banks to make new loans with deposits rather than notes.

Michigan was actually the first state to adopt free banking. It did so in 1837, months ahead of New York. Rockoff (1985) drew attention to the Michigan experience and presented some arguments about why the significance of the losses in Michigan had been exaggerated. Recently, Dove et al. (2014), on the basis of newly collected data, have gone further in minimizing the amount of wildcat banking in Michigan.

One conclusion that emerges clearly from the studies of free banking in the United States before the Civil War is that wildcat banking was at most a rare phenomenon. One indicator that contemporaries understood this is that the National Banking Act, passed during the Civil War, was simply another free banking law, although one that provided a higher level of security for noteholders. National Bank notes had to be backed by federal government bonds. Riskier state and municipal bonds were not eligible. It is usually said that the National Banking Act was modeled on the successful free banking law of New York, but it should be mentioned that Salmon Chase, the secretary of the Treasury who helped create the National Banking system, was the former governor of Ohio, another state with a successful free banking law.

Other studies of free banking laws (Rockoff 1975b; Ng 1988; Economopoulous and O'Neill 1995; Bodenhorn 2000; Chabot and Moul 2014) have focused on a potentially positive part of the case for free banking: whether freedom of entry improved the supply of banking services and possibly accelerated economic development. It is a difficult question to answer. Obviously, it is hard to imagine economic growth without an expansion of financial intermediation, just as it would be hard to imagine economic growth without an expansion of the transportation network. But showing that removing or adding legal restrictions on banking would affect the rate of growth of the financial sector, and then that better or increased intermediation would affect the rate of economic growth overall, is a tall order given the limited amount of data and the absence of clear natural experiments. Yes, some states had free banking laws while others had individually chartered banks, but as Economopoulous and O'Neill (1995) point out, the passage of free banking laws in some states led to liberalization of bank chartering rules in other states, so that comparisons of different states will fail to distinguish clearly the effects of changes in regimes. Moreover, it appears that there was a high degree of integration in financial markets during the antebellum period so that a dearth of financial intermediation in one region might be offset by an influx of finance from other areas. And the free banking laws required that notes be backed by government bonds, usually of the state where the bank was located. This meant that the seigniorage procured by issuing bank notes was funneled into the coffers of the state government rather into the local economy.

Despite these difficulties, cliometricians have tried to delineate the effect of various forms of banking on economic growth. Rousseau and Sylla (2005), although focused on an earlier period, should be mentioned here because of their unusually clear statement and test of the idea that a deep and efficient financial system is a prerequisite for rapid economic growth; growth in their view was "finance led." Rockoff (1975a) argued that the data suggested that liberal banking regimes provided better services and encouraged the use of bank money. Bodenhorn (2000), focusing on the later antebellum period, summarizes the literature and performs a battery of additional tests to explore the power of the finance-led growth model. He concludes that finance and banking clearly were required for economic growth; and more cautiously that the system bank regulation, while appearing unnecessarily fragmented, allowed individual states to find regulatory systems suited to their own economies. Jaremski and Rousseau (2013), on the other hand, concluded that free banks did less well in generating economic growth than chartered banks. In related work, Atack et al. (2014) described a "virtuous cycle" in that banks encouraged railroad building and railroads then encouraged banking.

The relationship between railroads and banking in the Middle West brings to mind Fogel's (1964) studies of the railroad, one of the foundations of cliometrics. To my mind, Fogel's studies provide a helpful analogy for thinking about the role of banks. The economic growth of the United States required some form of transportation: trails or roads or canals or railroads. But Fogel showed that the difference between the economy as it was with railroads and an economy as it would have been with only canals and roads improved with the money spent on railroads would have been positive but surprisingly small. The same may be true of banking. Some form of banking was necessary for economic growth but the difference between the systems in place and the next best alternative that would have developed in their absence might not have been transformative. I once asked Robert Fogel the following: "if building the railroads does not explain the rapid economic growth of the United States in the nineteenth century, what does? His answer was that it was a "full court press." Similarly, banks undoubtedly contributed to economic development, and banking laws affected how they did so, but we should not forget that many other forces were also pushing the USA forward.

Although free banking was the outstanding feature of antebellum banking as far as banking historians have been concerned, other systems have come in for scrutiny. The banking system of Louisiana, usually referred to as the "Forstall System" after its founder Edmund J. Forstall, garnered considerable praise from earlier generations of economic historians (Helderman 1931; Redlich 1947; Hammond 1957; Neu 1970). The system was put in place after the Panic of 1837. It prohibited the entry of new banks, required high specie reserves, and restricted lending to short-term paper as emphasized by the real bills doctrine. George Green's (1972) *Finance and economic development in the Old South; Louisiana banking, 1804–1861,* which is still the main source for information about the functioning of the Forstall system, provided a different view. Although much heralded for its legal restrictions, Green's evaluation is somewhat critical, arguing that the system retarded economic growth and that the structure of the system cannot be credited with assuring that it effectively surmounted the Panic of 1857, which was generally less severe in the South.

Even more attention has been paid to the Suffolk System of New England. Trade patterns in New England meant that notes issued by New England country banks tended to collect in Boston. Typically, the notes were purchased there at a discount, frustrating consumers and country bankers. The solution was to designate one bank, the Suffolk Bank, as the redemption center for New England notes. The Boston banks set this system up and funded it by purchasing stock in the Suffolk Bank. Country banks were required to maintain deposit balances at the Suffolk, but in exchange the country bank notes were purchased at par. The system seemed to work well, pleasing the public because New England notes always circulated at par through out the region. The country banks, however, chafed under the system because they thought the deposit requirements were too severe, and eventually set up a rival. However, it was in operation only a few years before the Civil War (Lake 1947; Mullineaux 1987). Calomiris and Kahn (1996) looked at dividend payout ratios and related variables and showed that the Suffolk System was not simply a means of exploiting country banks, but rather one that created benefits for the system as a whole. Rolnick et al. (1998) and Bodenhorn (2002) however, argued that the country banks did bare an excessive share of the costs of maintaining the payments system. Moreover, while the Suffolk System produced (perhaps unfairly in terms of the distribution of the costs) many benefits for bank customers in New England, Smith and Weber (1999) argued, primarily on the basis of a model that they constructed, that the claim that it solved all of the potential problems of a privately issued currency would be going much too far.

Although chartered commercial banks were the most important, there were a number of similar institutions that were active during the antebellum years. For one thing, as documented by Richard Sylla (1976), there were many private bankers. And many of them evaded laws that prohibited private banks issuing notes. The most famous of the private bankers was George Smith, who's Wisconsin Marine and Fire Insurance Company issued "certificates of deposit" and checks in denominations as low as one dollar that circulated from hand to hand as cash. Smith's remarkable career as a private frontier banker is described in Smith (1966). At its peak in 1852, Smith's various banks were issuing nearly $1.5 million in notes while another private banker was issuing almost $2 million. Together, these two alone added about 2% to the paper currency (Sylla 1976). There were also a variety of savings banks, trust companies, bill brokers, and investment banks. Indeed, there were financial institutions that would now be labelled shadow banks. Just as we think of the failure of Lehman Brothers as the trigger for the Panic of 2008, before the Civil War people thought of the failure of J.L. and S. Joseph as the trigger for the Panic of 1837 and the failure of the Ohio Life and Insurance Company as the trigger for the Panic of 1857. Today both would be counted as shadow banks (Rockoff 2018). With the exception of the Ohio Life, there has been little cliometric work on the private bankers, in part because records their activities are not easily assembled, if they still exist at all.

Although most of the regulations that affected banks are to be found in charter provisions or the clauses of the free banking laws, there were other parts of the legal environment that influenced banking. One important set of legal restrictions was to be found in the usury laws. Rockoff (2009) was impressed by the relatively high

maximum rates of interest and low penalties for violating them in the West, and argued that this pattern reflected interregional competition for capital. An often-expressed view of economists is that because there is generally no active enforcement of usury laws – typically they were invoked only as a defense when a borrower was sued for nonpayment – they were honored in the breach. Bodenhorn (2007) found some evidence for this in New York State. Benmelech and Moskowitz (2010), however, found that the usury laws did influence economic activity. And they argued that the usury laws, although detrimental to economic activity in general, often favored the interests of the elite who supported them.

The Gold Inflation of the 1850s

The true sources of the Jacksonian Inflation were hard to see and many contemporary observers and latter day historians blamed the banks. It took the cliometricians to show that the big story was an increase in the monetary base produced by foreign flows of specie. The inflation of the 1850s was another story. It was obvious that the discovery of gold in California and subsequently in Australia produced an increase in the monetary base and an increase in the stock of money that in turn produced inflation. The banks expanded their loans, notes, and deposits, but that was because bank reserves were rising. Some relevant data is shown in Table 3. As in Table 2, all of the time series have been converted into indexes to make the table easier to read by dividing each observation by the value of the series in 1849 and multiplying by 100. These series are not as reliable as modern series for the same variables; but they are probably sufficient for some broad conclusions. The first column shows that the stock of money in the United States rose rapidly in the 1850s; but the second column shows that the money multiplier did not. In other words, as in the 1830s, banks were not creating more and more dollars of deposits and notes relative to the amount of coins; the increase in the stock of money was driven by the increase in the monetary base. The third column shows that, as in the 1830s, the inflation was mild by today's standard. Prices rose a bit more than 2.5% per year between 1849 and their peak in 1857. Some asset prices, the price of land and in the South the prices of slaves, were rising more rapidly. Indeed, slave prices rose about 6% per year between 1849 and 1857 (Carter et al. 2006, series Bb210). Real GDP, moreover, was rising rapidly, at 5% per year over the same period.

In some areas of economic history the use of quantitative methods and formal economic theory began with the "New Economic History" in the 1960s. But in monetary history the use of these methods is much older. One of the first quantitative studies of the effects of the gold discoveries was by the outstanding nineteenth century economist William Stanley Jevons (1863). Various aspects of the gold discoveries were explored by cliometricians during the early years of the "New Economic History." Martin (1973) examined the consequences of the gold discoveries for the institutional framework of the monetary system. Stevens (1971) reexamined the data on the stock of money. And Temin (1974) analyzed the effect of the gold discoveries in the context of the relationships among gold flows,

Table 3 Money, prices, and output in the 1850s

Year	Money	The ratio of money to coin (the Money Multiplier)	Prices (the GDP deflator)	Real GDP
1849	100	100	100	100
1850	114	94	102	104
1851	129	97	100	112
1852	143	93	101	122
1853	160	102	100	135
1854	161	99	109	141
1855	169	104	112	142
1856	182	108	110	149
1857	151	89	113	150
1858	173	106	106	154
1859	179	116	107	162

international capital flows, and macroeconomic trends. The episode appears to be a good natural experiment revealing the relationship between money and economic activity. For that reason, one might have expected even more research on this episode. Perhaps the clarity of the story has discouraged research by economic historians hoping to score a hit by overturning the conventional wisdom. One issue that might be fruitfully explored is Jevons's contention that prices in more competitive markets responded more quickly to the increase in the stock of money than prices in monopolistic markets because information was disseminated more rapidly in competitive markets.

Conclusion

The antebellum years have proved a fertile source of questions and data for cliometricians. Indeed, with the exception of the Great Depression, it may well be that there is no other period that has more to offer the financial cliometrician than the three decades before the Civil War. There were increases in the monetary base that produced substantial increases in the stock of money with important macroeconomic effects: an influx of silver in the 1830s and the discoveries of gold in the 1850s. There were banking panics in 1837, 1839, 1854, and 1857, which in some ways bear a striking resemblance to the Panic of 2008. And there was a wide array of experiments with ways of chartering and regulating banks, including the famous experiments with "free banking." Cliometricians have made considerable progress in all of these areas by carefully amassing empirical data and employing increasingly sophisticated theoretical models and econometric methods to analyze the data. They have analyzed the impact on prices and production of the surges in the stock of money and the role of the banking system in transmitting those surges. They have analyzed the causes of the banking crises. And they have delineated the

circumstances in which free banking produced something that might be called wildcat banking. What of the future? Has all the silver and gold been mined? We can't be sure, but my guess is that cliometricians will continue to find the antebellum era an important source of information and ideas about how banking systems work.

Financial Markets and Cliometrics

Larry Neal

Contents

Abstract

The study of financial markets is a growing part of cliometrics for at least three reasons. First, appreciation of the role financial markets played in the rise and spread of capitalism has grown, along with concerns about financial crises. Second, accessibility to the immense amount of data generated by financial markets keeps improving thanks to continued advances in digital communications technology. Third, analytical techniques for determining the behavioral patterns of time series have advanced. While typically only price data for financial assets are available without the corresponding volume of the assets being traded, the consequences of sharp, or sustained, changes in the price of financial assets can be detected in other economic data. Interesting insights on fundamental historical issues are also possible by applying economic and political theory to cliometric studies of financial markets.

Keywords

Bills of exchange · Sovereign bonds · Credible commitment · Threshold auto regression · Cointegrated time series · Adverse selection · Asymmetric information · Financial crises

Introduction

The repeated occurrence of financial crises, especially the unexpected length of recovery from the global crisis that began in 2007, continues to generate interest in historical studies of financial markets. Each crisis seems to elicit the reaction of what went wrong this time? Then, why didn't we learn the right lesson from the last one? Trying to extract lessons from the history of past crises drives financial historians (as well as policymakers, speculators, and journalists) in their research on financial markets. Beyond the narrow concerns raised by financial crises, however, financial history can also shed new light on fundamental historical issues. Examples include how long-distance trade was sustained among ancient and medieval societies, how fiscal states arose in early modern times, and, ultimately, how societies move from economic relationships underlying personal exchanges to institutions that allow impersonal exchanges to be sustained. Once scholars recognized the importance of finance for enabling these important transitions in human history to occur, the opportunities for meaningful research into financial markets by cliometricians kept expanding. Further, data generated by financial markets in the past can serve as useful measures of the success or failure of previous economic efforts, provided, of course, that they are interpreted correctly by modern cliometricians. To illustrate just a few of the possibilities for getting illuminating insights as well as for making mistaken inferences, this essay surveys two different literatures that have arisen over the past half-century, first on financial markets for sovereign government bonds and then on financial markets for bills of exchange. Bringing the two strands of analysis together for a better appreciation of the interplay between short-term finance and long-term assets is the next step in a research agenda that keeps expanding.

Sovereign Government Bonds

An extensive and growing literature has arisen from the realization that financial markets for sovereign government debts can be analyzed from a variety of perspectives and that governments issuing these debts kept records that are increasingly accessible to modern researchers equipped with digital cameras and laptop computers. The classic study by P. G. M. Dickson (1967) introduced the term "financial revolution" to the profession and also provided a useful finder guide to the wealth of material readily available in British archives. That material, combined with the daily price data on British funds from January 1698 on available in John Castaing's *The Course of the Exchange, & c.* (1698–1907), enabled Neal (1990) to demonstrate weak form efficiency[1] of the securities market for sovereign bonds issued by the British government in London. Combining these data with pricing of British funds in

[1]Weak form efficiency of efficient financial markets: all past prices of a stock are reflected in today's stock price, which typically follows a random walk.

Amsterdam, Neal also showed that these two preeminent financial markets were closely integrated, especially after the bubble year of 1720. Later work by Koudijs (2011) expanded these data to determine more precisely whether "news" affecting the securities widely traded in both Amsterdam and London arrived first in London or Amsterdam, depending on the arrival of the mail packet boats that sailed regularly between the two cities. The combined results from the London and Amsterdam markets suggest semi-strong efficiency[2] for these early stock markets, with news affecting the prices of English government securities typically reaching Amsterdam first. Beach et al. (2013) further examined the Amsterdam prices of British securities to argue that they were spot, not time, prices as Neal had inferred in his original work.

Beyond such technical issues concerning the efficiency and integration of the eighteenth-century financial markets through analysis of the prices of widely held and traded securities, the enthusiasm of Dickson for finding an early "financial revolution" corresponding to the Glorious Revolution of 1688/1689 in England became the basis for new ideas for economic policy generally. North and Weingast (1989) took Dickson's finding of a sharp, sudden fall in the interest rates offered on new debt issues after 1688 as strong evidence that the constitutional arrangements between the new monarchs of Great Britain, William III and Mary, and the Parliament had created a "credible commitment" that the British government would no longer interfere with private property rights. This constitutional arrangement, according to North and Weingast, laid the basis for the eventual industrial revolution in England and the initiation of the current era of modern economic growth. The appeal of this argument has spawned a growing literature on its own, both pro and con.[3] Assessing the price evidence from private banking accounts before and after the Glorious Revolution, Quinn (2001) found that interest rates on short-term bankers' loans actually rose after 1688. Sussman and Yafeh (2006) argued that the bulk of government debt issued to finance the two subsequent wars over the next 25 years had to pay higher interest rates than during peacetime. This, they argued, showed the importance of war finance over constitutional commitments, an argument they extended to later periods and other cases (Mauro et al. 2006). Wells and Wills (2000) tested for robustness of the later fall in long-term yields and found that the "credible commitment" of William III and the Whigs in 1688 was subject to severe shocks for at least 50 years after 1688 due to the persistence of the Jacobite threat to restore the Stuart dynasty.

Because these analyses that cast doubt on the North and Weingast interpretation of Dickson's findings relied simply on price data, the question does arise whether the quantity data, which were of most interest to Dickson, might give different results. Sussman and Yafeh disputed whether interest rates fell for British sovereign debt after 1688 as the demands of war finance forced the government to sell fresh issues of both short-term and long-term debt at increasing discounts, forcing up the actual

[2]Semi-strong efficiency: all public information available is incorporated into a stock's price.

[3]See (Coffman and Neal 2013) for an extended analysis and review.

market yield above the nominal interest rate. Nevertheless, they could not overturn Dickson's evidence on the huge sustained increase in the volume of sovereign debt issued and the eventual rise in its market price as the government continued to pay the promised interest. Even Quinn in his examination of private finance before and after the 1688 revolution found that the size of banking business expanded sharply and permanently. The increased volume of sovereign debt that continued to be serviced by whichever party was in power laid the basis for a remarkable expansion of banking business in London and later throughout the kingdom.

MacDonald (2013) argued in fact that it was the 1710 election of Tory party to power in Parliament that confirmed the commitment of the Stuart monarch (now Queen Anne) and Parliament to continue service of the outstanding debt, both short- and long-term. Stasavage (2003) used the price data on sovereign debt for Britain to show that interest rates fell when the Whig party was in power and rose whenever the Tory party replaced it. Moreover, yields on British sovereign debt fell after each war without defaults, unlike the case for French sovereign debt (Luckett and Lachaier 1996; Velde and Weir 1992).

Using game-theoretic constructs to find useful political variables in addition to the standard "fundamentals" used by economists as determinants of yields on sovereign bonds, Stasavage searched for evidence on bond yields from other political entities in Europe before the financial revolution in England. Stasavage (2011) concluded that in early modern Europe smaller cities, governed by more cohesive merchant elites, generally paid less interest on their sovereign debts. This helped explain Epstein's earlier finding (Epstein 2000), that Italian city-states paid much lower rates on their public debts for centuries before the constitutional commitment in England that had fascinated first Dickson and then North and Weingast. Epstein argued that the Italian success was due to solving coordination problems over a larger range of market activities, exemplified by the success of Milan in recovering from the effects of the Black Death.

City-states that maintained their own mints, tax systems, and financial records proliferated in Western Europe from the eleventh century on and their records become increasingly available after 1400. The Italian city-states of Venice, Florence, and Genoa in particular kept detailed records that have been the subject of studies by quantitative historians, economists, and sociologists. Luciano Pezzolo (2003, 2013, 2014) has compared the market interest rates paid by those three leading Italian city-states with those paid by the papacy in Rome in an effort to determine which political structure conveyed the most confidence for its creditors through the vicissitudes of state-building to 1700. Republics did best, until they fell under the rule of a prince (Florence) or of a closed oligarchy (Venice). David Stasavage expands the sample of sovereign city-states beyond Italy to include others in Spain, Germany, and the Low Countries (Stasavage 2011) to find that smaller city-states with more cohesive merchant groups did best of all.

Tomz (2007) enhanced the game theory underlying government commitment mechanisms for servicing their debt by adding the possibility of learning and political change to standard models for building and sustaining reputations. These modifications to cooperative game theory allowed him to predict uncertainty

premiums on issues by new governments, seasoning effects on prices of bonds that continue to be serviced by established governments, exclusion from existing markets for defaulters, and reentry of governments when compensation is offered to previous lenders, all with specific historical examples. His qualitative search for evidence of the factors that determine a government's reputation at any given time helped him explain apparent anomalies in the historical pricing of various sovereign bonds. Exploring the sources of reputation building opens up further avenues of research for cliometricians.

One of the most interesting episodes for testing various economic and political theories for explaining the attractiveness of sovereign bonds is the first so-called Latin American debt crisis, which occurred in London from 1822 to 1830. The new Latin American states that emerged from the collapse of the imperial authority exercised from Spain and Portugal at the end of the Napoleonic Wars all attempted to finance their new governments by issuing bonds on the Paris, Amsterdam, and London markets. All of them offered 6% interest on their bonds, and London investors willingly bought them at discounts up to 20% to get yields between 7% and 7.5% – until they learned more about the inability of the new governments to cover their current expenses with taxes, much less pay interest due on their outstanding debts. This was a classic early example of the "lemons" problem being solved by lenders assigning an arbitrary risk premium to the loans sought by new, untried borrowers. When news arrived of the shortfalls suffered by the various governments, the prices plummeted, implying sharp rises in yields as shown in Fig. 1.

Tomz (Chap. 2) uses these data to illustrate both the lemons problem (solving adverse selection with risk premium from 1822 to late 1825) and seasoning (maintaining prices for French bonds as well as a new price level for Brazil bonds

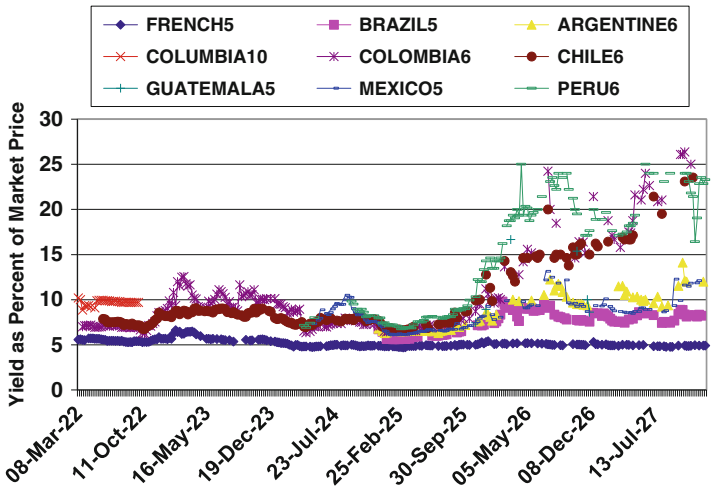

Fig. 1 French and Latin American Bond Yields in London, 1822–1827

while varying risk premiums for other Latin American bonds). Later work by Flandreau and Flores (2009) examined the role of the respective investment banks that took the lead in marketing each of the bonds to find out why yields stabilized for the Brazil and Argentine bonds. The answer, they found, was in the way Rothschilds (who handled the Brazil bonds) and Barings (who dealt with Argentina's bonds) imposed conditions upon those governments before lending their reputations to the issue. Indeed, Rothschilds issued bonds for a variety of new European governments – Austria, Belgium, Naples, Prussia, and Russia – in the decades following 1815 without any defaults, even during the revolutions of 1848. One may speculate on how the Rothschilds accomplished this, perhaps through monitoring the respective country mints and public banks for each country and imposing effective conditionality. Whatever was the secret to the success of the bonds underwritten by the Rothschilds, Flandreau and Flores argue that their effective "branding" of a country's debt enabled each government to save on future interest payments and cover the underwriting premium charged by the House of Rothschild.

Led by the merchant bankers Rothschilds and Barings, London and Paris became the centers for international sovereign bonds for the remainder of the nineteenth century. The faithfully recorded prices of the numerous government bonds have gradually been encoded and analyzed by an increasing number of cliometricians, for a wide variety of purposes. One study focused on the case of Peru, whose bonds stabilized marvelously in mid-century despite being one of the "lemons" in the 1825 crisis and despite enduring a series of unstable governments. Vizcarra (2009) explained this was due to the role of the British merchant banker Gibbs and Sons, who also managed the sale of guano in London and made sure that their clients who had purchased the bonds were given first claim on the guano revenue. A similar arrangement turned out to be the case for the kingdom of Denmark when it borrowed from Dutch merchant bankers at the end of the eighteenth century. In that case, the Dutch banking houses collected the tolls in advance from shippers leaving Amsterdam for Baltic ports. In that way they could assure these payments were applied to the interest due on the Danish bonds (Van Bochove 2014). An even earlier example of using tax collection authority to maintain reliable payment of interest on long-term sovereign debt was the bonds issued by the city of Paris to provide their occasional tributes to help finance the wars of François Ier (Vam Malle Sabouret 2008).

Over the course of the nineteenth century, however, states gradually took control of their own revenues to free themselves from external domination. Dincecco (2009) analyzes the bond yields for 11 European governments for varying periods from 1750 to 1913. He then tests for the relative importance for creditworthiness of each government of (1) centralized control over tax revenues versus (2) limitations on executive power. He considers these to be the two essential elements of the commitment mechanisms used so adroitly by the British throughout the eighteenth century to create a permanent market for their sovereign bonds. He finds that both effects are important individually, but most effective when they are combined, as was the case for Britain after 1688. Ending with this anodyne conclusion, Dincecco managed to avoid confronting directly the contentious issues raised by earlier scholars who had used the evidence of bond yields to validate their preconceptions.

Probably the most stimulating work was Bordo and Rockoff (1996), who argued it was the adoption of the gold standard as "a Good Housekeeping seal of approval" that allowed countries to increase their creditworthiness. This would be further confirmation of earlier work by Bordo and Kydland (1995) that the gold standard as such was a powerful commitment device to restrain governments from excessive, much less unwarranted, issues of debt or money. Ferguson and Schularick (2006), however, took evidence on bond yields from a larger group of countries during the classical gold standard period, 1880–1913, to argue that it was the rule of law, specifically British law, that allowed countries under the sway of Britain to assure creditors, regardless of their formal commitment to a gold standard. Then, Accominotti et al. (2011) showed that it made a lot of difference within the British Empire whether the colony was settled by British emigrants or simply ruled by British civil servants. The British guaranteed payment on bonds issued by the settlement colonies but not on bonds issued by non-settlement colonies with local rulers, which created yield spreads favoring the white settlement colonial government bonds. Similar effects of third party guarantees were also found for debt issued by the Ottoman Empire during the Crimean War, which enjoyed low rates of interest when jointly guaranteed by the British and French governments.

Later issues of Ottoman debt without such guarantees, however, suffered badly until ad hoc international financial commissions finally took control of the Ottoman revenues dedicated to service of the bonds in the 1890s (Tuncer 2011; Pamuk and Karaman 2010). Formal sanctions against defaulting governments, enforced by the so-called gunboat diplomacy during the nineteenth century, seem not to have been very effective and were seldom used. Private initiatives by European stock exchanges to refuse formal listing of new bonds by previous defaulters were coordinated by non-governmental institutions such as the Council of Foreign Bondholders (Esteves 2013). The Roosevelt Corollary of 1904 (to the Monroe Doctrine of 1823 that defended decolonization in the Western Hemisphere) reinforced the reluctance of the British government to undertake military measures against defaulters, especially in Latin America. Nevertheless, the Roosevelt Corollary had a noticeably positive effect on the markets for Latin American government bonds given the willingness of that American administration to use force (Mitchener and Weidenmier 2005, 2010).

Thanks to the ongoing revolution in information and communications technology, there is an overwhelming quantity of historical data on financial markets available for continued research and controversy. For example, Global Finance Data (https://www.globalfinancialdata.com/index.html) is a for-profit provider of the data sets created by various academics (including Neal (1996), at http://www.icpsr.umich.edu/icpsrweb/ICPSR/studies/1008) as well as by governments and other commercial firms. Individuals can subscribe for a limited free trial, or use their academic affiliation to access many of the 20,806 data series available as of February 14, 2014. The provenance of those data, however, has to be taken on faith, whereas for sovereign bonds, the European State Finance Database (http://www.esfdb.org) provides the academic sources for each of the data sets available there. These data were originally collected under the auspices of a project on "The Origins of the

Modern State in Europe, 13th to 18th centuries," directed by the Rev. Professor Richard Bonney with the assistance of Dr. Margaret Bonney from 1989 to 1992. It is now maintained by D'Maris Coffman at the Centre for Financial History housed in Newnham College, Cambridge University, and new data sets are added regularly from various academic studies. As most of these data are in nominal prices, investigators wishing to make current comparisons can access the database at Measuring Worth (http://www.measuringworth.com), which has price conversions as well as additional long-run data. Many scholars are making their data available as well at EH.net Data bases (http://eh.net/databases/), which is constantly adding new series underlying published, and sometimes unpublished, work.

Short-Term Commercial Finance

The regular publication of discount rates on commercial bills of exchange for the major cities in Europe and the Americas starting in the nineteenth century allows this kind of statistical analysis to complement analysis of movements in yields of government bonds, especially during financial crises or wars or changes in political regimes. For earlier periods, some cliometricians have taken advantage of the regular publication of exchange rates among major financial centers to extract the implicit interest rate from the difference between spot and forward rates. The pioneering study by Eagly and Smith (1976) focused on just the London quotes for bills on Amsterdam. Nevertheless, they were able to show a high level of financial integration between the two dominant money markets of eighteenth-century Europe. Further, if the gap between the time price of foreign exchange and the spot price widens, the intensity of the crisis can be measured as well. The first mark of a scramble for liquidity in London, which was the sudden, but short-lived, spike in the price of the pound sterling, I labeled "the Ashton effect" (Neal 1990, p. 67). Sometimes a reaction followed quickly to produce an offsetting spike in the price of *schellingen banco* as merchants in Amsterdam scrambled for liquidity in response to the difficulties in London. This movement I termed "the Kindleberger effect," as it was a clear marker of contagion in Kindleberger's view (Kindleberger 2000), but interdependence as Forbes and Rigobon (2002) would see it. Schubert (1989) demonstrated the initial integration of the exchange markets in the eighteenth century and their increasing disruption from the Seven Years' War on as both Ashton and Kindleberger effects increased in magnitude and frequency. Later work by Quinn (1996) highlighted the disruption caused by the pressures of war finance on the Amsterdam-London markets for bills of exchange after the currency reform in England in 1696. While restoring the previous value of the pound sterling in terms of gold, the reform also set the pound at a value in silver that made gold more valuable than silver in England relative to the Netherlands or France. Through the use of bills of exchange, Quinn showed how exports of silver from London to Amsterdam were often covered by imports of gold from Amsterdam to London, both financed by issuing bills of exchange.

More extensive work on these markets for commercial finance by Flandreau et al. (2009b) covered a wider range of exchange rate markets but Flandreau et al. (2009a) focused on the comparative interest rates for merchants in the three major mercantilist countries. Their findings also showed the effects of wars and occasional financial crises on private interest rates, but while London rates became lower than Amsterdam rates, which were also lower than Paris rates generally, none of the three were constrained by the usury laws that limited rates to 5% annually. They did find generally rising rates in the last quarter of the eighteenth century for all three cities, and more variance among them as did Schubert.

The intensive study of the European market for Mexican silver in the seventeenth and eighteenth centuries by Nogués-Marco (2013) reflects the incentives both for encoding more financial data from previously underexploited resources and for extracting more analytic insights from applying more sophisticated statistical techniques. While Nogués-Marco only confirmed that Great Britain was on a de facto gold standard even while maintaining it had a de jure bimetallic standard throughout the eighteenth century, she also managed to demonstrate why the Netherlands could be so closely connected financially with Britain while maintaining both a de facto and de jure bimetallic standard at a different ratio between gold and silver (14.65 for Amsterdam and 15.21 for London). She was building in part on the path-breaking work done by her thesis advisor, Marc Flandreau, on the sustainability of the bimetallic system in the nineteenth century (Flandreau 1996, 2004), as well as implementing the theoretical analysis of Velde and Weber (2000). It was Flandreau's intensive empirical work on the public and private actions in France over the tumultuous period of 1840–1878 that demonstrated how the stock of both monetary metals could be maintained at sufficient levels to warrant continuation of the bimetallic standard despite the huge increases in gold supplies entering world markets after 1849.

The theoretical work of Velde and Weber demonstrated that bimetallism could have been maintained indeed well into the twentieth century. The elimination of bimetallism in 1873 was probably due to the French decision not to subsidize Germany's plans to convert its diverse silver standard areas into a unified gold standard for the empire by buying up the excess silver released from German mints while decreasing French gold supplies. While general deflation followed globally, with much of the pain suffered by a defeated and diminished France, Velde and Weber's theoretical analysis suggested that both France and Germany were better off by adopting a single metal standard, whether it would have been gold or silver. US legislation in 1873 also made the fastest growing economy in the world committed to a gold standard thereafter, replacing its original de jure bimetallic and de facto silver standard before the Civil War and its fiat money inflation during the War Between the States.

The gold standard then became the dominant monetary standard for the world economy after 1873, the combined result of US legislation and French policy action. Lawrence Officer (1996) set the standard for empirical work on the operation of private bankers dealing with the exchange of dollars and sterling over the period 1791–1931. Officer's extensive studies were stimulated in turn by the seminal work

by Davis and Hughes (1960), two of the co-founders of the cliometrics meetings while they were both assistant professors at Purdue University. Most recently, Canjels et al. (2004) took the cliometric study of exchange rates yet another step forward, by increasing the quantity of data to obtain higher-frequency exchange rate quotes from the printed sources of the late nineteenth century and then applying more sophisticated econometrics, threshold autoregressive (TAR) time series analysis, than was available for earlier researchers.

TAR was developed to determine the price bands within which prices of a given good could vary without affecting the prices for the good in an adjacent or distant market. Used successfully to determine the degree of market integration for commodities over space and time, they could also be used to examine what were the effective gold points for arbitrage between London and New York when both countries were committed to a gold standard. Canjels et al. further extended their analysis to see if actual gold movements did occur when exchange rates hit or exceeded their estimated gold points, and found enough confirmations to reassure them. But the most reassuring aspect of their findings was that their estimates of the gold points were very much the same as those determined by the more tedious efforts of Officer (1996) and Flandreau (2004), namely, to find historical evidence of the actual costs of shipping, insurance, and interest payments incurred by operators in the foreign exchange markets of the time.

The demonstrated usefulness of TAR econometrics overall has stimulated other work on exchange rates in historical settings of financial markets for short-term commercial credit. Volckart and Wolf (2006), for example, use TAR to derive the implications for the extent of market integration and the speed of adjustment to changes in mint ratios for fourteenth- and fifteenth-century Flanders, Lübeck, and Prussia. They find that it took about 8 months for deviations between Flanders and Lübeck to fall back within bullion points but twice as long for adjustments to occur between Flanders and Prussia, showing the importance of seaborne trade for northern and central Europe. Following up on this study, Chilosi and Volckart (2011) apply TAR analysis to the 13,092 exchange rates that Volckart (1996) collected mainly from account books of guilds, merchants, ecclesiastical organizations, and city authorities in central Europe for the period 1400–1520. They used these data to determine which cities were integrated with each other and how integration changed over time. The results show that long-term trends toward improved financial integration dominated the cycles of debasements that occurred regularly, but also that integration seemed driven more by rising trade than by political unification. Work on the dominant role of Genoese bankers in the sixteenth and seventeenth centuries by Pezzolo and Tattara (2008) uses cointegration analysis of interest rates on rechange bills marketed in the Bisenzone fairs dominated by the Genoese. They find that the Genoese money market was directly affected by news from Spain about the war expenses or arrival of silver from America, but these shocks also affected the money markets in Florence and Milan, while Venice remained unaffected. The risks of dealing with short-term Spanish *asientos* by the Genoese therefore explain why short-term interest rates in Genoa were consistently higher than the yields on long-term Genoese government debt.

While Volckart's data are accessible on his website, Volckart (2014) the fourteenth- to sixteenth-century exchange rates, perhaps the most extensive data set is maintained at Rutgers University as *The Medieval and Early Modern Data Bank* (Bell and Howell 1998), http://www2.scc.rutgers.edu/memdb/. Researchers at the University of Reading (Bell et al. 2013a) have applied times series analysis to the exchange rates recorded there as well as higher-frequency rates recorded by the Tuscan merchant, Francesco Datini (downloadable from the Datini Archive 2014). They find evidence of seasonality, occasional trend breaks associated with debasements and military conflicts, and overall an inverted term structure of interest rates for early modern Europe. Long-term sovereign bonds appear to have been guaranteed against debasements in monetary regimes based on precious metals while commercial credit was subject to higher idiosyncratic risks for specific trades (Bell et al. 2013b).

Next Steps

As useful and insightful as these studies have proven to be so for, the next step – in addition to continuing to extract and encode ever more data from historical financial markets and continuing to apply ever more sophisticated statistical techniques to the data – should be to see how the markets for long-term sovereign debt interact with the markets for short-term commercial credit. Practitioners in finance have long acknowledged the importance of the existence of long-term government debt for facilitating the short-term finance of commercial activities but it took the work by Gelderblom and Jonker (2004) to document precisely how this occurred at the start of financial capitalism. Using the accounts of the Amsterdam merchant Hans Thijs in the period 1595–1611, they found that the interest rates he paid to investors in his various ventures dropped permanently once he invested in the permanent shares of the Dutch East India Company, founded in 1602. This was because he could now pledge the shares as collateral for loans from a much wider range of potential investors than before. Marketable financial assets backed by the commitment of revenue by the issuing government or corporation provide merchants with reusable collateral that can be posted repeatedly against short-term loans from any potential investor. This insight provides the logical link between the markets for sovereign bonds and short-term commercial credit, but one still has to determine how to test for the reciprocal effects between the two sets of financial markets.

One approach, taken by Neal and Weidenmier (2003), was to take financial crises as given and then to see whether contagion occurred during the subsequent crisis, all to indicate what kind of learning process might have been going on among policymakers in major industrial countries during the classical gold standard era. As with all the studies covered in this survey, this approach required the two steps of acquiring new data (high-frequency short-term interest rates) and applying new statistical techniques (adjusting standard deviations for heteroskedasticity). Given the interest in financial crises, which always start with a shock to the supply of short-term commercial credit somewhere in the payments system, and the possibility of

contagion to other parts of the financial system, whether domestic or international, short-term interest rates are equally interesting for cliometricians. Mishkin (1991) reviewed the financial crises in the USA from 1857 through 1987 to show that rises in short-term interest rates preceded each crisis. Increased spreads between the yields of lower rated commercial or corporate securities and government securities for both short- and long-term assets then accompanied each financial crisis.

Neal and Weidenmier (2003) found similar results for international financial crises dating from 1825 to 1907, although in their methodology contagion was limited to only the 1907 crisis. That corresponded to the similar rejection of the contagion thesis found by Forbes and Rigobon (2002) for the Asian financial crises in the late 1990s as well as for the Mexican crisis of 1994 and the US stock market crash of 1987. Their argument, which hasn't yet entered conventional wisdom, is that increased volatility of asset prices during a financial crisis increases standard measures of correlation across markets, which may or may not have been interdependent before the crisis. Adjusting for heteroskedasticity in standard deviations that accompanies financial crises allows one to determine if correlations among markets really did increase and therefore to differentiate between interdependence and true contagion. For Neal and Weidenmier, the anomaly of 1907 came when previous interdependence of the New York and London markets for short-term finance was disrupted by the decision of the Bank of England to prohibit dealing with American commercial paper earlier that year. Odell and Weidenmier (2004) traced this decision back to the gold outflows needed to cover the payouts by British insurance companies for the losses from the 1906 earthquake in San Francisco.

A complementary approach to combining analysis of markets for short-term and long-term financial products is taken by Schularick and Taylor (2012). They also take crises as given from a consensus of the profession, but they then extend the number of crises from 1870 through 2008. Further illustrating the theme of this essay, they both collect new data and apply new statistical techniques. Their new data are measures of bank credit (loans by financial institutions of all kinds and their total balance sheet assets) for 14 major countries, which they can compare with previously developed measures of money supply. Next, they apply new statistical techniques (and a new acronym, AUROC – area under receiver operating characteristic) to test which of their measures of financial markets, credit or money, do the best job of predicting financial crises, country-by-country and overall. The interesting finding is that both the credit and money measures perform equally well in predicting financial crises from 1870 up to World War II, but thereafter the credit measures become increasingly more powerful as predictors of crises. While the importance of credit booms for generating following crises even in the nineteenth century is not surprising for financial historians,[4] the failure of money measures to correlate closely with credit changes after 1948 is disappointing for economists trained in the monetarist school. Both the increased willingness of public authorities to inject high-powered money into the economy during a crisis and the increased

[4]See, for example, Davis and Gallman (2001) and Kindleberger and Aliber (2011).

reliance of private banking firms upon repo borrowing in place of deposits suggest that this is a permanent change.

The classic work of Friedman and Schwartz (1963) created a master framework for studies ever since by measuring the supply of money, broken into various components, over the near-century that included financial crises before the Great Depression and the financing of the US role in the two world wars of the twentieth century. But the authors saw the role of financial markets as at best secondary to the driving role of the public's demand for money interacting with the government's control over the supply of money, even during the Great Depression. Nevertheless, the "monetarist" movement among economists that they fostered was a necessary step away from the economics profession's focus on the "real economy," measured by adjusting for adventitious movements in monetary prices. Later work on the balance sheets faced by banks led to emphasis on the problem of debt deflation (Bernanke 1995, 2000; Calomiris 1993). By pointing out "just the facts," cliometricians not only force other historians to re-evaluate their interpretations of economic development in the past but also encourage economists to re-think their theories and policy prescriptions.

Concluding Remarks

Financial markets and cliometrics have a checkered history despite their obvious complementarity. Financial markets have always generated and publicized masses of data and quantitative historians supposedly desire lots of data to process and analyze. Why, then, have there not been more studies to draw on to date? The problem seems to be two-fold: first, secondary markets for securities often produce far too much data for the lone investigator to process readily and, second, the analysis will always be challenged for its usefulness, even theoretically much less practically. The first problem is well on the way to being overcome thanks to the continued technological progress in digitizing and encoding data from printed sources onto electronic formats, which in turn can be used to carry out any number of statistical analyses. The second problem has only gradually succumbed to acceptance that price data alone, even without measures of trading volume for the underlying securities, can yield interesting insights into historical issues of consequence. Do the movements in prices of financial assets in organized markets reflect simply the "madness of crowds" or the workings of efficient markets? Even if financial markets are efficient, what "real" fundamental factors determine the prices?

The efforts of financial historians, as well as historians in general, tend to separate them into those who hope that patterns can be found and those who resign themselves to human folly. In financial history, these alternative narratives are between those who hope that market participants jointly can learn to devise time-consistent rules for self-governance and those who are convinced that financial markets need prudential regulators and lenders of last resort. Cliometricians enter these ideologically and politically driven disputes with trepidation, but find that their focus on the past is no refuge from the conflicts of the present. Indeed, issues raised in each new

crisis help pose new questions for analysis of previous episodes, whatever the personal predilection of the historian may be. The meltdown of global financial markets with the unexpected bankruptcy of Lehman Brothers investment bank in September 2008, for example, brought renewed attention to the way banks finance their long-term loans with short-term debts as well as with demand and time deposits. The investigative report by the US Senate (2011) pinpoints the causes of the crisis as high-risk behavior by mortgage lenders, regulatory failure, inflated credit ratings, and investment bank abuses. The individual case studies provide the justification for many elements of the Dodd-Frank bill that were specifically designed to remedy the practices that led to the financial crisis of 2008. But as Gorton (2010) notes, every financial crisis has a unique pattern of events leading to a crisis that first shows up in the market for short-term credit but the unwinding of the crisis takes a particular course depending on historical circumstances and the responses made by governments, banks, and capital markets.

Gorton's unique analysis of the panic of 2007 remains a standard for cliometricians to emulate, eschewing the temptation to generalize found in works like Reinhart and Rogoff (2009) or Kindleberger and Aliber (2011). But using the evidence from the 2007 panic, cliometricians have found new interpretations for earlier crises that are enlightening, starting with the Mississippi Bubble of 1719–20 (Neal 1990, Chap. 4; Velde 2009, 2012) and the South Sea Bubble of 1720 (Neal 1990, Chap. 5; Carlos et al. 2002; Carlos and Neal 2006; Shea 2007, 2009; Frehen et al. 2013; Kleer 2013). Even the little known financial crisis of 1763 in Amsterdam and affecting all of northern Europe has had fresh interpretations in light of modern analysis of financial markets. Schnabel and Shin (2004) show how the chain of short-term credit based on acceptances covered by various commodity contracts broke down with a sudden price shock at the end of the Seven Years' War. Quinn and Roberds (2012) go further by showing how the Bank of Amsterdam acted as an early lender of last resort in response to the crisis, letting one merchant bank fail while supporting the others with repo finance based on silver coins and bullion as collateral. Their earlier work (Quinn and Roberds 2009) explained how the Bank of Amsterdam in the seventeenth century had created "inside" or "high-powered" money so it could play the role of a central bank in the future. Carlos and Neal (2011) argue, nevertheless, that the 1763 crisis marked the eclipse of Amsterdam by London as the center of European finance thereafter. Flandreau et al. (2009a) found that the combined effect of the Seven Years' War and the crisis of 1763 raised all short-term interest rates throughout commercial Europe leading up to the French Revolution. After the end of the French Revolutionary and Napoleonic Wars, the defining moment for British finance in the nineteenth century was the government's regulatory response to the crisis of 1825 (Neal 1998) with ripple effects in the USA (Hilt 2009).

One of the most intensively studied episodes that is still generating new scholarly findings by cliometricians is the international crisis of 1907, which started in the USA with the failure of the Knickerbocker Trust Company, much as the crisis of 2008 started with the bankruptcy of Lehman Brothers. Neal (1971) lauded the benefits of trust companies, while later work by Moen and Tallman (1992, 2012)

pieced together the way the crisis propagated after the initial collapse of a leading trust company and then how the private organization of the New York Clearing House intervened to limit the possibility of contagion. More recent analysis of balance sheet detail from the existing banks and trust companies in New York by Frydman et al. (2012) goes even further to show how information about the specific trust companies affected the pressures placed on them, much in the spirit of Gorton's plea for attention to information flows and content before, during, and after a crisis in financial markets.

Of course, the Great Depression has generated most of the work by cliometricians including dealing with the international aspects, often overlooked by American economists. The key role of bank borrowings to finance their foreign loans caught the original attention of economists at the time, as reported in the Hoover Commission reports at the time (President' Conference on Unemployment 1929, 2 vols), but has recently been reevaluated by cliometricians, first for the USA (White 1984, 1990; Calomiris 1993; Wheelock 1991), Germany (Schnabel 2009), and then for Great Britain (Accominotti 2012). The initiating role of France in undermining the newly established gold exchange standard by resuming its prewar demand for monetary gold was also appreciated at the time, but subsequent work focused on the futile efforts of the USA to cooperate with the UK as financial hegemons (Kindleberger 2000). While Eichengreen (1992) basically blamed the obsession with gold for the general dysfunction of the international financial markets, Irwin (2011) reprised the UK-American argument at the time that France's obsession with gold brought on the Great Depression. Only by reducing the prices of export goods could the rest of the world meet the excess demand for gold created by French policy. Worldwide deflation, as in the 1870s–1880s, again undercut the ability of emerging countries to service the sovereign bonds they had issued. Work by Wandschneider (2008, 2009) shows how differing central bank policies in central Europe created different responses to the challenges of servicing sovereign bonds while maintaining domestic output.

Work continues by cliometricians to pursue Gorton's plea for more in-depth studies of particular crises to see how information flows are disseminated among the various players in each case. Atack and Neal (2009) is one effort to collect deep historical case studies united by a common theme. Atack motivated the introductory chapter by the September 2007 run on Northern Rock's branches throughout the UK and Neal's concluding chapter assessed the evolving subprime crisis in the USA. Echoing the theme of Reinhart and Rogoff, we argued that this crisis had its historical antecedents, going back at least to seventeenth-century Amsterdam. But each author developed his own interpretation of a particular episode. At the heart of each story was the severing of the personal ties that had always been the basis of banking and then substituting reliance upon government agency oversight of the impersonal financial markets that allowed effective securitization for assets in secondary capital markets. The individual authors argued that credit institutions, capital markets, and governments always had difficulty in learning how to coordinate effectively the role of all three sets of organizations in the financial sector whenever financial innovations occurred, usually from the pressures of war finance

upon governments. The concluding chapter, *mea culpa*, argued pessimistically that policymakers usually misread the supposed lessons derived from previous crises. But it also noted optimistically that the current set of policymakers both in the USA and Europe had studied a number of past crises, some quite recent, and perhaps they could learn more quickly from their mistakes than was often the case in the past.

Financial Systems

Caroline Fohlin

Contents

Abstract

This chapter elucidates the key debates surrounding the optimal design of financial systems and institutions: bank-based versus market-based; universal versus specialized banking; relationship versus arms-length banking. The chapter also examines the historical pattern of financial system development – explaining the economic, legal, and political factors that influenced the shape of these systems as well as the long-run growth outcomes observed among the group of economies that underwent industrialization prior to World War I. The extensive evidence and analyses available indicate that financial systems historically took on a wide and complex range of forms that are difficult to categorize narrowly, yet provided

similar functions; thus arguing for a functional, rather than institutional, approach to financial system design and regulation. Moreover, the research to date strongly supports the idea of persistence and path dependency in financial system design, that economic conditions at the time of industrialization help set the initial conditions that shape financial system and banking institution design, and historical political conditions, such as centralization of power, plays an ancillary role via the extent of regulation on banks and the development of free capital markets. In other words, history matters.

What Does a Financial System Do?

The financial system is the set of institutions and markets that gathers excess funds from savers – whether households or businesses – and allocates financial capital to entrepreneurs and others in need of credit. In the process, the financial system produces information and distributes risk throughout the economy and among its participants. Merton (1993) summarizes even more succinctly the primary function of any financial system: "to facilitate the allocation and deployment of economic resources, both spatially and temporally, in an uncertain environment."

Well-functioning financial systems must provide several core functions (Merton 1993; Merton and Bodie 1995):

- Clearing and settling payments
- Pooling or mobilizing resources
- Transferring economic resources, inter-temporally or geographically
- Managing risk
- Pricing information
- Dealing with information and incentive problems

Financial systems may provide these services via a wide range of institutions and markets. Financial institutions include, among others, commercial banks, savings institutions and thrifts, credit cooperatives, investment banks, insurance companies, trust companies, pension funds, mutual funds, hedge funds, and private equity. Institutions come in a wide range of sizes and ownership structures – from private partnerships to enormous multinational conglomerates to government-owned enterprises. Financial markets offer centralized, liquid trading in essentially any financial claim, from debt to equities, commodities to foreign exchange, and a wide array of derivatives.

The core components of modern financial systems grew out of small, rudimentary, and entrepreneurial initiatives at the earliest stages of economic activity: the merchants of the medieval era, the goldsmiths of seventeenth-century London, and the fairs and early commodity markets that dotted Europe throughout the medieval

and modern periods.[1] In their own way, each of these organizations participated in payments clearing and settling, capital pooling and mobilization, risk management, information aggregation, asset pricing, incentive matching, and agent supervision.

Financial systems grew and diversified as industrialization took hold in England and then the European continent. New forms of financial contracting, institutions, and markets evolved to handle more extensive and complex needs of funding the larger-scale and scope of industrial enterprises. Thus, financial and industrial revolutions progressed largely in parallel, with entrepreneurial financiers innovating to serve the incipient demands from all sectors of the economy – industry, agriculture, transportation, and trade. Political boundaries and legal institutions also continued to shift repeatedly throughout this early stage of financial and industrial development, and monetary systems developed and changed as well. Some countries with stronger central government control instituted central banks and fiat currency, though the degree varied among countries and over a wide time span.

The greatest leap toward modernized financial systems came in rapidly industrializing areas of the early to mid-nineteenth centuries and spread with industrialization to most of the rest of the world over the remainder of that century. Significant shifts and redesigns of financial systems came with the crisis of the Great Depression, the post-WWII reconstruction, the wave of liberalization of the 1980s–1990s, and most recently in response to the global financial crisis of 2008 and the ensuing "great recession." For the most part, these episodes caused some reshaping of institutions and markets and their regulation by the government, but they did not set off fundamental change in the functions of the financial system or the existence of institutions and markets that provide these functions.

Academic study of financial systems dates back to the beginning of financial systems and continues unabated. The literature covers a wide array of topics, some of which provoke significant debates. The changing regulation and organization of financial institutions and markets in the late 1980s through the 1990s, along with several areas of transformation in political and economic systems, set off an active academic literature on financial system design that became particularly active in the late 1990s and early 2000s and continues today.

Three of the key areas of research and debate revolve around the following topics:

1. The design of financial institutions and systems: functional versus institutional approaches.
2. Why do financial systems differ across countries: legal origins versus political and economic explanations?
3. Does financial system design affect an economy's long-run economic growth rate?

[1] On the London goldsmith bankers and the British financial revolution, see Temin and Voth (2013).

The next three sections take up these topics in turn, providing a survey of the current thinking and remaining issues for further research. The discussion focuses on corporate finance systems and related areas of corporate governance.[2]

Designing Financial Systems: Functions Versus Institutions

Financing modern industry hinges on a system that allows those with surplus resources to convert their excess into financial capital and channel those funds into productive investment opportunities. This process often means connecting entrepreneurs with capital owners outside the entrepreneurs' circles of friends and families, creating a need for contracting and enforcement devices as well as a means for coping with asymmetric information and incentive problems. Virtually all developed economies employ limited-liability, joint-stock corporations to facilitate external financing. Most of these countries formalized, standardized, and liberalized incorporation and legal liability systems during the nineteenth century – many during the wave of heavy industrialization of the 1850s–1870s. Within a decade or two thereafter, businesses and entrepreneurs in these countries turned to corporations in order to grow and diversify, financing an unprecedented scale of operations. The acceleration of incorporation in most places during the last years of the nineteenth century and into the twentieth spurred rapid advancement in the corporate financial sector and of the securities markets. Despite their considerable differences in culture, society, legal systems, and political processes, the world's most advanced economies all created well-functioning systems for corporate finance by the late nineteenth century.[3]

For businesses in this period, banks often served as one of the most important sources of outside capital, whether for short-term trade credit or longer-term investment finance. Thus, industrial development usually proceeded hand in hand with the growth of commercial banking. As economies industrialized, financial intermediaries changed, and industrial organization of banking changed as well. The largest banks grew larger, and densely networked, nationwide banks emerged nearly worldwide.[4] Commercial banks took on a varying array of functions, sometimes quite narrowly focused on short-term credit, other times offering investment banking, brokerage, and even strategic advising.

[2]Given space and time constraints, the chapter leaves out monetary systems and central banking.

[3]Fohlin (2012) and Allen et al. (2010) provide detailed historical comparisons of the corporate finance systems of the United Kingdom, the United States, Germany, Japan, and (in Fohlin 2012) Italy. Fohlin (2012) also compares more schematically the financial systems of a larger set of industrialized economies of the prewar period. Morck's (2005) edited volume contains historical studies of the corporate governance systems of several different countries.

[4]Regulatory restrictions prevented the natural progression of banking in the United States. Even there, a few banks grew very large, and banks developed a correspondent system to replicate national branching.

Commercial banks also differed in their responses to changing needs in industrial finance and their engagement in corporate governance. The corporate firms that emerged over the last half of the nineteenth century began to loosen the ties between families and the firms they started. As corporate management began to separate from ownership, investors required new modes of corporate governance. Trading corporate securities on secondary markets often dispersed the ownership of firms and demanded oversight mechanisms to protect smaller shareholders. Thus, industrialized economies developed corporate governance institutions, and banks played varying roles in those arrangements as well.

All of these dimensions of the financial system – the organization of banks, the extent of securities markets, the relationship among banks and markets, and corporate governance – differ to some extent over time and across countries. Thus, financial systems can be characterized along these various dimensions, most notably by the functions they serve or the organizational forms they take.

Post-WWII economic historians took up this topic most actively with the publication of Gerschenkron's *Economic Backwardness in Historical Perspective* and Goldsmith (1969) *Financial Structure and Development*, among others. Gerschenkron, in particular, influenced a generation of financial historians to differentiate among the types or organizational forms that financial institutions could take, positing a relationship between the level of economic development of a country and the type of banking institutions they created. By the 1980s, when Germany and Japan were growing rapidly and the United States saw itself lagging, attention turned to the design of financial systems to explain why. Those cross-country comparisons led to the deregulation of US banking and the Big Bang in the United Kingdom – among other efforts to stimulate the development of German-style universal banking and relationship banking that seemingly helped produce the postwar economic miracle. These events led to a resurgence in interest and ultimately to a reevaluation of Gerschenkron's and Goldsmith's ideas on financial institution and system types and their importance for economic growth.

The Standard Paradigm of Financial System "Types"

The study of financial system types subsumes a number of issues: the organizational design of institutions and markets, the activities and functions of different institutions, and the relative use of financial institutions versus markets. The literature on financial systems focuses on the distinction between bank-based and market-based financial systems, between universal and specialized organizational forms of banking, and between relational versus arm's-length approaches to banking.

These distinctions, however, fit empirical observation only in a rough manner: most financial systems are better characterized using a functional approach that can mix the individual components of one or the other system "type." Still, the notion of type animates a long line of research on both historical and contemporary financial systems, and some kernel of truth remains in the notion of types of systems and of institutions. In this literature, systems and their respective

institutions are divided along three chief dichotomies: universal versus specialized banking, relationship versus arm's-length banking, and more generally bank-based versus market-based systems. The following considers the three issues in turn. The subsequent section examines what we know about historical cases.[5]

Universal Versus Specialized Banking

Banking institutions provide a range of functions, from very short-term credits to longer-term debt to underwriting of securities. The combination of services that an institution provides dictates how it is categorized. Institutions are commonly divided into two main types: universal or specialized, with the former offering a broad scope of services and the latter naturally providing a more limited range. A true universal bank is allowed to provide almost any financial product or service. However, the fundamental distinguishing feature of universal banking historically is the combination of commercial banking functions (short-term credit, deposit taking, payments clearing, bill discounting) with investment banking services (underwriting and trading in securities). Modern universal banks also sell insurance, mortgages, and investment funds, and they create and trade more complex financial products, usually through affiliates. The counterpoint to universal banking – so-called "specialized" banking – separates investment and commercial banking into separate sets of institutions.

Relationship Versus Arm's-Length Banking

The constructs of "relationship" and "arm's-length" banking classify institutions by their involvement in corporate governance. Compared to universality, there is less agreement over what precisely constitutes "relationship banking" in a formal, measureable sense. The term is sometimes used loosely to refer to banks that work closely with customers, but most research considers some combination of the following three types of more formal relationships: proxy voting of deposited equity shares taken by banks, equity shares held directly by banks, and corporate board positions filled by bank directors.[6]

The three methods of engaging in relationships bring different levels of ownership and control rights. The strongest relationship, direct ownership of equity, gives banks both ownership (cash flow) rights and control (voting power) rights. Equity stakes theoretically align banks' incentives with those of other firm shareholders and promote efficient provision of financing. In some cases the banks employed an indirect method of gaining control rights over corporations: proxy voting rights signed over by shareholders. In the proxy voting system, shareholders grant the bank power of attorney over their shares, resulting in additional voting power for the banks. Before the subsequent unraveling of the system in 1990, German banks held on average approximately 24.3% of effective voting rights due to direct equity holdings and 29.5% on average due to proxy voting rights at

[5]This section is based on Fohlin (2012).

[6]See Fohlin (2012, Chap. 3) and on Germany specifically see Fohlin (2005, 2007a, b).

general meetings of their current clients.[7] From this example, it is clear that the proxy voting system can provide banks with significant power over firm management even without ownership rights.

Using their voting power, whether direct or indirect, banks can theoretically help elect their chosen representatives to a company's board of directors and can vote or appoint their representatives into various positions within the corporate boards. These positions then allow the bank to influence the selection of management and other key corporate decisions.[8]

Relationship banking may prove even more important among firms that are organized without publicly traded equity. In these cases, relationship banking necessarily takes an informal shape. While these relationships consist of weaker legal connections, they may actually prove stronger, if firms have limited access to capital market alternatives. Presumably, relationship banking ought to also imply that banks provide helpful advice to young firms, but that sort of criterion is difficult to formalize or measure.[9]

In the dichotomy of financial systems, the natural opposite of relationship banking is "arm's-length" banking. In arm's-length systems, banks simply provide financing, perhaps in a one-shot deal, and take no enduring corporate governance role in nonfinancial firms. In "arm's-length" systems, profit motive theoretically drives information gathering that supersedes the need for closer monitoring by bankers. No system would fit this extreme characterization, and a few even match a weaker form of it.

Market-Based Versus Bank-Based Financial Systems

The third financial system dichotomy distinguishes between market-based and bank-based systems. Systems supporting large, active securities markets, and in which

[7] 1990 data taken from a survey of 144 large German firms' general meeting minutes, quoted in Elsas and Krahnen 2003.

[8] For historical country studies of corporate governance practices, see the volume edited by Morck (2005). A recent volume edited by David and Westerhuis (2014) provides long-run country studies more specifically on corporate networks. The *Oxford Handbook of Banking* edited by Berger et al. (2014) contains several relevant chapters on banking generally. In more recent times, the proxy voting system has come to incorporate a range of financial institutions, such as mutual funds and investment advisors. See Ferreira and Matos (2012) on the impact that proxy voting by banks has on corporate lending globally.

[9] Many studies of young firms focus on venture capital financing and the role of venture capitalists, as in Hochberg et al. (2007). Most young firms do not find financing from venture capital organizations but rather from banks. See Hellmann et al. (2007) on venture capital activities of banks. Ivashina and Kovner (2011) use proportion of lending to measure relationship strength in their study of the impact on lending costs of relationships between LBO firms and banks. Santikian (2014) emphasizes the role of noninterest revenue generation and added connections with new borrowers as measures of relationship strength. The Kauffman Foundation (2013) sponsored a large longitudinal survey of US firms founded in 2004, and they report results on their website: http://www.kauffman.org/~/media/kauffman_org/research%20reports%20and%20covers/2013/06/kauffmanfirmsurvey2013.pdf.

corporate firms use market-based financing, are often referred to as "market oriented." Systems in which banks provide the majority of corporate finance are known as "bank based."

Connections Among the Three System Dichotomies

The literature usually associates bank-based financial systems with universal banking and market-oriented systems with specialized banking. Bank dominance has become nearly synonymous with universality while market orientation has become linked to specialization.[10] The past literature also typically assumes that relationship banking is part and parcel of universal banking, perhaps because of Gerschenkron's focus on the German financial system of the late nineteenth century and similar systems.[11] Putting it all together, we arrive at the three-part financial system paradigm that aligns universal banking, relationship banking, and bank-oriented financing, on the one hand, and specialized banking, arm's-length lending, and market orientation, on the other.[12]

There is some justification for the view: banks and markets may compete in both the initial placement and the ongoing trading of securities. If universal banks internalize market functions, they may impinge on the liquidity of stock exchanges, implying a lower level of market development.[13] For example, universal banks that provided brokerage services may have traded securities among their customers and taken only the net transaction to the market. In contrast, market-based systems by definition support large, liquid equity markets. While such internalization could be plausible in a rudimentary financial system, or in thinly traded securities, universal banking generally works with, not against, active securities markets. A bank cannot become "universal" without investment banking operations – underwriting and brokerage services – to perform. And investment banking requires the use and intermediation of securitized financial instruments. The existence of markets in which to trade securities facilitates the use of these instruments and therefore promotes the investment side of the universal banking business.

Setting up banks and markets as opposites misses the fundamental complementarities between them and ignores their complexity and heterogeneity. The bank versus market dichotomy therefore provides a false sense of clarity in comparing national financial systems, as an examination of historical financial systems demonstrates.

---

[10]See Levine and Zervos (1998) on the 1990s and Fohlin (2012) for historical and long-term patterns.

[11]Gerschenkron's seminal work is his 1962 *Economic Backwardness in Historical Perspective*. He had also written on Italy in 1955 and later on Russia (1970). See also Gerschenkron (1968). Sylla and Toniolo's (1991) edited volume contains several essays relating to and analyzing Gerschenkron's work. See, in particular, Sylla's chapter on banking.

[12]The stylized view is most succinctly laid out by Dietl (1998).

[13]See Bhide (1993) and Levine (2002).

Classifying Historical Systems

The idea of financial system types arose mainly from observation of a relatively small range of countries and time period. Thus, to understand how well the typology fits the historical evidence more broadly, Fohlin (2012) went about classifying historical financial systems based on examination of 26 national financial systems starting in the mid-nineteenth century and extending to the late twentieth century.[14] The study included all countries for which reliable information was available, including a sampling from Europe (e.g., France, Germany, the United Kingdom, Denmark), North America (the United States, Canada, and Mexico), South America (Argentina and Brazil), and East Asia (India, Japan). The classification scheme included the three primary dichotomies of financial system structure and also examined the extent of bank branching:

- Universality versus specialization (whether or not commercial banks also perform investment services)
- Relationship versus arm's-length banking (the existence of any equity stakes, proxy voting, or interlocking directorates between banks and nonfinancial firms)
- Bank-based versus market-oriented system (heavy use of bank funding versus securities markets)

In addition to the broad-based survey evidence, the study included in-depth analysis of five classic cases: Germany, Italy, and Japan in the "universal relationship bank" category and the United States and United Kingdom in the "specialized arm's-length market" category. After pulling together a large array of qualitative and quantitative evidence, Fohlin (2012) argues that financial systems have no fit within clear, unchanging categories; however certain financial system characteristics do allow a rough classification (Table 1).[15]

Universality Versus Specialization

The necessity for investment banking services naturally grew with the onset of free incorporation and securitized debt, as investment bankers provide the intermediation between investors and issuers. The spread of publicly traded stocks and bonds propelled the development of secondary markets in which to trade these securities,

[14]For most of the countries listed, the determination of banking characteristics stemmed from exhaustive searches of secondary literature as well as discussions with several scholars who have studied these systems. Gaps remain where information is too sparse to support a certain categorization. Further studies have appeared since, including Musacchio's (2009) extensive study of Brazil and Colvin et al.'s (2014) analysis of a large sample of Dutch banks in the 1920s crisis there.

[15]One may also consider national laws and regulations regarding banking scope, corporate governance relationships, bank branching, and operations of securities markets. Because regulations constraining banking operations vary in their intensity and enforcement, as well, systems have historically differed even in the absence of regulatory restraints; the "de facto" approach may better capture actual rather than hypothetical differences among systems.

Source: Fohlin (2012, Table 6.1)

[a]In many cases, the extent of proxy voting by banks is difficult to measure accurately

[b]In most cases, branching proceeded slowly until after the second half of the nineteenth century or even later

[c]After 1934, mixed banks were required to split into deposit banks and holding companies and the banks could not hold shares

[d]Some universal banks, some specialized. French universal banks moved more toward straight deposit banking after 1880

[e]Japanese banks combined commercial and investment banking but underwrote little corporate equity; they were prohibited from acting as dealers in secondary markets

[f]Some universal, some primarily commercial. (Jonker argues that Dutch banks were universal only between 1910 and 1920. After about 1924, through WWII, the Dutch banks reverted to primarily commercial banking, with some low-risk company flotations)

[g]Intentional acquisition of shares was illegal until 1909. Shareholdings could result from collateral held on bad loans

[h]Bank structure varied considerably. Services were combined through commercial bank subsidiaries of investment banks. Compliance to (or interpretation of) the new laws also varied

especially toward the end of the nineteenth century. Thus, banks that provided underwriting and brokerage services evolved in a variety of functional and legal forms over the course of the nineteenth century, with the most rapid development in many countries in the mid-nineteenth to late nineteenth century – typically in conjunction with related developments in corporate and securities laws and institutions.

Germany, with its dozen or more large-scale universal banks, offers the classic example of universal banking (Fohlin 2007a), but most of continental Europe followed a similar pattern. Universal banks had emerged in Belgium even earlier and in France almost simultaneously. Universal banking spread to several other European countries in the 1890s: Finland, Italy, Spain, Sweden, Ireland, and Switzerland. In Italy, the financial system remained compartmentalized until the early 1890s, when it suffered a severe crisis and the failure of many banks. The crisis prompted the establishment of a central banking system and the importation of German-style universal banking.

Universal-type banks spread over many parts of the industrialized world in the nineteenth century. Even where universal banking institutions grew up and dominated the corporate banking scene, other types of institutions often thrived. For example, in Belgium, a small number of large-scale, typically limited-liability universal banks operated along with smaller, specialized banks focusing on a narrower range of services. To varying degrees, this mixture of institutions emerged in all parts of continental Europe (Denmark, France, Germany, Greece, Italy, the Netherlands, Spain, Sweden, and Switzerland), parts of Latin America (e.g., Argentina, Brazil, and Mexico), and, in a limited way, even in Australia, New Zealand, and the United States.

Specialized banking grew out of the more advanced economic context of England and its long history of commercial and merchant operations around the globe. The investment banks and merchant banking houses evolved separately from the commercial banks in part as a natural consequence of the extent of the markets for those services and the fact that the early investment banking services revolved heavily around government finance with little possibility to gain from economies of scope between investment and commercial banking.[16] Commercial and investment banking remained mostly separated in the British financial system throughout the nineteenth and much of the twentieth centuries. Most countries with similar financial systems imported their legal and financial structures through colonization or other close ties with England.[17] American banks retained significant legal and organizational separation even while combining functions in some institutions and creating close operational ties between investment and commercial banks. Thus, Fohlin (2012) refers to the US banking system as quasi-universal in the pre-WWI era.

Some countries, such as Australia, France, the Netherlands, Belgium, Italy, Russia, and the United States, developed universal banking practices in the

[16]See Collins and Baker (2004) on commercial banking in England and Wales from 1860 to WWI.

[17]See Fohlin (2012) for a list of countries and further discussion.

nineteenth century, but then restricted or abandoned it at various points later on.[18] Notably, the United States began the twentieth century with (quasi-) universal banking but sharply restricted it with the passage of the Glass-Steagall Act in 1933 and the Bank Holding Company Act in 1956, both as responses to the Depression Era bank failures. Even into the 1990s, the United States did not develop unrestricted universal banking. The Glass-Steagall Act persisted until its repeal in 1998, after much debate and as financial and political reality overtook the antiquated law.[19] Yet another group of countries developed mixed or partially restricted systems: Argentina, Belgium, Brazil, Canada, Greece, India, Mexico, New Zealand, Norway, and Russia.

Germany, Austria-Hungary, and Portugal were the only countries to maintain universal banking institutions continuously from the late nineteenth century into the late twentieth century. Germany is the archetype of the universal system, having developed joint-stock universal banks in the mid-nineteenth century and then using these institutions to mobilize extensive capital to finance a growing population of corporations and large private enterprises.[20]

Relationship Versus Arm's-Length Banking

The historical evidence on prevalence of relationship banking remains incomplete, and there is no precise way of determining whether a particular set of banking institutions constitutes a relationship banking system. Recent efforts toward categorization have turned up new evidence and have established some classification parameters regarding bank engagement in some mixture of the three primary attributes: bank representatives on firm boards, direct equity shares held by banks, and proxy voting. The crucial point is that banks' activities gain them significant formal control over the management decisions of nonfinancial firms; ownership, or rights to the companies' cash flows, takes a lesser priority.

Prior to WWI, formalized banking relationships developed gradually and unevenly in different places. Until the 1860s–1870s, when many countries liberalized incorporation laws and instituted corporate governance requirements, such as boards of directors, the opportunities for formal bank connections remained constrained. Few studies have attempted to quantify the extent of these practices, but the qualitative descriptions available suggest that most banks played a small role in nonfinancial corporate governance for most of the nineteenth century.

The first industrial banks of the 1850s in Germany, Belgium, France, the Netherlands, and elsewhere often took over the capital of a few firms for which the banks

[18]See Amidei and Giordano (2010).

[19]The merger between Travelers Insurance Group and Citibank in early 1998 was a direct challenge to the early twentieth century banking acts.

[20]Gerschenkron (1962) provided the seminal postwar exposition of the German system; however, Riesser (1910 German original; translated by the US National Monetary Commission in 1911) and Jeidels (1905) offered detailed contemporary accounts of the German banking system, and Whale (1930) added further analysis – all of which seem to have influenced Gerschenkron's thinking on the German banking system. See the discussion in Fohlin (2007a).

were managing a new issue. The downturn in the markets of the mid- to late 1850s left the banks holding major stakes in a few firms, and a significant number of banks failed. The losses taught the surviving banks and newcomers to avoid such costly mistakes in the future (prominent examples include the French Crédit Mobilier and the German Disconto-Gesellschaft and Darmstädter Bank). Equity participations were largely accidental, in this case a result of the market declines, and were not pursued as a means of corporate control. In fact, historical studies highlight the dismay of bank shareholders when bank funds became tied up in long-term equity holdings.[21]

Fohlin (2007a) argues that interlocking directorates arose in Germany most extensively toward the end of the nineteenth century, and from the viewpoint of the early decades of the twentieth century, Germany not only had one of the largest and most complete universal banking systems but had also developed relationship banking practices of various sorts. The banks could vote their representatives onto corporate boards using proxy voting rights gained by taking equity shares placed on deposit by customers. The larger the bank and the more widely held the corporation, the more likely the bank would receive proxy votes with which to vote its representatives onto the company board. Banks in a number of countries took to relationship practices much more actively around the turn of the twentieth century, but relationship banking practices varied quite a bit in their origins and importance. In some systems, what looked like equity stakes in fact arose out of underwriting activities of the investment banking arms of universal banks. Most banks, as in Germany, engaged via proxy voting and board positions, rather than long-term, direct equity stakes. Moreover, banks took board positions in a minority of firms.

Fohlin (2012) also evaluated relationship banking practices in the sample of 26 countries, demonstrating that not all universal banks perform the complete range of relationship banking functions and not all financial institutions that provide some of these functions are universal banks. The study showed that the strength and prevalence of relationship banking practices varies across countries and across time periods. In the late nineteenth century, Austria-Hungary was the only country (for which there is data) that engaged in the full range of relationship banking activities in a widespread fashion: seats on company boards, equity share holdings, and proxy voting.

Proxy voting data is difficult to collect, so we cannot say for sure how widespread the practice was. In Italy, the Netherlands, Russia, Spain, and the United States, banks in the late nineteenth century also took seats on company boards and held equity share holdings. In none of these cases is there comprehensive data on proxy voting. Anecdotal evidence from well-known bankers – such as J. P. Morgan – suggests that some version of proxy voting did provide bankers with a measure of corporate control rights. Certainly German, Austrian, Belgian, and Italian universal banks took positions on a significant number of firms' boards, but they did so primarily in the largest firms with publicly traded equity.[22] Most of the large banks

[21] See Paulet (2002) on the Credit Mobilier and Fohlin (2007a, b) on the German case.

[22] See Fohlin (1997, 1999, 2007b) on Germany and Italy. See Van Overfelt et al. (2009) on Belgium.

geared toward industrial finance held board positions and possibly proxy votes, but few held long-term equity stakes. Thus, we can surmise that most industrializing economies practiced a relatively high degree of relationship banking by the early twentieth century.

Notably, Fohlin (2012) finds that universal banking existed without widespread and comprehensive relationship banking (at least 9 of the 26 historical cases of universal banking examined), suggesting that universal banks do not require formal banking relationships to remain viable. This institutional independence is important, because some have hypothesized that formal institutions help enforce repeated interaction between individual firms and a single bank – the German "house-banking" idea – that in turn yields informational economies of scope.[23] In many cases, firms developed relationships with multiple banks, particularly if the firm was large enough to require substantial securities issues, and therefore underwriting or lending from a consortium of banks. Thus, historical evidence also suggests that firms do not always engage in exclusive, long-term banking relationships.

Moreover, banks in "specialized" systems also formalize and maintain relationships through some combination of equity stakes, proxy voting, or sitting on the board of the client firm. Of the primarily specialized systems identified in Fohlin (2012), bankers took up board positions in Canada, Finland, Greece, Japan, the United States, and also in financial systems that had become specialized (Belgium, France, and Italy) during the regulatory initiatives of the interwar years. England was home to apparently the least engaged bankers. However, even there, a new study estimates half of the members of the parliament held seats on corporate boards.[24]

Among the hybrid banking systems (neither truly universal nor specialized), the United States stands out. J. P. Morgan and George F. Baker (respectively, the preeminent investment banker and the chairman of the board of First National Bank of New York) and other investment and commercial bankers played such a high-profile role in US industrial firms in the pre-WWI era that Congress undertook an investigation into the so-called Money Trust through extensive hearings in 1912 and 1913 and passed the Clayton Antitrust Act in 1914.[25] For the majority of the twentieth century, legal restrictions, such as stipulations on equity stakeholding or board memberships, have hindered, but not eliminated, the development of close and formal relationships between US banks and their clients. In a study of more recent times, US bankers sat on the boards of one third of large firms.[26]

It is also worth noting that the United States pioneered the development of intensive "relationship banking" for new firms in the form of post-WWII venture

[23]See Calomiris (1995) for a review of these and related arguments.

[24]Braggion and Moore (2013).

[25]See American Bar Association (1984) on the Clayton Act provisions regarding interlocking directorates.

[26]Kroszner and Strahan (1999). G. William Domhoff, a sociologist at UC Santa Cruz, maintains a website that provides extensive information on interlocking directorates in the United States: http://www2.ucsc.edu/whorulesamerica/power/corporate_community.html.

capital organizations. Venture capitalists fund predominantly untested projects for which the market has yet to enter the picture, and therefore asymmetric information problems may stand in the way of financing externally. Indeed, venture capital financing is most viable for firms with a high chance of ultimately going public and accessing market-based finance. In other words, financing needs vary by stages of individual firm development and may necessitate varying levels of relationship banking over time.

Bank Versus Market Orientation

While it is exceedingly difficult to gather accurate and comprehensive historical measures of securities market activity, the data that are available for a few countries along with qualitative evidence from historical studies indicate that virtually all industrializing economies supported thriving secondary markets for securities before WWI. Later developing countries supported markets as well: stock markets appeared in Istanbul, Madrid, Belgrade, Athens, and elsewhere. Even some of the poorest economies, such as India, Russia, and Brazil, had one or more relatively active financial markets.[27] Only a few countries – Finland, New Zealand, and Norway, for example – lacked significant capital markets. Thus, the evidence so far available indicates that financial markets emerged regardless of banking design. The list of true bank-based systems might dwindle down to nothing. Even Japan is not viewed as an entirely bank-based system, but a hybrid of bank- and market-based systems plus the addition of the zaibatsu (before WWII) as an extra complexity.[28]

In some cases, governments intervened in markets, usually in response to crises. In the archetypal universal banking system of Germany, the government intervened in financial markets and institutions, including requirements on stock market listing, levying of taxes on issues and trades, and imposition and removal of a ban on futures, trading on nearly all industrial shares. The government also created among the most advanced accounting, reporting, and corporate governance standards. One tax law did seem to temporarily shift trading activity from markets to large banks: a tax loophole that failed to impose trading taxes on all orders, even those executed through banks, allowed Berlin-based universal banks to offer savings to their customers who traded through them instead of through smaller intermediaries or brokers. The more trades the banks could gather and net out within their own client networks, the further the eventual net trading fees were spread. This loophole was closed by 1900, but even before that, it did not prevent the expansion of the Berlin exchange. This example, however, may say more

[27]On Brazil, see Mussachio (2009). For a general examination of stock market development, see Michie (2006). See Battilossi and Morys (2011) for a brief survey of markets in Madrid, Vienna, Belgrade, Bucharest, Sofia, Athens, and Istanbul.

[28]Dietl (1998) and Hoshi and Kashyap (2004). See Morck and Nakamura (2005) for an exhaustive treatment; they explain the (substantial) differences between the modern (post-WWII) keiretsu and the prewar zaibatsu.

about the idiosyncratic influences of the government than the innate substitutability of financial markets and universal banks.[29]

The German experience suggests that universal banking became useful and successful because financial markets existed in which to trade securities. Germany was home to several active securities markets, with thousands of share companies listed.[30] In 1905, approximately 30% of the 5,500 German *Aktiengesellschaften* (joint-stock companies) maintained listings on one or more German exchanges – with the majority of these listings in Berlin. Listings grew rapidly after WWI into the 1920s.

It is worth noting the element of path dependency and idiosyncratic development in market development. The first countries to develop liquid securities markets could draw foreign firms to list securities with them, reducing the role of national securities markets in other European or North American countries. Countries that led the prewar international monetary system, such as Great Britain, France, the United States, and Germany, also took the leading role in international financial markets of the late nineteenth and early twentieth centuries. So, London, Paris, New York, and Berlin topped the list of financial markets around the turn of the twentieth century, regardless of differences among their banking organizations.

Bank Branching Versus Unit Banking

One additional characteristic of banking systems that falls somewhat outside of the three dichotomies of financial system design is the question of bank branching and whether it relates to the size and structure of banks. The survey of banking systems conducted in Fohlin (2012) indicates that extensive, national branch networks emerged in most industrialized economies around the world by the early twentieth century. Only Portugal, Denmark, Norway, and the United States failed to develop widespread branching before WWI. The study also finds that the reasons for a lack of branching are not entirely clear: while the United States imposed a variety of restrictions on branching, even in states with no anti-branching law (notably, California), branching developed gradually over the 1910s and after. Likewise, Portugal, Denmark, and Norway did not prohibit branching. Their lack of branching might be attributed to lack of economic development, except that many far poorer countries, such as India, Brazil, Mexico, and Japan, did maintain branch networks.[31] Moreover, although these three non-branching countries were on the European periphery, so were several branching countries: Spain, Russia, Finland, and Sweden, for example. Finally, even though these three countries were small and had small industrial sectors, so were New Zealand, Finland, Ireland, and Greece. In any case, by the early post-WWII years, only the United States perpetuated the unit banking system

[29]See Fohlin (2000).

[30]Fohlin (2007a, b).

[31]Apparently, Brazil imposed restrictions on interstate branching by domestic banks but permitted branching within states. Foreign banks could branch as they pleased.

in many parts of the country – but even then branching within states was taking hold in several states, to the degree it was permitted.[32]

In other words, the available literature indicates that branching appears in all types of financial systems and is neither necessary nor sufficient for universal banking to arise. As the previous discussion explains, universality arose in most places in the middle of the nineteenth century, and branching followed in most places decades later, when the level of development encouraged larger-scale banking. Fohlin (2012) points to two cases that illustrate the point: on the one hand, Germany developed joint-stock universal banking by 1848 but, like most other countries, created widespread branch networks only in the 1890s; England, on the other hand, maintained specialized deposit and investment banking even throughout most of the twentieth century, but developed an extensive nationwide branching system even earlier than the universal banking countries. The literature suggests that despite some modern theoretical arguments, universality of banking services historically required a very modest minimum scale of operations.[33] Thus, while bank branching surely affects market structure in banking and may impinge on the stability of the commercial banking sector, it does not link intimately with overall financial system design – such as the activity of financial markets or the structure of banking institutions.

Financial System Evolution Over the Twentieth Century

The tendency to identify universal-style banking with bank domination and specialized banking with market domination stems from the focus on the post-WWII era, as well as from the narrow range of cases examined. The typology is usually based on comparisons of the United States, Great Britain, Germany, and sometimes Japan in the 1950s through 1980s. The first two countries, having hosted the most important international financial markets for much of the twentieth century and having eschewed both universal banking and formalized bank relationships for most of that time (particularly in the United States postwar), head up the market-based, specialized, arm's-length group. Germany and Japan, with their enormous banks and widely discussed networks of clients and house-bank relationships, lead the bank-dominated, universal, relational group.

After WWII, Austria, Germany, Greece (to some extent – there is no data for proxy voting), Japan (also no data on proxy voting), the Netherlands, Portugal, Spain, and Switzerland all maintained some degree of relationship banking practices.

[32]See Calomiris (2000) for a collection of his previous articles dealing largely with branching and relevant political and regulatory debates. See Kroszner and Strahan (2014) for a study of US banking regulation mostly since the 1930s.

[33]See Benston (1994) for a survey of some literature on banking economies of scale and scope in postwar times and Fohlin (2006) for a historical comparison of banking scale in the United States, the United Kingdom, and Germany. It is important to keep in mind the times in which authors analyze banking scale and scope, because they are influenced by the contemporary macro-financial context (post-WWII boom versus later stagnation) and policy debates (e.g., regulatory tightening since the Great Recession versus deregulation in the 1990s and early 2000s).

In the late twentieth century, Italy, France, and Finland also developed relationship banking. At the same time, these practices became restricted in Japan. Most countries whose banks held seats on company boards allowed them to have equity share holdings in nonfinancial firms. On the whole, these two characteristics of relationship banking did appear to go together, but the extent of long-term stakeholding varied a great deal. When equity stakes coincided with board representation, the motivation was simple to understand: through board seats and equity stakes, banks could provide corporate oversight and simultaneously manage their investments.

The data on proxy voting is sufficiently patchy to make observations of broad patterns virtually impossible. In Germany, however, the data and qualitative evidence on proxy voting (testimony from contemporary observers) suggest that throughout most of the twentieth century, banks held significant control over corporate governance via proxy voting.[34] It is worth noting that US regulation prevented banks from holding equity in companies to which they provided financing – an arm's-length relationship, as discussed earlier.

Even these cases, however, defy rigid classification, since closer scrutiny has revealed a number of contrary facts: for example, a lack of widespread, exclusive house-bank relations in Germany, the unraveling of interlocking directorates and unwinding of equity stakes in Germany at the end of the twentieth century, the frequent appearance of bankers on American boards of directors (approximately one third of large US firms have at least one bank representative on their boards), the lack of universality in post-WWII Japan, and the large size and high level of activity of the securities market in Japan.

Moreover, many systems underwent significant upheaval in the aftermath of the two world wars, so that some systems changed significantly during the interwar and early postwar years. Banking institutions in a number of countries suffered both political and economic consequences of war and depression. Many countries enacted legislation in response to political pressure in the 1920s–1930s, and countries such as Belgium, Greece, Italy, Japan, and the United States went so far as to legally prohibit full-scale universal banking. At the same time, economic and political crises hit financial markets, particularly in the early 1930s and during and after WWII. Rajan and Zingales (1999) suggest that governments, because they could exert less control over markets than over firms, and because of the growing discontent of their constituents, found ways to effectively hinder or even shut down markets of all sorts. These authors argue further that the extent of the anti-market backlash varied most significantly with

[34]Fohlin (2005) surveys long-run patterns of corporate governance in Germany, and Fohlin (2007a, b) proposes the hypothesis that proxy voting by banks related closely to the listing of corporate equity on stock exchanges and the depositing of these shares by shareholders. For an early analysis, see Passow (1922). Franks et al. (2006) attempted to measure proxy voting based on shareholder lists from new issue offerings that were required to publish a register of all shareholders present at the preceding general meeting. By this measure, proxy votes cast by banks increased from 13.3% to 41.8%.

the legal-political system, civil law countries being more susceptible to centralizing command and control than common law countries.[35]

Germany presents, again, one of the most striking examples. The fallout after WWII included the cession of vast portions of eastern German industry and resources, along with the very site of the primary stock exchange (and important provincial exchanges), and the near obliteration of the vibrant Berlin market of the pre- and early post-WWI era. The weight of foreign occupying powers, the urgent bailouts of industrial firms by financial institutions, the strengthening of the social-welfare state, the imposition of hefty capital gains taxes on sales of shares, and other exigencies of postwar reconstruction conspired to produce a financial system in which banks were extremely large, industry partly subordinated its ownership and governance to financial institutions and the government, and markets failed to flourish. Yet, given the country's unique position in the events of the 1930s–1940s, Germany's path differs from the experiences in most other countries – even those with universal banks. Germany's experience therefore does not work as a paradigm case of a universal banking system. Particularly salient is the observation of a reunified Germany at the start of the twenty-first century that has moved away from the archetypal house-banking form, demonstrating that its existence stemmed from the particular needs of postwar Germany.

Elsewhere, the move away from universality varied in its implementation and lasted only a few decades even where it was enforced. By the 1990s, most systems had deregulated and reverted to something resembling their pre-WWI state (see Table 2 and 3). Using the traditional meaning of universal banking – the combination of investment and commercial banking by one institution – banking structure since the 1990s became highly correlated with structure in 1913. For those countries that had begun to industrialize by the mid-nineteenth century, the correlation persists back to at least 1850. Of the 26 cases surveyed, no system clearly and permanently switched from one category to the other over this period of 100–150 years. This evidence of path dependency is all the more impressive in light of government interventions specifically intending to alter institutional design.

Despite much continuity, of course, bank structures, activities, and instruments have evolved over time. Most banking systems, whether universal or "specialized" in the prewar era, underwent a conglomeration movement starting in the 1970s. This development created quasi-universal banking in nearly all industrialized countries, in the sense that financial institutions of several types began operating under the umbrella of bank-holding companies. Thus, even the steadfastly specialized system of England is home to financial services conglomerates. Likewise, the traditionally universal systems of Germany, Belgium, and many other continental European countries have outgrown the centralized universal banking form, so that the commercial and underwriting arms of banks are less closely integrated.

From the research to date, it is clear that attempting to fit particular countries into a few narrowly defined, overarching categories of financial system – for example,

[35]Sylla (2006) offers a critical appraisal of the Rajan and Zingales "great reversals" thesis.

Note: The variables securities, insurance, real estate, and nonfinancial firms may take values 1–4 as follows:
1. Unrestricted: banks can engage in the full range of the activity directly in the bank
2. Permitted: the full range of those activities can be conducted, but all or some of the activity must be conducted in subsidiaries
3. Restricted: banks can engage in less than full range of those activities, either in the bank or subsidiaries
4. Prohibited: the activity may not be conducted by the bank or subsidiaries
Stock market capitalization is given as a share of GDP. Market equals one if the structure index is positive and zero otherwise. All variables come from Levine and Zervos (1998)

the United States as a specialized banking system or Germany as a universal banking system – can be misleading.[36] Most financial systems have a mixture of characteristics and do not fit neatly into narrow classifications. Many economies undergoing industrialization in the mid- to late nineteenth century supported a small number of large-scale universal banks but simultaneously maintained many more specialized banks. Nationwide branching appeared in most countries between the 1890s and WWI; only the United States persisted with widespread unit banking after WWII, and this is related to regulatory factors. Relationship banking was more common in universal systems but the two institutional features also existed separately from each other. In addition, there has been no link between branching and the design of financial institutions.

The distant history of banking systems reveals that the relationship between universal banking and limited securities markets, to the extent that it exists, is a post-WWII phenomenon. The loss of highly active securities markets is much more persistent than changes in banking design. Among the countries surveyed, no system permanently switched from universal to specialized; banking structure exhibits path dependency, or path reversion, over the past 100–150 years. At the same time, financial conglomerates with fairly distinct functional units have emerged in most industrialized countries. This relatively recent phenomenon appears to be driving the partial convergence of financial system design: formerly "specialized" banks are becoming more universal, while traditional universal banks have become more compartmentalized. Over the past 150 years, banking systems in industrialized countries have become remarkably similar, regardless of their initial development, and many systems have evolved back to their pre-regulation configuration. Almost all countries today have extensive branch networks. And in most economically advanced countries, there are at least some universal banks and some of the attributes typically associated with relationship or house banking, even in systems that would not typically be associated with either institutional form.

What Causes Financial System Differences Historically?

The question of national financial system origins has stimulated much research and debate over the past decade or so. The literature is dense enough to have spawned extended literature reviews of its own. Thus, this section serves to provide a cursory overview and point interested readers to sources for further study.[37]

[36]See Levine and Zervos (1998) and the recent update in Beck et al. (2010) for the World Bank's effort in categorizing financial systems based on legal restraints on financial services. See also Rajan and Zingales (2003) and further discussion later in this chapter.

[37]For much more detail, see Fohlin (2012), Chap. 7, on which this section is based.

Theories: Economics, Law, and Politics

Gerschenkron (1962) offered probably the best known general hypothesis about the genesis of financial institutions, at least concerning industrial banking on the European continent in the nineteenth century.[38] In essence, he argued that banks played a more important role in industrialization for "moderately backward" economies than they had played for the earliest industrializer, Great Britain. Follower economies needed institutions capable of mobilizing a high volume of capital from disparate sources and also that were able to compensate for a shortage of entrepreneurship. In Gerschenkron's view, the German universal banks were just such an institution.

In situations of extreme underdevelopment, as in Russia, however, financial institutions were insufficient to support the transition to modernized industrial activity; such cases demanded centralized institutional intervention, mostly from the government.

In the past 20 years, the so-called "law and finance" literature has turned its attention to legal and regulatory factors that create variation in financial system structure. Government intervention may hamper all development or might promote certain institutions at the cost of others.[39]

Regulation of nonbank institutions – such as securities markets, corporate chartering, limited liability, and bankruptcy – may have further altered the shape of financial systems. For example, laws that protect investors, contracts, and property rights might be argued to encourage the development of all kinds of financial institutions and particularly atomistic market arrangements.[40]

Certain legal systems produce more enabling legislation than do others. Some have argued for the importance of legal traditions in determining the development of financial markets.[41] The modern evidence suggests that countries adhering to a French civil law system have both the weakest investor protection, through both legal rules and law enforcement, and the least developed capital markets. Common law countries fall at the other end of the spectrum, so that American and British

[38]Gerschenkron (1962, 1968, 1970). Sylla (1991) reviews Gerschenkron's theories and related work. Knick Harley (1991) addresses Gerschenkron's idea of "substitution for prerequisites" of industrialization.

[39]The historical literature (such as that spearheaded by Gerschenkron 1962) had always paid due attention to political and regulatory factors. The contemporary study by La Porta (1998), spawned an enormous literature, much of which attempts to reject their fairly simplistic framework, notably Rajan and Zingales (2003).

[40]On Germany, see the edited volume by Horn and Kocka (1979) especially those by Horn, Friedrich, and Reich.

[41]See the series of papers, La Porta et al. (1997, 1998, 1999). In Besley and Persson's (2009) model, if the cost of protecting property rights is lower under common law than under civil law, then common law would allow for more credit as a share of GDP. Pagano and Volpin (2005) make related arguments, discussed subsequently under "Political Factors." Of course, by now, many others have used a similar legal tradition indicator to help explain a number of financial and economic phenomena.

economies or societies have led to market-oriented financial systems. Similarly, Dietl (1998) lays out the poles, admittedly highly stylized, of neoclassical versus relational regulation. These extremes map directly to common law and civil law legal systems, respectively.

La Porta et al. (1998) conclude that countries that provide weak laws for creditor or shareholder protection or weak enforcement of those laws develop substitute mechanisms, such as concentration of ownership, to safeguard owners' rights. Acemoglu and Johnson (2005) argue similarly that individuals adapt their financial intermediation approaches to fit the constraints placed by contracting institutions.

Rajan and Zingales (2003) propose a related theory for the determinants of overall financial system development and specifically contrast legal and political influences. Directed primarily at the La Porta et al. series (1997, 1998), Rajan and Zingales point out that, except for the outlier, Britain, the most developed countries in 1913 maintained similar levels of financial development, regardless of legal system.[42] These authors argue that not legal systems, but political contexts – the support of financial institution growth by the government and interest groups – determine the course of development.

Verdier (1997, 2002) hits on similar themes, but lays out a political-economic view of the development of financial systems. In doing so, he takes direct aim at Gerschenkron's hypothesis about the relationship between the extent of economic backwardness and the role of financial institutions. In this view, political structure, not relative backwardness, determines the shape of financial systems. In particular, universal banking arose in the coincident presence of two conditions: first, a segmented deposit market dominated by nonprofit and provincial banks and, second, a reliable lender of last resort facility insuring liquidity in the banking system. Furthermore, Verdier argues these two preconditions for universality emerged simultaneously only when state centralization was sufficient to provide a strong central bank (with credible lender-of-last-resort status) but limited enough to permit coexistence of provincial and, in his parlance, "center" banks. The issue of legal system does not appear in Verdier's analysis, but the other work reviewed here suggests a possible connection. As Verdier concedes, however, political centralization was neither solitary nor decisive in determining financial structure in most cases. Thus, whether or not Verdier correctly characterizes the relationship between political and financial development, he does not clearly subvert Gerschenkron's hypothesis.

Neither political nor legal structure is clearly independent of economic development, and the three factors may be mutually enhancing, rather than mutually exclusive. For example, Pagano and Volpin (2005) find that proportional voting systems yield less shareholder protection (and greater worker protection) than majoritarian systems and vice versa. These arguments resonate with those in Besley and Persson (2009), who relate similar financial development with legal origins.

[42]On the advanced level of financial development in Britain, Schultz and Weingast (2003) argue that the emergence of liberal democratic political institutions in the seventeenth century prompted a financial revolution that expanded credit availability (government debt at that stage).

Thus, the existing literature leaves room for all three types of factors – economic, political, and legal – in determining the shape of financial development. The formal theoretical models have yet to rationalize endogenous development of distinct financial system designs. Given the variety of theories proposed, assembling a wider range of evidence may shed more light on the issue.

Empirical Evidence

While Gerschenkron's view of financial system development prevailed for several decades, it was rarely put to a rigorous, general test. The first such attempt, by David Good (1973), set out to test that (1) the level of banking development at the end of the so-called great spurt of industrialization or (2) the growth rate of the banking sector during the "great spurt" relates positively to the extent of backwardness at the time of initiation of industrialization. Good's effort underscored the difficulty of clearly specifying Gerschenkron's theory in a testable manner, but he succeeded in raising questions about its generality.

Fohlin (2012) took up the empirical challenge, evaluating economic, legal, and political origins of financial development. Fohlin finds that the economic factors show the greatest power in explaining financial system types and size. In particular, the stage of economic development helps predict the type of banking system that subsequently developed among the pre-WWI industrial nations and also factors into the strength of financial system development. The analysis starts by posing the following test of Gerschenkron: for Europe around 1880, the most and least developed economies should have the lowest rates of financial system growth, while the moderately advanced economies should have the highest rates. Based on the theoretical framework, the level of financial development may be high in the most industrialized economies, but it should certainly be high in the moderately advanced economies and low in the least advanced. Rates of economic growth, in contrast to levels, should yield an essentially linear relationship between economic and financial development: the fastest growing economies should have the most rapid financial development. In the traditional view, slow growers include both those that have passed their earliest phases of industrialization and those that have so far failed to industrialize. Notably, these tests get at financial development generally, as opposed to financial system type.

For the analysis of economic factors, Fohlin (2012) computes GDP per capita growth rates for various subperiods and also constructs a ratio of industrial to agricultural employment and its percentage growth rate from 1880 to 1913. Lastly, Fohlin measures industrial development as the product of GDP per capita and the industrial/agricultural employment ratio, in order to capture the combined effects of wealth and industrial development. The results confirm the hypothesized inverted U-shaped relationship between GDP per capita in 1880 and the level of financial system assets in both 1880 and 1900 (using a robust estimator to mitigate outlier bias). The results for financial development circa 1900 prove much more statistically significant than those for 1880. At the same time, the growth rate of financial assets

relates negatively with the level of GDP per capita in 1880, both from 1880 to 1900 and from 1900 to 1913. The level of GDP per capita in 1900 is also negatively related to financial system asset growth over the succeeding 13 years. Notably, the rate of growth of GDP per capita from 1880 to 1900 relates very strongly and positively to subsequent growth of financial system assets (1900–1913). The reverse relationship – from financial system asset growth to GDP per capita growth – does not appear.

Fohlin also tests the hypothesis that financial structure (both market orientation and universal banking) is related to the level of development and finds that a U-shaped relationship emerges between the structure index reported in Beck et al. (2000) and GDP per capita in both 1880 and 1900. For the most part, in these early industrial economies, market orientation is increasing in the level of development. Similarly, the ratio of industrial to agricultural employment also relates positively to market orientation. At the same time, universal banking was more likely in countries with lower levels of GDP per capita in 1880 and with higher rates of growth of GDP per capita between 1880 and 1900.

On the issue of political factors and financial system type, Fohlin's test analyzes the link between political centralization (a fiscal measure) and both the extent of universal banking at the time of development **as well as** the market orientation index from the late twentieth century. As predicted, state centralization as of 1880 relates negatively and very significantly to market orientation – even 100 years later. In contrast, state centralization cannot be linked statistically to the extent of universal banking. In a related but distinct vein, Fohlin also tests the legal origins theory that the growth (and, implicitly, the design) of financial systems is correlated with legal tradition. In general, markets supersede banks in common law countries. The evidence indicates only weakly that pre-WWI financial development proceeded faster in common law countries, though as expected, full-fledged universal banking only appeared in civil law countries. As Fohlin (2012) points out, the historical pattern may stem from the fact that common law countries are virtually all related to England and adopted English institutions and norms in banking and finance.

Financial Systems and Economic Growth

The principle reason that economists study financial system design is to understand whether the shape of institutions or systems influences the real economy and the welfare of the population. Most studies have focused on the role of finance generally in promoting economic growth, while a smaller literature centers on the varying effects of different systems.

Literature on the Finance-Growth Nexus

Empirical studies on the relationship between long-run growth and financial intermediation show that increased intermediation, or financial development more

broadly, significantly increases growth. Intermediaries presumably lower costs of investment by diversifying idiosyncratic risk and by exploiting economies of scale in information processing and monitoring; they also provide insurance for entrepreneurs, who cannot diversify their risk on their own.[43] Large fixed initial investment costs, R&D for example, can force entrepreneurs to seek external financing; without financial intermediaries, agency problems could make the cost of finance too high, discouraging innovation (and therefore growth). Joseph Schumpeter argued in 1912 that financial intermediaries promote innovative activities, decrease transaction costs, and improve allocative efficiency; in this manner, the financial sector becomes the "engine of growth." Without intermediaries, the cost of R&D projects would be prohibitively high. Financial intermediation also lowers the required rate of return on innovation by lowering fixed costs, thereby spurring growth through investment in R&D. The financial crisis of 2008 prompted a new look at the connection between financial development and growth, as in Beck (2012), and a greater concern for the impact of financial fragility – episodic crises – on economic activity.

In a range of cross-country empirical studies of the postwar era, financial development appears to help predict growth rates.[44] Historical studies, though a bit sparse, show a strong positive effect of financial intermediation in the pre-depression period as well.[45] In one such study, however, finance loses much of its explanatory power for growth when legal origin appears in the regression.[46] Yet none of the legal-origin factors are statistically significant, suggesting that if legal origin matters for growth, it does so through financial development. Moreover, political variables (proportional representation election systems, frequent elections, infrequent revolutions) correlate with larger financial sectors and higher conditional rates of economic growth. Caveats do apply: for example, small countries may import capital, so that for them, domestic financial intermediation sectors may not serve the same purpose as they do in large, diverse countries. Moreover, the link between finance and growth seems to differ depending on a country's level of development, appearing most significant in modern periods for countries at earlier stages in economic development. Countries that had already attained moderately high levels of GDP per capita in 1900 – but not necessarily

[43]These propositions surely seem almost preposterous in light of the crisis of 1907–1909 (and the financial crisis of 2007–2009). The severe drop in economic growth following the loss of liquidity and the general malfunctioning in the financial sector actually underscores the key part that a properly functioning financial system plays in permitting economic growth. Gaytan and Ranciere (2006) develop an overlapping generations model that incorporates liquidity crises and demonstrates a variable relationship between financial development and growth.

[44]King and Levine (1993) and Levine and Zervos (1998), for example. The cross-country growth literature does struggle with identification and other econometric problems. See Manning (2003) for some discussion.

[45]Rousseau and Sylla (2003) do a similar exercise as King and Levine for 17 countries from 1850 to 1997.

[46]Bordo and Rousseau (2006).

the richest ones – grew fastest in the years leading up to WWI.[47] The wealthiest countries in 1880 produced among the slowest growth of financial institution assets between 1900 and 1913, relative to GNP, arguably because they were already well along the path to industrialization by that time.

Time series analyses offer an alternative approach to evaluating the growth impact of financial development. While these methods improve the causal inference possible, the range of studies so far provides mixed answers to the question. Again, the differences among countries stand out, and for contemporary developing economies, Demirgüç-Kunt (2012) emphasizes the key role of government policy.[48]

Financial System "Types" and Long-Run Growth Patterns

Economists and other observers have hypothesized that the distinction between bank-based and market-based financial systems relates systematically to patterns of national economic growth.

For most of the post-WWII era, economists studying financial system design generally argued that financial systems based on banks engaged in relationship banking promoted effective corporate control, long-run perspectives on investment, and sustained economic growth.[49] This assumption stems from the view that banks play a positive role as intermediaries in collecting and disseminating information, in managing risks of various dimensions, and in mobilizing large amounts of capital quickly. By playing this regulatory and information sorting role, banks arguably enhance investment efficiency and thereby economic growth (Allen and Gale 1999), improve capital allocation and corporate governance (Diamond 1984; Gerschenkron 1962), and mitigate the effects of moral hazard (Boot and Thakor 1997). In this view, the long-run relationships that banks form with their clients enable them to smooth the flow of investments and reduce transaction costs and asymmetric information distortions. More recent work, based on the US deregulation experience, attributes firm-level efficiency gains to universal banking (Neuhann and Saidi 2014).

Still, analyses of long-run patterns of development have argued that markets may also enhance growth because they increase incentives to acquire and profit from information about firm performance; under market-based systems, managerial compensation may be more easily tied to firm performance and markets may reduce inefficiencies associated with bank control.[50] In general, the relative strength of banks versus capital markets, however, seems not to affect the overall availability of external finance, though it does relate to the composition of financing between short

[49]See Levine (2002) for a summary.

[50]See Levine (2002).

and long maturities. In less economically advanced countries, it appears that bank finance is particularly important for economic growth.[51]

Historical analysis indicates that neither financial system types – bank based versus market based, branching versus unit, and universal versus specialized – nor legal traditions in themselves can explain the different experiences across countries over the last 100 years or more (Fohlin 2012). That study, encompassing all countries with pre-WWI data available, shows that the wealthier countries among those that began industrialization before WWI tended to deepen their financial base more than the less well-off. In other words, financial and real development went hand in hand in that period of rapid industrial growth. Overall, the set of relatively developed economies at the end of the nineteenth century experienced remarkably similar long-run growth rates, even though they displayed different financial system types, rates of financial development, and legal orientation for most of the twentieth century. The wide range of historical evidence leads to the conclusion that the specific type of financial system or institutions that develop is far less important for economic growth than the development of *some* well-functioning financial system.

Conclusion

The literature on financial system design and development, particularly historical studies of financial institutions and systems, provides a vast array of evidence on how and why institutions take shape and what impact they have on the real economy. The body of research shows the complexity of financial systems among the industrialized economies of the nineteenth and early twentieth century and the range of institutions and markets available to individuals, businesses, and governments. These studies also demonstrate the variety of organization and design of these systems, all focused on similar functions and ultimately on mobilizing enormous amounts of capital toward productive ends.

The research has also shown that the strict dichotomy between market-based and bank-dominated systems does not capture historical or contemporary reality. History offers interesting insights into the multiplicity of financial system designs and the lack of tight links among various banking characteristics, suggesting that going forward, researchers should consider financial systems as an amalgamation of a set of functions rather than as a fixed typology of institutions. The split between universal and specialized banking is most relevant and pronounced in the historical period, before the conglomeration movement of recent years.

Moreover, the research to date strongly supports the idea of persistence and path dependency in financial system design that economic conditions at the time of

industrialization help set the initial conditions that shape financial system and banking institution design and that historical political conditions, such as centralization of power, plays an ancillary role via the extent of regulation on banks and the development of free capital markets. In other words, history matters.

The Cliometric Study of Financial Panics and Crashes

Matthew Jaremski

Contents

Abstract

Financial crises present an identification challenge. On one hand, declines in economic activity often lead to bank failures, while on the other, bank failures often lead to declines in economic activity. To understand the causes of crises and determine their influence subsequent growth, it is vital to untangle these various factors. Approaches require well-constructed empirical models as well as knowledge of existing data and institutions. Each section of this chapter highlights empirical approaches that have been successfully used to study specific aspects of financial crises. Starting with survival and hazard functions, the chapter goes on to cover data envelopment analysis, vector autoregressions, instrumental variables, and difference-in-difference models.

Keywords
Financial panics · Bank failures · Bank regulation

What makes it so vital to understand financial crises also makes them so difficult to study. Imprudent regulations, speculation, agricultural shocks, and declines in economic activity cause financial crises and bank failures, while, at the same time, large-scale bank failures lead to new regulation, financial innovation, and decreased economic activity. Therefore, to understand the causes and effects of financial crises, it is vital to separate the various determinants. Approaches require well-constructed empirical models as well as knowledge of existing data and institutions. Each section of this chapter highlights empirical approaches that have been successfully used to study specific aspects of financial crises. The chapter does not contain an exhaustive description of historical financial panics but rather is intended to be used as a primer for future studies.

Survival Models and Hazard Functions

Bank failures form the heart of nearly all financial panics. While failures are not a sufficient condition, they are a necessary one. Therefore, the majority of financial panic studies address why banks failed in the first place. Authors use a variety of methods to identify the cause of bank failures, but since survival analysis forms the foundation of a large number of papers, it is helpful to start by addressing these models in detail.

Survival analysis attempts to understand what proportion of the population (i.e., banks) will survive past a certain time based on a set of characteristics. Each bank i) is observed for j periods (with $j = 1 \ldots J_i$). The failure time for each bank is then defined as t_{i,J_i}. The cumulative distribution function for the duration T is given by $F(t) = \text{Prob}(T < t)$, with the corresponding density function $f(t) = \frac{dF(t)}{dt}$. The survivor function gives the probability that a bank will survive the period and is defined as $S(t) = 1 - F(t)$. The framework can also be used to study the probability of failure. The hazard function gives the probability of failure within the interval $(t, t + h)$, conditional on the bank surviving to time t, and is defined for period T as

$$\lambda(t) = \lim_{h \to 0} \frac{P(t \leq T < t + h \mid T \geq t)}{h} = \frac{\frac{dF(t)}{dt}}{1 - F(t)} = \frac{d(\ln S(t))}{dt}$$

The models observe banks each period, and the effect of the explanatory variables is identified off variation across starting and failure dates.

Researchers usually take one of two approaches when using this framework. First, some model the survival function, examining how long a bank lasted until it failed. These types of models are often called survival or duration models

(e.g., Calomiris and Mason 2003b; Richardson and Troost 2009; Carlson and Mitchener 2009). Second, some studies model the hazard function, examining the instantaneous probability of failure (e.g., Wheelock and Wilson 1995; Jaremski 2010). These types of models are often called hazard models. Both duration and hazard models are discussed in greater detail below, along with examples of how they have been used to study aspects of financial panics.

Branch Banking and Duration Models

Duration models examine the time it takes before bank failure or suspension occurs.[1] In order to implement this approach, a researcher must specify a parametric distribution (e.g., log-logistic, Weibull, etc.). As described by Kiefer (1988), each underlying distribution brings with it a unique survival rate. For instance, the log-logistic distribution (i.e., the most commonly used distribution in the financial panic literature) implies that the probability of failure rises over time and then declines as time goes to infinity. Log-likelihood ratio tests are generally used to choose from the various distributions.

In order to understand the use and approach of duration models, it is helpful to examine a single study as an example. Carlson and Mitchener's (2009) study of the long history of branch banking in California exemplifies the incisive value of using duration models to study financial crises. Branching allows banks to geographically diversify their loan portfolios, potentially making them more likely to survive idiosyncratic economic shocks.[2] Authors such as Calomiris and Gorton (1991) argue that the United States' general lack of branching laws was a factor in many financial panics. Studies at the state and county level generally also support this theory by finding that areas with branching had lower failure rates during financial panics (Mitchener 2005). However, at the same time, studies of individual banks find branch banks are more likely to fail (Carlson 2004). By examining the rise of branch banking in California from its inception in 1909 through the Great Depression, Carlson and Mitchener test (1) whether parent banks acquired weak banks to serve as branches and thus should have been more likely to fail and (2) whether branching had an effect on surrounding banks. Both of these tests are conducted using duration models.

Because most of California's branch banking resulted from acquisitions, the authors start by analyzing where banks were acquired and the types of banks acquired. The location-specific equation is a logistic model that measures the probability of a city having at least one bank acquired between 1922 and 1929. The explanatory variables consist of measures of the city's banking system,

[1] As a result, they produce opposite coefficients from the traditional discrete choice models. A positive coefficient, therefore, implies a negative relationship between the covariate and failure.

[2] Hanes and Rhode (2013) show that financial panics often coincide with exogeneous in cotton harvests.

population, agriculture, and geographic location. As might be expected, acquisitions were more likely to take place in populated areas with greater growth in agricultural income. Acquisitions were also less likely in locations with only one bank or locations close to San Francisco and Los Angeles.

Next the authors address what types of banks were acquired. The bank-specific equations are duration models that take the number of days from June 30, 1922 until a merger as a dependent variable. Lacking income data for non-Federal Reserve members, the authors estimate two separate duration models. The first contains balance sheet information for all banks, while the second contains balance sheet, income, and cost information for Fed banks.[3] The second model adds the return on equity, net losses on assets, and the ratio of administrative costs to total assets but drops many of the other balance sheet variables. The duration models show that banks did not take over weak banks but also did not take over the strongest banks either. Similar to modern mergers and acquisitions, parent banks preferred banks with low net losses and low return on equity. This result is likely due to the fact that parent banks kept the management and structure of the acquired banks and, therefore, wanted to choose a reliable operation that was underperforming. At the same time, the choice of acquisition also depended on preferences of the parent bank. Bank of America (one of California's largest acquirers) sought banks with low net worth and high cash reserves, and other acquirers preferred banks with high net worth and high cash reserves.

Carlson and Mitchener next examine whether the establishment of a branch bank altered the composition of surrounding incumbent banks. They use an Ordinary Least-Squares model (OLS) where the ratio of loans to assets, securities to assets, demand deposits to total deposits, or the growth rate of income-earning assets is on the left-hand side. The sample consists of banks present in 1922 and 1929 to avoid attrition bias. The explanatory variables include the bank and location characteristics that were in the previous models, but the variable of interest is a dummy variable for whether the city gained at least one large branch bank. The data indicate that the entry of a branch bank caused incumbent banks to shift from securities to loans, decrease their administrative costs, and increase their returns on assets. Incumbent banks thus shifted to active portfolios and became more involved in their communities upon facing competition with a large branch bank.

To test whether branching made other banks more stable, the authors examine bank performance during the Great Depression. Returning to a log-logistic duration model, the dependent variable is the number of days from June 30, 1929 until failure and the explanatory variables include the previous bank and location characteristics. The results are quite clear. Having branches in a city increased incumbent banks' number of days before failure (i.e., made them less likely to fail). The duration analysis shows that branch banking pushed unit banks to become more stable.

[3]The authors take a typical approach by including the log of assets to control for size and using balance sheet ratios to control for how portfolio compositions varied across banks.

Putting the results in a broader context, the paper suggests that a further expansion of branching across the nation would have reduced the number of failures and financial panics.

Free Bank Failures and Cox Proportional Hazard Models

Unlike duration models, hazard models examine the probability of failure. The dependent variable is a dummy variable for whether the bank failed between that observation and the following one. These models are similar to binary choice models such as probit and logit models, but they gain further efficiency by taking into account the time before failure.[4] In order to measure the impact of explanatory variables upon the hazard function, researchers typically assume that the explanatory variables act as a scale function on the base hazard rather than adjust the hazard function itself.[5] This is often referred to as a proportional hazard assumption as it allows the probability of failure of bank i given survival to the period t to be written as

$$\lambda(t, X_i, \beta, \lambda_0) = \lim_{h \to 0} \frac{P(t \leq T < t + h \mid T \geq t)}{h} = \lambda_0 g(X_i(t), \beta)$$

where λ_0 is the baseline hazard function common to all banks and the g function captures the effects of the explanatory variables X_i.

The proportional hazard model with time-varying covariates proposed by Cox (1972, 1975) is the most commonly used approach. The approach estimates the effect of the parameters without any consideration of the hazard function. It is thus a semi-parametric "partial likelihood" approach, as it requires the specification of the scale g function (usually an exponential function) but not the baseline hazard function. The drawback, however, is that additional assumptions on the initial hazard function need to be made before calculating the marginal effect of each variable. Thus, while the model can capture the direction of the effect of each variable and compare it to the effect of other variables, it cannot demonstrate the marginal effect on the probability of failure.

As before, it is helpful to discuss the hazard analysis in the context of a single study. Jaremski (2010) uses a Cox model to identify the causes of bank failures during the free banking period (1837–1862). Banks during this period were chartered in two different ways: either through a unique act of the state legislature (called charter banks) or through a general enabling law (called free banks). While both charter and free banks were susceptible to financial panics, free banks exhibited

[4]The addition of dummy variables for the number of years in operation to binary choice models has been used to approximate the same type of relationship.

[5]Alternatively, models can assume that the explanatory variables affect the time directly (often called accelerated time models). Similar to the duration models, however, these models must assume a distribution.

a particularly high susceptibility. Almost a third of all free banks were unable to reimburse note holders for the full value of their bank notes upon closure, compared to under a fifth of charter banks. Prior to Jaremski's study, papers written on the topic focused on two explanations. Free banks either were subject to poorly designed regulation (Rolnick and Weber 1984) or did not sufficiently diversify their asset and liability portfolios (Rockoff 1972). The two hypotheses are straightforward, but testing them separately provided inconclusive results. A comparison of bank failures and collateral bond prices would identify the negative correlation between the two but not prove that properly diversified banks also failed. As most free banking laws were not passed until relatively late in the period, a simple comparison of newly created free banks and old charter banks might also lead to biased estimates.

To account for relationships between explanatory variables, Jaremski's hazard model contains both a bank's financial (cross-sectional) and environmental (time series) information to estimate the roles that nature (bank structure) and nurture (market fluctuations) had in bank failure. Market price fluctuations are captured using the total appreciation or depreciation of a bank's bond portfolio since the bank was in operation, and the undiversified portfolio hypothesis is tested using the corresponding balance sheet ratios. The model also includes a free bank dummy to capture the differential failure rate between the bank types (i.e., the intercept difference in terms of the hazard function itself) and the interaction between the dummy and each explanatory variable to capture how each characteristic affected the different types of banks (i.e., the approximate slope differences).

Free banking's connection between bank notes and state bond prices is the underlying cause of the system's high failure rate relative to the charter banking system. While bond price declines were significantly correlated with free bank failures, they were not correlated with the failure rate of charter banks. Therefore, those banks that did not have to back notes with bonds did not fail because of depressed bond prices. Solvent free banks also diversified their assets away from bonds and their liabilities away from note circulation. Although the addition of balance sheet variables to the hazard model does not reduce the statistical significance of the bond price effect, their combined effect would have been sufficient to at least partially shield banks from bond price declines. After controlling for the time before failure, free banks were not helpless and could have decreased their probability of failure. The results thus show that the financial panics of 1837, 1839, and 1857 are likely tied to the large declines in bond prices that occurred just prior to the bank failures.

Financial Panics and Archival Scraping

A clear example of the need for cliometrics is seen in the attempts to document when financial panics occurred. For instance, if one wishes to understand the causes and effects of financial crises, one must first know when they occurred. Economic downturns and fluctuations often lead to bank failures, but this does not mean that every downturn was caused by a financial panic. Large-scale crises such

as the Great Depression and the Panic of 1907 are easily identified, but smaller panics are much harder to pin down. Many financial panics were also regional in nature, making their identification difficult and even more important for studying output fluctuations.

Researchers have created over nine different US panic series, which vary substantially. Some series document panics occurring roughly once a year, whereas others have panics occurring every 10–20 years. These differences are likely the result of the data being examined and the underlying definition of a financial panic. Unfortunately, the way that each series is calculated is not always clear. For instance, Sprague (1910) highlights periods of monetary stringency during the National Banking Period yet does not describe how he arrived at the dates, whereas studies by Bordo and Wheelock (1998) and Reinhart and Rogoff (2009) use previous studies to define their panic series. It was not until Jalil (2010) that a more consistent framework for identifying panics emerged. Rather than reaching for all the various types of financial panics, he measures banking panics rather than stock market panics or currency panics. This is important as each different type of panic would lead to different outcomes and be measured in different ways. While banking panics could be measured by the number of bank failures, the approach has a number of drawbacks. First, the data simply do not exist for all banks and periods. Weber (2005) has failures before 1861 and the Comptroller of the Currency's Annual Report has failures for national banks after 1863; however, there are no reliable data on the failures of state banks, private banks, savings banks, or trust companies after 1861. As these institutions make up the majority of the banking sector and were most susceptible to panics, their exclusion would dramatically affect the results. Second, bank failures and suspensions do not always result in a banking panic. For instance, 50 banks failing in 50 different states would not generally constitute a panic, whereas 5 banks failing in a large city might signal one. In this way, a panic series needs to examine where bank failures were located, the context, and whether they were correlated.

Jalil identifies banking panics using three large financial newspapers: the *Niles Weekly Register*, *The Merchants' Magazine and Commercial Review*, and *The Commercial and Financial Chronicle*. By consulting the index pages of each newspaper, he searched for terms associated with financial panics (e.g., bank failure, bank suspension, bank run, bank crisis, bank panic, etc.). He then defines banking panics by counting clusters of articles on bank suspensions. Specifically, a cluster is three or more terms with resulting articles that contain a reference to other bank suspensions or reports of a general panic.

The approach avoids scattered, unconnected bank failures and better captures the depth of the panic that the bank failures caused. Moreover, it allows a specific date for when a panic occurred as well as whether it was minor (i.e., local) or major (i.e., national) in scope. Jalil defines a major banking panic as a cluster that (1) spans more than one geographic unit (i.e., a state and its immediately surrounding states) and (2) appears on the front page of the newspaper. All other clusters are labeled as minor panics. Before the Great Depression, he finds evidence of seven major banking panics (November 1833–April 1834, March–May 1837, October 1839,

August–October 1857, September 1873, May–August 1893, October–November 1907) and about 20 minor, geographically specific panics. Using these dates, subsequent studies can better measure the causes and effects of banking panics.

Deposit Insurance, Efficiency, and DEA Analysis

Deposit insurance has often been implemented by legislatures to prevent bank runs. By promising that deposits will be repaid even after a bank's closure, governments hope that individuals will have no incentive to run on the bank. However, because deposit insurance reduces the incentive for depositors to monitor, insured banks might not have a large incentive to act safely. In this way, the legislation might trade idiosyncratic bank runs for larger financial panics. These perverse incentives clearly parallel the recent "too big to fail" discussions.

Testing whether deposit insurance leads to bank failures seems straightforward, but several complications stand in the way. First, most deposit insurance laws apply to all banks in a country. For instance, the FDIC's establishment in 1933 placed deposit insurance on all US commercial banks. This means that there is no variation in which to compare insured banks versus uninsured banks. Second, the creation of deposit insurance might be a response to the risk-taking of banks.

Wheelock and Wilson (1995) get around these issues by making use of a unique law in Kansas and accounting for bank efficiency. In response to the Panic of 1907, Kansas introduced a deposit guaranty system in 1909. Unlike most other systems, membership was optional in response to complaints from conservative banks. As many banks chose not to join the system, the period allows for a comparison of the performances of insured versus uninsured banks under the same regulatory and economic environment. If anything, the odds should be biased in favor of finding a stabilizing effect as insured banks were required to maintain minimum capital ratios and hold reserves with the state banking commissioner. Nevertheless, 94 of the 122 state-chartered banks that failed between 1920 and 1926 were insured banks.

In order to understand whether unstable banks choose to join the insurance system, Wheelock and Wilson measure efficiency using a data envelopment analysis (DEA). The nonparametric approach is a relatively simple idea (i.e., determine how close a bank is operating to the minimum inputs for a given level of output or maximum output for a given level of inputs) but is complicated to implement. Using Shephard (1970), the input and output distance functions are computed by solving the linear programs:

$$\left(D_i^{\text{in}}\right)^{-1} = \min\left\{\theta | y_i \leq Yq_i, \theta x_i \geq Xq_i, Iq_i = 1, q_i \in \mathbb{R}_+^N\right\}$$

and

$$\left(D_i^{\text{out}}\right)^{-1} = \max\left\{\theta | x_i \geq Xq_i, \theta y_i \leq Yq_i, Iq_i = 1, q_i \in \mathbb{R}_+^N\right\}$$

where $Y = [y_1 \ldots y_n]$, $X = [x_1 \ldots x_n]$, with x_i and y_i denoting the $(n \times 1)$ and $(m \times 1)$ vectors of observed inputs and outputs for the ith bank $(i = 1,\ldots, N)$, $x_i \in \mathbb{R}_+^n$ and $y_i \in \mathbb{R}_+^n$ for all $j = 1,\ldots, N$, and I is a $(1 \times N)$ vector of ones and q is a $(N \times 1)$ vector of intensity variables which serve to form a piecewise linear approximation of the technology.[6] The values of D_i^{in} and D_i^{out} measure the radial distance from the bank's observed point (x_i, y_i) to the boundary of the convex hull of all observations. In other words, the value of D_i^{out} measures how much output can be increased by holding inputs fixed but moving to the frontier production set, whereas the value of D_i^{in} measures how much the inputs can be decreased by holding output constant but moving to the frontier. While the distance provided by the analysis is in terms of the inputs or outputs, it is often normalized to represent the proportional increase of outputs or decrease of inputs that can be achieved.

The main choice when using a DEA analysis is the selection of outputs and inputs.[7] The most common approach is to look at outputs such as the value of loans, demand deposits, and time deposits and inputs such as labor, capital, and purchased funds. Wheelock and Wilson chose two outputs (loans and bond holdings, and demand deposits) and four inputs (time and savings deposits, borrowed funds, value of bank premises, and number of bank officers). They then calculate the value of D_i^{out} for each bank in each year.

Using biannual data for nearly all of Kansas' state-chartered banks, Wheelock and Wilson implement a Cox proportional hazard function. The model includes the measure of efficiency, a dummy for whether the bank had deposit insurance, total assets, and balance sheet ratios. The results show that efficient banks were the most stable, but being an insured bank does not matter. The authors explain that the insignificance of the insurance dummy is likely due to the suspension of payments in 1925. Once the suspension occurred, depositors lost confidence in the system and insured banks had to adjust their portfolios or face bank runs. Indeed, when the insurance dummy is split into years before and after the suspension, the former is statistically significant and positive whereas the latter is insignificant but negative. The paper suggests that deposit insurance schemes may cause the very problems they were intended to fix even after controlling for efficiency.

Fed Intervention and Difference-in-Difference Models

Friedman and Schwartz (1963) posit that the inaction of the Federal Reserve System was to blame for the Great Depression's continued waves of bank panics and the depth of the economic decline. They argue that instead of pumping liquidity into the system to prop up illiquid but solvent banks, the Fed's tight monetary policy caused the system's series of banking panics. Much like other topics in this chapter, the

[6]This description is taken from Wheelock and Wilson (2000) which also used a DEA.

[7]It is important to note that the model is relatively sensitive to outliers that would push the frontier out too far.

problem with testing whether the Fed could have halted bank failures is that there were many other factors in play and the majority of Federal Reserve District Banks acted the same way.

In an effort to test Freidman and Schwartz's argument, Calomiris and Mason (2003b) examine whether failures reflected fundamental deterioration in bank health or sudden crises of systemic illiquidity. To the extent that the failures can be explained by fundamentals, they argue that any actions taken by Fed or Congress would have had little to no effect.

The authors use a log-logistic survival model to estimate the log days until failure after December 31, 1929. Bringing forth an impressive database on all Federal Reserve member banks, they use a variety of bank-level characteristics (observed biannually), county-level characteristics (observed only in 1930), and state- and national-level characteristics (observed monthly or quarterly).[8] The bank-level variables include the bank's type, size as well as measures of its asset quality, liability mix, and costs. The county-level characteristics include measures of the local economic conditions, whereas the state-level and national-level characteristics include broader economic measures. The model measures waves of illiquidity using dummy variables for the panics that affected all regions (December 1930–January 1931, May–June 1931, September–November 1931, January 1933, February 1993, and March 1933) and the few regional-specific panics identified by Wicker (1996).

Bank fundamentals are significantly correlated with failure risk, but only the panics in January and March of 1933 seem to have induced more failures. The evidence supports the theory that contagion, liquidity crises, and the inaction of the Fed have less of a role in explaining the early part of the Great Depression; however, at the same time, the data do not explicitly measure the effect of Fed intervention. It is also possible that the Fed's inaction allowed bank balance sheets to deteriorate over time.

Building on Calomiris and Mason, Richardson and Troost (2009) take the analysis a step further by targeting the Federal Reserve's actions during the Great Depression. They do this by focusing on Mississippi, one of the few states served by two different Federal Reserve Districts during the Great Depression. The northern section was located in the 8th district (St. Louis) and the southern section was located in the 6th district (Atlanta). Because the Atlanta Fed was one of the few district banks that provided liquidity to member banks, the authors are able to study the effect of bank intervention with a natural control group. This difference-in-difference approach makes use of the idea that all banks in the same state should be subject to the same economic conditions and regulation and should only have differed through the actions of the Fed district banks. The authors primarily restrict the sample to banks within one degree of latitude of the border to ensure this similarity, but they also show the results hold when looking within 50 miles of the border or only in border counties.

[8]Given the varying frequencies, each observation is a bank-month.

Richardson and Troost start by calculating the raw survival function using the Kaplan-Meier Method and the smoothed raw hazard functions separately for each Fed district.[9] The Kaplan-Meier Method is a nonparametric approach to survival analysis which plots the fraction of banks that survive each period after correcting for censoring. The function is

$$S(t) = \prod_{t_i<t} \frac{n_i - d_i}{n_i}$$

where n_i is the number of banks in business at the beginning of time period t, d is the number of banks experiencing an event at time t, and t_i indicates the ith time period. Alternatively, the smoothed hazard function for period t is

$$g(t_i) = \sum_{z=-u}^{u} K \frac{d_{i+z}}{n_{i+z}}$$

where u is the bandwidth (chosen to be 28 days) and

$$K = \frac{(u+1)^2 - z^2}{\sum_{z=-u}^{u} \left[(u+1)^2 - z^2\right]}$$

The survival functions of the Atlanta banks are much higher than those of St. Louis banks, and the hazard functions are much lower, suggesting that Fed intervention was important for bank stability during the Great Depression.

To the extent that banks in the two districts are exactly the same, the simple comparison of the difference in the failure rates should be a reliable measure of the causal effect of Fed intervention on bank failures. However, Richardson and Troost apply a log-logistic survival model to further control for other factors. The dependent variable is the logarithm of days until bank distress (i.e., liquidation, suspension, or consolidation) from 1929 to March 1933. In addition to the fundamental variables included by Calomiris and Mason, they include a dummy variable for whether the bank was located in the Atlanta District and the interactions between the Atlanta dummy variable and the panic dummies. The Atlanta dummy variable captures whether Atlanta District banks were fundamentally different from St. Louis District banks and the interaction captures the importance of being in the Atlanta District when liquidity was provided. The model shows that banks in the Atlanta District had fewer days until distress (i.e., were more likely to fail) across all periods, but during each of the specific banking panics, the actions of the Atlanta Fed increased the number of days until distress (i.e., were less likely to fail). The actions of the Atlanta

[9]The approach was first developed in Kaplan and Meier (1958).

Federal Reserve thus seem to have had an effect on bank stability, and a more concerted effort across all the districts might have mitigated bank losses during the Great Depression.

The Effect of Bank Failures and Accounting for Endogeneity

So far this chapter has focused on the causes of bank failures and financial panics, but their effect on the economy is often just as important. Based on the work of scholars such as Friedman and Schwartz (1963), Bernanke (1983), and Reinhart and Rogoff (2009), financial crises and bank failures have a dramatic effect on the economy in two ways. First, bank failures cause a sudden decline in the money stock due to the loss of deposits and shareholder equity. This reduces consumer demand and dampens any recovery. Second, bank failures destroy institutional knowledge and increase the cost of credit intermediation. Those institutions that survive and new institutions that arise might not provide the same number of loans and might focus on safer borrowers. Despite these potential effects, studies have cast doubt on their importance. Cole and Ohanian (2000) show that state-level income was already declining before bank failures during the Great Depression. Chari et al. (2002) show that simple neoclassical growth models without nonmonetary effects predict changes in investment quite well.

As with most finance-led growth papers, endogeneity is a major issue and could be driving the contradicting results. Economic downturns are often responsible for bank failures, and bank failures are often responsible for economic downturns. Therefore, in order to view the causal effect of bank failures on economic activity, one must account for this feedback effect. The rest of this section examines three ways that this has been done in the literature.

Vector Autoregression (VAR)

One way to account for the endogeneity is to explicitly model it. Following many macroeconomic studies, Anari et al. (2005) model the effect of bank liquidations on output using a vector autoregression (VAR).[10] The VAR methodology investigates the dynamic interactions between variables without imposing a priori structural restrictions. It involves estimating a separate regression equation for each variable on its own lags and those of the other variables in the system. For instance, a VAR with three variables would be modeled as

[10]Bordo and Landon-Lane (2010) is another good example of the use of VARs to model the causes and effects of financial panics using Great Depression data.

$$x_{1,t} = a_{1,0} + \sum_{i=1}^{k} a_{1,i}x_{1,t-i} + \sum_{i=1}^{k} b_{1,i}x_{2,t-i} + \sum_{i=1}^{k} c_{1,i}x_{3,t-i} + u_{1,t}$$

$$x_{2,t} = b_{2,0} + \sum_{i=1}^{k} a_{2,i}x_{1,t-i} + \sum_{i=1}^{k} b_{2,i}x_{2,t-i} + \sum_{i=1}^{k} c_{2,i}x_{3,t-i} + u_{2,t}$$

$$x_{3,t} = c_{3,0} + \sum_{i=1}^{k} a_{3,i}x_{1,t-i} + \sum_{i=1}^{k} b_{3,i}x_{2,t-i} + \sum_{i=1}^{k} c_{3,i}x_{3,t-i} + u_{3,t}$$

where $x_{i,t}$ is the ith variable in period t. Each variable is thus allowed to affect every other variable. Usually a series of nested likelihood ratio tests are used to optimally select the lag length.[11]

After jointly estimating the coefficients, there are three ways to proceed using a VAR model. First, one can study how an exogenous shock to one variable affects the other variables. This is done by estimating the model's impulse response function. The impulse response function graphs how the time series of each variable would change after a hypothetical but exogenous shock to a single variable. Since the estimated relationship explicitly accounts for endogeneity, the shock provides realistic results of what is expected to happen; it does not estimate, though, exactly what happened. The approach is sensitive to the variable order specified by the author.[12]

Second, one can decompose the variance of the forecast error of the model. The forecast error variance decomposition (FEV) provides the fraction of the squared prediction error explained by each variable. Similar to an impulse response function, the estimate is calculated for each time period so that the size of the effect of each variable can be seen over time.

Third, one can study the effect of a variable on another variable using a Granger causality test. The test examines whether the past values of a variable are significant predictors of another variable. While identifying something more than a correlation, it is not a direct test of causality as variables could Granger cause each other. The validity of the approach also suffers when the underlying time series are not stationary. In general, the distributions of these tests are nonstandard when a VAR contains variables with unit roots, and differencing is usually required to ensure stationarity. Sims et al. (1990), however, show that Granger tests conform to standard distributions in tri-variate VARs with unit roots so long as a single cointegrating relationship exists among the variables.[13]

The authors concentrate on the model's FEV and impulse response functions for a four variable VAR. The four variables are (1) industrial production, (2) wholesale price index, (3) M1, and (4) stock of failed national banks' deposits for credit availability. The sample is estimated monthly from January 1921 through December 1940 in order to provide a large quantity of observations, capture preexisting trends

[11]The authors use the asymptotic chi-square test developed by Sims (1980) for the determination of lag order.

[12]Often variables are ordered more exogenous to least exogenous but this in itself must be based on the authors' opinion.

[13]Cointegration (i.e., the existence of a long-run relationship between the variables) is often tested using the approach suggested by Johansen (1991).

before the Great Depression, and view the entire slow recovery. Before estimating the VAR, they show that most of the variables have unit roots but there are also two conintegrating vectors, allowing them to estimate the model in levels.[14]

The FEV is quite clear. The effect of the deposits of closed banks were small in the short run but grew much larger over time. The value of closed bank deposits explains about 9% of the forecast error by 12 months, 20% by 18 months, and 21% by 24 months. In fact, the pattern of results is nearly equal to the effect of the money supply. On the other hand, the wholesale price index explains a significant proportion of the decline in industrial production regardless of the time period. Looking at the impulse response functions, a shock to closed bank deposits and money supply takes half a year to have a significant effect on production, whereas prices have an immediate effect. The impulse response functions also show that the effect of closed bank deposits does not seem to be permanent, while prices and money supply continue to have an effect several years into the future.

Anari, Kolari, and Mason find that the occurrence of bank liquidations had large effects on output. However, as with any approach, there are a few drawbacks to VAR models. First, the VAR framework cannot control for a large number of other variables. Recently, structural and panel VAR models have emerged to help account for fixed effects and common shocks, but they still are sensitive to the choice of main variables.[15] Second, the models are relatively sensitive to the choice of variables, lags, and the order of variables in the model.

Instrumental Variables (IV)

In a companion piece to their study of bank failures, Calomiris and Mason (2003a) use a two-stage least-squares (2SLS) model to test the effect of deposit and loan decline on the amount of state-level income growth. The approach attempts to isolate the portion of the change in deposits or loans between 1930 and 1932 that is exogenous to income growth over the same period. To do this, the authors find variables that are only correlated with state income growth through the change in deposits or loans and thus can be excluded from the main estimating equation. While only one instrument is needed per endogenous variable, Calomiris and Mason overidentify the equation by using three instrumental variables measured in 1929. The log of bank assets captures the initial amount of banking in the state and state regulation. The ratio of real estate owned relative to loans captures the previous amount of loan foreclosures and the exposure to agricultural loans. The ratio of net worth to total assets captures the buffer that banks had going into the 1930s. Because

[14]In systems with cointegtation, a VAR model with first differences is misspecified. However, Engle and Granger (1987) show that a VAR in levels avoids the problem.

[15]For instance, Kupiec and Ramirez (2013) apply a panel VAR to study financial panics across the various states.

these variables are all observed prior to the Great Depression, the authors argue that they are exogenous and excludable.

The 2SLS approach begins by modeling the endogenous variables as a function of the other explanatory variables and the instruments and then models the change in income as a function of the other explanatory variables and the predicted value of the endogenous variable from the first stage.[16] While standard OLS models are unbiased, 2SLS models do not have the same characteristic, and estimates from small samples could deviate from their target parameters. This is even more so when instruments are "weak" (i.e., do not significantly predict the exogenous variable). The standard practice is to report the F-statistic and test for overidentification in the first stage model. As long as the sample and the F-statistic are relatively large, then the second-stage model's estimates are generally accepted.

In the first stage, the log of bank assets positively predicts deposit and loan growth, while the ratio of real estate to noncash assets negatively predicts loan growth and the ratio of net worth to assets positively predicts deposit growth. The second-stage model shows that the change in deposits and loans is significantly and positively related to state income growth even after controlling for the growth in building permits, production income, and the liabilities of failed businesses.

While the model produces stark results, the authors are concerned over the limited number of observations. They thus augment the analysis by looking at the effect of the change in loans on building permits for 131 major cities. The 2SLS model shows that the instrumented change in deposits over the early 1930s is positively and significantly related to permit growth. The authors thus conclude that banking distress was an important propagator of shocks.

Calomiris and Mason admit a couple limitations. First, the focus on mostly statewide data limits the number of observations and introduces potential measurement error. Second, the database only contains information on state income and city building permits but not information on manufacturing or production. Third, instrumenting with initial conditions could fail the exclusion restrictions when there is serial correlation.

Difference-in-Difference (DD)

In order to avoid the small sample and instrument problems with aggregated data, Ziebarth (2013) uses a difference-in-difference approach similar to Richardson and Troost (2009). Ziebarth collects a plant-level dataset from the Census of Manufactures taken in 1929, 1931, 1933, and 1935. The database contains information on revenue, output, price, number of workers, and hours per worker for manufacturing plants in Mississippi. By comparing plants in the St. Louis Federal Reserve District

[16]While these two equations could be estimated with OLS separately, the standard errors would not be estimated correctly because the second-stage estimates would take into account the fitted values instead of the original endogenous variable.

with those in the Atlanta District, the model compares plants in areas where bank failures occurred more frequently to those in areas where bank failures occurred less frequently. Because the district boundaries only affected banks, all plants should have been subject to the same economic conditions and regulations.

The approach controls for endogeneity, but the data present another potential problem: selection bias due to attrition. In addition to industry-specific time trends, Ziebarth uses a set of variety different specifications to measure and control for this problem. First, he uses an unbalanced panel of all plants and does not explicitly correct for selection. Second, he limits the sample to plants that survived the entire period, effectively eliminating any bias due to banks altering their behavior before exit. Third, he uses time-invariant plant-level fixed effects to at least partially control for the selection bias.[17] The main variable of interest is the interaction between a dummy for plants in the St. Louis District and a dummy variable for the bank panic in 1931, but the dummies are also separately included in the regressions to soak up any time-invariant differences.

The evidence shows that plants in the St. Louis District experienced a dramatic reduction in plant-level revenue, physical output, and hours per worker compared to Atlanta. At the same time, the Difference-in-Difference estimate does not have a consistent effect on price, average wage, or the number of workers. Plants thus responded to bank failures by reducing the number of hours worked and output but not by adjusting their price or firing workers. Extending his results across time, Ziebarth finds that most manufacturing plants bounced back after 1931. By 1933, there were no remaining differences between the two sections of Mississippi even though banks had not returned. In this way, the paper shows that bank failures can lead to large crashes in production, but recovery can still occur even before credit conditions improved.

Conclusion

Regardless of country or time period, financial crises are one of the principal causes of sudden economic change. Crises reduce production, income, and prices and also bring about broader regulatory and institutional changes. As such, it is critically important to understand their causes and effects. The study of historical financial panics, in particular, has become even more vital as authors (e.g., Sprague 1910; Friedman and Schwartz 1963; Wicker 2000; Reinhart and Rogoff 2009) continue to show that panics often occur for the same reasons. For instance, Carlson and Mitchener (2009) argue that had branching been allowed to spread beyond a few isolated states, the Great Depression would have been less severe, whereas Wheelock and Wilson (1995) caution that deposit insurance might allow banks to take too much risk even today. The conclusions of these studies are straightforward, but they

[17]The drawbacks are that the estimate of the effect of the Atlanta Fed's action would only be based on within plant variation and the limited number of observations available to study.

would not have been possible without first solving substantial identification problems. The use of cliometrics, therefore, is more than just a historical application of modern techniques. Rather, it is an attempt to better understand previous problems so that we might not repeat them.

Payment Systems

John A. James

Contents

Abstract

The payments system is the complex of financial instruments and relationships that transfer value between buyers and sellers to complete their transactions. The character and reliability of the payments system, the rules, practices, and institutions by and through which value is transferred from payors to payees, is obviously a crucial underpinning to a market economy. Cash is the simplest means of payment. However, the vast majority of transactions, especially in developed economies, involve non-cash payments instruments. The use of non-cash instruments in the payments process can take time and involve some risk since they are promises to make future payments. Payments system improvements that reduce costs and/or risks should have a salutary effect on the operations of a market economy.

In the absence of the "double coincidence" of wants, some arrangement is necessary to facilitate the exchange of goods. The payment system is the complex of financial instruments and relationships that transfer value (or good funds) between buyers and

sellers to complete their transactions. The character and reliability of the payment system, rules, practices, and institutions by and through which value is transferred from payers to payees, is obviously a crucial underpinning to a market economy. By the same token, payment system improvements, which either reduce costs or risks involved in making payments, should have salutary effects. The payment system is in Kahn and Roberds's words the "plumbing of the economy," essential and pervasive, the "glue that binds together the gains from trade" (2009, pp. 1, 19).

Cash is the simplest means of payment. Cash transactions directly transfer good funds (a generally accepted means of exchange) from buyer to seller and so constitute final settlement ("the final and unconditional transfer of the value specified in a payment instruction" which legally or effectively discharges any financial obligation of the payer to the payee (Juncker et al. 1991, p. 847)) without mediation by third parties. The vast majority of transactions however, especially in developed economies, involve noncash payment instruments like checks or credit card receipts. Unlike cash, they represent payment orders directing the transfer of good funds between intermediaries and ultimately each party's transactions account.

The use of noncash instruments in the payment process typically involves several steps: the transmission of the payment order to the buyer's intermediary, its verification and approval, the reverse delivery of funds to the seller's intermediary, and the crediting and debiting of each party's account. Needless to say, noncash payments can take time – several days in the case of checks and at least a month for credit card transactions. Consequently, the payment system is built on flows of credit, or to use somewhat dated terminology, noncash payment instruments are also credit instruments (Kinley 1910). In any case in which payment and settlement do not occur simultaneously, some risk is involved. Payments are generally promises to deliver funds of a certain amount. The recipient of a payment faces some uncertainty about receiving value (in cash or good funds) until settlement has occurred even though a payment has been made to them. The historical development of payment systems is in many respects a story of the evolution of economic institutions. Cliometrics, as we shall see here, can make and has made important contributions to this literature – both quantitatively, in assembling financial data on note prices and exchange rates, for instance, and analytically, notably in applications of network analysis among other modeling.

Coinage, Money Changers, and Deposit Banking

With the demonetization following the collapse of the Roman Empire in the west, both the demand for and supply of coinage declined (by the mid-fifth century and for 200 years thereafter, coins ceased to be used as a medium of exchange in Britain, e.g.). Some Roman coins continued to circulate for centuries in various states of degradation supplemented by the output of some former Roman mints then operated by barbarians (Spufford 1988). Monetary, as well as political, unity came in much of western Europe at the beginning of the ninth century as Charlemagne became Emperor of the Romans and the Carolingian silver penny became the standard of

exchange. Over time the coinage system evolved into one with three tiers – gold coins, large-value silver coins, and smaller-value (initially silver) coins. These different kinds of money served different functions – gold coins used by merchants in nonlocal trade, large silver coins used in large-value local transactions, and smaller-value coins used in retail transactions. In Kuroda's phrase (2008; Fantacci 2008), these were complementary currencies functioning in effect in parallel. Fantacci (2005, 2008) in turn draws out the distinction between the unit of account and medium of exchange in this period and in a most interesting model shows how the relationship between them could have been altered ("mutation") – through changes in metal content (debasement/reinforcement) or through changes in nominal value (abatement/enhancement).

Now back to the Carolingian silver penny – although the standard of exchange, they were necessarily used all that often. With essentially self-sufficient manors becoming the basic unit of economic organization, there was still little need for money both internally within the manor and also externally because there was little trade (other than in a few items such as salt). In the relatively few towns extant the value of the single coin, the silver penny was too large to be used in small payments – the daily wage of twelfth-century English domestic servant was around a penny, for example. As a result of the problems in using cash, many transactions necessarily involved the extension of credit.[1] For example, book credit could have been advanced until the debt could be discharged by a cash transfer. Or the butcher and the baker might have accumulated offsetting mutual obligations which at some point could have been settled through bilateral netting.

The subsequent political fragmentation of Charlemagne's empire was accompanied by a monetary fragmentation as well as local princes and lords began to mint their own pennies and then later other coins. With the revival of distance trade, merchants consequently faced a befuddling array of coins in circulation with varying weights and degrees of fineness as well as differing degrees of clipping and abrasion, plus the fact that they were heavy to carry around (see Kohn 1999c). Money changers then, with their specialized skills and expertise in assessing coinage in circulation, became essential intermediaries in transactions between merchants. De Roover (1948, p. 186), for example, observed that "in the Middle Ages, the regulation of the currency practically rested upon the money-changers; hence they performed a very important and quasi-public function."

Fairs, which brought together agents from distant locations for brief periods, developed as centers of long-distance trade. The archetype and most famous were the thirteenth-century fairs of Champagne which functioned as meeting places of northern (from Flanders) and southern (from northern Italy) European merchants. Once a merchant's coin holdings had been presented, the value of which was

[1] In contrast to the "historical" school of political economy which saw three main stages of economic development (and payments): "the prehistorical and early medieval stage when goods were exchanged for other goods; the later medieval state of 'cash' (money) economy, when goods were bought for ready money; and the modern stage of credit economy when commercial exchange was based on credit" (Postan 1973, p. 2; also, pp. 21–27).

assessed based on condition and exchange rates, and safely locked away with the money changer (Italians at the Champagne fairs and more generally not necessarily a he – money-changing being one of the few medieval professions in which there was no discrimination against women (de Roover 1948, p.174)), they could readily be used in payments. Since this assessment process was time consuming, thenceforth payment could be made by transferring ownership of the coins rather than the coins themselves. Such balances were "assignable" by oral order. The payer and the payee would appear together before the money changer (or bank), at which time the payer would order funds to be transferred from his account to the payee's account, rather than settling directly in coin. "Deposit contracts" were redeemable in full (at par) on demand.

Final settlement was generally deferred however. At the Champagne fairs, for example, trading took place in two periods. In the first Flemish merchants typically sold cloth to the Italians, while in the second the Italians sold spices to the Flemish. Italian purchasers in period one would have been allowed to overdraft their accounts in view of accumulating credits in period two. Final settlement of balances would then come at the end of the fair, or perhaps not. Merchants with debit balances at the end of the fair commonly extended their overdrafts until the next fair or else borrowed from those who accumulated a final credit balance.

Deposit banking therefore had its origins in money changing. Moreover, McAndrews and Roberds (1999) argue that the activity of payment was central to the original function of banks of deposit. Commodity money could adequately serve the purpose of a medium of exchange when settlement was immediate. But if the ability to enforce intertemporal commitments is limited, promises to pay are not completely satisfactory substitutes for cash transfers. In such a situation, profitable exchanges could be facilitated by a deposit bank lending to merchants via overdrafts with merchant deposits serving as collateral for the temporary overdrafts. Other merchants are willing to accept bank funds since incoming funds would be used to pay off their own overdraft loans. Roughly offsetting payments among merchants then are facilitated by the bank's provision of liquid payment services. In turn, or in reverse, banks are liquid because their customers' payments tend to be mutually offsetting. And there are liquidity economies of scale potentially at work here – more customers mean more mutually offsetting transactions and more liquidity. McAndrews and Roberds view this linking of buyer and seller as the "initial and key role of banks," with the function of intermediary linking saver and investor a consequence of the original payment intermediation (1999, p. 32).

Bancherii were known in Genoa as early as the twelfth century, and deposit banking was well established there by 1200 (spreading to Venice). In the North, in Flanders (Bruges), it was practiced by the second quarter of the fourteenth century (de Roover 1948, p. 247). The course of deposit banking, however, had its ups and downs. One of the downs came in the late fifteenth century when a wave of bank failures swept across Europe, importantly in Venice and Bruges. The Burgundian authorities in the Low Countries as a result decided to ban it completely – orders in 1489 prohibited the taking of deposits. In Venice there was a more delayed response. With the failure of the last two Rialto banks, in the wake of numerous earlier failures,

private banking there came to an end. In 1584 a monopoly public bank, the Banco della Piazza di Rialto, was established, the purpose of which was again to facilitate payments rather than financial intermediation. It proved so successful that by the close of the seventeenth century, public banks handled most of the deposit banking on the continent (Kohn 1999b, p. 25).

Amsterdam was one city which founded a public bank, the Bank of Amsterdam or Wisselbank, in 1609. It was city owned, accepted deposits, and did not lend. Its purpose was akin to the traditional money changers, to assure the quality of coins in the face of a proliferation of issues and issuers and accompanying risks of debasement. In circa 1600 there were between 800 and 1,000 different coins in circulation there, issued by mints in each province and many cities as well as by private mints (and not to mention counterfeits). When coins were deposited, the depositor was told the bullion value of and a receipt for the particular coins presented. Withdrawals could be made at a small fee, but more importantly transfers between accounts were allowed with no fee. In the 1680s when the Wisselbank abolished the right of withdrawal without a receipt, there was no protest, which could be taken as an indication that depositors were no longer interested in making withdrawals. Settlement of transactions was accomplished by the transfer of exchange bank money denominated in banco florins, a unit of account tied to no particular coin. As a result, Quinn and Roberds (2006, 2007) characterize the Wisselbank as the first modern central bank, one in which large-value payments were settled through the transfer of balances held there, the value of which were maintained through open market operations.

Bills of Exchange

Although the bill of exchange probably dates to around 1200, it began to come into its own later in the century as the fairs of Champagne began to wane (to be sure, fairs in general did not die out; they just shifted to other venues). As merchants became less itinerant and more "sedentary," it became increasingly necessary to make payments at a distance. Specie, coins or bullion, of course, could have been shipped, but that was costly and risky. The bill of exchange, an order to pay a certain person a certain amount (in a different currency) at a distant place, developed instead as the primary instrument of remittance (Usher 1914, pp. 569–570).[2] The typical bill involved four parties. First there was the remitter who wanted to make a payment abroad and provided the funds in local currency to the taker who in turn made out the bill to his agent or correspondent in a distant city. Then there was the payer or drawee on whom the bill was drawn and who was expected to pay it at maturity in the local currency and the payee, in whose favor the bill was made out (de Roover 1948, p. 53). For security two or three copies of the bill were usually sent. The taker on a

[2]A more comprehensive history of the bill of exchange than that which follows here may be found in Denzel (2010, pp. xxii–xlvi).

bill of exchange was often a trading company or merchant banker with branches or correspondents in several cities. Thus, merchant banking developed with the diffusion of the bill of exchange or vice versa.

Medieval bills were not discountable because of usury restrictions. But the price of a bill did reflect foreign exchange charges in which interest might be concealed. Bills of exchange were initially used to finance trade, but increasingly over time they were employed for purely financial purposes. Such transfers of funds over space and time, called "dry exchanges," were divorced from remittance. Indeed, as early as the fourteenth century, most bills of exchange were drawn out of financial, rather than trade, transactions (de Roover 1948, pp. 66–67; Kohn 1999a, p. 9). Such bills, later known as "accommodation paper," were held in low esteem in some circles because they did not arise out of real commercial transactions.

Medieval bills also were not negotiable. Bills were assignable, that is, the collection of the debt could be assigned to a third party. Agent A owes money to agent B as evidenced in a bill of exchange. B in turn might assign the right to collect the debt to a third party, agent C, by endorsing the bill on its back (this practice began in the 1570s, before that a formal document, an assignment note, had been drawn up, usually before a notary). If in addition the instrument was transferable, C would receive the full rights of B. Therefore if A, the original debtor, did not pay, C could have legal recourse against A, but not against B. With a negotiable instrument the debt to C is discharged only when he/she receives final payment. If A reneges, C has recourse not only against A but also against B (or against any other endorser in the chain of assignment). Thus, every additional endorsement strengthens the credit of the negotiable bill.

In Antwerp, where deposit banking had been banned, the principle of transferability was recognized by the courts by 1507 and that of negotiability by an edict of Charles V in 1536. As a result, in lieu of the transfer of deposits, negotiable bills became a standard means of payment among merchants. As bills were transferred from hand to hand, and they were in fact, with each subsequent endorsement, they became more secure. During this time in Antwerp, the practice of modern discounting developed as well, increasing the liquidity of bills outstanding (van der Wee 1977, pp. 322–332; Kohn 1999a, pp. 23–28). Usher (1914, p. 576) then could write "there can be little doubt of the essential perfection of the bill [of exchange] by 1650." The use of bills of exchange as a local medium of exchange spread to other areas as well, perhaps most famously in late eighteenth-/early nineteenth-century Lancashire where they served as the principal means of payment (Gilbart 1836, p. 79).

Notes, Checks, and Clearing Houses

In England there was no medieval tradition of banks of deposit evolving from private money-changing operations, because money changing had been the exclusive province of the Royal Mint. Instead, goldsmiths became the safe-keepers of cash and

valuables. Following the relaxation of regulations under Cromwell's Protectorate, many goldsmiths moved into deposit banking. By the time of the Restoration (1660), a network of bankers had developed in London (32 by 1670). These goldsmith bankers issued paper banknotes, promissory notes that were payable to, or redeemable by, the bearer at the issuing bank on demand. Such bearer notes could circulate without endorsement by each holder. When a bill of exchange was transferred by endorsement, each signer assumed a share of the collective responsibility for the final settlement of the bill. In contrast, the value of a banknote depended solely on the reputation of the issuing banker – each holder could transfer it in exchange without assuming any liability. The policy toward rival banks' note issues that developed among London goldsmith banks was one of mutual acceptance at par or face value and bilateral clearing without a formal coordinating institution (a pair of banks each presented the notes of the other, which it had accumulated over time. Any pair-wise imbalances were settled by a transfer of good funds – specie or later Bank of England notes). Quinn (1997) argues that mutual acceptance developed endogenously as a dominant strategy Nash equilibrium. Mutual acceptance produced positive externalities – each banker benefitted from the overall increased demand for notes and bills resulting from the expansion of participating agents. The practice of taking other banknotes at par did subject the accepting bank to the risk that the issuing bank might default, so rapid and regular clearing in which the issuing bank was presented with its notes for redemption lowered the receiving bank's exposure to default risk. Moreover, rapid and regular clearing performed an important monitoring or disciplining function of competitors in case issuing banks might become too enthusiastic (Quinn 1997).

By the time the Bank of England was founded in 1694, the practice of creating liabilities that would serve as a medium of exchange was already established. The London public should have been quite familiar with paper banknotes. The Bank however enjoyed some advantages in the issue of bearer banknotes. For one thing, it was granted a monopoly on joint-stock (incorporated) banking (until 1826 vis-à-vis country banks and 1833 vis-à-vis London banks), while private banks with more than six partners were forbidden from issuing notes. However with only the central office available for redemption, Bank of England notes typically circulated in or near London. By the last third of the eighteenth century, London private banks had largely given up on issuing their own notes in competition with those of the Bank of England.

Instead, the liability of choice among London bankers became the check (or cheque). A check is a simpler way of transferring deposits than having both parties appear in person before the banker, as was required in many medieval banks. It is a written order to pay a certain sum from the depositor's account to the payee when that order is presented at the depositor's bank. In practice, it is the local equivalent of a bill of exchange. The first checks appeared in Europe around 1400 in areas with deposit banks, but not always to universal approval – a Venetian ordinance banned checks there in 1526. In London they appeared with goldsmith banking in the mid-seventeenth century. As with banknotes, a system of mutual acceptance developed with bilateral clearing (Joslin 1954; Quinn and Roberds 2008, pp. 3, 7).

Checks offered several obvious advantages over notes – they were less subject to theft, provided a record of transactions, and were convenient for large-value transactions. On the other hand, they were "double claims," based on both the deposit bank itself and a particular agent's account there. Therefore, the recipient of a check had to consider both whether the bank upon which it was drawn would pay specie at par and also whether the check writer had sufficient funds in his/her account to cover the check. Both banknotes and checks were examples of "demandable debt," bank liabilities which may be converted into cash (specie) on demand. This feature enhanced their status as payment instruments by reducing uncertainty about their true value.[3] As checks were sent out for collection between banks, they began to hold credit balances with each other, particularly if the bank was in a distant location. These "interbank balances" were held in order to economize on shipping cash for immediate settlement of check clearances. As a result, banks needed to monitor and manage these implicit interbank loans. Goodfriend (1991, p. 12) argues that the same skills necessary to evaluate, monitor, and enforce loan agreements to nonfinancial borrowers proved useful to the efficient provision of payments services as well. Thus, "institutions specializing in information-intensive lending, i.e., banks, have applied their expertise jointly to the production of payments services and nontraded loans" (also see Kashyap et al. 2002).

The increasing volume of interbank exchanges led to the formation of the London Clearing House in 1773 by City bankers. These were the descendants of goldsmith bankers who dealt primarily with commercial customers and were located primarily in the City of London in and around Lombard St. This systematized previously informal private exchanges among bank clerks. Thirty-one of thirty-six city banks participated; West End bankers, originally located around the Strand and Fleet St. and dealing primarily with "gentlemen," were excluded. This was still a system of bilateral clearing and settlement, but at a central location on Lombard St., thereby minimizing the comings and goings of clerks around the City. The clerks came twice a day and dropped into the drawer of each those bank bills and checks payable, which were then summed up and offset by two salaried inspectors. Settlement at the end of the day was accomplished by transfer of specie or Bank of England notes.

In 1841 a single net payment system was finally adopted. In net clearing each bank calculated its net position against all other clearing house members, the total of checks it received which had been drawn on other banks compared with checks presented by other member banks drawn on it. Differences were settled by only one transaction between the bank and the clearing house. If the balance was positive, the bank's clearing house account was written up; if the balance was negative, good funds were transferred to the clearing house (after 1854 settlement was accomplished through transfers of Bank of England accounts). Multilateral net clearing certainly

[3]One other thing about banknotes here. Quinn and Roberds (2003) draw parallels between the development of privately issued banknotes and online currencies more recently, both motivated by the need to conduct transactions with strangers to provide a form of finality, "of being able to extinguish other debts by virtue of their transfer from debtor to creditor."

represented an advance in efficiency by reducing the level of reserves needed to be maintained for final settlement, but it also involved risk. The costs of the failure of any member fell on the clearing house as a whole. Nevertheless, as Seyd (1872, p. 56) wrote, "It would be difficult indeed to imagine anything more logical in construction and closer to perfection than the London Bankers' Clearing System . . . Were it not for the very dry matters of fact connected with the whole proceeding, a poet might be found to sing its praises."

Checks were essentially restricted to local payments. Within England the domestic or inland bill of exchange was the principal instrument used in nonlocal commercial transactions. Their negotiability made them a highly liquid financial instrument. Purchasing or discounting them (before maturity) became the standard method by which commercial banks extended credit. Secondary markets in domestic bills developed. They were intermediated by bill brokers who received bills drawn from net borrowing areas such as manufacturing districts and arranged their sale to agents in London or surplus agricultural areas. Initially, those brokers were just that, never taking a position in the transaction. Eventually they began intermediating these transactions using their own accounts. Over time the domestic bill drawn on London became the standard internal payment instrument even when neither party was located there.

The growth of bill brokers coincided with the growth of country (non-London) banking, in the second half of the eighteenth century. Country banks primarily issued paper banknotes which served as a local means of payment. Checks were used less as a means of payment than as an order to the bank to pay out cash. Not until the second quarter of the nineteenth century did they come into more general use in the countryside. Nevertheless, with the growth of industry and trade later in the eighteenth century so also was there an increase in the need to make payments at a distance. Although there were no formal legal restraints on size or branching, the six-member partner limitation inhibited raising substantial amounts of capital, as well as monitoring of distant locations. While family linked some banks together, most country banks were unit banks. As a result, correspondent networks developed between interior country banks on the one hand, and London banks on the other, to facilitate interbank transactions (Quinn 2004).

Every country bank needed a London agent or correspondent bank. The agent would collect bills payable in London as they matured, serve as a source of London funds for local customers who needed to make payments there, provide investment assistance and advice, serve as a redemption agent for any country banknotes that wandered too far from their issuer, and provide funds when needed by rediscounting bills held by country clients, among other things. Later, as the use of checks outside London increased, London banks began to clear country checks. The name of its London correspondent was printed in the corner of the check form. Checks received were sent to the London correspondent for presentation to the Clearing House which in turn mailed them to the banks on which they were drawn. Customers within 1 day's post from London saw their account credited within 2 days. The threat by country banks of starting their own clearing house led to the establishment of a separate Country Clearing section in London in 1858. Except for provincial

operations in Manchester, Liverpool, Birmingham, and a few small local exchanges, every check drawn on an English bank was collected through London. The price for such services was typically maintaining a substantial non-interest-bearing deposit with the London correspondent, although sometimes fixed annual fees were paid (James 2012, pp. 135–138). Ties between country and London banks weakened after 1826. The development of large joint-stock banks with nationwide branches meant that much clearing and settlement previously routed through London could be done internally ("on us"). As the Bank of England opened provincial offices, maintaining a London agent became less important.

Correspondent Banking Networks in Nineteenth-Century America

As internal trade grew in the early United States, so did the problems of making payments at a distance (distances were greater for one thing). The shipment of specie was again an obvious way of settling accounts, but this was rarely used in nonlocal, non-retail transactions (Colwell 1859, pp. 135, 190, 262, 447). Two institutional responses emerged both dating from the 1820s. First of all, private banknotes were sometimes used in payments outside their locality. Many banknotes issued by country banks all over New England made their way into Boston, the regional commercial and financial center, and circulated there in competition with those of local banks. Out-of-town notes were typically valued at a discount from par or face value because of the costs involved in returning them to the issuing bank for redemption. The initial response to this "flood" of "foreign" notes was to get them out of circulation and also make a little money in the process. Local banks bought them at a discount and returned them for redemption at par, but competition narrowed the spread between their par value and market price so that such an operation was "hardly profitable." The obvious solution was collusion, a strategy in which a coalition of Boston banks (in 1824) would pool their resources for purchasing country notes and then send them back for redemption. The redemption agent was the Suffolk Bank (hence this was called the Suffolk system).

Rather than country banks facing unannounced calls by Suffolk Bank agents presenting unpredictable sums of notes for redemption in specie, the system was systematized by their maintaining (non-interest-bearing) clearing and redemption accounts with the Suffolk Bank. The resulting arrangement was one of net clearing. Instead of gross clearing in which notes were simply returned to the issuing bank for redemption, country banks sent their accumulated out-of-town notes to the Suffolk Bank. There the submitting country bank's account would be credited for notes received from it and debited for notes issued by it received from other banks. Consider the Suffolk system as a private payment network/clearing system with positive externalities, the benefit to an individual member (from being able to clear at par the notes of distant banks, for one thing) increases as more users join the network. Such a region-wide net clearing system was quite efficient, in the sense of minimizing movements of specie necessary for settlement and ensuring that the

notes of system banks circulated within the region at par. It has been widely admired by many later historians and economists for such reasons. Calomiris and Kahn (1996), for example, in support of the "sanguine" view of the Suffolk system, find that New England banks were able to issue more notes, which traded at uniform and low discount rates, while maintaining lower specie reserves, as compared to Middle Atlantic banks (i.e., ones not in the Suffolk system). Nevertheless, in spite of its admirable efficiency, the Suffolk system was heartily despised by most system members, many of which defected promptly when a rival (Bank of Mutual Redemption) appeared in the 1850s, prompting its rather precipitous collapse. Bodenhorn (2002) explains this paradox of the Suffolk system, admired by outsiders but strongly disliked by insiders. First note that in networks pricing at marginal cost might not produce efficient configurations or usage. In particular, members who place low values on participation but bring large external benefits to others should pay only a small part of common costs, perhaps even less than marginal cost. Based on a calculation of the implicit cost of network membership in the network, he argues that the clearing services of the network had indeed been mispriced – the smaller country banks, which benefitted the least from participation, paid proportionately the most, while the large Boston banks, which benefitted the most, paid the least.

Second, from the 1820s through the mid-1830s, the Second Bank of the United States (SBUS) under Nicholas Biddle with its network of interstate branches dominated the system of interregional payments through its role in the market for inland (domestic) bills of exchange (Catterall 1902, pp. 138–143; Knodell 2003). Internal bills of exchange drawn upon a SBUS branch could be discounted by the payee at his/her local SBUS. The funds at the drawn upon branch could in turn be sold to other local customers who needed to make payments in that city in the form of a bank draft, a check drawn by one bank against funds deposited in another. The price of a bank draft reflected an (domestic) exchange charge, the price of funds in a distant city in terms of local funds. The Second Bank served as a market maker in domestic exchange – it was always ready to be a party to a transaction. If someone wanted to buy, it would sell; if someone wanted to sell, it would buy and generally at rates below what would have prevailed in a private market, consistent with Biddle's desire to promote internal trade.

The SBUS branch network made for a quite efficient national payments network based on collective settlement, minimizing the interregional shipment of specie necessary to settle account imbalances. Between the demise of the Second Bank of the United States (in 1836) and the founding of the Federal Reserve System, the United States lacked a central monetary authority to orchestrate the clearing and collection of payments among highly localized banks. The prohibition against interstate branching furthermore precluded the formation of nationwide banks that could mediate a national payment system. The closing of the interstate branches of the SBUS thus ushered in a period of financial disintermediation in interregional payments. Knodell (1998) measures the rise in domestic exchange rates (Cincinnati and Cleveland on New York) in the wake of the SBUS closing, and initially they were substantial. Note brokers and private bankers then became active participants in the now-decentralized system of domestic exchanges (Knodell 1998, pp. 717–719;

Bodenhorn 2000, pp. 177–185). Individuals needing to make payments in New York, for example, could buy bills payable there through a broker.

Private banknotes began to be used increasingly in transactions at a distance, being cheaper and more convenient to ship than specie. Secondary markets reemerged in these out-of-town notes. Local note brokers, which had been overshadowed by SBUS operations, bought, sold, and/or sent these "foreign" notes back to the issuing bank for redemption. Out-of-town notes were usually valued at a discount from par or face value because of the costs involved in returning them to the issuing bank for redemption (and the risk that when it was presented at the counter the issuing bank might refuse to pay for it[4]) with their current prices published regularly in periodicals called banknote reporters. Using such data, Gorton (1996, 1999) studies the pricing of banknotes and the process of reputation formation for new banks in the late antebellum period, arguing that market discipline (pricing bank risk) prevented widespread wildcat banking.

Alternatively, networks of private bankers developed in lieu of the interstate branch network of the SBUS (Knodell 1998, 2010). Private banks increasingly maintained deposits in other banks in distant cities, the locations of which were determined by the needs of local trade (Weber 2003). These interbank or correspondent accounts allowed local banks to sell drafts drawn on them to customers needing to make payments in distant cities. As New York City emerged as the commercial and financial center of the country, it also became the focus of these correspondent bank networks. By just before the American Civil War, virtually every bank in the country maintained a New York correspondent, and the sight draft on New York, or New York exchange, had become the dominant financial instrument used in interregional or intercity payments. Payments between agents in different cities, say New Orleans and Cincinnati, were generally settled in New York funds, the standard means of interregional payment, since virtually all banks held accounts there. The earlier bilateral payment relationships had evolved into one centered on New York in essentially a hub and spoke network. New York exchange became *the* currency for settlement of long-distance transactions. This in turn allowed for a quite efficient system of essentially net collective settlement of nonlocal payments. That is, transactions between parties whose banks shared the same city correspondent could be settled as an intrabank "on us" transfer of funds; those between parties whose banks had different correspondents in the same financial center (i.e., New York) involved only a local movement of funds, greatly reducing the necessary shipment of reserves.

New York became the "clearing house of the country," and the crucial institution there in turn was the New York Clearing House (NYCH), founded in 1853. It was a net settlement system in which members were exposed to the risk of default by other members. Any losses at settlement were covered by the NYCH as a whole. As a

[4]The Second Bank of the United States notes however had been redeemable at par at any branch, regardless of the city of issue. The fact that their value did not decline with distance made them the paper money of choice for long-distance payments before 1836 (Temin 1969, p. 36).

result, membership was closely guarded, and applicant banks to the "club" were carefully scrutinized for soundness (James and Weiman 2011). In times of some financial crises in order to reduce pressure on reserves, the NYCH issued clearing house loan certificates to be used internally in settlement. Whether because of its select membership or the usefulness of clearing house loan certificates, the failure rates of NYCH banks during panics were very, very low. This ability and willingness to create high-powered money in times of panic have led some writers to hail the NYCH as an incipient quasi- central bank and lender of last resort (Gorton 1985; Timberlake 1984). Such a view, however, neglects the fact that because of internal conflicts among members, the NYCH was not in fact so effective in forestalling financial crises when they loomed. In both 1893 and 1907, NYCH banks nevertheless suspended payments, i.e., temporarily reneged on the commitment to pay out cash for deposits at par on demand (see Wicker 2000; Sprague 1910). In turn, these breakdowns of the payment system, which quickly spread nationwide, had serious consequences for real economic activity (e.g., see Sprague 1910). James et al. (2013) argue that such suspensions acted as severe adverse supply shocks and offer econometric evidence based on monthly data that contractions intensified during suspension periods (with a statistically significant decline in real activity of around 10–20%).

Business customers making payments in New York could buy a bank draft drawn on his/her local bank's correspondent there (New York exchange). In turn, such customers also sold exchange to their banks by depositing drafts or checks drawn on a New York bank. Banks would then remit these items to their correspondent for collection and receive payment usually in the form of ledger entries to their correspondent balances, rather than shipments of cash. In the course of providing routine payment services to business customers, banks would deplete and replenish their city correspondent balances. At any point in time, therefore they could find themselves with deficient or excess correspondent balances. To remedy these imbalances, interior banks could arrange to ship cash to or from their New York correspondents, but that again would then incur significant transaction costs. As a cheaper alternative, banks developed local wholesale or interbank markets in exchange where they bought and sold surplus correspondent balances, in other words local markets for domestic or New York exchange (Garbade and Silber 1979). The system of internal or domestic exchanges was a fixed exchange rate regime. The value of a dollar (in terms of gold) in New York was the same as that of one in Chicago. The spot price of New York funds in Chicago could differ (in normal times) from the mint parity exchange rate (one) within the currency points, which reflected the cost of shipping cash from Chicago to New York or vice versa, without eliciting an interregional/intercity currency flow. James and Weiman (2010) investigate longer-term changes in domestic exchange markets, particularly the dramatic decrease in variability or volatility over the late nineteenth century.

The practice of deposit banking, in which deposits rather than banknotes were the primary bank liability and means of payment, expanded rapidly from urban areas into interior regions in the decades after the Civil War. By the 1880s bank customers began to make payments to distant parties with checks drawn on their local banks

rather than through city drafts, undermining the centralization of payment operations made possible by drafts (James and Weiman 2010). The legal framework was not well designed for collecting checks used in interregional payments. Under the common law and commercial code, no bank could charge for payment on checks presented at its counter. As a consequence, the process of interregional clearing became more complicated, with New York banks utilizing their correspondent networks to act as collection agents for their country bank clients. Existing correspondent bank networks provided the structure to orchestrate their clearing, the process of transmitting, reconciling, and confirming payment orders. Settlement was still typically accomplished in New York by a transfer of funds between the payer and the payee banks' city correspondents. New York exchange therefore remained the means of settlement in long-distance transactions. Nevertheless, the resulting system was widely criticized for its perceived inefficiencies – primarily indirect routings of checks passed along from correspondent to correspondent on their (sometimes circuitous) way to be presented for collection and excessive charges by some (generally rural) paying banks for remitting settlement funds on checks not presented directly at their counter. More recent assessments however (Lacker et al. 1999; James and Weiman 2014) have suggested that such criticisms were exaggerated at best (see next section). Probably a more serious criticism was that the proliferation of interbank accounts for clearing and collection purposes led to substantial holdings of excess reserves overall under the *ancien régime* (Laughlin 1912).

The Twentieth Century

Soon after its founding in 1914, the Federal Reserve, the new US central bank, entered the check clearing market with the goal of displacing the myriad private correspondent and clearing arrangements that had been in place. Its stated goal was to enhance the efficiency of the payment system by standardizing banks' procedures for the clearing and collection of checks and centralizing their reserve holdings. How successful this effort was will be addressed in a few moments. But note here that the Fed system might be regarded as something of a template for modern clearing and collection operations. First of all, settlement between banks was accomplished through transfers of their balances or reserves held at the Fed. Central bank money replaced New York balances as the settlement medium of choice. To be sure, this was not entirely new – London banks, for example, settled among themselves by transfers of Bank of England notes and later deposits from early on in the nineteenth century. But notwithstanding, Norman et al. (2011) in their survey of the history of interbank settlement characterize the convergence of monetary systems around the world toward ones with interbank settlement in state-backed central bank money as a general twentieth-century phenomenon. Indeed, Charles Goodhart (1988) argued that pressure to devise efficient clearing and settlement procedures was very important in the development of central banking in general (and the centralization of reserves).

Second, from 1918 clearing and settlement was accomplished via an exclusive leased telegraph wire network known as Fedwire. This was an arrangement of real-time gross settlement (RTGS), the first, in which each payment is separately settled as it is sent. Every payment from one bank to another represents an irrevocable transfer of central bank funds at the time the order is transmitted, in continuous or real-time settlement, as opposed to a final net settlement at the end of the period. Although multilateral net settlement in clearing houses reduced the amount of funds needed to be transferred to settle accounts at the end of the period, it also exposed member banks to collective risks that another member might not be able to settle. In "secured" net settlement systems, all participants might be required to post collateral, which in total should be adequate to cover any failed positions. Gross settlement, while absolving individual banks of such collective risk bearing, imposes much greater liquidity demands on them. Over the course of a day, depending on the timing, there could be times when a bank's reserves might dip perilously low. Similarly, payment blockages might arise when one bank's outgoing payment waits on the arrival of an incoming payment from another bank. Smooth operation of a RTGS system then depends importantly on the provision of intraday credit by the central bank to offset temporary adverse movements in member bank's reserve positions. Since repayment is required by the end of the business day, such loans are called daylight overdrafts.

There has been "virtual agreement among major central banks that gross settlement makes wholesale payment systems more immune to widespread financial disruption" (Emmons 1997, p. 24), and over the late twentieth century, there has been a general move toward RTGS payment systems in most major industrialized countries. This has been particularly the case for countries participating in the European Economic and Monetary Union, which needed to establish common standards for interlinking in the TARGET (Trans-European Automated Real-time Gross Settlement Express Transfer system) payment network (later succeeded by second-generation TARGET2).

Fedwire is an example of a "wholesale" payment system, one which accomplishes periodic large-value transfers between financial institutions. Many of these represent a derived demand for settlement of claims arising from retail payments. In the United States, large-value settlement is not a government monopoly – Fedwire's major private rival/alternatives being CHIPS (Clearing House Interbank Payments System), a subsidiary of the New York Clearing House with a limited membership of large US and foreign banks using net deferred settlement (NDS), and CLS (Continuous Linked Settlement) in the foreign exchange market.

Now shift the focus from contemporary large-value payment networks back to smaller-value "retail" networks and back in time again to the founding of the Federal Reserve. In view of the perception of the then existing system of check clearing and collection as flawed and inefficient, virtually from its inception, the Fed vigorously pursued strategies to establish universal par clearing, in which checks drawn on any bank would be paid in full at par without deduction for any presentment or remittance fees. This was the final step in a true national monetary union. This was however vigorously resisted by so-called non-par banks. These were banks that were

not members of the Federal Reserve system, located primarily in rural areas, and which often relied heavily on such fees as important revenue sources. The battle was fought in the Congress, state legislatures, and the courts, making par clearing and collection one of the major issues of the early Federal Reserve period. The Supreme Court decided in 1923 that since Congress had not required the Fed to establish nationwide par clearing, it could not force nonmember banks to pay checks at par. The Fed then abandoned universal par collection as a policy objective, and non-par banks persisted for decades – in fact until 1980 when they were abolished by the Congress.

Some more recent writers have cast doubt on the wisdom of the Fed's objective of universal par clearing and collection of checks. In an influential paper William Baxter (1983) argued that in payment networks characterized by joint costs and interdependent demand side payments, or interchange fees, between financial institutions (imposing a gap between the price the buyer pays and the sum the seller receives) could be necessary to achieve equilibrium. Remittance fees, which in effect supported a more geographically extensive or comprehensive payment network than otherwise would have been possible, might be considered as such an interchange fee. Also along these lines, Lacker et al. (1999) characterize the pre-Fed check collection system as a payment network with externalities in which pricing could/should diverge from marginal cost. They take the dispute about remittance fees as one really in fact about who bore the costs of the payments network – the collecting (often city) or the paying (often country) bank. The advantage of the Fed was not in greater efficiency, but a legal one, being able to present checks for payment through the mail, a practice which was not available to private banks. Correspondent networks in turn were configured consonant with the needs of trade, so the odd indirectly routed check that passed from bank to bank was just an outlier. Gilbert (2000) on the other hand finds an increase in payment system efficiency due to the Fed as evidenced in decreased ratios of bank cash to total assets as banks overall no longer needed to hold as large or as many correspondent accounts for check clearing and collection.

In any case, the US check clearing and collection system did not, in fact, develop into one dominated by the Fed. While member banks could use the Fed's facilities for clearing and collection, they were not obliged to do so (the only obligation here was to pay at par on any checks presented by the Fed), and if the checks had been drawn on local banks, a more attractive option was often to continue to clear through local clearing houses, which still continued to function. Indeed a rough division of labor developed in which out-of-town checks were typically cleared through the Fed, while the clearing house handled local ones. Starting from zero, by 1934 the value of checks processed by the Fed had risen to around two-thirds of those handled by private clearing houses (Gilbert 1998, p. 133).[5]

[5]By 2010 Federal Reserve banks processed slightly less than half the value of interbank paid checks.

Furthermore, after 1980 when Federal Reserve banks were required to charge full costs for payment services, their share in both large- and small-value payments began to decline (but has bounced back more recently). This trend toward greater privatization has been noted with approval by some, for example, Lacker and Weinberg (1998) and Green and Todd (2001), who saw the provision of payments services as superfluous to the Fed's core central bank functions of conducting "monetary policy, banking regulation, and financial stabilization." James and Weiman (2005) disagree pointing to the Fed's significant roles in standards setting and coordination and as clearing house of last resort. Indeed, doubts had been raised that the risks of disruption in the operation of the payment system had increased due to the diminished role of the Fed in processing payments and the increased importance of private channels (Summers and Gilbert 1996). Such fears might be allayed, for now at least, in view of the decisive actions taken by the Federal Reserve in response to the terrorist attacks of September 11, 2001. Potential payment system gridlock as a result of disruptions to the Fedwire system was averted by the temporary provision of unprecedented amounts of liquidity to the banking system (McAndrews and Potter 2002).

The widespread use of checks in retail payments has been primarily a phenomenon of the Anglo-Saxon world. In contrast, in many/most Continental European countries (as well as in a number of others elsewhere), giro transfers dominated. In this case the payer ordered his/her institution to transfer funds from his/her account directly to the account of the payee with no action by the latter required (as compared with the case when a payer writes a check to the payee who must then present it to his/her bank, and the transaction is complete only when the check has been collected by the depositing bank from the bank upon which it was drawn). In the absence of well-developed concentrated banking systems accessible to many households on the one hand, or extensive correspondent banking networks on the other, payers in many European countries often turned to government institutions, such as the postal service or the central bank, which could offer payment services (credit transfers) through nationwide networks of branches (Hein 1959; Bank for International Settlements 1999).

With the development of electronic noncash payments methods (Bank for International Settlements 1999, pp. 13–14), there has been some convergence in the use of retail payment instruments across countries as check-using countries employ more direct transfers (obviously, rather than giro-based systems using more checks). In the United States, for example, the use of direct credit transfers in the form of the ACH (automated clearing house) system grew rapidly over the 2000s so that they constituted 51% of the value of total cash payments by 2009 (although only 18% of their number), along with the increasing use of direct debit transfers as well. Nevertheless, the distinctive (or anomalous) feature of the US retail payment system relative to those in other developed countries remains the continued relatively widespread use of paper checks. In 2009 checks accounted for 22% of the volume of noncash payments and 44% of their value in contrast with figures below 10% in most European countries (France being the exception with an 18.3% share of total transactions) and below 1% in some countries such as Germany.

Other payment instruments experiencing rapid growth in recent years are credit and debit cards. In the United States in 2009, they accounted for over half of all noncash transactions (20% for credit cards and 35% for debit cards). The average value per transaction was relatively low however, accounting for only 5% (credit cards 3%, debit cards 2%) of the total value of 2009 US noncash payments. Similarly, in most eurozone countries in 2008, they made up between one- and two-thirds of noncash transactions (excepting Austria, Germany, and Slovakia) (Kokkola 2010, p. 176).

Plastic card clearing and settlement networks (e.g., Visa or Master Card) are private joint ventures of depository institutions. In such networks interchange fees impose a gap between the amount buyers pay and sellers receive. So, notwithstanding the efforts of the Federal Reserve to stamp them out in the 1920s, non-par payment networks are back and occupy an integral part of the payment system.

Summary

There are trade-offs between risks and costs in payment systems. A system, for example, in which all payments were made in cash, might have low risk, but high costs, particularly for payments at a distance. On the other hand, payments based on credit arrangements, check or drafts, might reduce costs (of shipping cash) but would involve more risk. Innovations or improvements in the payment system then would shift the frontier or trade-off curve inward – increasing payment system efficiency at a given level of risk and/or decreasing risk at a given level of costs (see the model in Berger et al. 1996). Goodfriend (1991, p. 9) observed that "the evolution of the payments system has been, in large part, driven by efficiency gains from substituting credit, i.e., claims on particular institutions, for commodity money," but many payment system innovations did both – reducing risk and also improving efficiency (lowering costs).

Even the use of cash, the simplest form of payment, in the medieval period involved some risks. Locally there were problems in assessing the value of the myriad coins in circulation, as well as counterfeits. Money changers both provided expert assessments of such coins presented and offered a safe place to store them. Assignment of these deposit accounts held with banks or money changers in turn both reduced costs by decreasing necessary physical transfers of specie and also facilitated exchange between strangers. For nonlocal transactions, those at a distance, merchant networks dealing in bills of exchange fulfilled similar functions.

With the growth of banks in the more modern period, institutions developed to clear and settle bank liabilities, notes or deposits (i.e., checks), more efficiently. The Suffolk system both greatly reduced the need for physical transfers of cash and reduced risk, as evidenced in the elimination of discounts on New England banknotes. Local clearing houses similarly minimized physical cash transfers and offered timely final settlement for checks. Within the United States the development of correspondent bank networks focused on New York allowed settlement between distant banks to be accomplished simply through transfers of bankers' balances held

there rather than through large cash movements. In the twentieth century interbank settlement has increasingly been in terms of central bank money, providing finality, and accomplished through real-time gross settlement, free of systemic risk, rather than by net settlement at the end of the business day.

Acknowledgements I would particularly like to thank David Weiman for his thorough, penetrating, and most useful comments.

Abstract

Many influential cliometric studies have examined interest rates in order to assess the investment efficiency, the integration of markets, the economic effects of changes in policies or institutions, the sources of macroeconomic cycles, and so on. The common feature of this approach to economic history is that it is based on the crucial assumption that interest rates are the market prices at which demand meets supply. In this perspective, most debates focus on how to calculate yields or compare different rates of return on capital. Cliometricians developed innovative methods to construct yields and lending rates that were not specified in historical sources. It is only quite recently that economic historians have turned to cases where interest rates are not market-clearing prices. In such cases, there is little connection between interest rates and the state of the economy. Highlighting market imperfections, some recent studies have challenged earlier historical interpretations that overlooked the potential disconnection between prices

Interest rates · Internal rate of return · Market yields · Return to capital · Central banks · Institutions · Market integration · Financial history · Market clearing · Credit rationing · Government bonds

Introduction

"The problem of interest has engaged the attention of writers for two thousand years, and of economists since economics began."[1] The first sentence of the famous book, *The Rate of Interest*, published in 1907 by the economist Irving Fisher (1907), reminds us that the rate of interest is not a concept recently formalized and used by historians to examine past economic practices. Interest rates were mentioned, applied, registered, and negotiated from ancient to modern times (Homer and Sylla 2005). Their use and the debates that surrounded them involved religious, cultural, and legal considerations (usury law being the most noted example; see, e.g., Hoffman et al. 2000; Botticini and Eckstein 2012). So quantitative economic historians are not the only historians interested in interest rates. Then, what makes the "cliometric" contribution to the study of interest rates specific?

Cliometricians have looked at interest rates as a market price in order either to infer some information about individual, collective, or policy preferences or to directly assess the efficiency of the economy. The reasons cliometricians have looked at interest rates, and the way they did it, are indeed much in line with what Deirdre McCloskey (1978, p.15) said about the general development of cliometrics: "Not counting but economic theory, especially the theory of price, is the defining skill of cliometricians, as for other economists." In light of price theory, interest rates are typically examined as an indicator of the integration of markets, the rationality of actors, their expectations, or the confidence in a corporation, a polity, or a government. Some important contributions to economic history that will be presented in this survey used interest rates (either profit rates or market rates) and built on economic theory to challenge conventional history, claiming that the information previously gathered by historians was too scattered or subjective. In this perspective, the study of interest rates is seen as a means of inferring

[1]Due to space limitations, many important articles on the subject had to be left out. Therefore, this survey should not be seen as an attempt to fully discuss the most recent work on this issue. What I have tried to achieve is to present the widest possible variety of methods, to highlight the pioneering work of early cliometricians which have inspired many subsequent researchers, and to highlight and criticize the strong theoretical assumptions that were the basis for standard studies of interest rates by economic historians. Although an attempt has been made to paint a general picture of the work of cliometricians, this survey obviously reflects the author's biases and research interests.

coherent and valuable information from the market, and it is considered superior to alternative methods based on limited qualitative sources, which may suffer from undergoing selection bias (Conrad and Meyer 1958; North and Weingast 1989; Rappoport and White 1993; Willard et al. 1996).

Various theories have been used to interpret interest rates. Neoclassical growth theory views the interest rate as the price that equates investment and saving and enables a productive allocation of factors. In microeconomic theory with rational agents but asymmetric information, the equilibrium interest reflects information problems. In financial theory (with perfect or imperfect information), the interest contains information about expectations. Building on Keynesian theory, the interest rate is the price that equals the demand and supply for money. Counting is not a minor issue, however. The reliance on theory, beliefs in market mechanisms, and the quest for historical market prices pushed quantitative economic historians to compute market yields that were not specified in contracts and to construct returns on investment based on actual or expected earnings. This is done even when historians have no specific information on whether and how economic agents actually computed such returns. Thus, as recalled by Homer and Sylla (2005), many rates of interest used by quantitative economic historians were not nominal rates specified in contract. They are not interest rates that contemporaries saw as such. They are estimations based on assumptions. Many innovative methods were applied to calculate yields when there was no information on prices or interest rates (Conrad and Meyer 1958; Davis 1965; Sussman and Yafeh 2006). Such methods created – and still create – many debates on the potential limitations of such computations and their underlying assumptions. As we will see in this chapter, this generated many controversies between cliometricians. Using historical interest rates led to provocative and fruitful research, but, in some areas, little consensus has been reached on how to construct and interpret the level and movements of interest rates in light of price theory.

Much less debated in the cliometric literature have been cases where interest rates – found in historical archives or calculated ex post – cannot be used to infer information about behavior or markets, because rates were not market prices. The practice of usury rates in the early modern and modern period has received a lot of attention in the historical literature (Hoffman et al. 2000; Temin and Voth 2005; Botticini and Eckstein 2012). This tends to obscure the fact that usury laws still exist today in many countries (not only in those where a religious law prevails) and, more generally, that many interest rates have been determined by regulation, manipulated by market markers (governments or oligopolies), or that markets cleared through quantities rather than prices. One position would be to say that, given its methodological premises, the cliometric literature has nothing to learn from fixed, nonmarket-determined interest rates. A more nuanced view is that there is still much to be learned about the functioning of an economy if one understands why some interest rates were not market-clearing prices. It is also a way to challenge earlier historical interpretations that overlooked the potential disconnection between prices (interest rates) and quantities (Hoffman et al. 2000, 2019; Temin and Voth 2005; Monnet 2014).

The Rate of Return on Investment and the Production Function

A standard way to assess profitability, or yield, in finance is to calculate the internal rate of return. This is the rate at which the total present value of the investment cost equals the total present value of future earnings. In Keynes's terminology, the internal rate of return is called the marginal efficiency of capital. For investment to take place (or to be rational), this has to be higher than the interest rate, which is the rate of return on a safe asset which can be purchased easily (i.e., a market rate). In one of the first cliometric studies published in 1958, Conrad and Meyer (1958) calculated the rate of returns on slaves in order to assess whether slavery was a profitable activity. By reconstructing investment costs and earnings of a cotton plantation in the south of the USA, they found rates that were much higher than in other activities. The issues at stakes behind such calculations were enormous and were further developed in Fogel and Engerman's landmark work, *Time on the Cross* (1974). If slavery in antebellum America was a profitable activity, then it meant that economic forces alone would not have brought slavery to an end without the necessity of war and political change.

Conrad and Meyer's study offers a prominent example of the new methods and questions, as well as new controversies, that the quantitative "new" economic history (or cliometrics) brought to history. As explained by Fogel and Engerman (1974, p. 65 et al.), discussions on the profitability of slaves had been limited by the lack of sources on the matter before the study of Conrad and Meyer. Leaving aside the question of whether slave owners themselves were making profitability calculations, Conrad and Meyer decided that "the basic problems involved in determining profitability are analytically the same as those met in determining the returns from any other kind of capital investment." They moved away from the debate framed by the accounting concept of profitability and turned to a purely economic concept of profitability, based on theoretical reasoning rather than on historical accounting practices. They derived a rate of return from estimates of the cost (investment) of slaves and their lifetime earnings. Their approach was not limited to calculating the rate of return from the investment and revenues of a typical cotton plantation. They had to compare it to alternative interest rates in order to assess whether slavery was an "efficient business." Hence, they had to find alternative rates of interest (whether commercial paper or investment in other activities) and, most of all, justify that such markets existed and were accessible to slave owners.

The underlying argument of Conrad and Meyer is that if an investment turns out to be profitable (in theory) but is not realized, it is because social or political constraints have prevented this investment. Agents are assumed to be sensitive to market incentives, and interest rates are assumed to be the price at which supply and demand meet. Then, if slavery disappeared despite being profitable, it was because of political choices. The calculations and comparisons of rates of return were, for these authors, a way to understand the determinants of historical changes. In a totally different context but in a similar perspective, Jean-Laurent Rosenthal (1990) applied the same method to examine the economic consequences of the French revolution. He calculated the rate of return of irrigation (building a canal) in

Provence and found similar values before and after the Revolution, whereas the construction of a canal started only after 1789. From this comparison of hypothetical interest rates based on financial theory, he stated that canals were not built before the revolution because political institutions prevented the transfer of property rights.

In a follow-up to Conrad and Meyer's (1958) article, Sutch (1965) described the method of the previous authors as "reconstructing the production function" of the cotton plantation. It means that the authors had to use historical sources to come up with detailed estimates of the cost of investment, as well as lifetime earnings. However, the method of calculating internal rates of return does not require the specification of a full-fledged production function formalizing how factors are combined to produce output. On the contrary, other economic historians have relied explicitly on a neoclassical production function to shed light on the relationship between the rate of return and the factors of production. The objective was not to compute an internal rate of interest based on the present value of cash flows but to express the marginal rate of return on capital, based on a production function. The theory underlying the interpretation of interest rates is thus different, although the terminology is sometimes quite similar. A typical way to proceed in this way is to take a market interest rate as given and assume that it equals the marginal return on capital in order to infer some information about the factors in the production function. In an influential but controversial paper, Peter Temin (1966) used such a method to assess whether labor scarcity (and hence high-real wage compared to the UK) was prevalent in the nineteenth-century US economy. Temin observed that market interest rates (yields on government bonds) were higher in the USA than in the UK. From this observation, making the assumption that market forces should equate different interest rates within a country, he concluded that rates of return in American manufacturing were higher than in British manufacturing. Since the rate of return of a neoclassical production function is positively related to the labor-capital ratio, Temin concluded that labor was more abundant in the USA and capital scarcer. One key assumption of Temin's result was that technologies were similar in the USA and the UK, so that labor and capital were used in the same way to produce manufacturing goods. Even if one is ready to accept this assumption, Fogel (1967) and Drummond (1967) showed that a higher interest rate in the USA is still compatible with a lower labor to capital ratio in this country, if one consider different factor prices or include land in the production functions. In Fogel's words, there was a specification problem in Temin's work: a single empirical observation was compatible with several theories. Moreover, the implicit assumption that two countries have reached their steady state is debatable.

The method of Conrad and Meyer (1958) was to calculate the internal rate of return based on estimations of capital and labor used for production, and then to compare this return to a market interest rate in order to assess efficiency. Temin's method, on the contrary, was to use the neoclassical theory of economic growth to make a statement about the relative importance of production factors, based on the observation of empirical interest rates. While no method is perfect, since they all rely on a specific set of important assumptions, the second method is more prone to

a specification or identification problem (i.e., several theoretical formulations are consistent with one empirical observation), as underlined by Fogel.

Theoretical and Effective Interest Rates

Critics of Temin's article raised an interesting question as whether market interest rates on financial assets are good proxies for the return to capital in the standard neoclassical model. Many pieces of evidence point to large discrepancies between yields on financial assets and the rate to capital that may correspond to the standard neoclassical model (Mulligan 2002). For this reason, some authors dealing with macroeconomic historical questions, like Allen (2009) and Piketty (2014), have preferred to compute profit rates from wealth estimates rather than use market interest rates in order to interpret historical economic evolution in light of growth theory.

Dealing with a more recent period, Caselli and Feyrer (2007) calculate the profit rate (marginal product of capital) for a panel of countries based on estimates of total income and the capital stock. They explain that comparing market interest rates at the international level is not informative and problematic "because in financially repressed/distorted economies, interest rates on financial assets may be very poor proxies for the cost of capital actually borne by firms" (p. 536). Many economic historians had already warned us not to interpret historically observed (real) market rates as the rate of return on capital in neoclassical growth theory (Harley 1977). Moreover, Harley's contribution to the debates around the Gibson paradox in the nineteenth-century Britain (i.e., the unexpected correlation between interest rates and the price level, rather than the rate of inflation) recalled that the assumed positive relationship between nominal interest rates and the rate of inflation is not warranted. This cast doubts on the relationship that economists usually expect between nominal and real variables.

Barsky and Summers (1988) proposed to solve the Gibson paradox by claiming that during the gold standard, the real interest rate was in fact determined by the relative price of gold. Since the writings of Keynes, the Gibson paradox has been seen as a prominent example showing that taking for granted some standard assumptions of economic theory about interest rates may lead to biased interpretations. It has been argued instead that economic theory should not be taken as a basis for interpretation but should be refined to provide predictions that are consistent with the historical evolution of interest rates. More generally, there are many monetary, financial, or institutional factors that may explain the differences between the observed real rate of return on financial assets and the return to capital derived from a standard neoclassical production function in an environment of perfect capital mobility. Some recent estimates of return on real and financial assets show that they often substantially differ (Jorda et al. 2017). It is therefore an open question as to whether the rates of return on financial assets can be interpreted in the light of neoclassical growth theory, and it is fair to say that no consensus has been reached by economic historians on this issue.

In their standard history of interest rates, Homer and Sylla (2005, p. 10) acknowledged the lack of agreement on the matter: "It is not the purpose of this book to analyze the causes of interest-rate levels and trends. There is a vast literature on this subject but little area of agreement." Partly for this reason, we shall see in the next sections that much of the cliometric literature has not focused on explaining the level of long-term interest rates but has been interested in explaining the short- or medium-term variations of these rates (or differences in rates) with the aim of clarifying historical market characteristics or agents' reactions to political or economic changes. Building new theories to explain the historical evolution of interest rates in the long run has not been the main objective of cliometricians. Consistent with McCloskey's (1978) principles, they are more inclined to use available standard interest rate theories to shed light on historical episodes.

Market Interest Rates: Sources and Calculation Methods

At first sight, it may seem much easier to calculate a market interest rate than the internal rate of return or the marginal rate of capital. Computations of the internal rate of return and the profit rate rely on sometimes-crude estimates of the values of investment, future earnings, or production factors. On the contrary, the market gives us a direct estimate of the value of an asset at a given time. The current yield is simply equal to the investment's annual income (interest, coupon, or dividends) divided by the current price of the security, as quoted on the market. It would be wrong, however, to think that this computation is an easy task. All textbooks in investment finance contain endless pages on how to calculate yields, depending on the assumption that are made on whether the bond is held toward maturity, whether investment returns are compounded, etc. In their introduction, Homer and Sylla (2005) give key definitions and highlight important pitfalls in the calculus of market interest rates. Many economic historians have formulated similar reflections, including Klovland (1994) in an important paper about the yield on British consols in the nineteenth century. Since the interest rates used by historians are often yields on government bonds (the yield on British consols being a prominent example) because these assets were traded continuously for a long time, debates on the methods to calculate the yields have received a lot of attention in the literature, and the pitfalls should be known to users. A conceptual clarification is first necessary. A distinction has to be made between what Homer and Sylla call the "nominal interest rate," which is the rate specified in the loan contract (the interest expressed as a percentage of the nominal, face, or par value of the loan), and the "market yield," which is the rate of return to the buyer at the market price. It is impossible to enter here into all details and pitfalls of the calculation of yield. However, it is enough to emphasize just how sensitive yield calculations are to the seemingly minor institutional details of price quotation and to assumptions about the date of redemption of the bonds (Klovland 1994).

The computation of average market yields relies on a chosen set of bonds. Issues of averaging and the choice of relevant bonds arise, creating considerable discussions for both market investors and historians (Homer and Sylla 2005).

Short-term interest rates on government bills do not face the same issues of redemption as do long-term interest rates. However, there are still issues regarding the choice of the quoted purchase price of the bill as well as the best method to calculate the yield. We have mentioned earlier formulas to calculate yields on long-term bonds that offer a coupon, but many short-term bills do not. Such bills, like the US treasury bills, are issued at a discount from par value. For such cases it is debatable whether to use the discount yield formula [((par value – purchase price)/par value) ∗ 360/days to maturity)] or the investment yield method [((par value – purchase price)/purchase price) ∗ 360/days to maturity)]. For all these methods to be reliable, the market needs to be sufficiently liquid for prices to be quoted with regular frequency. This is why we have so few long-run yield series. The exceptions are government securities in major countries with a stable government and well-developed financial markets since the nineteenth century. Thus, the available long-term series of interest rates on financial assets have a strong selection bias (Homer and Sylla 2005; Jorda et al. 2017): they exist only when financial markets were sufficiently developed and liquid. Little is known about lending practices and contracts in less developed markets.

Money market (interbank) rates are another type of animal. Since the interbank market is an over-the-counter market, there is no quoted price. The rates at which funds were borrowed are known from declarations of market participants, as for the LIBOR (London Interbank Offered Rate) today. For historians using such rates, it is not always easy to identify the types of assets that were traded on the market and the actors involved. For example, the widely used interest rates published by the British newspaper, *The Economist*, in the nineteenth century, were limited to a premium market whose conditions were presumably different from most credit conditions in the country (Bazot et al. 2016). The recent dataset of Mitchener and Weidenmier (2015) reminds us that short-term interest rates (either government bills or interbank markets) are available for few countries in the late nineteenth century, despite the period being quite integrated with developed capital markets worldwide. For lack of a better alternative, the discount rate of the central bank is often used as the best proxy for short-term interest rates, but this is hardly a market price. Few sources provide a call money or a repo rate.

Long-term series of bank lending (or deposit) rates do not exist. This is simply because very few countries had banking regulation before the interwar period, so that no central authority collected and registered the interest rates applied by banks. Banks themselves did not make public a series of their average interest rates. Even in the USA – which is a notable exception because banking regulation existed as early as the nineteenth century, meaning that banks had to send their balance sheets to the regulator – such data do not exist before the second half of the twentieth century. Yet, armed with unique bank balance sheet data that have no equivalent anywhere in the world, US scholars have been able to compute proxies of interest rates for the postbellum era by dividing bank earnings by their stock of earning assets (Davis 1965). In other countries, such as England, estimates of bank lending rates have often been based on few case studies (see Temin and Voth 2005 for a review).

Market Integration and Market Risk: Differences Between Rates in Several Areas

Collecting and estimating interest rates is not an easy task. But this hard work often generated landmark studies that shed a new light on historical debates. An influential study in this area was the article by Lance Davis (1965), which estimated regional interest rates for the USA from 1870 to 1914 and showed a striking and persistent divergence between these rates until the war. The evidence of such low integration in US capital markets led to countless studies trying to understand why it was the case and how growth could occur despite low integration (see Landon-Lane and Rockoff 2007 for a review).

Many authors have looked at interest rates differentials in order to study the integration of national or international capital markets. At the international level, spreads between market interest rates (when available) or estimations of profit rates (marginal return to capital) have also been used as a measurement of financial integration and its evolution over time (e.g. Obstfeld and Taylor 2004; Flandreau et al. 2009; Caselli and Feyrer 2007).

One problem with comparing interest rates or average returns between different geographical areas is that it is not always possible to compare interest rates on assets with the same risk, as Eichengreen (1984) showed in his study of mortgage lending in the USA. And when this is possible, it is not always enough to assess financial integration. McCloskey (1970) underlies the fact that British rates on safe bonds (railway or government) were close to rates abroad with the same risk, but overall, the average rate of return perceived by British investors on British assets in 1911–1913 was twice as high as the return on capital abroad. McCloskey recalls that contemporaries had already noted such discrepancy and had not interpreted it as the result of a bias toward safer assets abroad but as a deliberate policy of the financiers of the City of London to favor foreign capital and maintain high rates in the country. She quotes J.M Keynes writing that the effect London's investment policy was "to starve home developments by diverting savings abroad and, consequently, to burden home borrowers with a higher rate of interest than they would need to pay otherwise" (McCloskey 1970, p. 452). McCloskey assumes that the maximum spread between foreign and domestic rates of return could be a measure of market imperfection created by the City of London. She calculates whether, in this case, British national income could have been much higher without such an imperfection. She finds that, had imperfections been smaller, the growth of British national income would not have been much higher. Thus, she refuted the argument that slow growth in Britain during the Victorian era could be attributed to the outflows of capital to other countries.

Besides assessing whether capital markets were efficient and estimating the degree of integration, differences between interest rates of several countries have also been used to discuss the autonomy of domestic monetary policy relative to the world. Full integration of international financial markets would mean that countries have no ability to set their interest rates independently from others. As is the case with regional interest rates, there were in fact differences in worldwide interest rates,

either because of voluntary or involuntary capital market imperfections. Economic historians are interested in understanding what these differences reveal about the geopolitics of finance. Morys (2013) showed that the discount rates of central banks in Eastern Europe under the gold standard were influenced by discount rates in Berlin and London to a similar degree. This finding suggests that the functioning of the gold standard was less London-centered than had been hitherto assumed and that Germany was the policy reference for most countries in the "periphery." Obstfeld and Taylor (2004) interpreted the spreads between the domestic interest rates and an index of several leading international rates as a measure of the constraint of international finance (the "trilemma"). A high spread is evidence of higher autonomy. They looked at how this autonomy varied over time and depended on the international monetary regime.

An influential study by Bordo and Rockoff (1996) looked at the spread between the domestic long-term interest rate in several countries and the British rate during the gold standard. They showed that gold standard adherence lowered the spread between domestic and British rates, and they interpreted this finding as evidence that the gold standard was a signal of financial rectitude, a "good housekeeping seal of approval," that facilitated access by peripheral countries to capital from the core countries of Western Europe. A large literature followed from this article (enlarging the sample of countries and using different definitions of interest rates) whose common point has been to discuss the potential benefits of gold standard adherence by looking at spreads between the domestic interest rate and the leading international rate (see Alquist and Chabot 2011; Mitchener and Weidenmier 2015; Chavaz and Flandreau 2017 for recent additions and a literature review). Bordo and Rockoff's argument was international in nature but was influenced by neo-institutionalist theory that discussed how a change in institutional settings (the gold standard in this case) affected the cost of government borrowing by creating a credible commitment to financial and fiscal rectitude ("good housekeeping seal of approval" in this case). The landmark paper in this literature was North and Weingast (1989), to which we now turn our attention.

Interest Rates and Political Regimes

In a controversial and groundbreaking paper, North and Weingast (1989) famously claimed that the new institutional setting arising from the 1688 revolution in England allowed the government to commit credibly to upholding property rights and that this made the financing of the public debt cheaper and contributed to the development of private markets as well. They used interest rates (on public debt) as a way to assess the influence of institutions on the government's ability to borrow and to discuss the benefit of institutional reforms.

Few historians still accept the conclusions of North and Weingast (Coffman et al. 2013), but the paper remains influential in shaping a new approach to examining interest rates and interpreting them in the light of neo-institutional theory. The North and Weingast thesis was attacked for many reasons. Some argued that there was no

evidence that the 1688 revolution guaranteed property rights and that it was mainly because of the parallel development of financial markets that sovereign debt became a safe and liquid investment vehicle with a low interest rate (Coffman et al. 2013). Others went on to build new interest rate series to challenge North and Weingast's conclusions about a decline in government bond yields after the 1688 revolution (Sussman and Yafeh 2006).

There was no high frequency listed price of government bonds for this period, so the estimates rely on fragmentary data. To overcome this limitation, Sussman and Yafeh (2006) calculated the cost of British government debt as the ratio of debt service payments to total government debt (dividing government debt service expenditures by a series of the stock of total debt). They found that the interest rate on British debt remained high for several decades after the 1688 revolution, especially in relation to the Dutch interest rate. Based on various sources from private financial institutions, several other authors have also found no change in interest rates after the revolution (see Temin and Voth 2005; Coffman et al. 2013 for a review).

Not all economic historians share the neo-institutionalist perspective of North and Weingast on the link between the cost of sovereign debt and the "quality" of institutions. But it has become a common practice to look at changes in interest rates to interpret the effects of political events. Willard et al. (1996) look at the Greenback market during the US Civil War and use econometric techniques to identify breaks in the price. The USA issued an inconvertible currency called the Greenback starting in 1862. Its value in gold fluctuated over time, reflecting the expectation of future war costs. The authors use data on the gold price of Greenbacks and compare the reactions of participants in financial markets to significant military events during the Civil War. Their findings highlight the importance of some events (especially expectations of victories and end of the war) that had not been viewed as crucial by historians, but seemed to have created major changes in the expectations of contemporaries.

Ferguson (2006) studied the behavior of interest rates of long-term bonds quoted in London between 1848 and 1914 and found that political events had a much smaller effect on the bond market after 1880. He interpreted this result as the consequence of the deepening of national and international financial markets in the late nineteenth century. Most of all, he showed that the outbreak of the First World War was not anticipated by the market. He used this result to challenge the traditional view, which tended to over-determine the beginning of the war.

In a similar vein, Hautcoeur and Sicsic (1999) examined the interest rate of French and foreign bonds in interwar France to shed new light on the monetary unrest and political troubles of this period. They showed that two types of information can be extracted from interest rates: expectations of taxation (a capital levy should lead to a drop in the price of taxed capital assets) and expectations of a devaluation (through the price of long-term bonds whose coupons were indexed on the pound/franc exchange rate). Expanding the work of Klovland (1994), they also emphasize the role of the political context and the importance of assumptions on the risk of redemption and conversion to provide meaningful calculus of the interest rate on perpetual bonds.

These three papers made different uses of interest rate series and discussed in a different way the potential limitations of the calculus of interest rates, but they shared the premise that expectations of major political events are reflected in market prices. Looking at interest rates in this way is a novel method of assessing what contemporaries really thought about the likelihood and importance of political events. This method is more precise than looking at other sources – such as the press or parliamentary debates – which are difficult to exploit in a comprehensive way. Since the interpretation relies crucially on the assumption of efficient markets, the articles quoted above devoted a lot of attention to justify that the market they were looking at was efficient, in the sense that they were liquid and without barriers to entry.

Interest Rates, Financial, and Macroeconomic Cycles

The link between politics and interest rates has not just been studied through the lens of institutions and expectations. The interest rate is a key variable in any macroeconomic model and, as such, deserves attention to understand macroeconomic fluctuations and their mechanisms. It is standard for macroeconomists to look at whether interest rates respond to economic shocks in a way which is consistent with theory and to model monetary shocks as an increase in the interest rate. These common questions and methods have been applied to historical data to inform both economic modeling and our understanding of the past. Robert Barro (1987) studied the response of interest rates to changes in government spending in the nineteenth-century England. His main motivation was to test for Ricardian equivalence, which predicts that an increase in public debt will be matched by a higher present value of future taxes, and thereby has no effect on desired national saving or interest rates. Barro's results show that interest rates rose after increases in spending only during wars, but not during the few episodes where budget deficits were caused by other reasons (compensation payments to slave owners in 1835–1836 and political disputes over the income tax in 1909–1910). During the gold standard, there was no relationship between monetary growth and changes in government spending.

Economic historians have also used the econometric methods of macroeconomists and references to theory to study the impact of central bank decisions on the economy ("monetary policy shocks"). Monnet (2014), Bazot et al. (2016), and Lennard (2017), for example, applied standard VAR (vector autoregressions) to assess the impact of changes in the central bank discount rate during periods whose institutional features of central banking were very different from what we know today. One advantage of these methods is to provide an estimation of the share of variance of main macroeconomic or financial variables, which is explained by changes in the discount rate of the central bank.

The use of recent econometric techniques has helped economists and economic historians to better understand the channels of transmission of main fluctuations and to assess the importance and impact of policy choices in these

fluctuations. Although short- or medium-term macroeconomic cycles have attracted much attention, seasonal variations have not been left aside. As with many variables reflecting economic activity, interest rates are often seasonal. Seasonality was particularly strong when agriculture accounted for a large share of national income and credit increased during the storage period of crops. This well-known pattern has been the topic of numerous studies (Homer and Sylla 2005). It was also recognized by contemporaries and, in some cases, generated policy interventions of governments or central banks, whose objective was to smooth and harmonize rates within a country (Miron 1986; Bazot et al. 2016). Miron (1986) shows that the size of the seasonal movements in nominal interest rates declined substantially after the US central bank – the Federal Reserve System – was established during the First World War. The Fed conducted seasonal open market policy to eliminate the seasonality in interest rates. These Fed operations not only mitigated the seasonality in interest rates but also the frequency of financial panics, which were themselves partly caused by the seasonality of interest rates. Bazot et al. (2016) pointed out that the Bank of France – the French central bank – was smoothing seasonal fluctuations in the interbank market. In addition, they provided evidence that central bank interventions were partly absorbing the effects of international financial shocks on the French money market rate.

The link between interest rates and financial panics has also been the topic of considerable interest. One key question is whether cheap credit or loose credit conditions – reflected in interest rates – caused a financial bubble and then a crash. In a paper entitled "Was There a Bubble in the 1929 Stock Market?", Rappoport and White (1993) used interest rates as a test to answer this question. They look at interest rates for brokers' loans, which investors used to fund stock purchases. During the 1928–1929 stock market boom, lenders required a large premium in this market (over other money market rates) because they thought that stock prices might collapse during the term of a loan and jeopardize the collateral. They interpret this finding as evidence of a bubble in the stock market at this time, which was in fact expected by some market investors.

At first sight, the studies on interest rates and the macroeconomy may seem somewhat more agnostic about the efficiency of financial markets than the studies which merely aim to extract relevant information from market prices. Yet, the macroeconomic studies still assume that interest rates are prices that clear markets and, thus, that they reflect changes in demand and supply. When they do not share the neoclassical view of interest rates as the price that equals savings and investment, they at least subscribe to Keynesian principles that interest rates reflect demand and supply for liquidity. Such an assumption is usually made about the central bank leading interest rate, so that the central bank would move the quantities necessary to reach the target rate, and agents would adjust their behavior to that rate. These assumptions may be valid in some contexts, but certainly not at anytime and anywhere. Thus, to avoid unduly narrowing their field of study, economic historians have had to deal with situations where interest rates provide little information on the functioning of the economy. The last part of the survey is devoted to research in this area.

When Interest Rates Do Not Clear Markets

Hoffman et al. (2000) chose a highly revealing title for their groundbreaking study of private credit markets in Paris over two centuries (the mid-seventeenth to mid-nineteenth centuries): *priceless markets*. The title follows from the finding that client-specific information – and thus quantity rationing – was far more important than price in clearing the credit market. Interest rates did little to allocate capital or inform participants in the credit market. Such findings were based on a wide sample of private and public loan contracts taken from Parisian notarial records. The study was then extended at the national level in Hoffman et al. (2019). Notaries were the most important financial intermediaries during this period. Loans were usually granted at a rather similar rate, whatever the maturity and the risk. But willingness to lend and non-price conditions of the loans reflected characteristics of the borrowers. Although usury laws (until the French revolution) and later on interest rate regulations were an incentive to keep stable interest rates, the authors argue that the practices of notaries and the informational structure of the market mainly explain the insignificance of interest rates. This conclusion about the unimportance of interest rates for financial markets was based on microeconomic evidence and a detailed study of the market infrastructure and bears important consequences for macroeconomic or political economy analyses. It means that we only observe a stable interest rate, from which it is impossible to infer information about demand and supply. Hence, there is no single average interest rate that could be interpreted as the price of capital in the economy, and there is no interest rate differential that could be interpreted as evidence of borrower selection or imperfect capital integration. Was there a price – any other interest rate – to which we can relate the amounts of credit observed on the Parisian credit market? Could we say, for example, that notarized loans were not offset by interest rates, but that a market interest rate from other financial transactions was nevertheless a good indicator of credit conditions in the private credit market mediated by notaries? The authors say no. They examined the available short-term and long-term government bond yields over this period and concluded that "it is remarkable how little a connection there was between interest rates and the state of the economy" and "following the variations of either the long or short-term interest rate series is thus unlikely to tell us much about the scarcity of credit except when the scarcity is driven by politics" (Hoffman et al. 2000, p. 43).

The unimportance of interest rates was not specific to French notaries. Temin and Voth (2005) challenge the premise of the debate that followed North and Weingast (1989) (see supra) by claiming that interest rates in the seventeenth- and eighteenth-century England were not indicative of credit conditions. Not only did Temin and Voth (2005) address the debate on the cost of financing after the 1688 revolution but they also joined in the discussion of crowding out during the British Industrial Revolution. A common explanation for slow growth during the eighteenth and nineteenth centuries is that wartime financing crowded out private investment, which should have translated into higher interest rates in wartime. Temin and Voth (2005) first review the work of previous scholars and conclude that, in both debates (effects of the 1688 institutional change and crowding out), evidence based on

interest rates has been scarce and contradictory. According to them, using interest rates to solve these debates is illusory because "private-sector interest rates are not the right indicator of scarcity in the case of 18th-century finance – for both practical and conceptual reasons. In contrast to good markets, where price is an efficient way of allocating scarce goods, credit markets rarely reach equilibrium through changes in interest rates alone" (Temin and Voth 2005, p. 326). Rationing occurred because of usury laws and because of asymmetric information, which pushed financial intermediaries to discriminate by means other than interest rates. Borrowers willing to pay very high interest rates were inherently bad risks, so banks needed to find other margins on which to allocate credit. Based on the analysis of one English bank (Hoare's bank) whose balance sheets and archives have been kept, the authors show that 92% of all loans were made against interest at the usury limit. In such conditions, a negative shock to the private credit market (such as the issuance of government debt, which reduced bank deposits and the ability of banks to lend) was not reflected in higher interest rates.

Nonmarket-clearing interest rates are not specific to usury laws of early modern Europe. It has been typical of government interventions to attempt to smooth fluctuations of interest rates and maintain them at a low and stable level. This can be accomplished either by regulation or financial markets interventions that manipulate the level of market interest rates. Such policies can achieve several objectives, such as providing a low cost of financing for the government (Reinhart and Sbrancia 2015), harmonizing interest rates across the country, allowing individuals to borrow at cheap rates, or protecting savings against inflation. The central bank is likely to play an important role in maintaining low and stable interest rates in a way that differs from what would have been the market outcome (Miron 1986; Bazot et al. 2016).

In economies with high financial regulation and capital controls – which have been widespread throughout the twentieth century, including in non-Communist countries (Reinhart and Sbrancia 2015) – the central bank typically maintains stable interest rates and use quantitative rationing (credit controls, reserve requirements, etc.) to fight inflation. Studying monetary policy in postwar France (1945–1973), Monnet (2014) showed that the discount rate of the central bank provides a misleading indicator of the stance of monetary policy. The French central bank did not move interest rates. Rather, they usually relied on credit ceilings (limits on bank credit growth) to limit credit creation and curb inflation. Such central banking practices took place in a planned economy with segmented credit markets where many sectors benefited from subsidized loans, such that interest rates were not market-clearing prices. It was also consistent with the objective of the government to maintain low and stable interest rates. The use of quantitative credit controls led to a disconnection between the level of interest rates and the overall monetary policy stance (or credit conditions).

Since many interest rates were regulated and credit markets were segmented, a tight credit policy did not lead to higher market interest rates. Hence, looking at interest to assess the impact of monetary policy leads to a mismeasurement of the policy stance and misleading results. Acknowledging such central bank strategies is also crucial to interpret gaps between interest rates at the international level. Central

banks could assign the interest rate to the external side while managing domestic credit expansion with direct quantitative controls. As a result, a low spread between national interest rates cannot be interpreted as a lack of autonomy of monetary policy (Monnet 2018). The method of Obstfeld and Taylor (2004), which looks at interest rate differentials across countries to assess the autonomy of domestic policy, is only valid when the interest rate is the main policy instrument on the domestic side. There is much historical evidence that over the long run this was not always the norm, especially outside of the UK and the USA.

The various studies mentioned in this section criticize the common use of interest rates by economic historians. They point out that either because of imperfect information, government policies, or institutional rules and norms, interest rates were rarely revealing anything other than market imperfections. They were not a market-clearing price. If this is the case, interest rates cannot be used to assess the market integration, the autonomy of domestic policy, the impact of institutional reforms, etc. Earlier, I quoted the work of economists (Caselli and Feyrer 2007) who decided to estimate the marginal return to capital in order to assess the efficiency of capital allocation at the international level, because market interest rates were deemed imperfect indicators of actual credit conditions. "Because in financially repressed/distorted economies, interest rates on financial assets may be very poor proxies for the cost of capital actually borne by firms" (Caselli and Feyrer 2007, p. 536).

What economic history has recently shown is that repression and financial distortions were indeed so prevalent in the past – and still are today in many countries – that one should be very cautious in drawing conclusions about market returns or interest rates set by financial intermediaries, governments, or central banks. However, these conclusions are not all negative. Assessing the unimportance of interest rates provides important historical information on how markets functioned and how government interventions took place in the past. It also pushes researchers to develop innovative ways of circumventing the absence of significant changes in interest rates. However, since it is no longer possible to infer market information from a single price, researchers must look for data on quantities. Such work is often much more data intensive and time consuming (Hoffman et al. 2000, 2019; Temin and Voth 2005; Monnet 2014).

Conclusion

From Conrad and Meyer's (1958) study on the rate of return of slaves, to Davis (1965) on the integration of financial markets in the USA, to North and Weingast (1989) on the 1688 revolution in England, interest rates have been central to some of the most influential cliometric studies. As McCloskey (1978) points out, the theory of price was the defining skill of early cliometricians. The interpretation of historical interest rates on the basis of standard price theory has been a constituent element of cliometrics. This method was widely and provocatively applied in order to attack traditional history, arguing that the sources of earlier work had been too scattered and

biased to provide sound economic conclusions. Considering the interest rate as a market price was one way to draw more rigorous conclusions from sometimes-Spartan historical sources. Since cliometric studies were – and still are, to a large extent – focused on the UK and the USA in the modern period, the assumptions underlying standard price theory were often seen as valid. The yield on British consols has probably been the most observed series of interest rates in history and epitomizes what is a market price in well-developed financial markets.

Cliometric studies of the rate of interest have not been without criticism. Questions were raised about the most relevant interest rate to consider, how to calculate yields on financial assets, and how to relate observed prices to the neoclassical theory of growth, which Fogel (1967) saw as a prime example of the specification problem in economic history. It is only quite recently that some studies have begun to discuss nonmarket-clearing interest rates and incorporate them into a quantitative perspective of economic history. The common feature of these various studies is that they declare that some significant historical interest rates cannot be interpreted as market prices. It is therefore not possible to obtain precise information on preferences, demand, and supply from interest rates. Therefore, it is necessary to go beyond interest rates and accumulate data and information on quantities, since markets did not clear through prices. Some of these studies directly question the earlier results of cliometricians, such as the possibility of assessing the impact of institutional changes on financial markets (Temin and Voth 2005) or of measuring monetary policy autonomy by examining the gap between national and international rates (Monnet 2018). Yet their main message is not to get rid of price theory and interest rates in economic history. Some interest rates were undoubtedly market prices that can be considered as such, but, in the end, they could be exceptions rather than a rule. Looking at how interest rates were set by private actors and governments out of the market – and what were the economic effects of such manipulation – is an area of further research.

Abstract

This chapter describes and explains the course of aggregate real activity and inflation in America from 1929 through 1937–1938 within the theoretical framework of "new Keynesian" models with "financial market frictions." Those models point to plausible causes for the initial downturn, the depth of the subsequent decline in real activity, and the path of inflation and real wages over 1929–1933. One key factor was Federal Reserve interest-rate policy as constrained by the "zero bound" on nominal interest rates and adherence to the international gold standard. Another was the development of a massive financial crisis in which the Federal Reserve System failed to act as lender of last resort, mainly because Fed policymakers did not believe a lender of last resort was needed. The course of the economy after 1933 presents some open questions, especially about the extremely high inflation rates observed over 1934–1937 and causes of the second downturn in 1937–1938.

Keywords

Great depression · Business cycles · New keynesian models

Introduction

In the United States, most people use the term "Great Depression" to refer to a long stretch of depressed real activity that began in late 1929 and did not end until after the outbreak of the Second World War. Figure 1 plots estimates of real GDP and unemployment over 1928–1939 (annual) along with the Federal Reserve Board's index of industrial production (monthly). Vertical lines mark business cycle turning points (NBER chronology). The Depression began with a downturn from a cyclical peak in August 1929 to a trough in March 1933. A brisk expansion followed, but before employment and output had recovered to their pre-1929 trends, there was another downturn, from a peak in May 1937 to a trough in June 1938. These were two distinct business cycles and appeared as such to contemporaries. They referred to the first as "the Depression" and to the second as "the Recession." But in American historical memory, the two cycles together constitute one big slump. In the historical memory of economists, such as it is, the American Great Depression is a case study in bad monetary and fiscal policy. Economists of our day often blame the Depression mainly on decisions of policymakers in the Federal Reserve System. In 2002, Ben Bernanke, then a Federal Reserve Board Governor, half-jokingly took responsibility for the Great Depression on the part of the Federal Reserve System: "we did it. We're very sorry...but we won't do it again" (Bernanke 2002).

In this chapter I review economic literature on the Great Depression to explain the course of aggregate real activity and inflation in the United States from 1929 through the beginning of the 1937–1938 recession. There are many excellent short overviews of the Great Depression in the United States (e.g., Romer 1993; Temin 2000). This one is different in that it is specifically directed at readers who are new to economic history but well-acquainted with current macroeconomic theory, especially "new

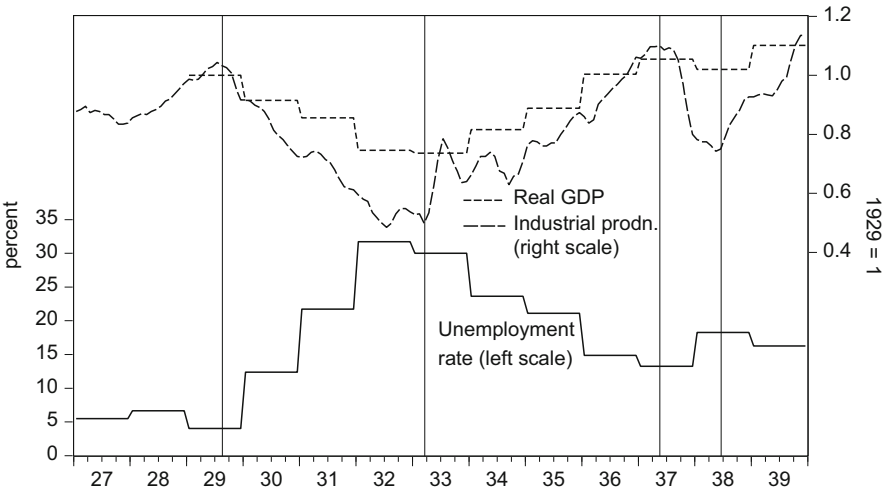

Fig. 1 Unemployment rate and industrial production index 1927–1939, real GDP 1929–1939. (Sources and notes: real GDP from United States Bureau of Economic Analysis (https://www.bea.gov/iTable/index_regional.cfm). Federal Reserve Board index of industrial production (seasonally adjusted) from Federal Reserve Bank of St. Louis (https://fred.stlouisfed.org/series/INDPRO). Private nonfarm unemployment rate from Weir 1992, Table D3. The household surveys that underlie postwar unemployment rate series were not taken in the 1920–1930s. Weir estimates annual employment from a variety of sources and defines the unemployment rate in ratio to an estimate of the "usual labor force" constructed from Census data. Weir excludes agriculture, government, and relief workers from both the employment and labor force figures. Weir excludes agriculture because, absent survey data, there is no reliable way to estimate short-term variations in agricultural employment (since so much farm labor is family labor). By excluding government workers, Weir sidesteps a debate as to whether the large numbers of Federal relief workers in the 1930s should be classified as employed or unemployed)

Keynesian" models with financial market "imperfections" or "frictions." In those models, the channel from monetary policy and financial market conditions to real activity runs through the economy's default-free real interest and/or the spread between the interest rate and the cost of borrowing to "credit-constrained" (or "liquidity-constrained") agents. I argue that it is easy to explain the 1929–1933 Depression in terms of such models. They point to plausible reasons for the beginning of the downturn and the depth of the subsequent decline in real activity. One key factor was Federal Reserve interest-rate policy, as constrained by the "zero bound" on nominal interest rates and America's adherence to the international gold standard. Another was the development of a massive financial crisis in which the Federal Reserve System failed to act as lender of last resort. New Keynesian models also account for the course of wage inflation, price inflation, and real wages over 1929–1933. About the 1933–1936 recovery and the 1937–1938 recession, the models define some puzzles and open questions.

There have been attempts to account for the Depression using "real business cycle" (RBC) models, as the result of an exogenous negative shock to production technology or unusual institutional developments over 1929–1933 that widened the

"wedge" between the marginal disutility of labor and the cost of labor to firms. I ignore these because economic historians have found no evidence for either phenomenon.[1]

With more misgiving, I also ignore monetarist explanations of the Great Depression, though monetarism frames many of the best studies of the Depression starting with Friedman and Schwartz (1963). In monetarist theory, fluctuations in aggregate demand affect real activity and inflation much as in Keynesian theory. But the key variable determining aggregate demand is not interest rates and borrowing costs as in Keynesian models. It is rather the "money supply": the quantity of currency held by the public *plus* checkable deposits *plus* any other similarly liquid assets. Monetary policy and financial market conditions affect aggregate demand through changes in this money supply (Woodford 2010, pp. 22–23). Keynesian economists complain that monetarists generally, and Friedman and Schwartz (1963) particularly, never laid out exactly what they had in mind as the transmission mechanism from the money supply to aggregate demand (Bordo and Schwartz 2004; Romer and Romer 2013).[2]

In the first section of this chapter, I review key elements of new Keynesian macroeconomic models and also models that describe the nitty-gritty mechanics

[1]Cole and Ohanian (2007) observe that conventionally measured aggregate total factor productivity fell a lot from 1929 to 1933. They argue this may represent an exogenous shock and can account for over half of the 1929–1933 decline in real GDP. Ohanian (2001, p. 37) speculates this TFP decline was due to "a decrease in organizational capital, the knowledge and know-how firms use to organize production...There are a number of reasons why this large stock of capital could have fallen, including breakdowns in relationships with suppliers that lead to changes in production plans, and breakdowns in customer relationships that lead to changes in marketing, distribution, and inventory plans." Studies that account for variations in labor and capital utilization find little or no decline in productivity over 1929–1933 (Inklaar et al. 2011, Watanabe 2016). Across the entire 1929–1939 decade, average productivity growth was remarkably rapid for reasons clearly related to the introduction and diffusion of new technologies (Field, 2011). On the labor wedge, Ohanian (2009) argues that Hoover administration policies prevented large industrial employers from cutting nominal wages after 1929. Thus price deflation, due to a drop in nominal aggregate demand, raised real manufacturing wages in a practically exogenous and historically unique way. In fact, as I will argue below, there was nothing at all unusual about the behavior of nominal wages over 1929–1933; manufacturing wages fell just as one would predict from the usual "Phillips curve" relationship. Rose (2010) looks for evidence that Hoover's policies affected the timing or magnitude of wage cuts. He finds none.

[2]Some authors (e.g., Bordo et al. 2000; Christiano et al. 2005) attempt to represent monetarist views within a new Keynesian model. In these models the interest rate that governs aggregate demand is indirectly determined by the quantity of a variable called "money" that is directly controlled by a central bank. The interest rate is related to "money" because "money" pays no interest, and the ratio of money to the price level is an argument of the representative agent's utility function. Bringing the model to data, the authors match the model's "money" to monetary aggregate statistics such as M1, which correspond (at least roughly) to the monetarist notion of the money supply. That does not do justice to the data: most assets within M1 pay interest at market-determined rates. It does not do justice to monetarists: they never argued that the money supply affected aggregate demand only (or even primarily) through interest rates on financial assets (Bordo and Schwartz 2004). And it gives a misleading notion of the way a central bank controls interest rates.

of interest-rate control by a central bank ("monetary policy implementation"). The latter are probably unfamiliar to the reader, but they are needed to understand the nature of the zero bound constraint in the Depression. In the second section, I describe peculiar institutional features of the American financial system in the 1920s, a necessary background for understanding the Depression. In the third section, I describe, narrate, and explain the 1929–1933 Depression. In the fourth I cover the 1933–1936 recovery. In the final section, I briefly discuss the 1937–1938 recession.

Theoretical Background

New Keynesian Macroeconomic Models

Consider a closed-economy "New Keynesian IS/LM" model of the simplest kind (e.g., King 2000) in which price adjustment is subject to a Rotemberg (1982) or Calvo (1983) constraint and all agents can borrow and lend at the same default-free interest rate per period. Let x^edenote today's expected value for a future variable x. The new Keynesian IS and AS ("new Keynesian Phillips curve") equations are:

$$y_t = y^e_{t+1} - \alpha r_t + \epsilon_{1t} \tag{1}$$

$$\pi_t = \delta \pi^e_{t+1} + \gamma y_t \quad \text{where} \quad 0 < \delta < 1 \tag{2}$$

where y is the "output gap," here defined as the difference between aggregate output and "flex-price equilibrium" output in the long-run steady state. ϵ_1 describes effects of temporary disturbances to preference parameters or government purchases of output. r is the spread between the short-term (one-period) real interest rate and the long-run "natural rate of interest" (the rate at which $y = y^e{}_{+1} = 0$ when $\epsilon_1 = 0$).

The model is closed with a mechanism representing the monetary regime that determines r subject to a lower bound on the nominal interest rate usually assumed to be zero – hence the "zero bound." The mechanism (usually an interest rate rule or a loss function minimized by a central bank as in Clarida et al. [1999]) must ensure the existence of a unique long-run steady state with $\pi^e = 0$. Generally:

$$y_t = \sum_{\tau=0}^{\infty} \left[-\alpha r^e_{t+\tau} + \epsilon^e_{1t+\tau} \right] \tag{3}$$

The output gap depends on the path of expected values of the short-term real interest rate from the present through the distant future. Meanwhile inflation depends on expected values of the output gap over the same horizon:

$$\pi_t = \gamma \sum_{\tau=0}^{\infty} \delta^\tau y^e_{t+\tau} \tag{4}$$

In standard models expectations are fully rational, but a weaker condition, the "law of iterated expectations," is actually sufficient for (3) and (4) (Adam and Padula 2011).

Many studies find that, in reality, expected values of future output (e.g., real GDP) generated by the most sophisticated forecasting methods are usually quite close to simple autoregressive forecasts (literature surveyed by Chauvet and Potter 2013). Thus, it is realistic to assume that the public's expected values for future output are close to AR(1) forecasts except under special circumstances. Describe the public's expected value of the output gap in a future period $t + \tau$ as:

$$y^{e}{}_{t+\tau} = \rho^{\tau} y_t + z^{e}{}_{t+\tau} \tag{5}$$

where ρ is the serial correlation coefficient from an AR(1) estimate. $z^{e}_{t+\tau}$ summarizes effects of unusual events that cause the public's forecast for $y^{e}_{t+\tau}$ to differ from the AR(1) forecast. Most of the time, $z^{e}_{t+\tau}$ must be small relative to fluctuations in y – otherwise AR forecasts would not work as well as they do. Together with (5), (3) and (4) give:

$$y_t = -\frac{\alpha}{1-\rho} r_t + \epsilon_{2t} \quad \text{where} \quad \epsilon_{2t} = \frac{1}{1-\rho}\left[\epsilon_{1t} + z^{e}_{t+1}\right] \tag{6}$$

$$\pi_t = \gamma \frac{1}{1-\delta\rho} y_t + \gamma \sum_{\tau=1}^{\infty} \delta^{\tau} z^{e}_{t+\tau} \tag{7}$$

Exogenous increases in the real interest rate should be associated with decreases in real activity. Decreases in real activity should be associated with declines in inflation. Unusual events that cause expectations of future real activity to deviate from their usual relationship with current real activity, that is, nonzero values of z^{e}, cause output to deviate from its usual relationship with the current real interest rate and also cause inflation to deviate from its usual relationship with real activity.

In more complicated new Keynesian models, there are mechanisms that create *lags* in effects of interest-rate shocks and *persistence* in disturbances to real activity, such as "habit formation" in consumption and costs of changing the rate of investment in capital (e.g., Christiano et al. 2005; Smets and Wouters 2007). The labor market is imperfectly competitive, and nominal wage adjustment is subject to the same kinds of frictions that apply to prices (following Erceg et al. 2000). Wage and price inflation can be affected by "wage markup shocks," that is, fluctuations in the spread that the wage setting process effectively seeks to maintain between wages and workers' opportunity cost of employment (Gali et al. 2012). In open economy models (Gali and Monacelli 2005), real activity is affected by foreign demand for domestic output. There can be a variable corresponding to the unemployment rate which is negatively related to output and has a long-run steady-state value corresponding to the "natural rate of unemployment" (e.g., Gali 2011). Many new Keynesian models include mechanisms to create persistence in inflation (e.g., "indexing"), but those are not needed to understand the Depression as I will explain below.

New Keynesian models can include financial market "imperfections" or "frictions." The real interest rate within r above is the return to default-free assets. With realistic constraints on contracting and "asymmetries" in information, some agents cannot borrow at that rate. If these "credit-constrained" agents can borrow at all, it is through contractual relationships with pledges of collateral to particular lenders who incur costs to collect private information about the borrower and enforce the contracts. In models, the spread between the default-free rate within r and the cost of funds to a credit-constrained borrower depends on the borrower's net worth or "wealth." A "financial intermediary" is an agent that lends to credit-constrained borrowers with funds the intermediary borrows himself at the default-free rate or through yet another set of contractual lending relationships. In the latter case, the cost of funds to a credit-constrained borrower depends not only on the borrower's own wealth but also on the net worth or "capital" of financial intermediaries (which affects the spread between the default-free interest rate and the rate *intermediaries* must pay for funds). Several models place financial market imperfections within a new Keynesian macroeconomic setting (e.g., Bernanke et al. 1999; Gertler and Karadi 2011; Curdia and Woodford 2016). In these models, financial market imperfections magnify effects of changes in r on real activity – the "financial accelerator" – and create several additional factors that can affect real activity, including current taxes ("Ricardian equivalence" fails), wealth of households or net worth of firms producing output, and financial intermediaries' capital.

Generally, more complicated new Keynesian models imply:

$$y_t = -\sum_{\tau=0}^{i} \beta_{yr\tau} r_{t-\tau} + \sum_{\tau=1}^{j} \beta_{yy\tau} y_{t-\tau} + \epsilon_{yt} \tag{8}$$

$$\pi^P{}_t = \beta_{\pi py} y_t + \epsilon_{\pi pt} \tag{9}$$

$$\pi^W{}_t = \beta_{\pi wy} y_t + \epsilon_{\pi w t} \tag{10}$$

π^P and π^W are, respectively, price and wage inflation. ϵ_y still reflects fluctuations in preference parameters or government purchases of output and unusual expectations of future real activity. But it can have many additional components: exogenous factors affecting demand for exports, taxes, and government transfer payments, wealth of households and firms producing output, and capital of financial intermediaries or anything that causes a withdrawal of lending to financial intermediaries (Woodford 2010). $\epsilon_{\pi P}$ and $\epsilon_{\pi W}$ can be affected by wage markup shocks (Gali 2011). Equations 8, 9, and 10 can alternatively be written in terms of the "unemployment gap," the difference between the unemployment rate and the natural rate of unemployment.

New Keynesian models have no necessary implication for the relative magnitude of $\beta_{\pi wy}$ versus $\beta_{\pi py}$, that is, for the cyclical behavior of *real wages* (the ratio of the wage level to the price level). Real wages may be procyclical ($\beta_{\pi wy} > \beta_{\pi py}$), countercyclical ($\beta_{\pi wy} < \beta_{\pi py}$), or acyclical ($\beta_{\pi wy} \approx \beta_{\pi py}$) depending on the relative degree of nominal rigidity in wages versus prices, among other things (Gali 2013).

Runs on Financial Intermediaries

A financial intermediary that borrows short-term and holds illiquid assets such as loans can be vulnerable to "runs." In a run, short-term lenders *to* an intermediary withdraw their loans *en masse* (or lend less to the intermediary on a given amount of collateral). To repay its creditors, the intermediary must sell off assets including the loans it has made. As assets, however, most loans made by intermediaries are "illiquid" – hard to sell quickly at the highest possible price. A buyer needs private information to assess the probability of default on the loans – that is why the borrowers had to take out loans in the first place rather than borrow at the safe interest rate. If an intermediary suffering a run is unable to find informed buyers quickly, it may have to accept low prices from uninformed buyers (in a financial "fire sale") and be left unable to pay off all its creditors even if it would have been solvent absent the run (Shleifer and Vishny 2011). The intermediary must then go out of business or at least "suspend payments." In a suspension of payments, an intermediary subject to a run refuses to pay off its short-term borrowings as originally pledged but promises to pay later in hope that the run will stop or it will be able to find informed buyers for its assets in the meantime. Either way, the intermediary stops lending at least for a while. A wave of runs on many intermediaries at once is a "financial crisis." Gertler et al. (2017) present a new Keynesian macroeconomic model with financial intermediaries subject to runs, in which a financial crisis depresses real activity.

In models runs are set off by conditions that would arise in a business cycle downturn (e.g., Allen and Gale 1998; Gertler et al. 2017). Thus runs may be another mechanism amplifying the effect of an increase in r (increasing β_{ry} and $\beta_{lag\ y}$). The relationship between economic conditions and runs is abruptly discontinuous because an individual lender to an intermediary has greater incentive to withdraw his loan if other lenders withdraw ("strategic complementarity") (e.g., Morris and Shin 2000; Goldstein and Pauzner 2005). In some models runs can be triggered by events not obviously related to macroeconomic conditions (e.g., Chari and Jagannathan 1988) or even occur *randomly* ("caused" by "sunspots") as in the well-known model of Diamond and Dybvig (1983). That implies runs can be a source of exogenous shocks to output (more components to ϵ_y in 8).

Generally, models of runs imply they can be prevented by an insurance system that pays off lenders to an intermediary if the intermediary defaults. Runs can also be prevented or mitigated by a "lender of last resort." A lender of last resort provides funds to an intermediary in exchange for its illiquid assets, valuing the illiquid assets at the relatively high prices they would fetch eventually from informed buyers. A lender of last resort can provide funds either by buying the illiquid assets outright or by taking illiquid assets as collateral for loans. Because a lender of last resort needs either stupendous wealth or the ability to create funds at will, the most obvious real-world institution that can act as a lender of last resort is a central bank.

Mechanics of Monetary Policy Implementation

Macroeconomic models skim over *minutiae*. New Keynesian macroeconomic models ignore, or describe in wildly unrealistic ways, the mechanism by which the value for a short-term interest rate desired by central bank policymakers becomes the market rate. This mechanism is, however, described in realistic models of monetary policy implementation. Most central banks today use variants of the same basic setup (described by Ennis and Keister 2008). Firms and households make payments to each other by transferring ownership of short-term loans – "deposits" – to certain financial intermediaries – "banks." Banks make payments to each other mainly by transferring balances in "reserve accounts" at a central bank. "High-powered money" is the total of these reserve balances and currency. The central bank pays a "reserve interest rate" on reserve-account balances and charges a higher "penalty rate" for short-term loans to banks. The market overnight rate cannot fall below the reserve interest rate (the return to lending overnight funds to the central bank) and cannot rise above the penalty rate (the cost of borrowing overnight funds from the central bank).

A bank that suffers a shortfall in its reserve account is required to borrow at the penalty rate to cover the shortfall. A shortfall might be an overdraft or a failure to meet a regulatory minimum "reserve requirement." A bank's "excess reserve" is its reserve balance less its reserve requirement. A bank's "free reserve" is its excess reserve *not* including funds borrowed from the central bank at the penalty rate. The total supply of free reserves is equal to high-powered money less currency less banks' required minimum balances less their penalty-rate borrowing. The central bank adds to (subtracts from) free reserve supply when it buys (sells) assets on the open market.

There is a cost to a bank of holding free reserves: it loses the spread between the reserve interest rate and the market overnight rate. But there is also a benefit. It is hard to predict exactly when some reserve-account payment orders will go through. A bank that aims to keep a free reserve of zero may actually suffer a reserve shortfall and have to borrow at the high penalty rate. As a bank trades off the cost of holding free reserves against the benefit, aggregate demand for free reserves is a downward-sloping function of the market overnight rate, between the upper bound of the penalty rate and the lower bound of the reserve interest rate. This reserve-demand curve is shifted up (down) by an increase (decrease) in the penalty rate and/or the reserve interest rate. The market overnight rate equates the demand for free reserves to the supply.

A central bank can control the market overnight rate because it controls the supply of free reserves, the penalty rate, and the reserve interest rate. A central bank can reduce the market overnight rate by adding to free reserve supply or by lowering the penalty rate and/or reserve interest rate. A sufficiently large free reserve supply can drive the market rate all the way down to the reserve interest rate. At this point banks will be indifferent to holding even more funds in their reserve accounts, so further increases in reserve supply will have no effect on market short-term rates.

Also, there will be no borrowing at the penalty rate to cover reserve-account shortfalls, because each bank holds a large enough free reserve to entirely eliminate the danger of a shortfall.

The ultimate lower bound on short-term nominal rates is the lowest possible value the central bank can pay for reserve balances. This might be the nominal interest rate on currency, which is zero, hence the "zero lower bound." When the market overnight rate has been pushed to the ultimate lower bound, the economy is in a "liquidity trap."

Historical Background: The American Economy in the 1920s

America's Banks

On the eve of the Great Depression, the American financial system was more vulnerable to crises than other countries with sophisticated financial markets such as Britain, Australia, and Canada. By the late 19th century, each of those countries had a few large banks with nationwide branch networks which lent to businesses and households all over the country. Defaults by borrowers in a particular region did not threaten such a bank's solvency. Bank assets included illiquid loans, long-term bonds, and two types of liquid short-term assets: "call money" loans and "acceptances." Acceptances were bills (transferrable short-term debts) which had been guaranteed – "accepted" – by a firm of well-known solvency, the "acceptor." Some acceptances financed purchases of securities. Others – "real bills" – financed purchases of materials, inventories, or goods for shipment. An accepted bill was usually liquid, easy to sell on secondary markets, because its default risk depended on the perceived solvency of its acceptor not the original issuer. Call money loans were overnight loans collateralized by stocks, bonds, or acceptances. They were taken out mainly by speculators and dealers in cities with big financial markets. Banks made call money loans through their branches in those cities.

In the world's largest financial market, London, the Bank of England had taken on the functions of a central bank and lender of last resort. The Bank could lend to practically anyone on almost any kind of collateral and did so in crises (Bagehot 1873, pp. 51, 196). However, the Bank could do a great deal to stabilize financial markets without lending directly to anyone in particular. In a crisis acceptances could become illiquid as doubts arose about acceptors' solvency. The Bank helped to maintain bills' liquidity, hence intermediaries' ability to pay off their creditors on short notice, by making a standing offer to purchase ("rediscount") acceptances at a standard rate (Bagehot 1873; Clapham 1970; Bignon et al. 2012).

The United States was different. Prior to 1914 it had no central bank. American regulations prevented a bank from operating offices in more than one state (or even, in some states, more than one city). Most banks lent mainly to businesses and households within a small region. A merely regional downturn could threaten the solvency of a bank. Fewer types of liquid assets were available to banks. Accepted bills did not exist, partly due to regulations (national banks were not allowed to

guarantee bills).[3] An American bank could make call money loans, but there was little demand for such loans outside New York City, the country's main securities market. Most banks outside New York made few if any call money loans. Their main liquid asset was interest-paying "interbank" demand deposits in New York banks which lent the funds on in the New York call money market (James 1978). The prevalence of interbank deposits added an extra source of potential instability to the American financial system. Just as depositors in the hinterland might run on their banks, hinterland banks might run on New York banks (Chari 1989). In the decades before 1914, America suffered several national financial crises in which depositors started to withdraw deposits *en masse* from hinterland banks, hinterland banks started to withdraw their deposits *en masse* from New York banks, New York banks suspended payment, and banks throughout America suspended payment because their main liquid asset had become illiquid (Wicker 2000).

These crises occurred in the wake of cyclical downturns and stock market crashes, which caused fears of defaults on bank assets (Calomiris and Gorton 1991). The cyclical downturns were in turn caused by hikes in American interest rates due to foreign financial crises or domestic monetary factors (Hanes and Rhode 2013). A national financial crisis accelerated a downturn, not just because it restricted the supply of loans from financial intermediaries as in new Keynesian models but also because widespread suspension of bank payments made it harder to hire labor and sell things. Factories closed because they could not get cash for weekly payrolls. Trade declined because it was harder to make payments between cities. James et al. (2013) describe these effects. They show that widespread suspensions of bank payment were coincident with sharp drops in real activity. Real activity stabilized or turned up when banks resumed payment.

At the beginning of the Great Depression, American banks were still prohibited from setting up branches in more than one state. Several state governments had attempted to set up systems of deposit insurance that could prevent bank runs by paying off depositors of a failed bank. But all these schemes had failed (Federal Deposit Insurance Corporation 1998).

The Federal Reserve System

The Federal Reserve System – the "Fed" – started operation in 1914. It was a confederation of 12 "Reserve banks" placed in major banking cities. One was in New York. Each Reserve bank had a geographically defined "district." The whole system was overseen by a central Board (later known as the Board of Governors) that

[3]The closest thing to accepted bills in American financial markets was a type of bill called "commercial paper." Commercial paper was less liquid than accepted bills, with no active secondary market, because it had no guarantor (James 1978). Its value depended on the perceived solvency of its original issuer, typically a firm that was relatively large but not as widely known as firms that accepted bills in Europe.

met in Washington. It was not clear exactly which potential actions of a Reserve bank required Board approval.

A bank could become a "member" of the Federal Reserve System. A member bank was required to hold a reserve balance in its district Reserve bank subject to a required minimum balance called a "reserve requirement." A member bank could use its reserve balance for payments to and from other banks and the federal government. Some banks (those chartered by the federal government, called "national" banks) *had* to become members. Other banks (chartered by state governments) could choose whether or not to join. Many chose not to because members were subject to costly extra regulations, and the Fed did not pay interest on reserve balances (Wingfield 1941).

The designers of the Fed hoped that it would eventually be able to operate as the Bank of England did, interacting with banks primarily through a market for acceptances. To that end American regulations were changed to encourage creation of acceptances, called "banker's acceptances" in America. Each Reserve bank set an "acceptance rate" at which it bought acceptances. By 1929 a market in acceptances had begun to develop, but banks outside New York still did not hold many of them (Ferderer 2003).

The Federal Reserve's ability to lend to financial intermediaries was strictly limited by the law setting up the Fed, the "Federal Reserve Act," and later amendments to that law. A Federal Reserve Bank could ordinarily lend only to a member bank. To lend to a nonmember bank, a Reserve bank needed special permission from the Board in Washington. A Reserve bank could buy, or take as collateral for a loan, *only* banker's acceptances, federal debt, or certain types of bank loans – "eligible paper." To be "eligible" a bank loan had to be short-term (original maturity 90 days or less) and "for producing, purchasing, carrying or marketing goods in one or more of the steps of the process of production, manufacture or distribution." A loan was *not* eligible if it had been used to finance purchases of stocks or bonds or "for permanent or fixed investments of any kind, such as land, buildings or machinery" (Steiner 1926). The rates at which Reserve banks bought ("rediscounted") or lent against eligible paper could vary across Reserve banks. They became known as Federal Reserve "discount rates." A bank that acquired funds this way was "borrowing through the discount window."

Discounting of eligible paper and purchases of banker's acceptances occurred at the initiative of member banks. At its own initiative, a Federal Reserve Bank could buy and sell federal government debt in "open-market operations." By the late 1920s, most Reserve banks' open-market operations were managed through a system-wide committee (later called the Federal Open Market Committee [FOMC]). Federal Reserve Banks also made a standing offer to buy and sell gold at a fixed price. This put the United States "on the gold standard" as described further below.

By the late 1920s, a market had developed in uncollateralized overnight loans of Federal reserve funds – "federal funds" (Meltzer 2003, p. 164), which operated alongside the long-established market for overnight call money. The level of market overnight rates for federal funds and call money was influenced by two factors under

the control of the Federal Reserve System: Reserve bank discount rates and the supply of free reserves. The mechanism (described by Hanes 2006) corresponded to the models described in section "Mechanics of Monetary Policy Implementation" except that the reserve interest rate was always zero. The "penalty rate" facing a member bank was its Reserve bank's discount rate (lacking acceptances, a bank short of funds usually had to borrow through the discount window). Free reserve supply was total reserve balances in excess of reserve requirements less funds supplied through the discount window. Fed purchases (sales) of gold, or of federal debt in open-market operations, added to (reduced) free reserve supply. A sufficiently large free reserve supply could push the market return to overnight lending down to the zero rate paid on reserve balances. At this point the economy would be in a liquidity trap.

Fed policymakers knew that their operations influenced short-term rates. But they had a different theory of the mechanism. Today their theory is called the "Burgess-Riefler doctrine" after two Fed staffers who developed it (Wheelock 1990, Meltzer 2003, pp.141, 161). This theory assumed banks wanted to hold a certain total quantity of reserve balances. If the Fed supplied less than this quantity through gold purchases and open-market operations, banks had to borrow the difference through the discount window. But banks were "reluctant to borrow." A bank that had borrowed through the discount window would curtail lending to pay its debt to the Fed. An increase in free reserve supply reduced discount borrowing and, hence, made banks more willing to lend and reduced market short-term interest rates. A decrease in discount rates had the same effect because it made banks more willing to remain in debt to the Fed.

The Burgess-Riefler doctrine implied that there was a limit to the Fed's influence on interest rates similar to the liquidity trap. Once free reserve supply was great enough to entirely eliminate discount-window borrowing, further increases in reserve supply could have no effect on financial market conditions (Wheelock 1991).

The Gold Standard and the Fed's Monetary Policy Strategy

In the late 1920s, the United States and most of its international trading partners were in an international gold standard system. Each country had a monetary authority, usually a central bank, that exchanged currency and central bank reserve balances for gold at a fixed price. This held foreign exchange rates close to the values implied by the countries' relative gold prices ("gold parities"). The authority of a country running a balance of payments deficit could cover it by selling reserves of foreign assets, but once those were gone, it had to sell gold. A country's long-run equilibrium price level was determined by its gold price and world prices, in gold, of tradable goods. The world gold price level was in turn determined by the balance of world gold supply against gold standard countries' demand for gold reserves. Overall the gold standard monetary regime appears to have kept inflation rates close to zero in the very long run (Taylor 1999). Thus it satisfied the precondition for new Keynesian models that the long-run expected inflation rate be close to zero.

For an individual country, the gold standard was in most respects simply a commitment to fixed exchange rates. This placed a constraint on monetary policy. If international capital mobility had been "perfect" (so that "uncovered interest-rate parity" held), the constraint would have been very tight for all countries all the time: each country's nominal interest rates would have to equal foreign rates. In fact international mobility was "imperfect" (as in textbook models, e.g., Romer 2006, pp. 236–241; Mankiw 2010, pp. 153–161). A country's interest rates need not equal foreign rates, but its net inflow of international investment, hence its balance of payments, decreased if foreign interest rates rose relative to the country's domestic interest rates. Thus the gold standard constraint on monetary policy was "asymmetric," tight on a country running a balance of payments deficit and loose on a country running a surplus (Temin 2000). Authorities of a surplus country did not have to eliminate the surplus. They could just keep buying up gold (or foreign assets); to prevent the high-powered money supply from increasing and reducing domestic interest rates, they could "sterilize" gold purchases by simultaneously selling bonds in open-market operations. Authorities of a deficit country, on the other hand, had to eliminate the deficit because they must run out of gold sooner or later. To eliminate the deficit, they had to raise domestic interest rates. In the short run, that did the trick by drawing in international investment. In the long run, it depressed real activity, lowered the domestic inflation rate, lowered the country's nominal wage and price level, and hence depreciated its real exchange rate. The gold standard's "rules of the game" called for a surplus country to allow its purchases of gold (or foreign assets) to boost its high-powered money supply and lower its interest rates. That would help other countries get back into balance. But there was nothing to *force* this policy on a surplus country.

Over most of the 1920s, the United States ran a balance of payments surplus. Federal Reserve banks usually held no foreign asset reserves, just gold. The most influential person in the Federal Reserve System was Benjamin Strong, head of the New York Reserve bank. Sometimes Strong called for decreases in US interest rates to help deficit countries remain on the gold standard. More often he wanted to sterilize gold purchases and use the Fed's influence on financial market conditions to stabilize the American price level. Strong and his staff monitored indicators of inflation and real activity. When there were signs of inflation or too-rapid growth, Strong pushed for increases in discount rates and/or open-market sales of securities to reduce free reserve supply. When there were signs of deflation or slow growth, Strong pushed for the opposite.[4] Strong usually managed to get support for his

[4]Strong explained the transmission mechanism from monetary policy to the price level this way: "when we have very cheap money, corporations and individuals borrow money in order to extend their business. That results in plant construction; plant construction employs more labor, brings in to use more materials for plant construction, and gives more employment. It may cause some elevation of wages. It creates more spending power; and with that start it will permeate through into the trades and the general price level" (quoted in Hetzel 1985, p. 7).

preferred policies (Meltzer 2003, pp. 169, 177, 209, 230). Thus, over the 1920s the Fed followed something close to a Taylor rule with a zero inflation target (Orphanides 2003).

But Strong's monetary policy strategy was not universally accepted among Federal Reserve policymakers. Many Reserve bank heads and most members of the Board in Washington were adherents of the "real bills doctrine." According to this doctrine, a central bank should not, and probably could not, use free reserve supply and discount rates to stabilize the price level.[5] Its discount rates should follow market rates, not control them. The important thing was to discourage "speculation" by hindering the supply of loans to finance purchases of securities. Thus, a European central bank should accept only real bills for rediscount. The Federal Reserve System should accept as collateral at the discount window only bank loans analogous to real bills. That was the idea behind the definition of eligible paper in the Federal Reserve Act.

Benjamin Strong died in 1928. His successor as head of the New York Reserve bank, George Harrison, shared Strong's views on strategy but lacked Strong's influence in the system (Eichengreen 2016).

The 1929–1933 Depression

1928: The Federal Reserve Hikes Short–Term Interest Rates

In 1928 there were no signs of inflation. Real activity was sluggish, if anything. But there was a developing boom in the stock market which Federal Reserve policymakers wanted to stop. They began to raise discount and acceptance rates and sold bonds to reduce free reserve supply. The idea was to raise short-term rates and choke back bank lending, in order to hinder the supply of loans to finance stock purchases (Meltzer 2003, pp. 224–225, 228, 235). Some Fed policymakers warned that this could have an undesirable side effect: it could cause a recession and unwanted deflation (pp. 225, 230, 239). Hoping to stop bank lending to finance stock purchases *specifically*, the Board directed Reserve banks to apply "direct

[5] Adolph Miller, the "dominant personality at the Board" (Meltzer p. 138), argued that arguments for price-level targeting relied on faulty assumptions: "One of those assumptions is that changes in the level of prices are caused by changes in the volume of credit and currency; the other is that changes in the volume of credit and currency are caused by Federal reserve policy. Neither one of those assumptions is true...undertaking to regulate the flow of Federal reserve credit by the price index is a great deal like trying to regulate the weather by the barometer. The barometer does not make the weather; it indicates what is in process" (quoted in Hetzel 1985, p. 10). Miller further argued that there was nothing the Fed could do to stop a recession: "you can not stop the recession by the lowering of the discount rate, the cheapening of the cost of credit, or making credit more abundant" (p. 12). The head of the Philadelphia Reserve bank said he did not believe the Fed should attempt to resist changes in the price level: "When the movement of prices is underway, it seems to me that it is always a doubtful and generally a dangerous thing for any outside agency to interfere with and attempt to alter the current" (p. 12).

pressure" against such lending. This meant "restricting the [discount] borrowings from the federal reserve banks by those member banks which were increasingly disposed to lend funds for speculative purposes" (Miller 1935, p. 454) and requiring "interviews between Federal Reserve Bank officials and member banks whose [discount-window] borrowing appeared to be excessive or too continuous" (Burgess 1930, p. 16). In effect, Federal Reserve Banks were to *ration* discount-window credit to banks that appeared to be lending on stock collateral.

The immediate result was a big increase in overnight rates. From December 1927 to May 1929, the call money rate rose by more than 4%. The overnight federal funds rate rose by about 2% (Willis 1957, p. 10). Both call money and federal funds rates rose well above the New York Reserve bank's discount rate, which had previously set a ceiling on market overnight rates, perhaps because "direct pressure" rationing raised the effective cost of discount borrowing above the posted discount rate (Beckhart and Smith 1932, p. 46; Wheelock 1990). A relatively clear indicator of the return to overnight lending (or at least the return to overnight lending expected to prevail within the next few weeks) is the rate on very short-term Treasury debt. This is plotted in Fig. 2 on a monthly frequency, along with the yield on long-term Treasury bonds.

The Initial Downturn 1929–1930

On October 24, 1929 ("Black Thursday"), the stock market crashed. Real activity had turned down before that. The NBER cyclical peak is August 1929. The obvious

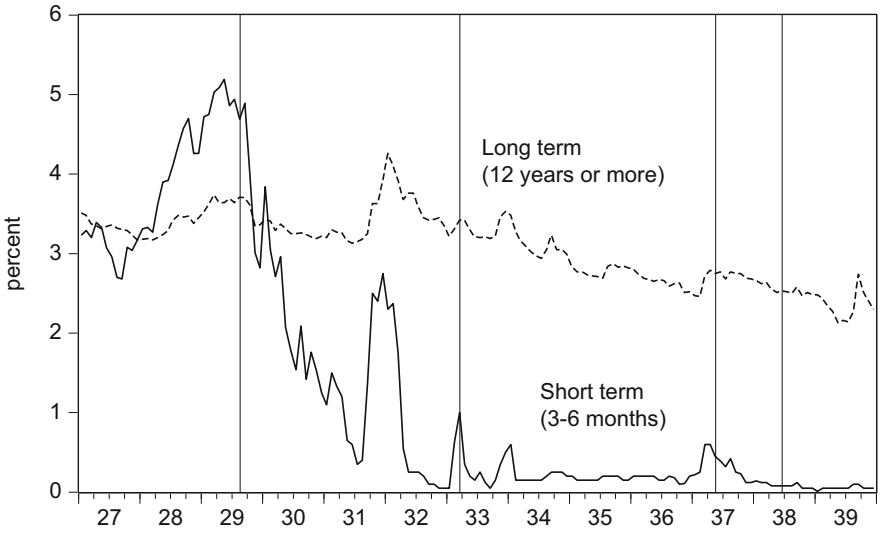

Fig. 2 Treasury interest rates 1927–1939. (Sources and notes: short-term 1927–1928 from US Federal Reserve Board (1943), Tables 122, 3- to 6-month Treasury notes and certificates. Short-term 1929–1939 from Cecchetti (1988), Table A1, 3 Months. Long term from US Federal Reserve Board (1943), Table 128, US government)

explanation of the downturn is the preceding hike in interest rates. This was plausibly an exogenous shock to real activity because it was not a response to inflation or rapid growth. From December 1927 to May 1929, short-term Treasury rates rose about 2% (Fig. 2). This compares with increases in short-term Treasury rates in postwar (after the Second World War) policy tightenings engineered by the Fed. Romer and Romer (1989) identify six instances in which the Fed hiked short-term interest rates for reasons unrelated to current or forecast inflation. Around some of these tightenings, across a 6- or 12-month window around the date of the policy change, 3-month Treasury rates rose more than 2%. Across many of them, 3-month Treasury rates rose *less* than 2%. *All* of the tightenings were followed by cyclical downturns.

After August 1929, however, the decline in real activity was extraordinarily sharp. On current estimates by the US Bureau of Economic Analysis (BEA), from 1929 to 1930, real GDP fell by about 8 1/2%. After the end of the Second World War, real GDP never fell that much in 1 year, even in the most severe recessions. The decline in real GDP at the beginning of the "Great Recession," from 2008 to 2009, was less than 3%. What can explain the violence of the 1929 downturn? Was there something about the economy in 1929 that magnified the effect of an increase in interest rates? Were there other exogenous shocks that contributed to the downturn?

New Keynesian models imply that the immediate decline in real activity associated with a hike in interest rates is unusually large if people expect the current recession to be unusually bad, so that expected future real activity deviates from its usual relationship to current real activity (negative values of z^e in (5)). That cannot explain 1929–1930. There is no evidence expectations were unusually pessimistic at the beginning of the Great Depression. It appears people believed they were facing a normal cyclical downturn (Mathy and Stekler 2017). Business managers forecast a slowdown in real activity less severe than the one that actually occurred (Klug et al. 2005). There was nothing unusual about that. At the start of deep recessions in the postwar era, forecasts of real activity have been similarly overoptimistic (Mankiw 2010, p. 449).

The stock market crash may have worsened the downturn. It was a big hit to households' net worth (Mishkin 1978). In New Keynesian models with financial market frictions, a reduction in wealth reduces real activity. To the degree the crash reflected a decline in rational expectations of future corporate earnings, this was part of the financial accelerator. If the crash was the bursting of an irrational bubble – a debatable point (White 1990) – it was an additional cause.

Had the American economy built up some type of "financial fragility" that supercharged the financial accelerator? In models of financial frictions, the decline in real activity resulting from a negative shock is greater if households have previously taken on lots of debt in a "credit boom," so that their net worth is already low at the time the shock hits (Gertler and Gilchrist 2017). Perhaps such a credit boom had taken place in the 1920s (Eichengreen and Michener 2004). New forms of debt had been created to finance purchases of new "consumer durables" such as automobiles and radios. Much of this debt was on the "installment plan," which gave borrowers strong incentive to cut back on other spending in response to a decline in current income. This may have caused household spending to decline more after 1929 (Olney 1999). Also, around 1925 there had been a nationwide boom in residential real estate: an increase in house construction, rising house prices, and

an unprecedented increase in mortgage debt. The boom ended before 1929: over 1925–1927 prices fell off a bit, and construction fell off a lot. But the boom may have left something behind, such as more mortgage debt that affected spending after 1929. Over 1929–1933 the cities that had seen the biggest booms around 1925 suffered the biggest declines in house prices and the highest mortgage foreclosure rates (Brocker and Hanes 2014).

Continued Decline 1930–1933

Real activity continued to decline through 1933 – 4 years in a row. This is what made the Great Depression great. In most postwar recessions, real GDP fell for just 1 year. There were just two postwar recessions in which real GDP fell for as long as 2 years (1973–75, 2008–2010).

One factor that probably did *not* contribute to continued decline was fiscal policy. The response of the federal government led by the Hoover administration was to boost spending while raising tax rates as needed to maintain a balanced budget (Fishback 2010, pp. 402–403). Figure 3 plots real purchases of goods and services by all levels of government (federal, state, and local). Government purchases rose from 1929 to 1931 and fell only modestly from 1931 to 1933. Figure 4 plots taxes, government transfer payments to households, and the ratio of taxes net of transfers to national income. New Keynesian models with financial frictions imply that an increase in this ratio might reduce spending of liquidity-constrained agents. The ratio did increase after 1931 but not much. Marginal personal income tax rates were lower over 1930–1933 than they had been in 1929 (Meltzer 2003, p. 563).

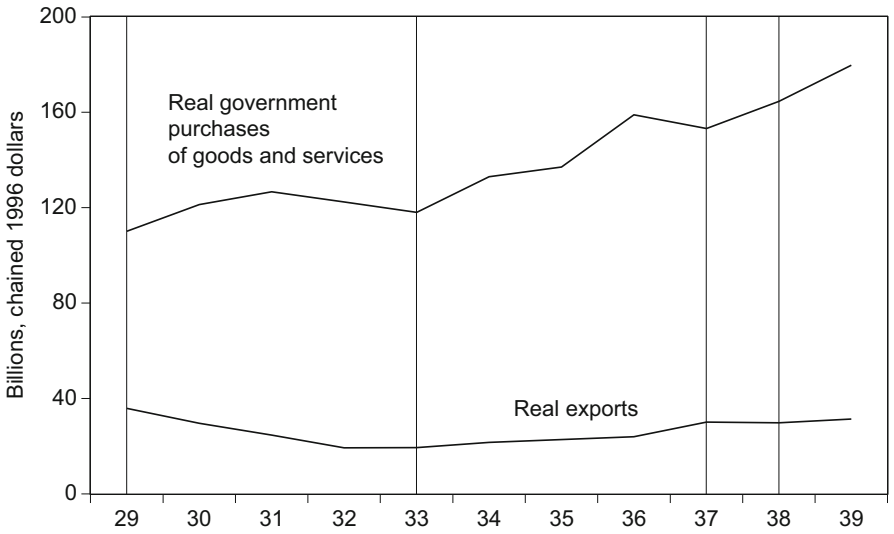

Fig. 3 Real government purchases of goods and services, real exports 1929–1939 (Sources and notes: both series from Carter et al. (2006), government purchases series Ca89, exports series Ca87)

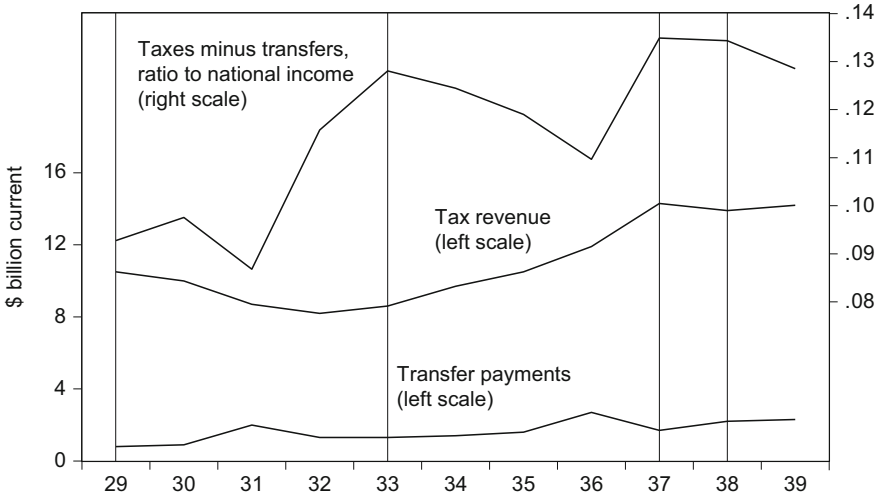

Fig. 4 Taxes, government transfer payments, and ratio of taxes minus transfers to national income 1929–1939. (Sources and notes: United States Bureau of Economic Analysis (https://www.bea.gov/iTable/index_regional.cfm) Table 3.1 for taxes and transfers, Table 1.17.5 for national income. Taxes are current receipts including social insurance contributions. Transfers are government transfer payments to persons. National income is gross national income)

A factor that did contribute to decline but only in a small way was a drop off in demand for American exports. Real exports, plotted in Fig. 3, fell steadily from 1929 through 1932. This was largely blowback from the American interest-rate hike of 1928–1929. Along with the stock market boom, the hike in American interest rates drew in international investment, increased the American balance of payments surplus, and drained gold from foreign monetary authorities. To save their gold reserves, they raised domestic interest rates. That, and a series of financial crises in Europe, put foreign economies into recession and decreased their demand for American goods (Eichengreen 1992 p. 246). But exports were a small portion of American GDP. Thus this (and the "Smoot-Hawley" tariff increase of 1930) cannot have made much difference (Temin 2000, p. 305).

So what explains the persistence and depth of the decline in real activity after 1930? One obvious cause was a perverse hike in short-term interest rates engineered by the Fed in the midst of the downturn. Another was an increase in bank failures that started in late 1930 and ended in 1933 in a massive financial crisis. New Keynesian models imply both of these factors could prolong and deepen the Depression.

Federal Reserve Interest Rate Policy

On the heels of the October 1929 stock market crash policymakers at the Federal Reserve Bank of New York bought bonds in open-market operations, hoping to help stabilize financial markets. They did not ask the Board in Washington for

permission, which annoyed members of the Board. At the beginning of November, the Board allowed the New York Reserve bank to cut its discount rate but only on condition that it suspend open-market purchases (Meltzer 2003, pp. 243–44).

By January 1930 it became apparent that a recession had begun (Meltzer 2003, 291). As the recession deepened, Fed policymakers became aware of its severity (p. 315). Fed policymakers did not agree on what their response should be. Some, including George Harrison of the New York Reserve bank, wanted to lower market interest rates and spur bank lending to fight the recession (consistent with Benjamin Strong's strategy). Others, adherents of the real bills doctrine, opposed any such actions (Meltzer 2003, p. 290). Harrison's side mostly prevailed. From 1930 through the middle of 1931, they pushed through several cuts in discount and acceptance rates. Free reserve supply grew rapidly as the system purchased bonds in open-market operations and refrained from sterilizing gold inflows. Overall, Fed interest-rate policy in the first year of the Depression was similar to policy in postwar downturns including the post-2008 Great Recession. In the Great Recession, the Fed began to cut its target federal funds rate in July 2008; over the following year, the market federal funds rate and 3-month Treasuries both fell about 3 1/4%. From October 1929 to October 1930, federal funds rates fell by about 4 1/4% (Willis 1957, p. 10); short-term Treasuries fell about 2 3/4% (Fig. 2).

In late 1931 all the Fed's information indicated that real activity was still falling. But the Fed took steps to raise short-term rates. As shown in Fig. 2, short-term Treasury rates rose almost 2 1/2% from August to December 1931. The increase in short-term rates was accompanied by an unusually large increase in long-term rates.

Why did the Fed act in this perverse way? To maintain the gold standard. Over 1930–1931 many foreign central banks had raised domestic interest rates to prevent gold outflows. In summer 1931 German authorities stopped outflows of international investment and gold with regulations (exchange controls). In September 1931 authorities in Britain and most dominions of the British Empire stopped paying out gold for domestic currency, effectively floating their currencies (Temin 2000 p. 312; Meltzer 2003, p. 342). International investors feared the United States would follow suit. They sold American assets and bought gold. The Federal Reserve's gold reserve was draining out. To show commitment to the gold standard and stop the drain, the Federal Reserve System acted to raise American short-term interest rates, mainly by hiking discount rates (Eichengreen 1992, pp. 293–294).

The interest-rate hikes did what they were supposed to do. Gold outflow stopped in November and reversed in December (Meltzer 2003, p. 354). Relieved, Fed policymakers began to discuss steps to lower interest rates. But they were stymied by a provision of the Federal Reserve Act which required each Reserve bank to hold a minimum gold reserve (valued at the official price) equal to 35% of the balances held in that Reserve bank plus 40% of the Federal Reserve notes (a type of currency) issued by that Reserve bank. Some Reserve banks were up against these minimums. Without "free gold" they could not cover the increases in reserve balances that would result from open-market bond purchases or increased discount-window lending to banks (Meltzer 2003, pp. 354, 357).

In February 1932 Congress passed a revision to the Federal Reserve Act that loosened the free gold constraint. The Federal Reserve began to buy bonds in open-market operations. The New York Reserve bank cut its discount rate and cut it again in June. By late spring 1932, Federal funds rates were at the lowest level ever observed in the 1920s–1930s (1/8 of 1%), and there was almost no discount borrowing (Willis 1957, p. 10). Three-month Treasuries were down to 1/4% (Fig. 2).

In July 1932 the Fed stopped buying bonds. Why? Eichengreen (1992, pp. 315–316) argues that Fed policymakers feared further bond purchases might raise doubts about American authorities' commitment to the gold standard and trigger outflows of international investment and gold like those seen in 1931. Epstein and Ferguson (1984) argue that Fed policymakers feared that low short-term interest rates would depress bank profits. According to Hsieh and Romer (2006, p. 169), "the Federal Reserve decided to slow the monetary expansion in mid-June in part because its model of monetary policy led it to believe that monetary conditions were already loose and that further purchases would be of little use." They refer to the Burgess-Riefler doctrine which implied that open-market purchases and discount-rate cuts lost their stimulative power once free reserve supply was so great that banks had no debt to the discount window. Hsieh and Romer call the Burgess-Riefler doctrine "a flawed model of the economy" (p. 172).

The Burgess-Riefler doctrine was indeed a flawed model, but new Keynesian models imply that Federal Reserve policymakers were right about one thing: further increases in reserve supply or discount-rate cuts were useless. Short-term rates were at the zero bound. As shown in Fig. 2, by the end of 1932, 3-month Treasuries were less than a tenth of a percent. This is about the same as the 3-month Treasury rate that prevailed in 2010, when the Federal Reserve's overnight rate target was practically zero. The absence of discount borrowing in 1932 confirms that the economy was indeed in a liquidity trap. Recall that in the correct model of overnight rate determination described in "Mechanics of Monetary Policy Implementation," when the return to overnight lending is equal to the reserve interest rate (zero in this case), banks stop borrowing at the penalty rate to cover reserve-account shortfalls.

Unfortunately, the Fed was unable to leave interest rates on the floor for long. The gold standard took one more bite. In February 1933 international investors again began to fear that American authorities would devalue the dollar. The balance of international investment again turned against the United States. The New York Reserve bank, which sold most gold for export, was running out of gold. In accordance with gold standard orthodoxy, Fed policymakers allowed market interest rates to rise as gold sales reduced free reserve supply by refraining from sterilization and hiking discount rates (Meltzer 2003, p. 379). But this time the increase in short-term rates did not stop the gold drain (Friedman and Schwartz 1963, p. 326; Wigmore 1987, p. 748; Meltzer 2003, p. 387). On March 6, 1933, the incoming president, Franklin Roosevelt, solved the problem by suspending Federal Reserve Banks' obligation to exchange gold for dollars (Friedman and Schwartz 1963, p. 328).

Bank Failures and the Financial Crisis of 1933

From late 1930 through 1932 there were waves of bank failures. Their timing is indicated by Fig. 5, which plots total deposits in banks that suspended payment and reopened later or went permanently out of business in a given month, as a fraction of deposits in American banks. The first wave hit in October 1930. Another peaked in October 1931, while the Fed was raising short-term rates in the wake of Britain's devaluation. Until late 1932 failures remained confined to a few cities or regions, and the fraction of deposits in failed banks was very small. These failures may nonetheless have significantly disrupted financial intermediation. Total deposits, also plotted in Fig. 5, began to fall at the time of the first wave of failures and plummeted at the time of the second wave. At the same points in time currency held by the public increased (Friedman and Schwartz 1963, pp. 311, 313). It looks like regional bank failures caused nationwide withdrawal of funding from banks.

At the end of 1932, things got worse. A wave of failures that began in the far west spread to the Midwest and the then-important city of Detroit. In February 1933 New York banks began to see mass withdrawals of interbank deposits (Friedman and Schwartz 1963, pp. 324–326). In March 1933 there was a crisis worse than any of the pre-1914 era. Pre-1914 crises had been resolved by suspensions of payments organized by private bank associations (clearing houses) during which banks stopped handing out currency but still provided many other services. The 1933 crisis

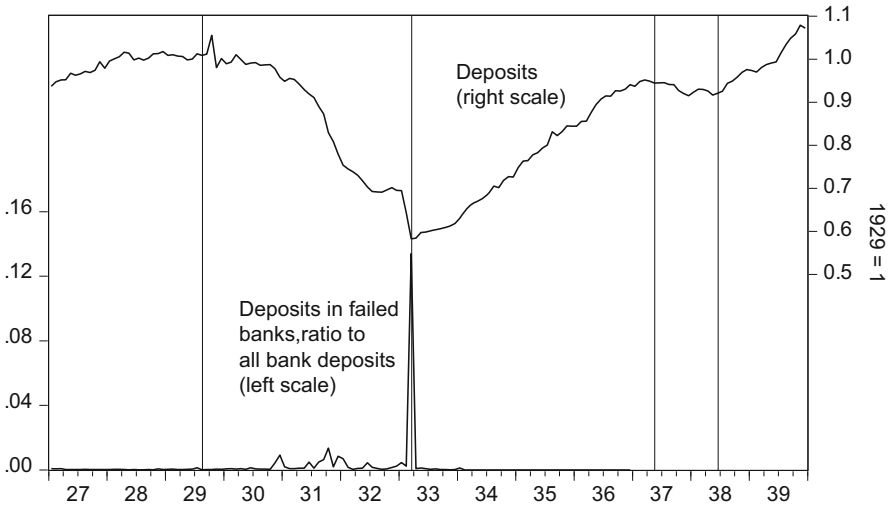

Fig. 5 Deposits in failed banks 1927–1936, deposits in all banks 1927–1939. (Sources and notes: deposits from Friedman and Schwartz (1963) Table A-1, total adjusted deposits in commercial banks. Deposits in failed banks from Federal Reserve Bulletin December 1937, p. 909. The failed bank series underestimates the intensity of failure in some months as it does not include banks that suspended or partially defaulted on deposits by "agreement" with depositors. Such agreements were common in 1931 and 1932 (Federal Reserve Bulletin September 1937, p. 1206). More importantly, it fails to include banks temporarily shut down by bank holidays)

was resolved by government-ordered shutdowns of all banks, cheerfully called "bank holidays," that stopped nearly all bank services. By the beginning of March 1933, nearly all states' governors had declared holidays. On March 6, incoming president Franklin Roosevelt declared a national bank holiday that shut down all banks in the country. At that time households and businesses in much of the country had already been without bank services for weeks.

Bank failures may have been an amplification mechanism more than an independent cause of the Depression. Up to 1933, at least, banks that failed appear to have been relatively close to insolvency *before* depositors began withdrawing *en masse* because of interactions between their prior investment policies and the Depression's effects on loan defaults and prices of relatively risky bonds (Calomiris and Mason 1997, 2003b). In any case bank failures and withdrawal of funding from banks must have deepened the Depression. In models of financial frictions, hindrances to the operation of financial intermediaries depress real activity by raising the cost of funds to liquidity-constrained borrowers. Bernanke (1983) argues that this mechanism was at work over 1930–1933. Christiano et al. (2003) present a new Keynesian model with financial intermediation by banks, specifically meant to describe the Depression era. In the model, withdrawal of deposits and increased demand for currency reduces aggregate output.[6] Recall that in pre-1914 financial crises, suspensions of payments appear to have depressed real activity by making it harder to produce and trade. There is abundant evidence that held over 1930–1933 (Rockoff 1993; Kennedy 1973, pp. 161–164). Over 1929–1933, across time and across geographic regions, bank failures were strongly associated with lower real activity (Bernanke 1983, Calomiris and Mason 2003a).

Where Was the Lender of Last Resort?

Some banks that failed over 1930–1932 were merely "illiquid" rather than "insolvent" (Richardson 2007). They closed only because their depositors had withdrawn *en masse* creating a financial fire-sale problem. Certainly, it was a liquidity crisis, not a wave of ordinary insolvency, that hit in 1933. In a liquidity crisis, a lender of last resort can prevent closure of financial intermediaries by purchasing their illiquid assets or taking them as collateral for loans. A central bank is supposed to act as a lender of last resort. What was the Federal Reserve System doing all this time?

Provisions of the Federal Reserve Act hindered the ability of the Federal Reserve System to act as a lender of last resort. In the regional crises of 1930–1932, many banks that needed to borrow were not member banks. Some member banks that

[6]In their model the shift from deposits to currency occurs because of a shock to preferences, not a response to bank failures. They also assume that the supply of high-powered money would not respond to the consequences of the shock, which is not realistic. But the model does illustrate how deposit withdrawal can affect real activity within an otherwise-conventional new Keynesian model.

needed to borrow did not hold enough assets the Fed would accept as collateral for a loan – Federal debt, banker's acceptances, and eligible paper (Carlson and Wheelock 2016). The Fed was not allowed to lend against many types of bank assets that were illiquid or became so in a crisis, such as long-term corporate bonds.

To act effectively as a lender of last resort, a Reserve bank had to "improvise and test the limits of the Federal Reserve Act" (Bordo and Wheelock 2013, p. 88). Some Reserve banks, most prominently the Federal Reserve Bank of Atlanta, did push the limits. Other Reserve banks, such as the Federal Reserve Bank of St. Louis, did not. Richardson and Troost (2009) examined a crisis in late 1930 that affected banks in a region that straddled the line between the Atlanta and St. Louis districts. They found banks were less likely to fail, and business activity remained stronger, within the Atlanta district. "If other Federal Reserve Banks had pursued similar strategies [to Atlanta's], fewer banks would have failed, and the depression may have followed a different course" (p. 1034). Unfortunately, most Reserve banks were like St. Louis.

In the absence of Federal Reserve action, President Hoover and Congress set up other institutions that could lend to more types of financial intermediaries and on more types of collateral. The most important was the Reconstruction Finance Corporation (RFC) established in January 1932. Unfortunately, the RFC's effectiveness was crippled by a law passed in July 1932 that "was interpreted as requiring the publication of the names of banks to which the RFC had made loans...The inclusion of a bank's name on the list was correctly interpreted as a sign of weakness, and hence frequently led to runs on the bank" (Friedman and Schwartz 1963, p. 325).

Why did Federal Reserve policymakers not try harder to act as lender of last resort? Because most of them did not think that was their job. Even the head of the New York Federal Reserve bank, George Harrison, opposed proposals to let Reserve banks lend on more types of assets or lend indirectly through less-constrained agencies (Meltzer 2003, p. 347). In February 1932 the same legislation that loosened the Fed's free gold constraint (the Glass-Steagall Act of February 1932) made it possible for Reserve banks to lend on any kind of collateral, under certain conditions (only to relatively small member banks and on approval of Board members [Carlson and Wheelock 2016]). Incredibly, Reserve banks failed to take advantage of this (Meltzer 2003, p. 358). The head of the Fed's Board from 1930 through early 1933, Eugene Meyer, supported the creation of the RFC and even served concurrently as chairman of the RFC's board. He did not appear to believe there was any overlap between the functions of the RFC and the Fed.

When the Fed was founded in 1914, its supporters argued that it would prevent the kinds of financial crises that had plagued the United States. But they did not expect it to do so by acting as a lender of last resort. They believed the United States had suffered financial crises before 1914 mainly because its supply of high-powered money did not adjust to seasonal fluctuations in money demand; by following the real bills doctrine, the Federal Reserve System would automatically adjust money supply and create an "elastic currency" so that "such a thing as a currency and credit panic can not exist under the Federal Reserve System" (Miller, quoted in Hetzel 1985, p. 12).

Some influential people in the Federal Reserve System believed that a lender of last resort actually did more harm than good. Henry Parker Willis was the Secretary of the Federal Reserve board 1914–1918 and research director at the board 1918–1922. In a book published in the wake of the 1933 crisis, he wrote (Willis 1936):

> The commonest and least precise idea of central banking is that which regards it as a form of "emergency relief" or "panic insurance." According to this viewpoint, ordinary banks are likely from time to time to get into "trouble".. . due to the acquisition of "frozen" [that is illiquid] assets...lack of confidence in which depositors or other creditors, believing they cannot at will convert their claims into cash, may bring about a "run," thereby forcing a bank into an embarrassed condition, or even forcing it to suspend...it may be possible to afford "relief"...through rediscounting or buying paper held in the embarrassed institution which it could not otherwise dispose of (pp. 5, 6)

> the view of central banking which considers it a means of helping out hard-pressed banks that have become "frozen" is not only theoretically unsound but is actually found in most cases to be injurious...When a central bank does so it merely tends to make a bad matter worse. (p. 15)

Willis believed that the constraints on Fed lending imposed by the definition of eligible collateral were a good thing *because they made it harder for the Fed to act as lender of last resort*:

> The fact that throughout the whole history of Federal Reserve banking, there has been continuous resistance to the observance of eligibility rules shows conclusively the need of them, and illustrates the danger involved in making the central bank merely a medium of emergency relief, to be availed of in times of stress...As long as this conception of central banking prevails, there will, of course, be continuous danger. (p. 138)

Meltzer (2003, p. 731) concluded that Fed policymakers were influenced by a "firm belief" that the system "could, or should, do nothing to prevent bank failures... Failures, they believed, were the inevitable consequence of bad decisions and speculative excesses that had to be purged before stability could return."

Aggregate Supply in the 1929–1933 Downturn: Wage Inflation, Price Inflation, and Real Wages

While real activity declined over 1929–1933, what happened to inflation? Pretty much what one would expect based on new Keynesian models and experience in other cyclical downturns.

In simple new Keynesian models, inflation rises and falls with the output gap (expressions (9), (10)). One of the conditions generating that relationship is that the public's expected value for the inflation rate that will prevail in the long-run future is zero. That condition seems to have held at the outset of the Great Depression. Inflation had been close to zero for several years. Judging from contemporary

literature, most people believed the gold standard would assure a roughly stable price level in the long-run future. Experts assumed the dollar's gold value would remain fixed and forecast a stable or slightly decreasing price level based on the balance of world gold supply and demand (Nelson 1991, pp. 6–7). Thus, new Keynesian theory implies that wage and price inflation should have fallen along with real activity over 1929–1933. That is what happened. Figure 6 plots inflation (percent change from the same month or quarter of the previous year) in a monthly index of average hourly earnings in manufacturing (the only high-frequency indicator of wage inflation from the 1930s that can be compared with series from other historical eras) and two price indices: a monthly CPI and a quarterly GNP deflator. Inflation started to fall almost immediately after the cyclical peak and fell more as the depression deepened. Because inflation was about zero at the start, this meant deflation.

There have been other historical eras in which expected long-run inflation was probably close to zero. Before 1914 the international gold standard could reasonably be believed to ensure a stable price level in the long run. From the 1950s through the mid-1960s and again after the 1980s, expected future long-run inflation appears to have been "anchored" at a low value by public confidence in monetary policy. Data from both of those eras are consistent with (9) and (10): wage and price inflation are positively (negatively) correlated with estimates of the output (unemployment) gap (Gordon 1990; Alogoskoufis and Smith 1991; Allen 1992; Gali 2011; Ball and Mazumder 2015; Blanchard 2016).[7]

The magnitude of deflation over 1929–1933 was about what one would expect from patterns in those other eras. Figure 7 is a scatterplot of annual data on wage inflation and unemployment rates from 1924 to 1939 and 1891–1914 and 1954–1965. I chose these particular sets of years to compare with the Great Depression because they are covered by comparable series on wage inflation and unemployment rates, and they were unaffected by wage and price controls.[8] The observations for 1930–1932 are in line with those from 1891 to 1914 and 1954–1965.[9] Observations from 1933 to 1938 are different: those years' annual wage inflation is anomalously high. I will return to this point later.

Returning to Fig. 6, note that over 1930–1931, the two measures of price inflation fell faster than wage inflation: real wages were countercyclical. That may seem odd. Most studies of postwar data find real wages to be procyclical or acyclical. But it was the usual pattern in recessions prior to the Second World War. It was not anything special about the Great Depression. Whenever one can compare similarly

[7]In some postwar years, from the later 1960s through the 1980s, real activity was correlated with the *change* in inflation – that is, inflation was strongly "persistent." Inflation persistence can be generated in new Keynesian models by "indexing" wages and prices to lagged inflation (e.g., Christiano et al. 2005). It can also be generated in models where the expected long-run future inflation rate varies over time. The latter possibility is tricky; see Ascari (2004), Kozicki and Tinsley (2002), and Cogley and Sbordone (2008).

[8]The Korean War controls were lifted in February 1953 (Rockoff 1984).

[9]It is sometimes claimed that nominal wages were unusually rigid in the 1929–1933 downturn (e.g., O'Brien 1989; Ohanian 2009). Obviously not true.

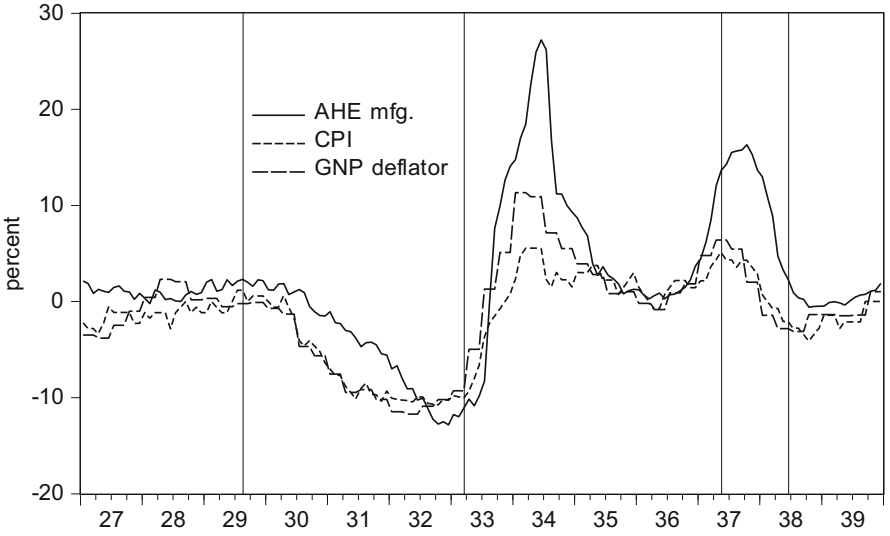

Fig. 6 Inflation in average hourly earnings, consumer prices, GNP deflator 1927–1939. (Sources and notes: average hourly earnings from Hanes (1996). Consumer price index from Federal Reserve Bank of St. Louis (https://fred.stlouisfed.org/series/CPIAUCNS). GNP deflator from Balke and Gordon (1986) Table 2. Both the CPI and GNP deflators are rougher estimates than their postwar counterparts constructed from lower-frequency estimates by interpolation on very limited data)

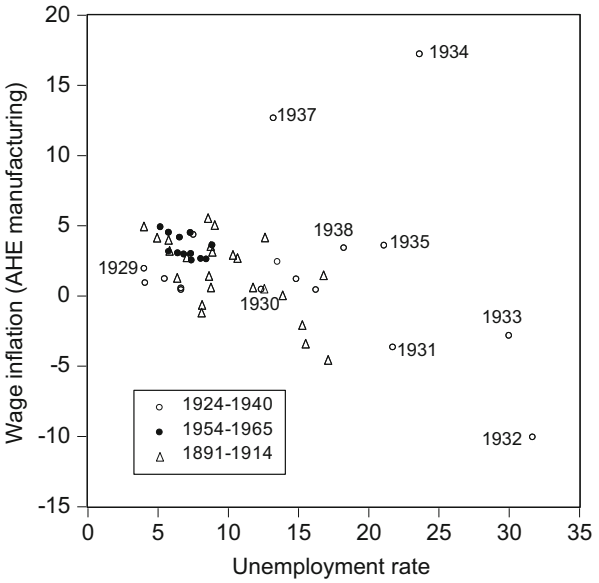
Fig. 7 Wage inflation and unemployment 1924–1940, 1954–1965, and 1891–1914. (Sources and Notes: annual average hourly earnings in manufacturing 1891–1914 from Rees (1961) "nine-industry" index; 1924–1940 and 1954–1965 from Hanes (1996). Private nonfarm unemployment rate from Weir 1992, Table D3)



constructed wage and price series across historical eras, real wages appear less procyclical, more countercyclical in eras prior to the Second World War (Hanes 1996). Huang et al. (2004) show that this historical development is consistent with new Keynesian models that allow for multiple stages of production, so that sticky-priced output is used partly as an input to production of more sticky-priced output. In these models real wages are more countercyclical if there is fewer number of stages or rounds of production before final sale. In the United States, both consumer goods and aggregate final output (GDP) were less finished, in this sense, in the 1930s than in postwar decades (Hanes 1999).

The Recovery 1933–1937

The recovery from the March 1933 cyclical trough was spectacular. On current BEA estimates, in *every* year from 1934 through 1936, annual real GDP grew faster than in *any* year after the Second World War. Three factors undoubtedly contributed to recovery. First, fiscal policy was mildly stimulative. Second, short-term nominal interest rates were as low as they could go: monetary policy pushed them back down to the floor and, this time, kept them there. Third, financial intermediaries were reactivated. Banks reopened and were reformed in a way that created confidence they would not fail in the future. Deposits flowed back in. That is, funding for loans to credit-constrained borrowers flowed back into financial intermediaries. Yet another factor may have contributed to recovery, but its existence is hard to prove. Monetary and exchange-rate policies adopted by the incoming Roosevelt administration may have created expectations of future inflation. In new Keynesian models, that would give an immediate boost to current real activity.

Fiscal Policy

Real government purchases of goods and services rose from 1933 through 1936 (Fig. 3), while the ratio of taxes net of transfers to national income fell (Fig. 4). Thus fiscal policy contributed to recovery. But most analysis has concluded that the contribution was modest at best (e.g., Brown 1956). In 1936 the federal government made a one-time "bonus" transfer payment (apparent in Fig. 4) to veterans of the First World War. Hausman (2016) argues that the bonus allowed credit-constrained recipients to borrow against expected future income growth and boosted 1936 GDP growth by as much as 1.6%. But that was not much relative to total real GDP growth in 1936, which was almost 13%.

Revival of the Banking System

Most banks were back in business less than 2 weeks after Roosevelt's proclamation of the national bank holiday on March 4, 1933 (Friedman and Schwartz 1963,

pp. 421–428; Awalt 1969; Kennedy 1973, pp. 179–202; Meltzer 2003, pp. 421–435). Within that short time, legislation had been passed that allowed the RFC to lend on security of low-quality assets and to make equity investments in banks to boost bank capital. Also, all banks had been examined by agents of existing bank regulators and triaged. Those that were clearly solvent and liquid were reopened over March 13–15. Deeply insolvent banks were sent into liquidation; owners lost their investment, depositors and other creditors received a fraction of what was owed them. (The process usually involved a loan from the RFC, so that illiquid assets could be sold off slowly and get a better price.). Marginally solvent banks were reorganized and reopened gradually (often with a capital contribution from the RFC). In January 1934 a new deposit insurance scheme started operation, backed by the federal government (Federal Deposit Insurance Corporation 1998, pp. 27–31).

Deposits began to flow back into banks quickly starting in January 1934 (Fig. 5). Of course, that does not mean the spread between safe interest rates and the cost of funds to credit-constrained borrowers snapped right back to pre-1929 levels. There is evidence loan supply remained impaired after 1933. Many banks still had less capital than before the depression, and they appear to have required higher expected returns on risky assets such as loans relative to safe assets such as government bonds (Friedman and Schwartz 1963, pp. 449–462; Calomiris and Wilson 2004).

The Path of Short-Term Interest Rates

In January 1934 the Roosevelt administration put the United States back on the gold standard, in the sense that American monetary authorities resumed exchange of dollars for gold at a fixed price. It was a new, higher price, however, which devalued the dollar against currencies of the many countries which continued to fix, or at least tightly manage, their gold exchange rates. Under the new institutional arrangements, the Treasury rather than the Fed exchanged gold for dollars (buying gold from anyone, selling gold only to foreign monetary authorities). But just as before, gold purchases added to high-powered money (Meltzer 2003, p. 458). Also as before the United States usually ran a balance of payments surplus. The Federal Reserve did not sterilize the effect of Treasury gold purchases, so high-powered money and free reserves grew rapidly. Overnight rates fell. In early 1934 the federal funds rate was back on the floor. Discount borrowing to cover reserve shortfalls was nil (Hanes 2006). This situation prevailed through the beginning of 1937, as indicated by the low Treasury bill rate in Fig. 2.

Expected Future Inflation

Many economists have argued that Roosevelt's suspension of gold payments in March 1933 and devaluation of the dollar against gold in January 1934 created expectations of future inflation (Temin and Wigmore 1990; Jalil and Rua 2016). That

would certainly have been true if expectations were sufficiently rational. Generally, exchange-rate devaluation raises import prices and the domestic price level (Eichengreen 2004). A commitment to a devalued exchange rate is effectively a promise on the part of the authorities that a higher domestic price level is coming sooner or later (Svensson 2003). Over 1933–1934, Roosevelt not only depreciated the dollar but pledged to "reflate" prices back to pre-Depression levels. Romer (1992) argues that realized increases in high-powered money supply from 1934 on also raised expected future inflation.

In standard new Keynesian models, when short-term nominal rates are stuck at the zero bound, news that inflation is coming in the future boosts real activity immediately. Recall that current real activity depends not only on the current short-term real interest rate but on the path of expected short-term real rates from now into the distant future (expression 3 above). Given the path of expected future nominal rates, a belief that inflation must come *sometime* lowers expected real rates for at least some future periods. Krugman (1998, p. 161) and Svensson (2004, p. 90) argue that Roosevelt's policy moves of 1933–1934 may have spurred real activity in this way. Eggertsson (2008) presents a new Keynesian model of the 1930s economy in which a mechanism of this type accounts for most growth in output over 1933–1937.

Unfortunately, there is no simple way to confirm that Roosevelt's policies and pronouncements really did affect beliefs of households and business managers in this way. There were no surveys of inflation expectations in the 1930s like today's Survey of Professional Forecasters or Michigan Survey.

Aggregate Supply over 1933–1937: Anomalous Inflation

Figure 6 shows that wage and price inflation picked up as real activity recovered after March 1933, as one would expect. But the rates of inflation, especially wage inflation, that prevailed after March 1933 were anomalously high. Output, though rising, was still far below the pre-Depression trend. Unemployment, though falling, was still high. In Fig. 7, annual wage inflation looks wildly high in 1934 and 1937.

One possible explanation of this anomalous inflation is the same new Keynesian expected-inflation mechanism that could have contributed to recovery of real activity. In new Keynesian models, extraordinary events that raise expected future inflation at any horizon, however distant, give an immediate boost to current inflation at any given level of current real activity. In terms of (7), such events mean higher values of $z^e_{t+\tau}$.

Another explanation is Roosevelt administration policies that fixed minimum wages, banned wage cuts, encouraged union formation, and strengthened union bargaining power (Samuelson and Solow 1960, p. 188; Weinstein 1980). There were historically unprecedented increases in the fraction of workers belonging to unions and engaging in strikes, especially over 1934–1935 and 1937–1938. It is plausible that these things were causes and effects of an increase in workers' bargaining power. In new Keynesian models, increases in worker bargaining

power correspond to "wage markup shocks" that should raise inflation at any given level of real activity (positive values of $\epsilon_{\pi P}$ and $\epsilon_{\pi W}$ in 9, 10).

The 1937 Downturn

At the end of 1936, full recovery was in sight. If output had continued to grow as it had over 1935–1936, real GDP would have been back to pre-Depression trend by the end of 1938 (Melzter 2003, p. 571). Instead there was another downturn, from a cyclical peak in May 1937. This recession was short; the trough was just a year later in June 1938. But it was sharp. Annual real GDP fell more than 3 1/4% from 1937 to 1938, more than in any postwar year. The 1937–1938 downturn has been studied much less than 1929–1933. Its causes are still unclear.

It must have been at least partly due to fiscal policy. From 1936 to 1937, real government purchases fell (Fig. 3). Taxes net of transfers rose as a fraction of national income (Fig. 4) due to three events that were all exogenous to macroeconomic conditions: the end of the veterans' bonus payment, legislation that raised personal income tax rates (the Revenue Act of June 1936), and the first collections of payroll taxes for the new Social Security system (Meltzer 2003, pp. 521, 563; Velde 2009). However, it would be hard to argue that the fiscal tightening alone can account for the magnitude of the decline in real activity (Romer 1992, p. 766).

What about monetary policy? In 1936 Fed policymakers had come to fear that the increasing supply of high-powered money must create uncontrollable inflation at some point in the future, because it was getting to be too large to drain with sales of Fed assets. According to the Burgess-Riefler doctrine, there would soon be no way to tighten policy because it would be impossible to reduce free reserves enough to force banks into the discount window. To head off this problem, the Federal Reserve Board reduced free reserves by hiking reserve requirements. In July 1936 the Fed announced a hike to become effective in August (Meltzer 2003, pp. 493–503). In January 1937 it announced more hikes to become effective in March and May 1937 (Meltzer 2003, pp. 507–510).

Meanwhile Treasury policymakers had come to fear foreign gold inflows might reverse in the future, creating uncontrollable *deflation* (Blum 1959, pp. 359–60). They developed a method by which the Treasury could sterilize gold inflows and build up a gold reserve to cover a future balance of payments deficit. The scheme was simultaneously announced and put into effect in late December 1936, at which time high-powered money growth ceased.

Together, the hikes in reserve requirements and cessation of high-powered money growth reduced free reserve supply substantially. In March 1937 short-term rates rose above the floor (Fig. 2). But they did not rise much, and the cyclical downturn came just 2 or 3 months later. The lag between an interest-rate hike and a consequent decline in real activity is usually longer than that, in postwar data at least (Christiano et al. 2005). The first hike in reserve requirements back in 1936 was not associated with an increase in short- or long-term interest rates (Fig. 2). Thus, the channel

through which reserve-requirement hikes and cessation of money growth could have actually caused the recession is not obvious. Eggertsson and Pugsley (2006) argue that the channel was the new Keynesian expected-inflation mechanism: the policy changes raised doubt about policymakers' commitment to a future increase in the price level, hence raised expected future real rates.

Conclusion

Graduate students should always be on the lookout for open questions to answer. So I conclude by pointing out some open questions about the Great Depression. In 1933, did suspension of bank payment services depress real activity by making it harder to produce and trade? How much did this matter relative to other effects of bank failures such as increases in costs of funds to credit-constrained borrowers? Why was inflation so high over 1933–1937? In 1937–1938, how did apparently small increases in short-term interest rates and a mild tightening of fiscal policy cause such a large recession so quickly? Some proposed answers to those questions rely on propositions about the response of the public's long-term inflation expectations to historically unique events. How can such propositions be tested?

Central Banking

Jon Moen

Contents

Abstract

The study of central banking is an important part of cliometrics today. However, economists and bankers have been studying central banking since well before the cliometric revolution began. Early eighteenth century British economists were studying the structure of the Bank of England in detail, and economists were closely involved in the debates leading up to the creation of the Federal Reserve System. Starting in the 1970s and 1980s, cliometricians began studying central banking and related issues in great detail. The study of bank panics of the National Banking Era and Great Depression in the United States has revealed that lender of last resort activities have been undertaken rather timidly, ranging from the incomplete responses of clearinghouses to the failure of the Federal Reserve during the Depression. Cliometricians have also added several large and rich sources of evidence to the study of central banking.

Introduction

Cliometricians have not always been involved in the study of central banking. But the cliometric approach, that of using the economic and quantitative tools available at the time, has been used from early on. Even before there were formally recognized economists, banking practitioners were as much involved in the analysis of the effects of central banks as were historians. This sets the study of central banking apart from the study of other fields, such as slavery or railroads, fields that were eventually dominated by cliometrics and cliometricians. To examine the contributions of cliometrics and cliometricians to the study of central banking, I look primarily at the economic study of central banking in the United States, prefaced with a brief foray into eighteenth and nineteenth century Britain.

The functions of a central bank can be divided broadly into banking versus monetary policy. Banking policy deals with functions like note issue, check clearing, lending, discounting, and emergency lender of last resort functions. Monetary policy deals more with macroeconomic issues. Before the twentieth century, monetary policy tended to deal with the relationship between note issue and the price level or exchange rates. Issues related to modern macroeconomic theory and policy, especially a central bank's ability to alter business cycles and economic activity in general, became predominant after the Great Depression and Keynes' General Theory. I will leave modern macroeconomic theory to macroeconomists and will focus on banking policy and early monetary policy.

Cliometricians have made several important contributions to the understanding of central banking. The first set of contributions deals with the structures and institutions of central banking. As important precursors to central banking in the United States, clearinghouses and the correspondent banking system are all better understood because of cliometrics. We have a clearer understanding of bank panics, what happens during a panic, the actions of lenders of last resort that may or may not have helped and, hence, these same behaviors in more recent panics. Cliometricians have also made new sources of evidence available to researchers, either by discovering new sources or by making old sources computer readable. Having a better grasp of what happens during panics also sets the stage for better theories of panics.

I will start with a brief survey of pre-cliometric studies of banks and central banks. A mainly chronological survey of cliometrics and central banking will follow, starting with the antebellum United States. While the postbellum United States had no formal central bank, institutions arose that took on some central bank-like functions. In particular, I will examine the cliometric study of clearinghouses and their nascent central bank functions during the postbellum period. The actions of the New York Clearing House during the Panic of 1907 influenced the subsequent creation of the Federal Reserve System in the panic's aftermath. The remainder

of the survey examines cliometric studies of the Fed and central banking. It finishes with a review of databases relevant to central banking contributed by cliometricians.

Early Studies of Central Banking

The systematic study of central banking and monetary policy by contemporary observers goes back to at least the late eighteenth century. Henry Thornton and Thomas Tooke were early nineteenth century English economists and bankers who were involved in the bullionist controversy. Politicians in Great Britain were concerned about the effects of the issuance of paper currency on the price level and exchange rates during the Napoleonic Wars after Britain had suspended gold convertibility in 1797. This was a debate about the relationship between the level of prices and changes in issue of paper money by the Bank of England. The bullionists argued that convertibility was necessary to prevent the over-issue of currency relative to the gold in the bank's vault that otherwise would result in inflation. The anti-bullionists argued that the issue of banknotes was limited by the fact that they were issued in exchange for bills of exchange (real bills). Thornton's *An Enquiry into the Nature and Effects of the Paper Credit of Great Britain* (1802) is an early look at the relationship between currency issue and prices. He takes the anti-bullionist position to defend the bank of England from charges of excessive issue, although he argued that issuing currency for bills of exchange was not a sure guarantee against inflation. Adam Smith, in contrast, was a strong supporter of the anti-bullionist position. Thomas Tooke (1844) was more in the bullionist camp, supporting a return to convertibility, although he opposed the strict limits imposed on the Bank's discretion to issue currency by the Bank Charter Act of 1844. Both Thornton and Tooke held the position that bank-created money was the result of increases in prices, not the cause. Robert Hetzel provides a fine overview of Thornton as a central banker (Hetzel 1987).

David Ricardo was well within the bullionist camp and gold convertibility. He also presented a somewhat obscure plan for a formal central bank in Great Britain, *Plan for the Establishment of a National Bank* (1824). At that time, the bank of England was neither a central bank nor lender of last resort. Rather, it consisted of two sections, a bank of note issue and a lending bank whose customers included the government of Great Britain. Ricardo proposed splitting the two functions, making the government, or national, bank the sole issuer of paper currency supervised by an independent board of commissioners. Such a split would have no negative economic effects, but in Ricardo's view it would allow for better regulation of note issue. Quite recently, the bullionist controversy has been revisited by Joshua Hendrickson (2018). Using Bayesian econometrics, he provides support for the bullionist position. Pamfili Antipa (2014) comes to similar conclusions.

Several decades later, Walter Bagehot, a journalist and economist, examined the issue of currency and prices in *Lombard Street* (1873), arguing for a larger

reserve at the Bank of England. Here he made his well-known prescription for fighting a bank panic – that the bank of England should lend freely at a high rate of interest. As Milton Friedman and Anna Schwartz (1963) have argued in the context of the United States during the Great Depression, this prescription does not seem to have been followed that well, although the US Federal Reserve seems to have finally learned the lesson. Under the leadership of Chairman Ben Bernanke, in response to the disruption to financial markets in 2008/2009, the Fed did lend more freely than in the past and to intermediaries that had not been narrowly defined as banks. It appears to have barely lent just enough to have avoided a collapse of banking and the money supply, unlike during the Great Depression.

Even in history of thought, the early economists were contributing to the understanding of the relationship between money and the price level and short run vs. long run neutrality at a theoretical level. This goes back to at least David Hume (1985) and later Knut Wicksell (1934). See Blaug(1996) for an overview of the evolution of early banking theory. Both emphasize that changes in money can have short run effects on some real activity, but in the long run the effects are neutral and only affect the price level. All of these early discussions relate to the relationship between money and the price level, or level of various prices. How money changed real activity and the business cycle was not yet in the forefront of economic discussion.

Antebellum US Central Banking

Early in US history the role and impact of a national bank were widely discussed. Alexander Hamilton and Andrew Jackson, before there were even economists in the United States, sparred on the effects of the Bank of the United States on credit to small business owners and farmers in addition to the extent of the inflationary effects of centralized note issue. Richard Timberlake (1993) notes that the First Bank of the United States' high reserve ratio allowed it to manage currency and credit availability. It could restrain credit by presenting state bank notes for redemption in specie, while it could increase credit by loosening lending to businesses. It was, after all, in part a private bank, and the fact that it was competing with state banks contributed to its charter not being renewed.

The Second Bank of the United States was structured in ways similar to those of the first bank. One difference was that under the more active leadership of Nicholas Biddle, the Bank appeared to have been more aggressively managing credit. But Timberlake (1993) points out that the Bank was actively maintaining the workings of the metallic standard and the movements of international exchange, which may have been interpreted as intervening in credit markets for its own ends.

Jane Knodell (2003) has shown that the Second Bank of the United States was able to balance the trade-off between private profitability and performing its services for the federal government. Its large-scale dealings in domestic exchange and foreign transactions allowed it to profitably and efficiently provide regional and international payments, a basic function of a central bank.

In the midst of this period, the Suffolk banking system (1825–1858) flourished in the New England area as what may be referred to as an "operational" central bank, especially in the absence of the Second Bank after 1837. Although the key features of the system foreshadowed some characteristics of modern central banking procedures (lending reserves to other banks, maintaining the operation of the payments system, presenting the notes of country banks for redemption as a means to control note issue), the Suffolk system was not at the time viewed as a model for a central bank. Research by Rolnick et al. (1998) suggests that the actions of the Suffolk Bank during the Panic of 1837 helped the New England economy fare better than the rest of the country. New England banks were able to maintain loans and maintain the operation of the regional payments system. The Suffolk Bank may have played a useful monitoring role for the member banks in the system as well. Calomiris and Kahn (1996) show that the Suffolk system operated efficiently, with little rent-seeking or exploitation of the smaller, country banks within the note exchange system. Howard Bodenhorn (2002), however, questioned the ability of the Suffolk system to control note issue.

Postbellum Central Banking and Clearinghouses

As mentioned above, the Suffolk system provided some of the elements of central banking to the banks of its region, but these functions supplied mainly payments system efficiency without the central bank features of liquidity creation. From 1837 to 1914, the United States had no formal lender of last resort, an unusual feature for an advanced economy at this time. Esther Taus (1943) and Richard Timberlake (1993) describe how the Treasury employed some limited, central bank-like powers before the Federal Reserve System. Timberlake (1993) notes that the pre-Civil War independent Treasury developed monetary policy tools like open market operations.

Of these early central bank-like institutions to arise, the most important are the clearinghouses that appeared across the United States in response to a system of unit banking in the absence of a formal lender of last resort. Before the Federal Reserve System, the United States nevertheless had institutions in the form of the clearing houses across the country that in many instances served as proto-central banks. The most prominent is the New York Clearing House, although others have been studied as well. An early analysis of the Clearing House was carried out by O.M.W. Sprague (1910), writing for the National Monetary Commission in his famous *History of Crises under the National Banking System*. He highlights the unfortunate delay of the Clearing House in issuing clearing house loan certificates during the early stages of the panic of 1907. James Cannon, a president of the NYCH, produced a volume analyzing the structure of the more important clearing-houses in several large US cities (Cannon 1910). Even though Sprague and Cannon did not write much about central banking directly, the clearinghouses have been viewed as precursors to a modern central bank and as models for the Federal Reserve's initial decentralized structure. These two early authors have provided the

foundation for much of the modern, cliometric analysis of the central bank – like functions of clearinghouses.

Cliometricians have expanded our understanding of clearinghouses, building on the early work of Cannon and Sprague. Timberlake (1984) and Gorton (1985) describe how private and commercial banks formed among themselves a system of clearinghouse associations, starting with the New York Clearinghouse in 1853. Timberlake (1993) notes that as early as 1857 the New York Clearing House began exerting power in ways akin to a central bank through the issuance of clearinghouse loan certificates as a means to increase liquidity in the short run. The Clearing House also developed powers of examination of its members that resemble those of the Comptroller of the Currency and the Federal Reserve today. These responses to a banking system without a central bank were limited by the legal restrictions on banks and on the limitation of legal tender status to specie alone for tax payments. Furthermore, these measures to expand liquidity were temporary and regional at best, as the New York Clearing House could do little to expand liquidity outside of New York. Richard Timberlake (1978, 1984, and 1993) is most notable for his analysis of clearinghouses. He agrees that clearinghouses were providing some central bank-like functions. But he goes beyond that result and comes to the conclusion that with some minor modifications, clearinghouses could have adequately provided central bank or lender of last resort services without the establishment of a formal central bank like the Federal Reserve.

He points out that federally chartered clearinghouses in each state could have provided emergency liquidity during panics about as well as a government run central bank. The use of clearinghouse loan certificates could have been expanded to serve as the source of emergency liquidity. During panics, clearinghouses, New York's most notably, would allow banks to present securities to serve as collateral for the issuance of a quasi-currency that would serve as a settlement medium, one that would circulate among banks in place of legal tender or specie. The released legal tender and specie could then be used to pay panicked depositors, or more likely panicked correspondent banks in the interior. Critics of loan certificates viewed them as a poor substitute for actual currency, owing to the illegality of circulating the certificates to the general public. Timberlake asserts that just the opposite was true, given how readily they circulated among the public in cities where they were allowed to circulate in 1907. New York was a key exception, letting them circulate only among the member banks of the Clearing House. Even legal authorities in the Treasury ignored the illegality, given the obvious function they were providing to keep transactions continuing. Still, as Timberlake notes, the appearance of illegality and a "hucksterish" quality fueled the desire for an official currency, and the Fed and its notes prevailed.

Gary Gorton (1985) argues that the rise of the clearinghouse was in part due to the increasing use of checks and demand deposits in the middle of the nineteenth Century. Unlike banknotes, for which the private sector had produced methods of pricing notes, such as the regular publication of bank note detectors, it was much more difficult for the private sector and depositors to value or price individual demand deposits owing to their being a claim not just on an individual bank but also

on an individual's deposit. A secondary market was much less likely to arise on deposits than on notes, and one never developed. Gorton and Mullineaux (1987) elaborate on the point that the clearinghouse arose as a means to overcome the information asymmetries involving higher monitoring costs for deposits compared to banks and banknotes. Moen and Tallman (2015) argue that the big six national banks in New York City appear to have acted less in coordination as a central bank during the Panics of 1873, 1884, 1890, 1893, and 1907 than has been popularly believed. They show that the use of clearing house loan certificates during these panics appears to be much more bank-specific, with some issuing large volumes while others issued none.

This discussion foreshadows Gorton's (2010) more recent emphasis on the role of information sensitive and insensitive assets in the financial crisis of 2008. Information insensitive assets are simply those whose value is immediately and easily recognized, like currency or federal government bonds. During a crisis or panic, investors increase their demand for information insensitive assets to shed risk. Gorton also expands the analysis of the role of shadow banking in the recent financial crisis. He argues that it was the collapse of overnight lending in the Repo market that was the ultimate source of financial collapse in 2008, not the housing bubble itself.

Moen and Tallman (1992, 2000) show that the Panic of 1907 was surprisingly severe in the eyes of New York bankers because the panic was focused on trust companies, intermediaries outside of the formal protection of the New York Clearing House. They were participating in financial markets along with Clearing House members, the national banks, a type of shadow banking described by Gorton. They also show that the more complete coverage of all intermediaries, including trust companies, by the clearinghouse in Chicago led to much less disruption in intermediation than in New York. They highlight the role that incomplete coverage by a lender of last resort, in this case the New York Clearing House, can have on the market. In 1907 the clearing house did not protect state-chartered trust companies, which operated in the call loan market alongside the national banks in New York. They became the source of panic because they were not members of the Clearing House.

Christopher Hoag (2012) looks at Clearing House behavior and the use of clearing house loan certificates in the Panic of 1893. He shows that banks did not suffer from moral hazard when borrowing with loan certificates and that pre-panic balance sheet characteristics do not explain borrowing through loan certificates. Of course, during a panic even otherwise healthy banks would want to conserve on their legal tender reserves and use loan certificates instead. He also argues that Clearing House membership in New York did not mitigate deposit contractions during the panic.

Quite recently, Vincent Bignon (2017) has shown that clearing houses can fail, calling into question the ability of these private sector institutions to provide reliable lender of last resort functions. While he analyzes a stock market clearing house, his insights point to the consideration that a private sector lender of last resort may not be able to summon the resources to provide a substantial boost to net liquidity during a crisis.

The National Banking Era and Currency Reform

In the United States, the later nineteenth century was a hotbed of proposals for currency reform in light of the perceived "inelastic supply" of national bank notes. National bank notes were backed by Federal government bonds, the supply of which had no clear relationship to economic activity. This problem became an issue during the recurring bank panics of the later nineteenth Century. The keen emphasis on currency reform, however, diverted attention from creating a new lender of last resort, at least until 1907. But examining issues around currency reform helps illuminate the role of clearinghouses and the debate over the structure of the Federal Reserve System and the means to increase liquidity during a crisis. The function of clearinghouse loan certificates is important here. Viewing the amount of federal debt outstanding as a constraint on national bank note issue, a movement began to take hold that recommended replacing the government bond-backed National Bank notes with other notes backed by short-term assets of individual banks like commercial paper or acceptances. It was thought that such asset backing would allow the currency to expand and contract with business conditions. A secondary market for commercial paper in the United States never really developed under National Banking, and such a market never really became established until the Federal Reserve System. In addition, the acyclical nature of federal debt was credited with failing to ensure adequate volume of backing for the provision of liquidity and credit to commerce. The inelasticity of national bank note issue was left unexamined until recent research cast some doubt on the allegations. Charles Calomiris and Joe Mason (2008) show that national bank notes were never issued up to the maximum legal limit and that it was bank specific reasons that kept some banks from issuing more notes, not the volume of government bonds that could be used as backing for new note issue.

"Asset-backed" currency proposals began to appear regularly in public discussions in the 1890s. Essentially, these proposals were aimed at producing a financial system akin to the monetary system in Canada, but without the branch banking powers of Canadian banks. At the American Bankers Association Convention of 1894 in Baltimore, one plan arose to amend the National Bank Acts by replacing the bond-backed notes with notes backed by the short-term assets of the issuing bank. A guarantee fund was also to be established at the Treasury to redeem the notes of a failed bank. The support for such a currency came from the Laissez Faire branch of the Democratic Party identified by Richard McCulley (1992). Robert Craig West (1974) notes that some prominent New York bankers opposed the "Baltimore Plan." These bankers feared that without restrictions or powerful monitoring, questionable bank assets could be used to secure currency issues. James Livingston (1986) notes that New York City bankers would not support an asset backed currency proposal without branch banking provisions. Politically, neither proposal had potential as legislation. An asset backed currency was a cornerstone of monetary reform proposals coming out of the Midwest, particularly those of J. Laurence Laughlin, the first head of the Economics Department at the University of Chicago, and James B. Forgan, president of the First National bank of Chicago (McCulley 1992).

Despite the lack of early success in legislative action, the Baltimore Plan and the asset-backed currency issue did, nevertheless, influence later reform measures.

Most notable among them, the plan proposed by the Indianapolis Monetary Commission in 1898, written by a key member of the executive committee of the convention, J. Laurence Laughlin. It is therefore not surprising that his ideas were central to this proposal.

Laughlin was strongly against a bimetallic standard and favored gold, but he was also a proponent of an asset-backed note-issue. The Indianapolis Monetary Commission plan included a 5-year phasing out of the bond-backed national bank notes, to be replaced with asset-backed notes issued by the individual banks. The plan included a five percent guaranty fund to redeem the notes of failed banks, and it even included some branching provisions. But, it did not significantly alter the system of reserves present under the National Bank Act. A movement towards a central bank with a compelling message had yet to acquire a politically effective constituency.

The extended discussion over currency reform tended to overwhelm any discussions, academic or political, of establishing a formal central bank until the Panic of 1907 shocked the New York banking community into pushing for a central bank. The panic in New York City had been focused on the trust companies, state-chartered intermediaries outside the payments system controlled by the Clearing House, and competitors to the national banks. In the aftermath of the panic, the large New York national banks realized that even though they may have profited during earlier panics, the scale of the recent panic had been enough to convince the bankers that a panic more severe than that of 1907 would be beyond the resources of the New York Clearing House banks. They just didn't control enough liquidity to act like a lender of last resort in a more severe panic. Private financiers like Morgan and Rockefeller had to put up their own funds to support the stock market and call loan market until gold flows from Europe reached New York banks. Hence, the New York bankers threw their support behind the effort to create a source of liquidity and reserves that was outside of the banking system, and the creation of what became the Federal Reserve System was underway (Moen and Tallman 2007). Like policy debates today, the debates over the structure of the new central bank included concern over intermediaries outside of the traditional banking system, trust companies in particular, and overnight lending on the call loan market.

The National Monetary Commission and the Fed

One legislative outcome spurred by the disruption of the Panic of 1907 was the creation of the National Monetary Commission. The National Monetary Commission included economists and bankers, and it produced the series of monumental volumes on various aspects of banking, including a large volume of data. The immediate goal of the Commission was to provide background information and data from other countries with central banks to be used in the creation of a central bank for the United States. Their use as a critical academic reference point was not initially apparent or important. The volumes nevertheless remain important, for cliometricians today still rely on this data when investigating the panic and other aspects of the National Banking System. A. Piatt Andrew and O.M.W. Sprague were

the key economists serving on the commission. Andrew is noted for his research into currency substitutes used during the panic (Andrew 1908, 1910), while Sprague produced the key historical work on panics, *A History of Crises under the National Banking System* (1910). This particular volume is still heavily referenced by cliometricians. Commission member Paul Warburg, a banker rather than an academic economist, influenced the structure of the early Federal Reserve. Even though he was well versed in European central banking, he knew that only a decentralized system of last resort reserves would have any chance of success in the United States (Warburg 1930). A centralized bank along the lines of those in Europe would have no chance of gaining political support, as Americans would likely view a centralized bank as easily captured by Wall Street banking interests at the expanse of small businesses and farmers. Mehrling (2016) provides a survey of the influence of US economists contemporary at the time, including economist Irving Fisher and Lauchlin Currie, Marriner Eccles' personal assistant at the Board of Governors of the Federal Reserve System, in the design of the Federal Reserve System.

The Federal Reserve was more closely examined at the time by economists and politicians after its apparent ineffectiveness in expanding the money supply during the early stages of the Great Depression. The most notable was Lauchlin Currie, an economist trained at the London School of Economics. In *The Supply and Control of Money in the United States* (1935), Currie outlined what he perceived as the weaknesses of the original, decentralized Federal Reserve System. The weaknesses included the lack of universal membership, decentralized reserves, and lack of central control over the system's reserves. The absence of universal membership in the original Federal Reserve System resulted in intermediaries operating in the same markets as Fed members, but having no access to the Fed's liquidity. This would return to hinder the Fed's effectiveness during the Great Depression, during which state-chartered banks failed in disproportionately larger numbers than member Fed banks (Wicker 2000). Panic at the nonmember state-chartered intermediaries could drag down Fed member national banks in a pattern similar to that seen in the Panic of 1907, in which the non-Clearing House trust companies threatened the member national banks with the near collapse of the call loan market. Working with Treasury and Federal Reserve officials, Currie wrote much of the Banking Act of 1935, which gave the Federal Reserve System the centralized structure controlled by the Board of Governors we are familiar with today. Universal membership, however, still was not part of the Act. As noted earlier, the Fed stepped in to provide lender of last resort services to non-members and even non-banks in 2008/2009; some lessons can be learned.

Extended Histories of Central Banking and the Fed and the Rise of Cliometrics

Up to this point, it is clear that early economists and bankers had been influential in the study and structuring of central banks in Europe and the United States. While the application of cliometrics to the study of central banking was not as sharp

a distinction from "old" economic history practices as that seen in the study of railroads or slavery, a shift did appear. It brought explicit use of economic theory and econometrics to the study of central banking and for academic reasons, apart from those spurred by responses to crises or calls for reforms, as in the case of the currency debate.

If identifying a starting point for the cliometric study of central banking is important, then the cliometric "revolution" could have its inception loosely linked to the publication of Milton Friedman and Anna Schwartz's widely read book *A Monetary History of the United States from 1867 to 1960* (1963). It is a detailed study of the components of the money supply, the monetary base, velocity, and the structure of the US banking system. At least in the short run, it links movements in the money supply to movements in the economy. Friedman and Schwartz also provide estimates of the various components of the money supply from 1867 to 1960 in Appendix A of *The Monetary History*. They provide a detailed explanation of how the series were calculated from a variety of sources. Their constructed series include Currency Held by the Public and Deposits at Commercial Banks: Bank Reserves, including vault cash and deposits at Federal Reserve Banks; Federal Government Balances at the Treasury, Commercial and Savings Banks, and later at Federal Reserve Banks; US International Capital Movements; and estimates of the Velocity of Money. A subsequent volume to *The Monetary History*, *Monetary Statistics of the United States* (1970) provides more discussion of the construction of the 1867 to 1960 series. It also discusses extant measures of the money stock before 1867 and provides material for the construction of monetary series extended back to 1775. In their *Monetary trends in the US and the UK* (1984), they extend their analysis to the United Kingdom. Because *The Monetary History* was so influential in the study of the Great Depression, the critical chapter, The Great Contraction, 1929–1933 was later reissued as a stand-alone book, *The Great Contraction* (2008).

The Monetary History provides a comprehensive analysis of the Federal Reserve's conduct of monetary policy during the early stages of the Great Depression and beyond. Friedman and Schwartz describe the monetary policy followed by the Fed after 1929 as nothing short of "inept" when compared to its vigorous and active policy before 1929. They lay much of the blame on the shift of power within the Fed away from the New York bank to the Board of Governors in Washington D.C. The problems incurred by this shift were compounded by the death of Benjamin Strong in 1928, who had been governor of the New York bank since the start. He understood banking during panic conditions, having aided J.P. Morgan during 1907, and he was familiar with European central banking practices. His death, famously described by Friedman and Schwartz as "untimely," deprived the Federal Reserve of the expertise needed to deal with crisis conditions, with Fed policy makers reverting to a commercial banking mentality, one fraught with conservative, private sector responses to banks in trouble. Unlike the policy proffered by Bagehot for a central bank to lend freely on good collateral during a crisis, the Federal Reserve leaders contracted lending, as a commercial bank would during a crisis. Friedman and Schwartz also castigate some Fed officials for

believing that some banks should be weeded out during the Depression as a punishment for bad or careless lending during the headier days of the Roaring Twenties. For an in depth and extensive review of all the contributions of *The Monetary History,* see Michael Bordo (1989).

After *Monetary History,* more detailed and extended histories of central banks and the Federal Reserve appeared. Richard Timberlake's *The Origins of Central Banking in the United States* (1978) is a significant contribution to our understanding of how central banking came about in the United States. He points out that most economies go through stages of development in money and banking markets that do not inevitably lead to a central bank fully capable of controlling the money supply. A specie standard usually evolved to formalize a monetary system. Such systems were sometimes supplemented by banks that acted as the fiscal agent for a government, and while they were sometimes called a central bank, that did not mean they also were able to control the money supply. By the twentieth century, central banks as we understand them had come into being, with metallic standards eventually being replaced with fiat standards. But a central point in his argument is that they did not spring immediately into being fully formed. For example, the Federal Reserve System started out as a collection of banks modelled on the clearing houses and did not really become the central bank we know until the 1935 Banking Act centralized power in the Board of Governors. A subsequent and extension of this book, *Monetary Policy in the United States* (1993), adds a chapter on the central banking role clearinghouses before the Federal Reserve. It then extends the examination of monetary policy after the Federal Reserve up through the 1980s. In the end, he discusses what the Fed can and cannot do and makes a well-argued case for allowing more private sector control of the money supply. One example being that an extended clearinghouse system could have controlled the money supply during normal and panic conditions.

Charles Goodhart produced an important book, among several, on the importance and benefits of a central bank, *The Evolution of Central Banks* (1988). He outlines the historical arguments for and against a central bank, comparing Thornton and Bagehot's arguments for and against a system of decentralized reserves. He then discusses how central bank-like functions can arise within the private banking system, an obvious example being the rise of private clearinghouses. But he argues that there are limits to how far the private sector can go in providing these services, as self-interest can run up against efforts to serve the broader good. This problem can be significant if there are several large banks also competing with each other in more normal times, weakening the ability to create a private club whose members have competing interests. A natural solution was the creation of a non-competitive central bank unhindered by a narrowly defined profit motive, the evolution of the Bank of England being a prime example, subsequently followed by other countries when establishing their central banks.

Richard Timberlake (1993) argued that a central bank as described by Goodhart was not a necessary development in a modern economy. The expansion of the postbellum clearing house system in the United States would have provided a more than adequate solution to the lack of a secondary source of liquidity. A recent

article by Tallman and Jacobson (2015) provides some support for Timberlake's view that improvements to the clearinghouse arrangements may have been enough to provide adequate liquidity during a panic. They show that the new emergency currency authorized by the Aldrich-Vreeland Act used in conjunction with clearinghouse loan certificates successfully alleviated the liquidity crisis of 1914 brought about by the prospect of World War I. The emergency currency was issued by groups of national banks to provide liquidity among national banks, while loan certificates were used to provide liquidity to state banks and trust companies, intermediaries that could not borrow the emergency currency issued by the national banks.

Elmus Wicker has also made substantial contributions to our understanding of what happened during bank panics during the national banking Era in the United States and during the Great Depression. He has also provided us with a concise analysis of the political maneuverings leading up to the founding of the Federal Reserve System. *The Banking Panics of the Gilded Age* (2000) updates Sprague's *History of Crises* by applying more modern economic analysis and data collection. In *The Banking Panics of the Great Depression* (1996), Wicker tempers the Friedman and Schwartz "inept" behavior argument. He argues that Federal Reserve officials misinterpreted the increase in the currency to deposit ratio as showing monetary expansion. Today we realize that increase reflects a curtailment in deposit expansion and the money supply, even though the increase in currency in circulation initially gives the appearance of more money. Wicker argues that the proper interpretation of changes in the ratio was not yet clearly a part of monetary theory as it related to the multiple expansions of deposits, at least among banking practitioners, if not economists. Thus, he places more blame on limited knowledge rather than outright ineptness.

Wicker's book, *The Great Debate* (2005), provides a very accessible history of the politics leading up to the founding of the Fed. While Carter Glass conventionally is given credit for the legislation creating the Fed, Wicker shows that Senator Nelson Aldrich's bill proposing the creation of the National Reserve Association was heavily relied on in the creation of Glass's legislation. Aldrich's proposal arose out of his work on The National Monetary Commission, so his bill's influence is not surprising in subsequent legislation. Wicker's book also provides a useful review of recent literature on the founding of the Federal Reserve, much of which is covered in this paper. But he also goes to some length to analyze the contributions of two historians, James Livingston (1986) and Richard McCulley (1992), and the political scientist J. Lawrence Broz (1997). Their intensive use of archival materials and the papers of those responsible for crafting the final structure of the Fed, those of Glass, Willis, Aldrich, Warburg, Vanderlip, and Laughlin, is what set their research apart from earlier work.

Wicker argues that these three books by non-economists are important, as they help understand the politics underlying the founding of the Fed rather than the narrower economics. Livingston argues that the increasing centralization of corporate business in the United States led to the demand for a central bank to aid the banking sector in funneling funds into the corporate sector. Broz emphasizes the importance of a central bank in establishing the international importance of

the United States. In particular, he argues that a central bank was necessary for the US dollar to become the dominant international currency. McCulley, in Wicker's view, adds to our understanding of the political origins of the Fed by employing a three-way classification of the main interest groups and the legislative proposals emanating from those groups: Wall Street, LaSalle Street, and Main Street. While LaSalle Street was motivated by currency reform and establishing an asset backed currency, Wall Street interests were more concerned with minimizing government control of the central bank, a motivation that fortuitously was shared by both the LaSalle and Main Street interests. Wicker is clear to maintain, however, that these three authors contributed little to the economic analysis of the banking functions of a nascent central bank.

In the 1970s and 1980s, the cliometric approach to analyzing central banking really took off, and card-carrying cliometricians began to make their presence known. Friedman and Schwartz extended their work from *Monetary History* with several other volumes of data and analysis of banking in the UK (Friedman and Schwartz 1970, 1984). Anna Schwartz also contributed more research into panics and central banking responses well after the publication of *Monetary History*. From the perspective of lender of last resort duties, her paper "Real and Pseudo-Financial Crises" (1986) is required reading for anyone studying financial crises and bank panics. She makes a clear distinction between a real and a pseudo financial crisis. A pseudo crisis is one in which the equity of a financial or business firm is at risk of collapsing. A real crisis also involves a direct threat to the payments system, and hence the banking system, from the failure of one or more financial firms at great risk. Her prescription for the lender of last resort is that no action should be taken during a pseudo crisis, other than to perhaps reassure markets that the risk is contained to the specific firm. Excessive aid to firms in a pseudo crisis may resort in inflation or increasing instances of moral hazard. In a real crisis where payments could suspend and real effects spread to otherwise unrelated firms, the lender of last resort needs to assure that deposits will be convertible to currency regardless of what happens; failure of mismanaged banks or other intermediaries still could be allowed to happen.

Michael Bordo is one of the most prolific monetary historians today. Much of his research has concentrated on the workings of the classical gold standard and other exchange rate regimes. He has also examined in detail the role of the money supply in economic activity. For the purposes of this essay, I will focus narrowly on his contributions to the study of central banking and bank policy related to panics, along with the origins of central banking.

An early foray into central banking looked at why Canada established a central bank later than most countries. Bordo and Redish (1987) ask why it took until 1935 for a central bank to appear in Canada. They examine three explanations for the late appearance. The first was that a competitive banking system needed a central bank or lender of last resort to function properly. Another was that the banking system needed a central bank to maintain stability after the gold standard had been suspended after 1914. They reject these hypotheses in favor of one arguing that political rather than economic factors were key. Creating a central bank in response

to the disruption of the Great Depression was viewed as a politically expedient move in light of the urging from other governments and international groups like the World Monetary and Economic Conference to create a central bank to help coordinate international monetary efforts and cooperation.

One of his more recent contributions to Canadian central banking, along with Angela Redish and Hugh Rockoff, examines reasons for why Canada has had few, if any, bank panics when compared to the United States (Bordo, Redish, and Rockoff 2011). A key reason is that the Canadian Federal Government had the privilege of chartering banks, while in the United States both states and the federal government had such authority. This gave rise to the dual banking system in the United States, one characterized by small banks and a unit banking system. This made the United States prone to producing a shadow banking system, one characterized by bank-like intermediaries operating alongside the traditional banks but outside of the regulatory framework. This left the shadow banks vulnerable to runs on deposits, as was revealed in the panics of 1907 and 2008. In contrast, Canada developed a more oligopolistic and heavily regulated banking system that included extensive branching. It was stable enough that a Canadian central bank didn't even arise until 1935, and then only because of political pressure (Bordo and Redish 1987).

He also has provided a useful historical survey of lenders of last resort that includes a series of lessons to be drawn from the historical experience (Bordo 1990). He looks at four views of the lender of last resort, ranging from a classical view of freely lending to stem a panic to a free-banking view that no government agency need provide lender of last resort activities. The classical view is grounded in Bagehot's prescription to lend freely at a high rate but only on good collateral as valued at pre-crisis values. Another view (Goodfriend and King 1988) argues that open market operations, especially under a regime of branch banking, would be adequate to provide liquidity during a crisis, as the lender of last resort would not have to evaluate the conditions of individual banks. A more intense approach to lender of last resort operations is found in Goodhart (1988), in which a lender of last resort should even lend to insolvent banks. This is the case because during a crisis determining illiquidity from insolvency is not really feasible. At the other extreme are the modern proponents of free banking like George Selgin (1988). Free-entry and nation-wide branching would go far in preventing systemic runs on deposits and panics, even without a formal lender of last resort. More advanced clearinghouse associations could be employed to reduce uncertainty about the values of demand deposits held across member banks. After the survey, Bordo concludes that while a public authority should provide lender of last resort functions, it need not be a formal central bank. While free-banking alone, in his view, would not eliminate the problem of bank panics, moving in that direction would certainly work, especially by allowing branch banking.

In a broad survey, Bordo and Siklos (2017) examine the changing roles of ten central banks over the course of more than 350 years, starting with the Riksbank of Sweden, founded in 1668. In this extensive survey, they conclude that in smaller economies, the central bank tends to be more willing to modify its operating procedures and banking policy than banks in larger or more systemically important

economies. While maintaining price stability, and indirectly macroeconomic stability, has emerged as a preferred goal of most central banks, the recent financial crises have forced a reconsideration of maintaining the stability of financial markets. Of course, this was in part the reason the Federal Reserve System was founded in the aftermath of the Panic of 1907.

Finally, in a recent article Bordo presents two fascinating counterfactual worlds in which other lenders of last resort developed in the United States in place of the Federal Reserve System (Bordo 2012). The first counterfactual supposes that the Second Bank of the United States had its charter renewed by Andrew Jackson and that it survived to the present. He argues that it is likely that the bank would have learned to behave like a lender of last resort, as the bank of England learned after the Overend Gurney Crisis of 1866. An especially interesting speculation is that the Bank may have been able to finance the US Civil War more effectively, obviating the need to resort to Greenbacks. The need to establish the National Banking System may have even been eliminated with a well-functioning Second Bank. He also speculates the Second Bank would have been more likely than the Fed to have not followed a tight monetary policy based on the real bills doctrine inherent in the early Federal Reserve.

The second counterfactual assumes the US banking system played out as it had until the need to replace the National banking System with a real lender of last resort had become apparent. But rather than the Federal Reserve System being created, a central bank much closer to those of Europe would have been put in place. His United Reserve Bank, while less centralized than the central banks of Europe, would nevertheless rediscount bills of exchange and other commercial paper, providing a secondary market for these instruments that had been pretty much absent in the United States, unlike Europe. This market, controlled by altering the discount rate when deemed necessary, would provide liquidity for banks and eliminate the volatile call loan market. This would sever the link between the stock market and the payments system, the dangers of which became all too apparent during the Panic of 1907. He believes that a system more along the lines of that proposed by Warburg would have been more active in providing liquidity during the Great Depression. If this had prevented most of the bank failures of the early 1930s, Glass-Steagall with the separation of commercial and investment banking and the creation of the FDIC may never have happened. He concludes that while the Fed appears to have finally learned from past mistakes by the early 2000s, his counterfactual worlds may have avoided much of the disruption caused by early Fed mistakes.

Eugene White (1983) clearly outlined the nature and economic effects of the dual banking system on the US economy. This is a fundamental work on dual-banking He carefully analyzes the effects of the dual banking system having state and federal-chartered banks operating in similar financial and banking markets while having greatly different degrees of regulation imposed on the two classes of intermediaries, a system unique to the United States that also contributed to panics and even the Great Depression. The National Bank Acts and the Federal Reserve Act, as White clearly points out, established new structures on top of the old. Rather than really reform the previous system, the new regulations left old weaknesses in place because

of the entrenched banking interests. The National Banking Acts left the state-banks in place, as did the Federal Reserve Act. When a crisis erupted, the less regulated intermediaries were usually the source of concern, as in 1907. This problem remained under the Federal Reserve System, because state banks were not covered by the Fed's lender of last resort services during the Great Depression. Moen and Tallman (1992) use White's research on the dual banking system to reveal that a subset of state-chartered intermediaries, the trust companies in New York City, were the focus of the Panic of 1907.

Allan Meltzer's (2003) monumental two volume history of the Federal Reserve provides great detail and insight into Federal Reserve policy from its very beginning up through 1986. This well-documented work focusses on the operation of the Federal Reserve System, highlighting its origins in the turmoil of 1907. The first volume covers the origins of the Fed and its operations up through World War II. The second starts with the Fed/Treasury accord and goes up through 1986 and the end of the Paul Volcker era and the start of Alan Greenspan's terms as Chair of the Board of Governors. While Friedman and Schwartz spent a good deal of time on the Federal Reserve System and its operations, their scope is broader than Meltzer's, encompassing an effort to measure the money supply and document changes in the supply on the economy. Meltzer argues, as do Friedman and Schwartz, that maintaining the gold standard and the influence of the real bills doctrine led the early Fed leaders to follow faulty policies, ones that made crises during the Great Depression more severe. Benjamin Strong is also less of a hero in Meltzer's view in comparison to that of Friedman and Schwartz. In the case of the Great Depression, Meltzer argues that Fed officials viewed low nominal interest rates and low member bank borrowings from the Fed as a sign that monetary policy was easy. After an initial loosening after the stock market crash, the Fed returned to a normal to tight policy.

Meltzer is less convinced than Friedman and Schwartz that had Strong lived the Fed would have followed a more accommodative policy. He believes that the Fed was following what he refers to as the "Burgess-Riefler" doctrine, under which banks would borrow at the discount window only in times of emergency. The Fed would use open market operations to encourage or discourage lending. Low interest rates and low bank borrowings were viewed as signs of monetary ease under this doctrine, while we know today that they could also indicate low inflation and reluctance to extend more bank credit. Such a policy was in effect throughout the 1920s in Meltzer's view, while Friedman and Schwartz view the 1930s as a departure from an otherwise successful policy.

Friedman and Schwartz (1963) brought the modern discussion of Federal Reserve policy failure during the Great Depression to the fore, and it is still discussed today. Another key contributor to this debate has been David Wheelock. In his book, *The Strategy and Consistency of Federal Reserve Monetary Policy, 1924–1933* (Wheelock 1991), he examines the evolution of Federal Reserve policy. First, he notes that by 1924, Fed policy makers were aware that the Fed could affect credit conditions in ways that did not have to follow a real bills doctrine approach. Credit did not have to directly follow the course of business and could be eased if business

activity was slow. He credits this in part to Governor of the New York Federal Reserve Bank Benjamin Strong's experience with the Panic of 1907. Unlike Friedman and Schwartz (1963), however, Wheelock does not believe that the untimely death of Governor Strong was the main reason the Fed failed during the Great Depression. First, Strong's influence over the Open Market Committee might not have been as strong during the early stage of the Depression, as there appears to have been some consensus at the Fed, even some from strong himself, that policy may have been too easy during 1924–1927. This would have made significant open market operations during the early stages of the Depression less appealing to Reserve Bank governors. Second, Wheelock argues that during the Depression, as it had in the past, the Fed watched member bank borrowings as an indicator, with low borrowings indicating looser monetary policy. Observing this in the early 1930s led Fed policy makers to conclude that easing credit conditions was not necessary. Furthermore, the decentralized structure of the Fed at this time made it difficult for the banks to achieve a consistent discount-rate policy. Wheelock also notes that defending the gold standard was also a priority for the Fed. In short, the death of Benjamin strong was not as critical a contribution to inept Federal reserve behavior as Friedman and Schwartz argue; the Fed continued the policies it had established in the early 1920s. Nevertheless, he still argues that the Fed acted in ways that likely worsened the Depression.

Wheelock elaborates on some of these arguments in a paper with Michael Bordo (Bordo and Wheelock 2013). In addition to misreading monetary conditions based on observing discount window borrowing and its commitment to maintaining the gold standard by keeping interest rates up, they argue that there was another factor to consider. They argue that the Federal Reserve Act failed to recreate for US banking some of the desirable features of British or German banking. In particular, it did not establish an active and deep secondary market for banker's acceptances, one in which the Fed could intervene and buy large volumes of acceptances to inject liquidity into a contracting banking system. The decentralized structure and divergent opinions of the various Federal Reserve governors on how much monetary ease was legitimate meant that whatever intervention the Fed practiced during the early 1930s would not be adequate to provide liquidity. So, while there may be more to the story behind the inept behavior of the Fed than just the untimely death of Benjamin Strong, the story of misguided banking policy on the part of the Fed appears to remain solid.

The Payments System and Correspondent Banking

The functioning of the payments system has also been subject to cliometric scrutiny. John James and David Weiman (2010) analyze the flow of funds in the United States during the National Banking Era, and they estimate the size and extent of the currency premium that appeared with regularity during these panics. They show how the U.S. payments system during the National banking period developed, with the large New York national banks evolving into a de facto central bank providing

clearing services for the correspondent banking system. They argue that the correspondent system that developed during the later nineteenth century worked quite well in routing check payments, with the call loan market providing services similar to the modern federal funds market. A system of domestic exchange rates had arisen to mediate shipments of currency or exchange across banks and regions of the country, a system similar to that of international exchange having shipping prices similar to the gold points found in international exchange.

While the privately created correspondent system worked well, James and Weiman note that the Federal Reserve rationalized reserve holdings across banks by allowing banks to hold fewer reserves. The centralizing of member bank reserves at the Federal Reserve banks allowed for this. Coordinating clearing standards and prices and introducing the telegraph into clearing and payments further improved the payments system under the new Federal Reserve.

James et al. (2014) extend this analysis and show that clearing house loan certificates provided liquidity locally but segregated the country into local currency areas during panics, either because they could not circulate widely or, in the case of New York, could circulate only among Clearing House member banks. To a limited extent the Treasury could rearrange its deposits to expedite funds flows that could occur with loan certificates. But its resources were limited by the fact that the Treasury could not produce a net increase of new reserves.

Anderson et al. (2018) examine how joining the Federal Reserve System affected liquidity and lending at member banks. They show that even by the mid-1920s, less than a third of state banks and trust companies had joined the Fed. They show that state banks that faced seasonality in loan demand were more likely to join, reducing the variation in lending. Larger state banks higher up in the correspondent system were more likely to join as a way to gain access to the discount window, improving their ability to provide liquidity to smaller banks. Lending increased at these banks. Smaller state banks that were part of the correspondent system were less likely to join, as they still had indirect access to the discount window while avoiding the higher reserve requirements imposed by Fed membership. Incomplete coverage of lender of last resort services introduced an element of moral hazard and shadow banking.

Mark Carlson has published a number of papers on the interbank payments system and the effects of the Federal Reserve on the stability of the payments system. In a particularly insightful paper (Carlson et al. 2011) he shows that the infusions of cash by the Atlanta Federal Reserve Bank to banks in Florida suffering runs on deposits in the summer of 1929 were effective in preventing further runs on deposits. Because Reserve banks operated much more independently then, banks in districts with little previous experience with panics were less likely to respond during the Depression in a fashion similar to that demonstrated by the Atlanta bank in 1929. The Banking Acts of 1932 and 1933 authorized the reserve banks to lend on any collateral deemed valuable by the bank's governor, and the example of Atlanta may have been part of the impetus for these Acts.

Carlson and Wheelock (2016) show that the early Fed had helped to reduce seasonality in the flow of funds between banks. The Fed's reserve requirements could no longer be satisfied by correspondent deposits, reducing contagion risk in

the early years of the Fed. The decentralized nature of decision making and the large number of state banks outside of the Federal Reserve System left the banking system vulnerable to the massive liquidity shock of the early years of the Great Depression. This resulted in the significant reorganization and centralization of the Fed in 1935. Bordo and Wheelock (2013) elaborate on the reorganization of the Fed. The original Federal Reserve Act and the reforms of the 1930s, in their view, failed to promote a deep secondary market for banker's acceptances, a market that existed in Europe, contributing to the effectiveness of those central banks. Maintaining the dual banking system further hindered the effectiveness of the Federal Reserve's lender of last resort capabilities.

Finally, Stephen Quinn and William Roberds (2006) have pushed back the timeline for central banking and present the case that the Bank of Amsterdam, founded in 1609, became the first true central bank. In the early seventeenth century the Dutch Republic faced a coinage debasement problem owing to a wide variety of foreign coin circulating in the young republic. One regulatory approach to reduce debasement was the creation of an exchange bank in Amsterdam, the Bank of Amsterdam, in which commercial debts in the form of bills of exchange had to be settled through the bank with bank money, shielding creditors from payment with debased coins. Eventually, the bank's money was decoupled from any coinage, becoming one of the first "fiat" currencies. Quinn and Roberds describe this development as resembling modern day open market operations, in this instance the sale or purchase by the bank of receipts against deposits of gold or silver coin.

Clio and Banking Databases

Cliometricians have also added new and rich data sets to the analysis of banking in the United States. While many cliometricians use data sets in their research, several large data sets stand out. Caroline Fohlin has collected a substantial set of daily observations on the call loan rate, the rate charged on overnight loans made to stockbrokers on the New York Stock Exchange. While the call loan market was most notably a national banking institution, it survived well into the Federal Reserve period. Instability transmitted from the call loan market into the banking sector in 1907 gave rise to political support from the New York bankers for a lender of last resort independent of the Clearing House. Combined with the call loan data, Fohlin et al. (2016) use an amazing data set covering transactions prices, closing bid-ask spreads, and trading volumes for all stocks traded on the New York Stock Exchange for every trading day between 1905 and 1910. This data set is a subset of a larger, NSF funded set for every trading day between 1900 and 1925 (Fohlin 2015). They examine how market and funding liquidity changed over the course of the Panic of 1907, and they show that the more opaque the market for a particular stock was, the greater the wedge between bid and ask prices. Mining stocks were the most opaque, and the source of much turmoil in the early stages of the panic. Railroad stocks were much more transparent. In some cases bid-ask spreads remained elevated for months after the panic had subsided. Cash infusions to keep the stock market and its call loan

market functioning and liquid did not have lasting effects on trading volumes. They conclude that regulatory steps put in motion by the panic eventually led to the demise of unregulated securities markets, introducing more transparency to financial and banking markets.

With the help of David Weiman, Jon Moen and Ellis Tallman have collected information from the minutes of the New York Clearing House Committee, the committee summoned to oversee the issue and withdrawal of clearing house loan certificates during panics. This set contains the volume of loan certificates issued by each Clearing House member bank and when they were withdrawn from circulation, on a daily basis for the major panics of 1873, 1884, 1890, 1893, and 1907. They also link these daily observations to bank balance sheet information collected by the Comptroller of the Currency for the call date nearest the beginning of the panic. They are currently examining this data.

Matt Jaremski has collected several large sets of balance sheet data for national and state banks. They cover both the National Banking Era and the early Federal Reserve period. One contains all of the balance sheet information collected by the Office of the Comptroller of the Currency between 1865 and 1934. A related set contains similar evidence for state banks from various state banking departments, although its coverage is not comprehensive like that for the national banks. He has also identified the correspondents of national banks, state banks, and trust companies for 1890, 1893, 1897, 1900, 1910, 1919, and 1940 recorded in various bankers' directories. He has also identified the location of US clearinghouse for 1852 through 1920 and for 1929 and 1940. This information is also taken from various bankers' directories. He has produced a number of papers from these data sets, including Jaremski and Rousseau (2013), Jaremski (2014), and Jaremski and Wheelock (2017). One important result revealed by his research has been to highlight the importance of bank networks in reducing susceptibility to bank runs in the period before the Federal Reserve. His research also emphasizes the importance of the development of the banking system to the economic development of the real sector of the United States in the nineteenth century.

Conclusions

Cliometrics has contributed to a better understanding of central banking, especially in the United States. While many "non-cliometricians" now and in the past have contributed to the understanding of central banking, cliometric analysis has contributed most clearly along three lines. First, the collection of new sources of evidence, that of Matt Jaremski in particular, is a highlight of much of this work. Recent research tends to be much more disaggregated and even granular when compared to earlier research on the payments system. While traditional aggregated monetary and financial measures are still useful, the increasing availability and exploitation of individual bank data, sometimes even down to the depositor level, will open new windows into the study of central banking and the payments system. The work of Caroline Fohlin highlights this approach.

Second, the structures and institutions of central banking in the United States are now well understood. In particular, the role of clearinghouses in the establishment of the Federal Reserve System has been greatly advanced by cliometric research. In particular, the work of Moen and Tallman shows that while clearinghouses helped mitigate runs on deposits, their effectiveness was limited given that intermediaries outside of the clearinghouses, mainly state-chartered intermediaries, could not be aided by the tools available to clearinghouses before the advent of the Federal Reserve. The limited resources of the New York Clearing House in 1907 finally made the need for an outside source of liquidity apparent to the politically influential New York bankers. Along these lines, research into the workings of the National Banking System, especially that related to the dual banking system and the rise of correspondent banking and the call loan market, have provided better insight into the structure and early operations of the Federal Reserve System. The effects of incomplete coverage of lender of last resort functions, both before and after the Federal Reserve, have been shown to be a characteristic of banking in the United States, one that distinguishes it from banking elsewhere. The research of Eugene White has been a central contribution to this perspective. This line of research also helps explain the decentralized structure of the early Federal Reserve System, a structure that was modelled on the clearinghouses familiar to US bankers at the time (Timberlake 1993).

Finally, there is consensus among cliometricians that the Fed could have done a much a much better job during the Great Depression. Friedman and Schwartz clearly conclude that Fed leaders were unable to interpret basic monetary measures after the death of Benjamin Strong, producing contractionary monetary policy during the early stages of the Depression. Others agree that the Fed did not respond appropriately, but the failure of policy resulted rather from following policies that had worked well before 1930, including supporting the interwar gold standard. Incompetence is not the leading explanation in this thread. The extended work of David Wheelock presents this interpretation most clearly.

A question that remains to be fully answered, at least in the context of the United States, is just how formally organized does a lender of last resort have to be in order to provide central bank services, especially lender of last resort services. Richard Timberlake would argue, “not very.” Improved clearinghouses would have been adequate. Michael Bordo argues for more formality, but a centralized European bank was likely not necessary. There was and is room for private sector responses. Moen and Tallman agree on this point. Coming from a European viewpoint, Charles Goodhart would argue for the most centralized bank. Nevertheless, there remains much opportunity for cliometricians to contribute to this last question, especially along banking policy lines.

Sovereign Debt

Mauricio Drelichman

Contents

Abstract

Sovereign debt is one of the most enduring puzzles in economics. Why would anyone lend to an entity not subject to external enforcement? This chapter examines the emergence of sovereign loans, their transformation from personal to transpersonal debt, and their evolution through time. The different models that have been proposed to explain the rationale and sustainability of sovereign

lending are discussed and evaluated in light of the historical record, together with a brief discussion of data sources and the political economy of debt.

Keywords
Sovereign debt · Sustainability · Reputation · Sanctions · Default · Bonds · Loans

Introduction

Debt and time are inextricably linked. The very existence of debt requires at least two transactions – the disbursement of a loan and its subsequent repayment – at separate points in time. The price of debt, which is simply the interest paid on a loan, is determined by the time elapsed between these basic transactions. Government debt instruments usually mature over several decades, and lending relationships between states and financial institutions can last centuries. It is no surprise, then, that the study of debt relationships is central to cliometrics, a discipline fundamentally defined by the study of economic magnitudes, problems, and behaviors through time.

The element of time intrinsic in any debt contract introduces an implicit, yet unavoidable element of risk. Once a loan has been disbursed, it is always possible that the debtor will fail to repay it, either because of insolvency or because they judge that breaking the contract will have a lower cost than complying with it. Default risk, the probability that a loan is not repaid in accordance with its original terms and conditions, is a key determinant of the structure of debt instruments, the pricing of loans, and, indeed, the very existence of debt markets. If default risk is not addressed as part of the institutional structure of a debt market – that is, if any debtor can decide not to repay a loan with impunity – it is quite possible that no loans will be made in the first place. Without transactions, there are no markets.

Among the myriad institutional arrangements and legal instruments through which different societies, polities, and individuals have conceived and implemented debt through history, sovereign debt emerges as a special category, exercising an undying appeal for theorists, applied economists, and cliometricians alike. The reason is that there is very little to mitigate default risk when the debtor is a sovereign who holds both legislative powers and a comparative advantage in the exercise of violence. In the case of a loan to an absolutist ruler, to use an obvious example, it is usually impossible to compel a reluctant borrower to repay a loan. But even when the borrower is a democratic government subject to a large array of internal checks and balances, foreign creditors have found that legal frameworks can be changed with surprising speed, often to their detriment.

The study of sovereign debt, both as a theoretical subject and in its historical expressions, almost always converges to a well-defined set of lines of inquiry. Why is sovereign debt possible in the first place? Just how much debt can a sovereign carry? What is the nature of defaults, and what are their implications for the viability of sovereign debt? The remainder of the analysis expands on these questions and examines the interplay of theory and history in the scholarly efforts to address them.

The Big Questions

What Makes Sovereign Debt Possible?

Debt agreements subscribed between private parties usually fall under the legal jurisdiction of a state entity. In case of nonperformance, the creditor can, at least notionally, seek redress in court. Enforcement may pose complications, especially when the parties reside in different jurisdictions, but these are no different than the challenges in enforcing any other type of contract. Some debt arrangements, such as those extended by criminal organizations, fall outside the legal protections of the state, but in these cases, the creditor is typically the stronger party and usually has access to a coercion or punishment technology. The Mafia does not take out loans, and it is very effective at collecting the ones it extends. Sovereign debt is unique in that creditors are typically the weaker party, while debtors control the means of coercion.

Loans to sovereigns have not always been voluntary arrangements. Medieval city-states in northern Italy used forced loans on wealthy citizens, called *prestanze prestitix*, as their primary means of financing (Pezzolo 2003). Charles I of England also levied forced loans and imprisoned reluctant noblemen as part of his escalating conflict with Parliament (Cust 1985). Forced debt was also a preferred method of financing by German occupation authorities in Greece during World War II (Christodoulakis 2014). To the extent that these forced loans can be considered debt at all, rather than the outright confiscation of resources they often resulted in, it is not hard to see what makes them possible. Debtor participation is coerced under threat of violence.

The interesting case, therefore, is the one in which a lender freely enters into a debt contract with a sovereign entity. Because the sovereign can choose not to repay the debt with apparent impunity, the question of what makes sovereign debt possible might well be reformulated as "Why do sovereigns ever repay their debts?" or, extending the logical chain one step further, "Why would a creditor ever extend a loan to a sovereign?" These questions stand at the very core of the sovereign debt literature in economic theory and history. The first mainstream answer has emphasized reputation-based lending relationships, while an alternative explanation has focused on the possibility of creditors imposing costly sanctions on borrowers. Both these schools of thought are explored in detail further below.

How Much Debt Can States Carry?

Sovereign states carry a wide range of debt loads, using different instruments and committing themselves to varying repayment schedules. Some borrow very little and only for short periods. Others take on fantastically high obligations and may carry them for very long periods, even intending never to reduce their overall indebtedness. What explains these differences, and what are their determinants?

These questions relate to what economists call the "sustainability" of debt. The term is used in a somewhat ambiguous fashion throughout the literature, as it may refer to either the fiscal ability of a sovereign to service and repay their debts or to the

incentives and willingness to do so, regardless of fiscal capacity. The section on fiscal sustainability explores the first aspect, while the discussion of each model of repayment incentives elaborates on the latter.

The Nature of Defaults

Anyone extending a loan for a profit motive clearly expects to be repaid. Lenders facing a higher risk of default demand additional compensation in the form of higher interest or other guarantees. If the risk is too high, or the potential losses too large, lenders will choose not to lend at all. In such cases, a market for sovereign debt might unravel, or not emerge in the first place.

The traditional approaches to the theory of sovereign debt usually feature rational agents in a context of complete information. In these models, borrowers want to signal their willingness and ability to repay; lenders only lend to those borrowers that are solvent and credible enough. Incentives are aligned, debt is properly priced, and loans are repaid. In such an environment, however, there is no place for default. Even in contexts with uncertainty generated by external events, insurance markets can be used to spread the risk. Default is, in economic parlance, an off-the-equilibrium-path outcome.

The problem is, of course, that sovereign default is common – in fact, far too common to be explained away by informational mistakes. The history of sovereign debt is heavily punctuated by episodes of kings reneging on their obligations, developing countries declaring bankruptcy, and revolutions disowning the financial commitments of the preceding regimes. Nor are creditors always eager to punish states that default. Castile under the Habsburg monarchs decreed general payment stops seven times in less than a century, before finally falling out of favor with international financiers. Argentina and Venezuela boast comparable records in the nineteenth and twentieth centuries, with others not far behind. For the past five centuries, up to 10% of borrowers ended up suspending payments in any given period, with default rates reaching 20% in particularly turbulent times (Reinhart and Rogoff 2009). The notion of off-the-equilibrium-path phenomena appears insufficient to explain the general ubiquity of sovereign default and the surprising resilience of "serial defaulters."

Relying on advances in contract theory and on the idea of incomplete markets, the literature has begun to interpret defaults as part and parcel of sovereign debt transactions. In a new generation of models that reflect some of the myriad complex relationships in sovereign debt markets, defaults are more fully integrated into the potential equilibrium outcomes. Defaults that are triggered by unexpected, exogenous events through no fault of the borrower can be deemed "excusable" by lenders, and not held against a borrower's record (Grossman and Van Huyck 1988). In situations where lenders have market power, defaults can be a stable feature of the market equilibrium (Kovrijnykh and Szentes 2007). And, when markets are incomplete, the impossibility of creating provisions for every possible eventuality means that lenders and borrowers both operate in the knowledge that some states of the world will bring about defaults, and price their loans accordingly (Arellano 2008).

Why Does Sovereign Debt Exist at All?

Sovereign debt repayment may be subject to the whim of a ruler, plagued with the possibility of defaults, or susceptible to political upheaval and macroeconomic instability. Why would lenders put up with the uncertainties inherent in such a market and the vagaries of whimsical kings and turncoat politicians? The answer has been the same throughout history – because "there's gold in them thar hills." While some investors certainly suffered losses in individual crises, returns to sovereign debt have on average exceeded those of comparable safer investments over the long run, even after accounting for the effect of defaults. Lindert and Morton (1989), for example, found that between 1850 and 1983, government loans generated an average excess return of 0.4% over similar American or British bonds, considered to be reference safe assets. This also proves true going further back in history; even that most iconic of serial defaulters, King Philip II of Spain, generated profits for his lenders. Drelichman and Voth (2011b) showed how bankers that lent through the last two Castilian defaults of the sixteenth century earned an excess return of approximately 2% over safer bonds. A market for sovereign debt exists because it delivers a premium that risk-neutral lenders find attractive.

On the sovereign's side, the motivation for borrowing is no different from that of any other borrower – bridging a gap between expenditures and revenues. In a context of economic growth, debt can be a powerful tool to finance public investment. As long as the social rate of return on the projects financed with debt exceeds the interest rate paid by the government, state borrowing can increase overall welfare and contribute to a sustained development path.

Of course, not all loans are motivated by the desire to finance growth-oriented projects, and in any case sovereign debt predates the onset of modern economic growth by several centuries. Debt is often used to finance current expenditure rather than investment, and, both in current and historical times, the funding of military enterprises has been a prime motivator. In cases like these, borrowing is essentially an intertemporal transfer of resources, with future taxes being committed to pay for current expenditures. It is possible that, if a war financed by debt is won, the spoils might provide the means for repayment. These instances, however, are not common; the imperial expansion of eighteenth- and nineteenth-century Britain constitutes perhaps a rare exception. A sovereign's motive for borrowing need not change a lender's disposition, as long as future funds are available. However, if borrowing is motivated by short-term political vanity or survival, and is unlikely to result in a growth payoff, access to debt markets might well result in negative welfare consequences for the country as a whole.

Sovereign Debt in History

The study of state financing has always been one of the top areas of interest in economic history research, perhaps second only to that of economic growth. Its development as a scholarly field started long before the cliometric revolution,

yielding pioneering works like those of P. G. M. Dickson (1967) for England, that of Ramón Carande for Castilian short-term debt (Carande 1987), and the collected works of Giuseppe Felloni for Genoa (Felloni 1999), among many other prominent examples. This literary tradition, which continues to the present day, is typically focused on uncovering the institutional features of sovereign lending through history and, whenever possible, on quantifying its magnitude. This invariably requires painstaking archival work, parsing centuries-old documents to carefully reconstruct the minute details of each transaction. The resulting works are an indispensable foundation for any cliometric work, providing invaluable context to frame and interpret quantitative models and results.

Instruments and Innovations: A Very Short Summary

One of the main concerns of the historical literature is documenting the evolution of contractual and institutional instruments used throughout history – the "technology" of debt, in some sense. Of note is the fact that public debt largely did not exist before the twelfth century; not even the Roman Empire, with its sophisticated tax and coinage systems, had anything resembling public debt instruments. Europe would have to wait until the onset of the Commercial Revolution and the emergence of the merchant city-state to witness the first manifestations of what would become government obligations.

Since antiquity, rulers had issued token coinage, which can be thought of as a form of debt. In a full-bodied currency system, replacing a gold coin with a convertible token requires a degree of trust in the ruler if the token is voluntarily accepted or coercion if not. Devaluations, restampings, and debasements can all be thought of as a form of default. This conception of currency as a sovereign obligation lasted well into the twentieth century. After World War I, the British government used the notion of currency as debt to justify its deflationary impetus, eventually returning the pound to its prewar gold parity rather than devaluing (Eichengreen 1996).

The consolidation of city-states first and territorial states later made it possible for rulers to count on reliable tax revenues that could be used as security for debt repayment. The first sovereign loans were not very different from tax farming. A group of merchants would advance a sum to the state in exchange for the right to collect a specific tax for a number of years. This method was introduced by the Genoese *compere*, which are documented as early as the first half of the twelfth century and would later be widely adopted throughout Western Europe, eventually becoming the favored system of issuing long-term debt (Felloni 2006). Castilian *juros*, French municipal *rentes*, Dutch *renten*, and the Florentine loans to Edward III all used specific revenue streams as the source of repayments for cash advances to their governments. In some polities, such as Genoa, the management of public debt would become part and parcel of the city's mercantile activities. The Casa di San Giorgio, the company of Genoese merchants that lent funds to the Republic and administered its debt, introduced many of the innovations that would make modern

state financing possible (Felloni 2006). Debt secured by specific tax streams is commonly referred to as "funded debt."

David Stasavage (2011) has convincingly argued that, during this formative period, the ability of polities to issue and service their debts depended crucially on the presence of representative assemblies that gave strong voices to merchants, as well as on the ease of travel and communications between different merchant centers within the polity. This gave an initial advantage to city-states and small territorial units like the Netherlands over larger territorial states like Castile and France. The advent of the fifteenth-century Military Revolution, which saw the introduction of standing armies and complex fortifications, tilted the scales in favor of territorial states with the ability to muster the enormous resources required to finance them. Thus Castile, then the Netherlands, and finally France and England all accumulated debts whose size, relative to GDP, rivaled those of contemporary states (the section on fiscal sustainability below provides a quantitative discussion). The period also saw the rise of the legal construct of "state" debt in the context of territorial states. While in the Late Middle Ages, all loans were personally underwritten by the king and guaranteed by his revenues and demesne; by the sixteenth century, debt had become clearly transpersonal; it was an obligation of the Crown, rather than of the person wearing it.

The pledging of specific tax revenues, which underpinned almost all medieval, as well as most early modern debt issues, is quite removed from modern conceptions of debt. It elegantly solved the problem of the credibility of a ruler by transferring the exploitation of a revenue stream to a lender for a specified period or in perpetuity. The debt was treated like property and, being subject to the applicable jurisprudence, provided a certain level of security against repudiation. The format of pledging revenues also allowed for the circumvention of usury laws, as the transaction was considered a sale or a rent contract, rather than a loan. One step closer to modern instruments was taken with the appearance of unsecured debt instruments, which hinged only on a ruler maintaining their word. By far the largest unsecured loans by volume in the early modern era were Castilian *asientos*, debt contracts between the Habsburg kings and bankers from all over Europe. *Asiento* lending started in earnest under Charles V, who borrowed from the Fugger and Welser families. Fueled by the silver remittances from South American mines, it reached its maximum expression under Philip II, for whom Genoese bankers, building upon centuries of financing their own Republic, designed a system that had most of the characteristics of modern sovereign debt (Drelichman and Voth 2014a). As innovative as Castilian debt was, neither the *asientos* nor the tax-backed securities used by most rulers and municipalities were tradable in secondary markets (though *juros*, the Castilian version of tax-backed securities, could be reissued in a different name upon the payment of a fee). The innovation of tradable securities would be introduced by the Dutch Republic in the following century. The creation of the Wisselbank, arguably the first fully functional central bank, completed the Dutch financial revolution and established the first truly modern state financing system (Tracy 1985).

By the eighteenth century, the locus of innovation in the arena of public debt was shifting from Amsterdam to London. The reforms of the Glorious Revolution

(discussed below) enabled a large expansion of government borrowing, while military successes in Britain's many wars and the profits generated by imperial trade and industrial development provided the resources needed to keep public finances in good health. The early eighteenth century saw some experimentation with schemes using the stock of chartered companies as a vehicle for refinancing government debt. Variations of this idea were behind both the South Sea Bubble in Britain and the Mississippi Bubble in France (Carlos and Neal 2006; Velde 2007). Eventually, virtually all British debt would be issued and held in the form of consols, perpetual annuities that could be redeemed at face value. This allowed the government to take advantage of falling interest rates by offering coupon rate reductions. Consols would be the dominant form of debt in Britain until World War I, when the enormous financing needs imposed by the war required the issuance of shorter-term debt (Ellison and Scott 2017). The last British consols were redeemed in 2014. Nowadays, states the world over typically have a debt structure of bonds of different maturities, with those above 30 years being relatively uncommon.

Currency of Issue

One key choice for any government issuing debt in modern times is whether to do so in domestic or in foreign currency. Domestically marketed debt is almost always issued in a country's own currency. As for debt contracted with foreign lenders, the trade-off is clear: debt denominated in domestic currency can lose value as a result of inflation, while debt denominated in foreign currency leaves the borrowing government exposed to exchange rate risk. Governments with little credibility or with a small domestic market tend to prefer foreign currency-denominated debt issues as a way of attracting investors that would otherwise not be willing to take on the inflationary risk, while developed economies on a solid fiscal footing can often afford to issue debt denominated in their own currency.

Before the twentieth century, cross-border debt was overwhelmingly denominated either in gold or silver, or in a currency subject to a metallic standard, thus leaving little leeway for rulers to reduce the value of their debt by tinkering with the currency. Scholars have argued that for countries that were not major financial powers – the so-called periphery – issuing debt in foreign currency was a commitment device. Under the Classical Gold Standard, perhaps the most studied international monetary system in history, peripheral countries tied the value of their currencies to gold as an instrument to increase their creditworthiness – a "good housekeeping seal of approval" (Bordo and Rockoff 1996).

Data Sources

Some of the most important contributions of cliometricians to the sovereign debt literature are data collection efforts that cover several countries over long periods, thus enabling the panel analyses that are key for validating modern theoretical

frameworks. While a thorough enumeration of such compilations is beyond the scope of this chapter, there are nonetheless some noteworthy entries. For medieval and early modern times, Stasavage's (2011) dataset offers a window into the emergence of sovereign debt across 31 European countries and city-states, together with political and demographic correlates. Likewise, Bonney's (2007) European State Finance Database, while not as homogeneous, has become a repository for a wide variety of fiscal and financial data from European countries. Neal (1991) provides series of British and Dutch joint-stock company shares and government debt prices between 1710 and 1820. Homer and Sylla (2005), a work that has grown in scope and depth through its four editions in over four decades, offers the longest-term view of the return on all sorts of assets, including government obligations, from Babylonian times to the early 2000s. More recently, databases have prioritized comprehensiveness, attempting to capture the majority of known debt issues together with a large number of covariates suitable for the increasingly demanding quantitative analysis associated with newer-generation models. In this vein, one can find the contributions of Reinhart and Rogoff (2009) and Abbas et al. (2010), among others.

The Interplay of Theory and History

The main comparative advantage of cliometrics is the harnessing of quantitative data, in combination with detailed institutional knowledge, to evaluate the predictions of economic theory. Conversely, by using the deep repository of history to uncover situations and data types that may not be available in contemporary experience, cliometrics also contributes to the development and refinement of economic theory. This section explores how such a dialogue has emerged in the context of sovereign debt, reviewing the different models proposed to explain its main stylized facts, the inconsistencies pointed by historical studies, and the revisions introduced in theoretical frameworks as a result.

Fiscal Sustainability

One of the first empirical tests to which a sovereign borrower is typically subjected – both in scholarly scrutiny and in actual practice – is whether it can possibly repay the amount of debt it has taken or intends to take on. If a borrower does not have the means to repay a debt, there is no point in going forward with the transaction. For the purposes of this first evaluation, the borrower is assumed to be willing to repay and to employ their every last penny in doing so if necessary. The ability to repay a debt in the context of sovereign lending receives the name "fiscal sustainability." It should not be confused with the willingness or strategic convenience of a borrower to repay, for which the term "sustainability" (without the "fiscal" modifier) is also sometimes loosely employed.

The resources to repay government debt must ultimately come from taxation. At this point, it is important to distinguish between debt denominated in local currency and loans issued in foreign currency and some other unit of account over whose value the government has no power (e.g., precious metal weight). In the former case, the government might reduce the value of the debt through inflation. While inflation is typically interpreted by economists as a tax, it does have a particularly large incidence on holders of debt denominated in domestic currency, who see it erode the value of their future coupon and capital repayments. Lenders do, of course, factor in their inflationary expectations when pricing domestic debt, but a government can always print more money *ex post*. While unanticipated inflation may be regarded as a partial default on domestic debt, it can also help avoid an outright suspension of payments. A government whose debt is largely denominated in domestic currency, and which has access to effective monetary policy instruments, will therefore face relatively lax fiscal sustainability constraints. If, on the other hand, government debt is largely denominated in foreign currency, or the government must adhere to a nominal anchor (as in the case of a currency board, a dollarized economy, or a full-bodied monetary medium), then the means of debt repayment must consist entirely of real resources, and the fiscal sustainability constraint will be strictest. In order to provide a streamlined analysis, the discussion in this section focuses on foreign currency-denominated debt; the section on political economy provides additional insight into currency mix decisions and their effects.

As mentioned previously, some of the earliest forms of sovereign debt directly acknowledged the centrality of fiscal sustainability by tying loan repayment to a specific revenue source. As early as the fourteenth century, Castilian *juros* – perpetual or lifetime bonds – entitled the holder to regular interest payments sourced from a specific tax stream. The bond was said to be "placed" (*situado*) on the tax stream, which was described as having been "sold" (*enajenada*), and could not be used for any other purpose. The annual payment was typically collected directly from the tax farmer or administrator. As long as the tax stream generated sufficient revenue, there was no question about the sustainability of the debt. This practice was later adopted by the French Crown when it established the *rentes sur l'Hôtel de Ville* and echoed in the practice of earmarking, one of the key financial reforms of the Glorious Revolution (North and Weingast 1989). In the case of Castilian *juros*, the arrangement effectively shifted the risk of fiscal nonperformance to the borrower; if the tax stream on which the bond was placed dried up, the Crown was not obliged to make up the shortfall and was not considered to have defaulted. After the Glorious Revolution, the British government improved on this by guaranteeing debts regardless of the health of earmarked fiscal streams; a sinking fund absorbed surpluses and covered shortfalls.

Most debt, however, is not tied to specific fiscal sources. In order to assess its sustainability, it becomes necessary to consider the overall solvency of the state. Evaluating the solvency of an individual is a straightforward exercise conducted by banks and other lenders countless times per day; one asks whether the present value of the individual's free cash flow exceeds the present value of scheduled debt repayments. The formula can, in principle, be extended to a sovereign, with some

important modifications. First, while an individual's earnings are limited by their life cycle, a state is, in principle, an infinitely lived agent. This carries a key advantage, in that the state never has to repay the debt principal if it doesn't want to; it can simply refinance its loans indefinitely and only pay interest. The second difference is that, while an individual's earnings first grow and then decline over their life cycle, a state's revenues may conceivably grow indefinitely, and hence they could support an ever-increasing debt load without risking insolvency. A financial solvency test for a state may therefore be reformulated as requiring that the present value of revenues exceed the present value of future interest payments.

In practice, estimating the future growth path of state revenues is quite challenging, as government policies and the business cycle can introduce large fluctuations over the short run. An alternative approach is to operate on the assumption that the government has the tools to claim a relatively stable portion of GDP (especially if averaged over a longer period) and require that the debt-to-GDP ratio not grow in order to consider the debt load sustainable. This criterion, developed by the International Monetary Fund, is overwhelmingly favored by international lending organizations (IMF 2003). It is noteworthy that such a rule is agnostic regarding how large the debt level can be relative to GDP; a stable debt-to-GDP ratio implies that interest payments are being met out of ordinary revenue rather than new borrowing, and hence the debt is deemed sustainable. Conversely, unsustainability can be defined as a situation where a country needs to incur new debt just to pay interest on its existing obligations.

Assessing the sustainability of a country's debt during a particular period using the IMF methodology requires fairly complete information on its national accounts. The ideal data to carry out this exercise include annual or more frequent estimates of revenue, ordinary (noninterest) expenditure, interest payments, the stock of debt, interest rates, and the growth rate of the economy. These can be plugged directly into a sustainability criterion equation, as derived, for example, in Aizenman and Pinto (2005), to obtain a straightforward answer on whether the debt-to-GDP ratio is stable.

While the data needed to assess fiscal sustainability are often readily available for developed countries in modern times, they can pose significant challenges for the cliometrician working on pre-statistical periods. Annual GDP series are available for several developed economies from the early twentieth century onward; further back in time their frequency becomes more sporadic, their reliability declines, and obtaining continuous series requires increasingly strong assumptions. Currently, the most complete set of historical GDP statistics suitable for fiscal sustainability analysis is the one provided by Bolt et al. (2018), who rebase and extend the estimates originally compiled by Angus Maddison for 14 countries starting as far back as 1820. For earlier periods, the analysis must rely on increasingly noisy income estimates calculated at much longer intervals or focus on a different measure, such as fiscal revenue.

A second empirical hurdle is the compilation of fiscal accounts –revenue, expenditure, and interest payments – as well as estimating the stock of outstanding debt. The availability and completeness of these data vary enormously across time and

states. Gaps in the data, however, can sometimes be overcome by resorting to the standard accounting identities linking the different variables. The earliest usable continuous historical series is the one compiled by Drelichman and Voth (2010) for Castile between 1566 and 1596. Other early examples include the Netherlands between 1601 and 1712 (De Vries and Van der Woude 1997), the United Kingdom between 1698 and 1793 (Crafts 1995; Mitchell 1988), and France between 1720 and 1780 (Sargent and Velde 1995; Velde 2007). Additional fiscal accounts for these and other European countries are available in the European State Finance Database (Bonney 2007). Table 1, based on Drelichman and Voth (2014a), summarizes the data for the United Kingdom, Castile, and France.

The figures in Table 1 must be used with ample caution, as GDP estimates in particular are subject to substantial noise. Taking them at face value, however, these early modern economies appear, on many dimensions, similar to contemporary ones. Their debt-to-GDP ratios are in the same range as modern developed countries, and their rate of revenue growth matches or exceeds that of twenty-first-century economies. Where they differ is in the magnitude of debt service; while a country that devoted 50% of its tax revenue to paying interest would be considered in serious financial distress today, these pre-modern polities spent money on little else than waging war and paying interest on the debt they had incurred for fighting previous wars. Without a large civil service or a social safety net, they managed to generate large enough primary surpluses to keep their debt loads manageable. In fact, of the three economies represented in Table 1, only France found itself in a manifestly unsustainable equilibrium, largely for political reasons (Sargent and Velde 1995). Castile's debts were eminently sustainable (Drelichman and Voth 2010). The United Kingdom, for its part, reached debt-to-GDP ratios as high as 260% in 1821 without sustainability being called into question (Reinhart and Rogoff 2009). Deft fiscal management and effective government bureaucracy supported one of the largest imperial expansions known to history (Bordo and White 1991; Brewer 1988). The debt burden was progressively reduced throughout the nineteenth century on the strength of Britain's economic growth and the long Pax Britannica. The United Kingdom once again experienced very high debt-to-GDP ratios after World War II, peaking at 238% in 1947, but almost half of the outstanding obligations during that period were intergovernmental loans provided by the United States at preferential terms, rather than market-traded bonds (Ellison and Scott 2017).

Table 1 Fiscal accounts for early modern economies

	United Kingdom	Castile	France
Average debt service/revenue	43% (1698–1793)	51% (1566–96)	38% (1720–80)
Growth rate of tax revenue	1.47% (1692–1794)	3.30% (1566–96)	1.26% (1661–1717)
Primary surplus/revenue	19.5% (1698–1794)	31.50% (1566–96)	14.2% (1662–1717)
Debt/GDP	74% (1698–1793)	14.7–51.4% (1566–96)	81.1% (1789)

Any analysis of fiscal sustainability is only as good as its underlying data. When trustworthy statistics are readily available, correctly performed sustainability calculations are no more than a mechanical exercise that consulting firms and international lenders can perform without too much trouble. As the focus shifts to the pre-statistical past, the craft of the cliometrician becomes increasingly important in unearthing scant sources and compiling the bits and pieces of information that may eventually offer a glimpse of whether a king could actually repay his loans. So far, the literature has found that in the vast majority of cases, debt turns out to be sustainable. This is good news for *homo economicus* – it would be worrisome if lenders offered their capital to borrowers that could not possibly pay them back. The resources used to repay loans – or, at least, to pay interest in perpetuity – are by and large present in most historical instances of sovereign debt. The next step, therefore, is to ask what incentives sovereigns have to actually keep their commitments, why defaults happen, and why financiers still want to lend to seemingly fickle rulers and states.

First-Generation Reputational Models

The seminal theoretical treatment of sovereign debt in the economics literature is due to Eaton and Gersovitz (1981). At its core, the model features a repeated game between a borrower and one or more lenders. The equilibrium involves a trigger strategy. As long as the borrower services the debt and repays the principal on schedule, the lenders keep providing new loans or rolling over old ones. Should the borrower default, however, the lenders will permanently withdraw. The borrower loses access to the income smoothing provided by debt and must self-finance. This is a costly outcome, as the entire state operations will now have to be financed out of taxation or inflation, regardless of the business cycle.

The first requirement for reputational equilibria to be possible is that lenders must be able to maintain a solid boycott on defaulting borrowers. While this can be plausibly achieved in certain situations, it can prove problematic in others. Sustaining a boycott against a defaulter is easy if there is only one lender but becomes increasingly difficult as the number of market participants grows. If there are a large number of lenders, a defaulting borrower can attempt to overcome the boycott by offering a premium to some of them. In the absence of coordination, such a strategy is likely to succeed (Greif et al. 1994). To overcome this problem, second-generation models (discussed further below) incorporate coordination devices among lenders, such as cheat-the-cheater strategies.

The second requirement is that sovereigns must not be able to replicate on their own the income-smoothing services offered by lenders. A borrower with sufficiently deep pockets, for example, could institute a self-financing scheme. This could take the form of building a sinking fund or establishing a large deposit with a trusted financial institution, commonly referred to in the literature as a "Swiss bank." Whenever income exceeds expenditure, the government would deposit the surplus in the sinking fund or the Swiss bank. Conversely, when facing a shortfall, it would

withdraw from them, thus exactly replicating the financial flows provided by sovereign debt. It is nonetheless unlikely that defaulting countries would be able to save enough so as to effectively smooth over future budgetary shortfalls. The vast majority of defaults occur in times of fiscal distress, when governments are least able to put aside substantial resources to guarantee steady financial flows (Tomz and Wright 2007). As for Swiss bankers, despite their reputation as impervious to external pressures, they turn out not to be a great option when it comes to acting as financial agents for delinquent borrowers. Historically, international financiers have sometimes gone under, taking with them the deposits of foreign governments. In modern times, defaulting countries have found it extremely costly to operate in global financial markets before reaching a settlement with their creditors. After its 2001 default, the threat of legal action by creditors meant that Argentina was unable to hold any sizable financial assets outside its own borders until it reached a final settlement in 2016.

The Eaton–Gersovitz model is important because it establishes that sovereign lending relationships can exist even when lenders do not have access to legal or military enforcement mechanisms. The mere threat of losing access to capital markets is sufficient to keep borrowers honest. This feature of the theory aligns well with the historical record, as lenders seldom have the ability to impose punishments on sovereigns other than by withdrawing their loans. The model, however, runs into trouble when contrasted with other aspects of historical experience. The first one of these is that there are no cases in which a borrower has been permanently excluded from capital markets, something that typically happens only when a state entity is itself dissolved; even then, its debts are typically inherited by the successor state (Reinhart and Rogoff 2009). Most defaulters regain access to credit within a few years, often borrowing again from the same creditors. This is a common problem for theoretical frameworks focusing on why borrowers repay; its implications are discussed in the section on the nature of defaults further below.

The toughest hurdle for the Eaton–Gersovitz model comes from quantitative calibration exercises. Even assuming that defaulters can be effectively excluded from capital markets forever, the loss in utility to the sovereign resulting from the lost smoothing services is not large relative to the onetime gains from confiscating the lenders' assets. As a result, the simple reputational mechanism can only sustain very low levels of debt, typically around 10% of GDP (Arellano and Heathcote 2010). Since the vast majority of borrowers carry much higher debt levels, sometimes up to ten times more, alternative explanations are needed.

Sanction-Based Models

In the Eaton–Gersovitz setup, the only punishment a defaulter faces is an exclusion from capital markets, which appears to be insufficient to keep borrowers from engaging in opportunistic behavior. It is also unrealistic to expect that a defaulter would be excluded in perpetuity. If the marginal utility of a sovereign's debt is really high, it would make sense to offer high interest rates or a lump-sum settlement to entice one or more lenders to return to the market. In light of these shortcomings of reputational models, an alternative literature proposes that punishments above and

beyond the mere exclusion from capital markets – known as "sanctions" – are needed to sustain debt repayment as an equilibrium.

The first sanctions model was proposed by Bulow and Rogoff (1989). They noted that, at any point in the life of a loan, the contract can be thought of as an immediate cash transfer and a schedule of similar future transactions. For example, when a loan first originates, the disbursement is the immediate transfer, while the scheduled repayments are the promised transactions in the future. However, because the sovereign can default, the future schedule is essentially "cheap talk," as the parties can agree to renegotiate it at any time. A loan can therefore be thought of as a series of renegotiations – a "constant recontracting" process. Punishing defaulters with costs above and beyond the exclusion from capital markets (sanctions) provides appropriate incentives for borrowers to honor their debt obligations. In the parlance of game theory, the imposition of sanctions supports renegotiation-proof lending equilibria.

The central difficulty for any model based on sanctions is immediately apparent. How can a private lender sanction a sovereign? The relationship is by definition lopsided – the borrower has access to enforcement mechanisms and can exert some form of legitimate violence, while lenders, in principle, cannot. Bulow and Rogoff conceptualize their model by allowing lenders to cause a defaulting country to lose a fraction of its GDP, for example, by imposing trade sanctions or freezing assets held in foreign bank accounts. But can this idea capture actual events? In modern times, governments are reluctant to impose wide-ranging trade restrictions for the benefit of bondholders; Eichengreen and Portes (1989), for example, document that it was the Foreign Office's policy in the 1930s not to intervene on behalf of British investors in international credit disputes. Private efforts to freeze a defaulter's assets are similarly unlikely to succeed, either because of sovereign immunity or because defaulters are quick to shelter any liquid holdings from the reach of international courts (as Argentina did, e.g., after its 2001 default, thought at the cost of having its ability to operate in global markets severely curtailed).

There are, however, specific historical episodes that robustly support the sanctions view. The most obvious of these is the military takeover of revenue-generating assets, such as Britain's seizure of the Khedive's financing in the 1870s, before directly incorporating Egypt into the British Empire. Another example is the "Roosevelt corollary," an addition to the Monroe Doctrine, which saw the US threaten military action in Latin America in case of default; markets responded positively, and bond prices increased substantially. These extreme examples, dubbed "supersanctions" by Mitchener and Weidenmier (2010), clearly fit the Bulow–Rogoff framework and have been shown to increase borrower compliance. Supersanctions, by their very nature, require the cooperation of a military power; it is much harder to show that private parties could impose a punishment on the same scale, and there are virtually no historical instances of such an event.

Though it is unlikely that a country that does not honor its debts will be slapped with trade sanctions, trade does nonetheless shrink significantly following a default. Typically, no private party is granted a higher credit rating than the country in which it is based, and hence exporters and importers see their ability to borrow severely

curtailed. As a consequence, GDP falls sharply (Rose 2005). The loss of output and the difficulties of operating in international markets can be interpreted as a punishment beyond the exclusion from capital markets, thus providing additional support for the sanctions view.

The sanctions literature shares the same weak spot as first-generation reputational models. If the threat of punishment is effective, defaults should not be observed in equilibrium, as no lender would want to incur the steep costs associated with them. Under this theoretical framework, defaults remain an off-the-equilibrium-path outcome, and the ones that do take place should carry severe consequences for debtors, which are seldom observed in practice. While it is possible to interpret some features of sovereign lending at specific points in history as being consistent with the sanctions theory, the sheer prevalence of defaults, as well as the many debtors that emerge from them not much worse for wear, continues to suggest that a different approach is needed.

Second-Generation Reputational Models: Cheat-the-Cheater Strategies

The Eaton–Gersovitz and Bulow–Rogoff models were both seminal contributions to the sovereign debt literature. They provided powerful explanations for several stylized facts while capturing some important institutional features of sovereign debt arrangements through history. Nevertheless, historical evidence made it clear that important gaps remained, opening the door for a wave of second-generation models, in which reputation, aided by advances in contract theory, once again took center stage.

Reputational equilibria uniformly rely on the ability of borrowers to exclude a defaulting lender from further participation in capital markets. As hinted earlier, this can be a difficult proposition in a competitive environment. If a ruler is unable to self-finance in order to mitigate the consequences of sharp income fluctuations, the marginal utility for external financing is very high, setting the stage for attempts at breaking the boycott. A government in default could pick out one or two powerful financiers and offer them sufficiently attractive interest rates to break ranks with those refusing to provide funds. In a similar setup involving rulers that confiscate the goods of merchants, Greif et al. (1994) show how, absent a coordination device, rulers will always be able to find fresh trading opportunities by enticing individual merchants with richer-than-normal rewards.

In practice, boycott breaking in sovereign debt markets is rare. When observed, it is often the result of official lending for political reasons, rather than market-mediated transactions. For example, the Soviet-era lending to Cuba and the Venezuelan government loans to Argentina in the 2000s both occurred during international boycotts. The former, at preferential rates, was never repaid, while the latter, well above market rates, was quite profitable for the Venezuelan government. Importantly, both were extended for geopolitical reasons rather than for a strictly financial profit motive.

Kletzer and Wright (2000) asked how the boycotts underpinning reputational equilibria could be maintained in the absence of effective institutional enforcement on the lenders' side, which they termed an "anarchic" environment. Their model proposed a "cheat-the-cheater" strategy. If one lender, enticed by rich promises from a defaulting sovereign, breaks the boycott, all other lenders retaliate by refusing to conduct any further business with the boycott breaker and confiscating any assets they may be able to seize. A similar behavior between traders had been documented by Greif (1993) in his famous study on the Maghribi traders. Kletzer and Wright did not anchor their theory with any historical examples, but Drelichman and Voth (2011a) showed how Genoese and German bankers lending to Philip II of Spain operated under this exact principle. In normal times, lenders participated in what was by all accounts a well-functioning, competitive market. During the 1575 and 1596 default episodes, however, all lending stopped. Genoese bankers joined forces in a coalition that offered a single negotiating front to the king. At the time, virtually all bankers had dealings with each other outside of sovereign lending, engaging in commercial ventures, holding each other's financial deposits in several European locations, and marrying into each other's families. This provided ample opportunity for retaliation against boycott breakers and ensured the stability of the coalition. Although the king repeatedly tried to reach separate agreements with some of the richest families, the bankers always refused. Remarkably, cheat-the-cheater incentives also worked to keep non-Genoese bankers from breaking the boycott. The most notable case was that of the Fugger of Augsburg, who did not have any commercial or lending relationships with the Genoese. The king also tried to entice them to resume lending by offering twice the normal interest. The head of the German house declined, and their correspondence shows they feared that the king would use any new loan to settle his debt with the Genoese and default on the Fugger instead, effectively cheating on the cheaters.

Theories of Default

A lingering shortcoming of all the models discussed thus far is their treatment of defaults. The single-minded focus on explaining why sovereigns repay their debts often leads to ignoring that quite substantial proportion of loans – up to 20% in particularly troubled years – that are not serviced or repaid according to their original terms. Any theory where defaults are an off-the-equilibrium-path outcome will struggle with such a sobering statistic. Accordingly, from the very early studies of sovereign debt in both theory and history, scholars have been proposing ways in which defaults could actually be conceptualized as equilibrium outcomes, at least some of the time.

Bubbles, Sentiment, and Irrationality

One of the first and most enduringly popular explanations for the prevalence of defaults is that lenders are myopic. Braudel (1966) argued that most early modern sovereign bankruptcies were made possible by the greed of bankers, who, blinded by

the promise of high interest rates and easy profits, were time and again driven to their ruin by calculating, unscrupulous kings. An updated version of this argument underpins the work of Reinhart and Rogoff (2009), who argue that irrational lender sentiment is the common denominator of most defaults across the five centuries of history they examine.

Explanations based on irrationality are hard to reconcile with the central tenets of economic theory; individuals that are motivated by sentiment over reason, or are fooled by smart rulers, should be driven out of the market. In order for sovereign lending not to die out, it would be necessary for an endless supply of new myopic financiers to keep stepping up, replacing those that suffered the last suspension, only to be defaulted upon in turn. The historical record shows that such dynamics are implausible. When lending resumes after a default is settled, the lenders that provide the new funds are typically the same that were affected by the suspension of payments (Drelichman and Voth 2014a). They won't have necessarily profited from the episode, but they certainly are not ruined, nor do they appear to be chastised enough to abandon the market.

A different approach considers some defaults as being enabled by debt bubbles. Flandreau and Flores (2009) show how Latin American bonds in the early 1820s became extremely popular with investors, who drove up their prices only to lose substantial amounts in a wave of defaults from 1825 onward. Bubbles, however, need not rely on irrationality; investors may be fully aware that the market prices of an asset do not reflect its fundamentals yet will still buy it with the explicit intention to sell at a profit before the trend is reversed and the bubble bursts. All buyers in a bubble are, in a sense, rational; some are just unlucky. However, despite being clearly important in a few specific episodes, bubble dynamics seem to be of little importance in the vast majority of defaults.

Excusable Defaults

In an early adaptation of the Eaton–Gersovitz framework, Grossman Grossman and Van Huyck (1988) noted that not all defaults are the result of opportunistic borrower behavior. Countries sometimes face extreme adverse events over which they have no control and which seriously strain their ability to make timely payments on financial obligations. Foreign military attacks, the sudden collapse of a key commercial or productive sector through blockade or natural disaster, and a rapid and unanticipated rise in interest rates are all factors that can undermine the fiscal capacity of a sovereign. When exogenous events like these lead to a default, borrowers typically understand it as a consequence of *force majeure* and do not impose a punishment on the borrower. Further lending is suspended only until the extenuating circumstances are reversed; the borrower is allowed to make a settlement payment, some of the debt may be forgiven or rescheduled, and new loans are offered in short order. Such defaults are termed "excusable," as borrowers are not held responsible for them to the same extent as with opportunistic behavior.

Identifying excusable defaults in the historical record involves establishing that the suspension of payments was triggered by an exogenous event, that the exclusion from capital markets was lifted as soon as a settlement became feasible, and that the

borrower regained access to credit largely on the same terms as before the default. This necessarily involves setting thresholds for what should be considered a "standard" exclusion length. Benjamin and Wright (2009) calculate that, between 1800 and the present, defaulters are excluded from capital markets for an average duration of 8 years. Drelichman and Voth (2014b) argue that Philip II of Spain's defaults in 1575 and 1596 were excusable. Both episodes were triggered when delays in precious metals shipments from the Americas coincided with Castile's military adversaries ramping up military operations and requiring an increase in outlays. Both were settled in less than 2 years, and the financing terms available to the king after each episode were essentially unchanged from those that prevailed before.

Market Power and Incomplete Contracting

One approach considers that lenders, rather than competing with each other in an atomistic way, may possess a degree of market power (Kovrijnykh and Szentes 2007). This may happen because only a handful of financiers are willing to lend to the government or because there is a large concentration of capital in the hands of a few prominent bankers. In such cases, lenders will use their leverage to increase interest rates and obtain profits above those that would prevail in a competitive market. Because of these extraordinary profits, however, they will also be reluctant to completely sever a lending relationship after a default. Borrowers, knowing this, will find it optimal to renege on their obligations every now and then. The frequency of these equilibrium defaults will be higher the more concentrated the market power of lenders. Conjunctures like the extreme concentration of capital in the hands of Florentine bankers in the Late Middle Ages, or the outsize influence of the Rothschild and Morgan banking houses during the late nineteenth and early twentieth centuries, may be good fits for this type of framework.

A second line of research starts from the observation that it would be desirable for borrowers and lenders to write contracts that account for different possible future situations, usually called "states of the world" in the specialized literature. Thus, for example, if a country were to unexpectedly experience a serious recession, lenders might extend the repayment horizon, perhaps in exchange for a slightly increased interest rate. This type of contingent contract has the potential to avoid the costs associated with a default and an exclusion from capital markets. An early example can once again be found thanks to the seemingly endless financial creativity of sixteenth-century Genoese bankers. Many of the contracts they offered to the Spanish monarchy contained clauses that explicitly modified the repayment terms in specific circumstances, such as a delay in the arrival of the Atlantic treasure fleets (Drelichman and Voth 2014b). These contingent clauses typically increased the costs of borrowing following adverse events for which the king was deemed responsible (such as a unilateral rescheduling), but left them unaltered, or even reduced them, in cases that were outside his control (such as bad weather in the Caribbean delaying the arrival of precious metals). More recently, some emerging economies have experimented with GDP-linked bonds, which increase payments to bondholders in good years and reduce them in recessions.

Despite their apparent efficiency and desirability, and the ingenuity of Genoese bankers notwithstanding, contingent sovereign debt contracts are, in practice, extremely rare. One possible explanation for their lack of popularity is that it is difficult to find objective indicators tied to the state of the economy that cannot be influenced by the sovereign. Philip II did not control the weather, and, through its influence on treasure shipments, the weather happened to be directly tied to the state of his finances. But magnitudes like GDP or inflation are a different story. Governments can certainly influence GDP growth or inflation rates, although doing so to avoid debt payments would seem much too costly a strategy. More importantly, however, a government can tinker with the measurement of macroeconomic magnitudes, biasing them in a direction contrary to the interest of creditors.

Between the moral hazard issues and the sheer number of unpredictable circumstances that may exogenously impact the fiscal position of a government, implementing fully contingent debt contracts appears to be little more than a chimera. It is simply not possible to provide for every potential state of the world; this leads to a situation known in contract theory as "incomplete contracting." Arellano (2008) pioneered a literature showing that, in such circumstances, when events take a turn not contemplated in the original agreement, defaults can arise as an equilibrium outcome.

That lenders and borrowers cannot write complete contracts, however, does not mean that they are ignorant of the nature of the game. Quite to the contrary, every actor in the market understands that, if events take an unpredictable turn for the worse, default is a likely outcome. In technical terms, defaults are part of an "implicit contract," which will be reflected in the risk premium built into the interest rate of any loans. Lenders are not naïve; they lend to sovereigns fully aware that default is a potential outcome and are compensated for that risk. This also explains why lenders may "forgive" defaulters after a partial settlement: they have been already compensated earlier through the higher rates they received throughout the course of the lending relationship.

The incomplete contracting literature jives well with the excusable defaults interpretation. Both recognize the uncertain environment in which sovereign lending takes place, and both allow for reputational equilibria that do not require sanctions, thus matching many of the empirical characteristics of lending and default that emerge from historical data.

The Preeminence of Reputation

In the horse race between reputational and sanction-based models, both have found a measure of empirical support, and both bring important elements to our understanding of sovereign lending. The sanction story is clearly superior in instances where the use of force has been applied to collect loans or to deter sovereigns from defaulting, with the gunboat diplomacy era providing a few historical junctures in support of this view. The negative impact of defaults on a country's trade can also be interpreted as being aligned with the sanctions view, but trade represents an increasingly

shrinking source of income as one looks farther into the past. Tomz (2007) examined the universe of sovereign lending on a global scale during the last three centuries, concluding that reputation, rather than sanctions, was the central factor underpinning loan repayment and default settlement in the vast majority of cases. Coupled with advances that can account for defaults as an occasional equilibrium outcome, this evidence suggests that market mechanisms and incentives are sufficient to make sovereign lending viable. The final linchpin is that sovereign lending is also profitable. As mentioned earlier, investors in government bonds received an average premium over safe assets of 0.4% in the nineteenth and twentieth centuries and up to 2% in early modern times, after accounting for the losses sustained in defaults. Sovereign finance may be complicated, kings may be whimsical, and defaults may shock investors and even ruin some. However, when viewed through the long lens of history, sovereign debt markets have been remarkably resilient and, in their best incarnations, have needed little more than the usual self-interest of borrowers and lenders to deliver gains for both.

The Political Economy of Debt

The scholarly dialogue between the theoretical and historical literatures has shown that sovereign debt markets can work, sustained by reputational equilibria. As soon as the first reputational models emerged, however, a new set of questions appeared: how do rulers build a reputation? What makes a government trustworthy? These would become an integral part of the research agenda of the then-nascent "new institutional economics" (NIE), a field itself deeply rooted in the intellectual sphere of economic history.

The question of what underpins the credibility of a ruler is at the center of North and Weingast's (1989) study of the political and financial consequences of the Glorious Revolution, undoubtedly one of the most influential pieces in the entire economic history literature. Its main argument is one and the same with the central creed of the NIE: institutions, not individual behavior, determine the long-run outcomes of state policy and, ultimately, of states themselves. The Glorious Revolution was, at its core, a radical institutional reform that enshrined merchant interests at the heart of the British system of government (O'Brien 2009). By subjecting the Crown to parliamentary supremacy, it stripped the king of the ability to expropriate subjects and foreign lenders alike, while ensuring that overall government policy would be more aligned with the preferences of the triumphant commercial elites. This policy was, in turn, crystallized in a set of institutions, among which the most prominent were the earmarking of taxes, the sinking fund, and the establishment of the Bank of England. These acted as constraints on the government's borrowing ability and as safeguards that ensured the availability of funds for repayment. The boost in credibility they generated, North and Weingast argued, enabled Britain to issue unprecedented levels of debt while drastically reducing its borrowing costs. This financial capacity would then prove crucial in defeating its enemies militarily, establishing an overseas empire, and, ultimately, creating the conditions that fostered the Industrial Revolution.

While the central argument of North and Weingast continues to inspire scholars and politicians alike, its empirical analysis has been called into question. Sussman and Yafeh (2006) showed that the interest rates in North and Weingast's article, calculated on the basis of bonds' face value rather than auction prices, did not reflect Britain's true cost of borrowing. Once corrected, the effects of the Glorious Revolution are much harder to detect. Interest rates remained at pre-revolutionary levels for several decades, before finally inching down in lockstep with those of other European countries. In fact, the pace of military events would appear to be a better predictor of rates than political reforms. More recently, Cox (2011, 2015) has argued that political institutions, such as the establishment of ministerial responsibility under Walpole, played as important a role as financial reforms in the wake of the Glorious Revolution.

Conclusion

Four decades after the development of the first reputational model, the sovereign debt literature has reached a reasonably mature state. Cliometricians, by creating comprehensive databases of debt issues and defaults, painstakingly uncovering key institutional details, and taking testable predictions to sometimes centuries-old data, have been at the very frontier of these intellectual efforts. Historical research has provided inspiration for diverse historical frameworks, supplied the data to validate them, and pointed to areas where further advances were needed. It is fair to say that few areas of economic research are so tightly integrated with economic history as the study of sovereign lending.

Corporate Governance

Carsten Burhop

Contents

Abstract

This article provides information on how financiers of public limited companies in the past ensured that they achieved a return on and a return of their investment. I am investigating this with examples from the USA, Great Britain and Germany. First, I examine when and to what extent public limited companies were formed and whether and to what extent ownership and control were separate. Moreover, control and incentive mechanisms, e.g. monitoring by supervisory board or incentive pay to managers, are investigated.

Introduction

Problems of corporate governance arise if principals and agents have different targets, if information is asymmetrically distributed between the two parties, and if the writing or monitoring of fully specified contracts is too costly. In such situations, the governance structure of a corporation allocates the residual rights to certain actors by using contracts, charters, or the law. In the end, "Corporate governance deals with the way in which suppliers of finance to corporations assure themselves of getting a return on their investment" (Shleifer and Vishny 1997: 737).

The starting point of any analysis is thus to provide evidence regarding the existence of corporations and the separation of ownership and control. I deal with those questions in sections "The Emergence and Relevance of Corporations" and "The Separation of Ownership and Control" of this entry. One important way to assess the economic relevance of agency problems is, at least according to Shleifer and Vishny, the pay-performance sensitivity of management compensation. Are managers and rent-seekers extracting big pay-checks from corporations or do they receive adequate incentive pay? Therefore, I deal with management compensation in section "Managerial Incentives." Other potential ways to solve agency problems identified by Shleifer and Vishny are legal institutions (see section "The Emergence and Relevance of Corporations"), ownership by large investors (see section "The Separation of Ownership and Control"), dividend payments (see section "Dividends"), board structure (see section "Boards"), and product market competition (see section "Product Market Competition").

Morck (2007) and Herrigel (2007a, b) provide useful reviews of the older literature. Thus, I focus on work published during the last decade and on contributions using quantitative data. The papers published in the volume edited by Randall K. Morck focus on ownership structures around the world, whereas the article written by Gary Herrigel is broader in scope. He distinguishes "old" and "new" historical corporate governance research. According to him, old research focuses strongly on questions regarding ownership dispersion, legal protection of minority owners, the role of banks, and the depth of financial markets. More recently, the evolution of national systems of corporate governance became an important line of research. Moreover, research based on archival material became prominent, whereas the evaluation of printed or published sources was used by earlier researchers.

In the end, Herrigel (2007a) distinguishes four explanatory camps. According to the Chandlerian view, professional managers were hired by owners of firms once these firms have been grown in scale and scope. This growth is considered as a natural process, but it can be constrained by political, legal, or cultural obstacles. However, it is not clear why firm growth leads to a separation of ownership and control since, historically, most growth has been financed by internal resources, especially retained earnings, and not by issuing shares. According to the political view, ownership remains, or becomes, concentrated to counterbalance political power concentration (in the hand of left wing parties). Third, an interest group view of governance systems has been put forward. According to this view, interest groups in closed economies wanted to set up a political and legal system protecting

their own interests, and not the interests of a broad group of shareholders. Thus, ownership concentration varies negatively with the openness of countries. Finally, the law-and-finance-school put forward the legal history of countries as an explanatory force. In particular, the common law legal system protects minority owners better than the civil law legal system. Thus, dispersed ownership emerges in the former, but not in the latter system. Obviously, this rather static view does not help very much in explaining variations of corporate governance systems over time.

Over the last decade, the focus of analysis shifted from the macro explanations summarized by Herrigel (2007a) toward micro explanations based on firm-level data. Moreover, the recent literature goes beyond correlations and associations. Causal identification of governance relations became popular. Ownership structure is still an important area of research, whereas the law-and-finance hypothesis has been rejected by many scholars.

The Emergence and Relevance of Corporations

What is a corporation? This question is not easy to answer, since definitions vary by country and by period. Being a separate legal "person" and having entity shielding are common among definitions used in the literature (see Hannah 2014, 2015; Sylla and Wright 2013, for a debate). Without a clear definition, counting corporations is not straightforward. In the 2010s, approximately 50 million corporations existed around the world, but less than 50,000 were listed on stock markets (Hannah 2015). By comparison, in 1910 only about 460,000 corporations existed; most of them from North America (62%) and Europe (30%). The most important countries were the USA, Britain, and Germany (Hannah 2015). Thus, this entry focuses on these three countries. In addition, one should note that most corporations were not listed on stock markets, and when they were listed, the liquidity of their shares was rather low. For example, around 10,000 British corporations appeared in stock market manuals as being listed, but only 600 were actively traded (Hannah 2015). Stock market listing and a certain market liquidity seem, however, necessary conditions for the separation of ownership and control.

Locking in large amounts of capital with limited liability differentiates corporations from other forms of business organizations, such as partnerships. In particular, the survival of corporations does not depend on the survival of their owners and corporations make risky investments in large projects more likely. Nevertheless, corporations usually account for only a small fraction of enterprises and the relevance of corporations for the economy depends, among many other factors, on the organizational menu available to entrepreneurs. The corporation seems to be important for large scale and risky investments, but for small- and medium-scale enterprises, other types of legal organization are often superior (Guinnane et al. 2007). Furthermore, the size of corporations was skewed, i.e., relatively few firms account for most of the capital raised (Hannah 2015). Therefore, corporate governance is usually investigated by looking at the largest firms.

The menu of organizational choices available in the USA, the UK, France, and Germany reveals that ordinary partnerships were available in all four countries, whereas other types were not. For example, limited partnerships with tradeable shares were available in France and Germany, but not in the USA and the UK. Moreover, private limited companies, i.e., companies with limited liability but not tradeable shares, were available in Germany from 1892, in the UK from 1907, and in France from 1925. Corporations with tradeable shares and limited liability became available in Germany in 1870, in France in 1867, and in the UK in between 1855 and 1862. Thus, by 1870 free incorporation was possible in the major European economies – several decades later than in most states in the USA (Guinnane et al. 2007). Differences in the organizational menu lead to differences in the frequency of incorporation. On the eve of World War I, for example, 2.5 corporations for 1,000 people existed in the USA, but less than 0.1 in Germany (Guinnane et al. 2007).

In Germany, the majority of firms had been set up as ordinary partnerships until the interwar period. From the 1890s onwards, private limited liability companies became the second most important legal type of newly established firms. Corporations account for less than 5% of the newly established firms between the 1860s and the 1930s (Guinnane et al. 2007). In France, partnerships account for more than 60% of newly established firms from the 1850s to the 1920s. Right after the introduction of private limited liability firms, partnerships became unimportant and the new type of enterprise accounts for more than 60% of new firms. Corporations were more important than in Germany, accounting for around one in five of the newly established firms (Guinnane et al. 2007).

Until the second half of the seventeenth century, large commercial organizations needed support by the Crown to incorporate in England. After the Glorious Revolution, this power shifted to parliament (Freeman et al. 2013). The situation was different in Scotland, since bottom-up political organization implied bottom-up ways to incorporate. From 1641 to 1693, the Scottish parliament enacted and modified rules for general incorporation (Freeman et al. 2013). After the union in 1707, the Westminster parliament became responsible for incorporation in England and Scotland and the parliament became more reluctant to grant incorporations rights, in particular, after the 1720 Bubble Act. With the repeal of the Act in 1825, incorporation became easier in Britain. Free incorporation of unlimited liability companies was established in Britain in 1844, followed by limited liability for most companies in 1855/56. Limited liability was extended to banking in 1858 and to insurance companies in 1862. In general, the 1862 Companies Act consolidated former acts and established free incorporation for limited liability companies.

Sylla and Wright (2013) present evidence regarding the formation of corporations in the early USA. Almost no corporations were formed during the colonial period, but incorporation took-off after the turn of the century. Between 1790 and 1861, more than 22,400 corporations were chartered by various state parliaments, and at least 4,000 were set up under the reign of general incorporation laws. From the 1790s to the 1830s, New England and the mid-Atlantic states were hot spots of incorporation, with the Southern states subsequently catching up. In most states,

incorporation required a special legislative act by the state parliament. General incorporation laws came in force, starting with New York in 1811. Most states and territories moved to this system in the antebellum period, in particular during the 1840s and 1850s. From the 1830s through the 1850s, the number of newly incorporated firms grew substantially. More specifically, many banks and railroads were formed during the 1830s, whereas railway companies dominated during the 1850s.

By the 1870s, free incorporation was possible in most advanced countries. Nevertheless, important differences among countries remained. In a seminal paper, La Porta et al. (1998) measure to what extent legal rules of individual countries offer protection for shareholders ("anti-director rights"). They evaluate legal codes of 49 countries as they existed during the 1990s. It turns out that, on average, countries having a common law legal system offer the best protection to shareholders, whereas countries having a French-style civil law legal system offer the worst protection. Britain, the USA, and Canada offer the highest level of protection – the same level as India or Pakistan. La Porta et al. (1998) point out that the effectiveness of the rules depends on law enforcement. This variable is strongly correlated with economic development – law is much better enforced in richer countries, like the USA and the UK, than in poorer countries like India or Pakistan. Moreover, they show that countries with weak rules and enforcement tend to substitute legal rules with other mechanisms, e.g., mandatory dividend payments. Nevertheless, substitutes are not perfect. Thus, the level of legal protection of shareholders is positively associated with stock market development: the widely held listed corporation tends to be more common in countries offering good protection for minority shareholders.

This law-and-finance-story has been controversially debated. Spamann (2010), for example, recalculated the anti-director index and demonstrates that the legal protection of shareholders was comparatively weak in the USA at the turn of the millennium, but relatively strong in Germany, France, and Japan – three of the leading civil law countries. In contrast, just before World War I, protection of shareholders was strongest in the USA and weak to nonexistent in Britain, France, and Germany (Musacchio and Turner 2013).

Franks et al. (2009) demonstrate that legal protection of investors was basically nonexistent in Britain until World War II. The UK anti-director rights index was one out of six points until the 1948 Companies Act. From 1948 to 1980, the score has been three, subsequently rising to five. Moreover, the public enforcement index was zero until 1986. Only the private enforcement index, which can take values between 0 and 1, indicates some protection for shareholders. This index was zero in 1900, 0.5 in 1929, and 0.67 between 1948 and 1967. Yet, common law systems might offer protection to shareholders not via government action, but via court cases. The evidence is, however, unfavorable. Prominent court cases in 1843 and 1883 confirmed the absence of shareholder rights (Franks et al. 2009).

In the USA, corporate law is primarily determined by the individual states (see Cheffins et al. 2013a for a short review). During the late nineteenth century, a "race to the bottom" began when states attempted to attract corporations with low taxes and few constraints on managerial behavior. In the end, Delaware won the race, but before World War I, New Jersey has been the place to incorporate. Legislators in the

USA knew that New Jersey attracted many corporations. Thus, the government of Delaware decided to copy this successful corporate law in 1899. A few decades later, in 1933, almost 30% of the NYSE-listed companies were incorporated in Delaware – followed by firms incorporated in New York (18%) and New Jersey (12%). In 1899, legal standards were fairly high in New Jersey and in Delaware. Shareholders were allowed to vote by proxy, shares were not blocked before the general meeting, minority shareholders could mobilize judicial powers against unfair managerial behavior, and shareholders had pre-preemptive rights. Thus, both states scored four out of six in the anti-director rights index, which was very high when compared to shareholders in late Victorian Britain. Moreover, the score remained at that level until it was reduced by one point due to a legal reform in 1967 (Cheffins et al. 2013a). The race to the bottom seemed to take-off during the late twentieth, not the late nineteenth century.

Franks et al. (2006) provide a review of German corporate law, starting with the 1843 Prussian corporate law. Until World War II, major reforms occurred in 1861, 1870, 1884, 1897, and 1937, but only the 1861 reform had an impact according to the anti-director rights index. This index increased from zero to one, since 10% of the shareholders could now ask for an extraordinary shareholder meeting. Surprisingly, the index remained at this level at least until the early 2000s. The other indices of the law-and-finance school also showed a low degree of legal protection in Germany around 1900. For example, the private enforcement index stood at zero in 1900 and remained at this level until 1987. Thus, shareholders in Germany were basically unprotected over the course of the twentieth century resulting in a high ownership concentration.

The cases of Delaware and the UK demonstrate that legal rules were not fixed centuries ago, but were determined in the political sphere, and are thus subject to change. Indeed, Pagano and Volpin (2005) demonstrate that democracies with a system of proportional representation tend to offer better protection to managers and employees, whereas democracies with a majoritarian political system (e.g., Britain and the USA) tend to offer better protection for shareholders. In a pure cross-sectional econometric investigation, the legal origin still has an impact on the level of shareholder protection. However, once we consider the dynamics of political processes, i.e., when we account for the fact that political decisions change the legal rules over time, the legal system loses its significance for the level of shareholder protection (Pagano and Volpin 2005). Moreover, Pagano and Volpin (2006) suggest the existence of a positive feedback loop: countries with good shareholder protection see a rising number of shareholders and these shareholders vote for parties fostering shareholder rights. The reverse holds for countries with weak shareholder protection. Thus, a bimodal world emerges: one part is populated by market-oriented, shareholder friendly countries while the other is not.

Foreman-Peck and Hannah (2015) investigate the impact of law, politics, and culture on the number of corporations, the impact of corporations on economic growth and exports, and the feedback of economic growth and exports on the number of incorporations. An economy dominated by a narrow elite should, according to Rajan and Zingales (2003), be a closed economy, i.e., an economy

with a low level of foreign trade. Furthermore, according to Pagano and Volpin (2005), more inclusive political institutions, in particular parliamentary systems with proportional representation, should lead to more inclusive economic institutions, i.e., a large number of welfare-enhancing corporations. Foreman-Peck and Hannah (2015) mobilize new data about the number of corporations in more than 80 countries in 1910 and combine them with existing data on GDP, trade, legal origin, and various other explanatory variables. They end up with a sample of 51 countries from around the world. Using OLS, 2SLS, and 3SLS regressions, they demonstrate (i) that richer countries which are open to international trade and having a common law legal system do have a relatively large number of corporations; (ii) that the number of corporations is not associated with the intensity of foreign trade; and (iii) that the number of corporations is positively related to the level of GDP.

Within-country variations of legal rules have been used to refute the law-and-finance thesis. For example, Freeman et al. (2013) compare developments in common law England with those in civil law Scotland between 1600 and 1850. In particular, they draw on a large dataset of 452 corporate charters from the period between the 1720 Bubble Act and the 1844 Companies Registration Act. In contrast to expectations from the law and finance literature, Scottish firms offered better protection to minority owners than English firms. A comparison of civil law and common law systems within one country is also possible for the USA, since Louisiana operated a French-style incorporation system until 1845. The difference in outcomes when compared to similar US states was rather small. The number of incorporations was slightly lower in Louisiana, but the average size of a corporation slightly larger (Sylla and Wright 2013).

Compliance of firms is also an important point recently evaluated by Guinnane et al. (2017). The 1856 British corporate law did not contain detailed governance rules. Instead, the parliament provided a model set of governance rules to make life easier, in particular for small corporations (Guinnane et al. 2017). To what extent did firms follow the model and to what extent did they change the rules? Were the rules chosen by firms better or worse for (minority) shareholders? Do we observe differences between large and small firms or between listed and non-listed firms? In general, corporate statutes shifted power from shareholders to directors and this pattern became more pronounced over time. Guinnane et al. (2017) investigate the articles of associations for three randomly selected cross sections of firms newly established in 1892, 1912, and 1927. The 1892 sample, for example, includes 54 firms. Average share capital was about 40,000 pounds and nine of the firms had 50 or more shareholders. Less than 10% of the firms accepted the governance rules as provided by parliament (Guinnane et al. 2017).

Governance rules are often complicated and sometimes several rules interact to get a specific result. Thus, looking at individual rules often does not help to understand the governance system of a corporation. Keeping this in mind, we may look at individual rules. For example, about 80% of the 1892 sample adjusted shareholder voting rights by moving from the graduated voting scheme proposed by parliament to a one-share, one-vote rule. Election of directors and restricting the power of directors is also one of the key tasks of shareholders. In 74% of the firms,

shareholders never got to elect a full board and in 64% of articles, directors could name one of themselves managing director (Guinnane et al. 2017). Guinnane et al. (2017) do not use advanced statistical methods to disentangle potential correlations or causations in their sample. Instead, they compare mean values of some relevant variables. It seems that firm size did not play a significant role. Large and small firms adjusted statutes in the same way. Listed and nonlisted firms were also quite similar, and there is no time trend visible in the data.

Firm-level governance and performance data were also mobilized by Burhop (2009) to evaluate the impact of governance rules of German banks during the 1870s on their valuation and performance. More specifically, he looks at 202 corporate charters and analyses how these charters regulate 28 governance issues. For example, the 1870 German corporate law contains a one-share, one-vote rule as a default with the possibility to change this rule in the corporate charter. Indeed, more than 90% of banks changed the rule, usually by restricting the voting rights of small shareholders (e.g., by requiring multiple shares to cast one vote) and block holders (e.g., by restricting the maximum number of votes an individual shareholder can cast). In addition, Burhop illustrates how certain rules interact to generate specific outcomes. For example, one of Germany's largest banks stated in its charter that the general meeting had to be announced 14 days before it would take place. In another rule, the charter prescribes that shareholders had to register shares 28 days in advance. Thus, only insiders could register shares right in time to attend the annual meeting.

The association of 28 governance rules with firm performance (measured by Tobin's Q, the change in the market to book ratio, and survival) is evaluated using a set of univariate and multivariate regressions. Unsurprisingly, most governance rules had no systematic association with firm performance. For relatively large banks, use of a one-share, one-vote rule has been associated with higher firm valuation (Burhop 2009). In principle – and in accordance with the theory of information efficient stock markets – no variable had a statistically and economically significant association with changes of firm valuation. Furthermore, voting rights for small shareholders as well as an independent and relatively large supervisory board enhanced the probability of firm survival during and after the financial panic of 1873 (Burhop 2009). In general, voting and monitoring rights seem to improve governance outcomes.

The Separation of Ownership and Control

In global perspective, transparency of corporate ownership structures is rather low. Faccio and Lang (2002), for instance, present one cross section of ownership data for about 5,200 European listed corporations. Widely held and family controlled firms dominate among European corporations at the end of the last century. Families are more important for relatively small firms and for nonfinancial corporations. In nearly all countries, family-dominated firms are more frequent than widely held firms; Britain and Ireland are the exception to this rule. Outside of Europe, widely held firms are most important in Australia, Canada, Japan, New Zealand, the USA, and

South Korea (La Porta et al. 1999). Thus, "One of the best-established stylized facts about corporate ownership is that ownership of large listed companies is dispersed in the UK and the USA and concentrated in most other countries" (Franks et al. 2009: 4009).

Comprehensive historical corporate ownership data for the nineteenth and twentieth centuries are in short supply. Britain and, to a certain extent, the USA are the exceptions. Firms established under the 1856/1862 UK corporate law were required to submit shareholder registers to the Registrar of Companies. Using this source, Acheson et al. (2015) collected ownership data for five cross sections for the period 1865 to 1900. In total, they collect 890 records for 488 unique firms. On average, companies had 410 shareholders. The number of shareholders tended to increase over time from about 300 to about 600. Insiders (i.e., directors plus shareholders owning more than 10%) held about 18.5% of capital and 16.1% of votes. The five largest investors represented 26.6% of capital and 22.2% of votes. Breweries tend to have a high ownership concentration, whereas banks tend to have a low concentration.

Using a multivariate regression analysis, Acheson et al. (2015) demonstrate that ownership tends to disperse over time, and that firms headquartered in London and firms having their shares listed on multiple stock exchanges had more widely dispersed ownership. Mergers tend to increase ownership concentration. The size of the company, the par value of each share, and being listed at the official market of the London stock exchange did not systematically affect ownership dispersion. The existence of nonlinear voting schemes, which became less popular over time, did not affect ownership concentration, but it did affect the concentration of voting rights. Voting concentration was lower in firms operating nonlinear voting schemes, i.e., these schemes tend to disfavor large owners.

In general, ownership concentration was lower in Victorian Britain than in modern Britain. In Victorian Britain, only one in three firms had a single shareholder owning more than 10%. This is similar to S&P-500 firms today. Yet, directors owned a much larger share of capital in the nineteenth century than during later periods. From the 1880s to the turn of the century, the median ownership share of directors was 9%. This declined to less than 3% during the interwar period and less than 1% today (Acheson et al. 2015).

Post-1900 data are also available. Foreman-Peck and Hannah (2012) provide a comprehensive reassessment of the divorce of ownership and control on pre-World War I Britain by looking at the ownership structure of the 337 largest listed companies. In particular, they look at the number of shareholders per firm and they calculate the ownership share of directors in these companies. Moreover, they evaluate if large discrepancies between ownership and voting rights existed. The median firm had 3,000 shareholders, while the mean number of shareholders per firm was 6,177 (Foreman-Peck and Hannah 2012). The median number of shareholders varies substantially among sectors, with railways (4,750 shareholders) at the top and breweries (1,600 shareholders) at the bottom of the ranking. In total, the 1911 data reveal more than two million shareholders. Thus, Britain was a "shareholder society" already before the Great War. In nearly all companies, they observe a divorce of

ownership and control. Only 5–10% of the firms evaluated were perhaps controlled by manager-owners. On average, board members controlled 2.5% of the capital and 2.8% of the votes. Shares were higher in manufacturing and breweries. Taking the voting power of board members as an indicator of the divorce of ownership and control, they demonstrate that this divorce was stronger in the UK in 1911 than in the USA in 1935 or 1995.

Franks et al. (2009) track the development of ownership structure of British companies over the twentieth century by drawing several random samples. Moreover, they develop indices of ownership dispersion and ownership mutation to assess the dynamics of ownership structures beyond simple measures, i.e., ownership shares of the largest one, three, or five shareholders. It turns out that the ownership structure has been quite similar at different moments in time during the twentieth century. Yet insiders (i.e., board members) were replaced by outsiders (i.e., institutional investors) over the course of the twentieth century as dominant shareholders. From 1900 to 1960, they observe dispersion of ownership, and since 1960 a concentration of ownership. Driving forces behind ownership dispersion have been acquisitions by way of equity exchanges, increases of firm size, and directors selling out. Remarkably, investor protection indices are uncorrelated with ownership dispersion. Trust and the existence of provincial stock exchanges are put forward to explain ownership dispersion in times of weak shareholder protection. Shareholders tend to live close to corporate headquarters and close to the board members managing the firms. In 1910, more than half of the shareholders lived less than six miles away from the corporate headquarter. Mutation of ownership becomes faster over time. Thus, early in the century controlling shareholders held the shares, whereas controlling stakes changed hands with increasing speed later in the century. This mutation of ownership is significantly and positively related to investor protection indices. Better protection of outside shareholders improved stock market liquidity and facilitated the transfer of large ownership stakes from insiders to outsiders.

Another explanation for the high degree of ownership dispersion in Britain around 1900 has been put forward by Hannah (2007). He suggests that the two-thirds rule of the London Stock Exchange contributed to the divorce of ownership and control in Britain before World War I. According to this rule, at least two thirds of the capital of listed firms has to be distributed to outside owners during the IPO. Cheffins et al. (2013b) evaluate if this has indeed been the case. Based on a sample of IPOs from the period 1900 to 1913, they demonstrate that many firms retained an inside ownership of more than one third of the capital. Moreover, they show a stronger separation of ownership and control for firms listed in the special settlement section of the stock exchange. This is surprising, since the two-thirds rule did not apply for firms opting for special settlement – the rule only applied to firms opting for an official quotation. Thus, Cheffins et al. neither supported the result nor the reason given by Hannah. Responding to this critique, Hannah and Foreman-Peck (2014) make clear that they focused on relatively large and established firms, whereas Cheffins et al. focused on relatively small firms shortly after their IPO. Moreover, the sample size of Cheffins et al. is much smaller and thus less

representative. However, when Hannah and Foreman-Peck restrict their sample to relatively small firms, they find the same result as Cheffins et al. Thus, the two-thirds rule operated by the London Stock Exchange most likely did not contribute to the separation of ownership and control in British corporations before World War I.

To what extent ownership and control of US corporations has been separated is still debated (see Cheffins and Bank 2009, for a review). Hilt (2008) documents and analyses the separation of ownership and management in early US corporations. In contrast to hypotheses put forward by classical writers, he presents evidence for a divorce of ownership and management of New York corporations already in the 1820s. On average, firms had 74 shareholders and the Gini-coefficient of ownership stakes was 0.57. Moreover, ownership was more concentrated than voting rights since nearly half of the firms had graduated voting schemes. Yet, this deviation from the one-share, one-vote rule did not have a systematic impact on the distribution of shares. Furthermore, managers owned 28% of the firms, a relatively high share when compared to data from the 1930s or 1990s. In addition, Hilt observes a correlation between managerial ownership and the absence of graduated voting schemes. Firms with a high managerial ownership tend to follow a one-share, one-vote rule. This was not good news for investors: share prices tend to be higher when managerial ownership stakes were low and when voting rights were restricted.

Holderness et al. (1999) look at managerial stock ownership of large US corporations over the twentieth century. More specifically, they compare the ownership structures of 1,419 listed firms in 1935 with ownership structures of 4,202 listed firms in 1995. Their key finding is surprising: managerial ownership is higher in 1995 than in 1935. Mean and median managerial ownership shares of all companies and of NYSE-listed companies were higher in 1995 than in 1935. In addition, this finding also holds for all 13 branches and for old as well as young firms. Moreover, the inflation-adjusted average holding of insiders is four times larger in 1995. In a next step, Holderness et al. (1999) look at the holdings of the top officer, making their results comparable to data presented by Jensen and Murphy (1990) for the years 1938, 1974, and 1984.The mean ownership share in 1935 as well as in 1995 was 1.25%, and the median ownership declined slightly from 0.09% to 0.06%. Jensen and Murphy report mean (median) holdings of the top officer of 1.7 (0.3%) in 1938 and 1.0 (0.03)% in 1984. In 1935, managerial ownership stakes tended to be lower in regulated industries (e.g., public utilities), in larger firms, and in firms with volatile share prices. In 1995, regulation had no effect, but size and share price volatility still had the same effect. Moreover, older firms tend to have smaller managerial ownership stakes (Holderness et al. 1999).

Ownership data for Germany are in short supply since most firms used bearer shares and only shareholders attending the general meeting had to register their shares. Searching shareholder lists in the archives of individual companies is, obviously, quite time-consuming and it is thus difficult to sample shareholder lists. Some systematic evidence is available in public archives since firms had to submit attendance lists of a general meeting to stock exchange officials in case of seasoned equity offerings or similar events. However, this rule has been in force only since 1897 and it results, perhaps, in a biased sample.

Using this source, Franks et al. (2006) base their analysis of ownership structures on 156 shareholder lists from 55 companies. Before World War I, the median annual meeting was attended by 14 to 18 shareholders, with a maximum of 259 shareholders attending a meeting of Deutsche Bank. The numbers do not change much during the interwar period. The five largest shareholders present at annual meetings during the first half of the twentieth century represented about 80–90% of the share capital attending the meeting. On average, two-thirds of the total share capital was present at general meetings. Thus, ownership concentration was quite high in Germany and it tended to increase slightly over time. Moreover, large inside owners (i.e., members of the executive and supervisory board) were more important than large outside owners until the 1920s. In addition, we observe a pronounced move of voting power away from individuals toward banks and other firms. Banks did not invest their own money into shares. They mostly cast proxy votes for other investors.

Managerial Incentives

Executive compensation has been a hot topic in corporate governance research during the last three decades (see Edmans and Gabaix 2016 for a review). In particular, the steeply rising compensation of CEOs has been – and is – controversially debated. Economic theory puts forward four theories to explain rising compensation: managerial rent extraction, the provision of incentives, the scale of the firms, and increasing returns to general rather than specific skills. The rent extraction and the incentive explanation are obviously related to corporate governance.

Bayer and Burhop (2009) provide evidence for the incentive hypothesis by evaluating the impact of the 1884 German corporate law reform on executive compensation. This reform strengthened monitoring incentives and possibilities for shareholders and reduced the problems of asymmetric information between principals and agents. Thus, managerial incentives can be reduced. Indeed, using data for a sample of 37 manufacturing firms, they show that the sensitivity of executive pay and accounting profits declined by 50–75% after the implementation of better corporate governance rules. Robustness checks for banks and firms employing only one executive point in the same direction. Moreover, they show that total bonus payments increase after the reform and that the profit share of executives is broadly constant. The effect of the reform has thus not been the level of compensation, but the association of bonus payments with firm performance.

Impressive research has been conducted using data from the USA. The main reason is most likely the relatively easy access to large data sets. When the US government strengthened shareholder rights after the Great Depression, more financial information became available. Since 1938, firms had to disclose information regarding executive pay. Disclosure of pensions and deferred compensation followed in 1952 (Dew-Becker 2009). Using data available since the 1930s, Frydman and Saks (2010) document executive compensation in the USA between 1936 and 2005. Regarding the level of pretax compensation, they distinguish three phases: slightly declining real compensation from the mid-1930s to the early 1950s,

slowly increasing compensation from the early 1950s to the mid-1970s, and strongly increasing compensation subsequently. Moreover, they also document shifts in the composition of compensation. In the beginning, executives earned salaries and current bonuses. Long-term bonuses became more important from the 1960s onwards and stock options took-off in the 1980s.

While pretax compensation measures the costs of executives for the firms, it does not reflect incentives for executives, since incentives result from after-tax compensation. In the beginning, after-tax compensation fell more than pretax compensation since tax rates were high. Since the mid-1960s declining tax rates imply a stronger growth of after-tax compensation when compared to pretax compensation. Moreover, compensation grew relatively equally for all executives until the early 1990s. Afterwards, CEO compensation grew much faster than compensation of other top-level executives (Frydman and Saks 2010).

Over time, the association between executive compensation and firm size (i.e., the market value) changed substantially. The correlation between the growth of executive compensation and the growth of market value of firms has been 0.1 from the mid-1930s to the mid-1970s and about one afterwards). Quite similarly, the correlation between executive compensation and firm performance was also quite stable form the 1950s to the 1980s. Subsequently, the size of the correlation doubled (Frydman and Saks 2010. This changing correlation can neither be explained by firm size nor by underlying firm characteristics (like growth opportunities, return on assets, or industry regulation). Moreover, the pay-performance sensitivity is not affected by the size, the composition of the board, or the existence of a large outside shareholder. This latter finding leads Frydman and Saks (2010: 2128) to the conclusion that "corporate governance did not play a significant role in the rise of executive pay."

This, obviously, raises the question: What does play a role? Frydman and Molloy (2012) put forth the idea that unions affected executive compensation. Starting from the observation of declining executive compensation during the 1940s, they investigate the cause driving the decline. To do this, they mobilize four cross-sectional data sets covering the compensation of the three best paid executives from about 250 firms for the 1940s. Comparing the median compensation of executives with the average annual earnings in the economy, they calculate that executives earned 24 times the average annual pay in 1940, but only 17 times in 1949. Moreover, mean and median executive compensation not only declined when compared to average annual earnings in the economy, but also when compared to the inflation rate. Executives lost purchasing power during the 1940s. One reason for this extraordinary development might have been wartime regulation of pay. For example, increases of high salaries were prohibited between October 1942 and November 1946. Nevertheless, one quarter of executives received a salary increase. Remarkably, we do not observe huge differences between either war and nonwar industries or between high- and low-income industries. Furthermore, income tax regimes did also not affect executive compensation. Finally, they use a multivariate regression analysis to uncover factors associated with executive pay. The only factor depressing the relative – but not the absolute – level of executive compensation after the war is

the degree of unionization. The governance structure of firms, e.g., board size and board structure, did not affect executive compensation.

Managerial ownership can also mitigate agency conflicts between shareholders and executives. Calomiris and Carlson (2016) investigate this relationship by using data from the US banks from the late nineteenth century. In particular, they evaluate the endogenous emergence of governance mechanisms to limit rent-seeking and to keep risks in line with shareholder preferences. They employ examination reports for 206 national banks from 37 larger cities as a data source to test their hypothesis that corporate governance becomes less formal when managers (i.e., the president, the vice-president, and the cashier) own a relatively large share of the bank. Managerial ownership is, however, endogenous and they use unforeseen managerial turnover events (like death or illness of the manager) as an instrument to identify causal effects of ownership on governance. Governance is reflected in a five-component index (board meets at least monthly, high percentage of outsiders on board, active discount committee, president bonded, and cashier bonded). These components are positively correlated with each other and each is negatively correlated with managerial ownership.

On average (mean), the three managers owned collectively 24% of the share capital, outside directors on the corporate board owned another 15%, and 61% of shares were owned by outsiders (Calomoris and Carlson, 2016). By using a multivariate regression, Calomiris and Carlson demonstrate a negative and statistically significant association between formal governance and managerial ownership. Moreover, managerial ownership is negatively associated with managerial turnover. Using an instrumental variables approach, they demonstrate a causal impact of managerial ownership on risk taking – higher ownership results in a less risky loan portfolio and a lower probability of bankruptcy during the 1893 financial panic. Looking at the interrelationship between managerial ownership, formal governance, and rent seeking, it turns out that higher ownership shares are associated with higher managerial salaries, whereas more formal governance is associated with lower salaries. The level of insider loans depended neither on the size of managerial ownership nor on formal governance rules. However, the distribution of loans among insiders depends on these variables. Calomoris and Carlson observe a positive correlation between managerial ownership and loans to managers. Taken together, the evidence shows a positive association between managerial ownership and managerial rent-seeking, and a negative association between ownership and risk. Formal governance instruments were thus used to reduce rent-seeking.

Dividends

In perfect capital markets, shareholders should not care about dividend payments since they should not affect the value of a firm. When capital markets are imperfect, e.g., due to agency problems, dividend policy becomes relevant for firm value. For example, announcing a higher dividend may result in a higher stock price if money is

transferred from greedy managers to owners. La Porta et al. (2000) explain and test two agency models of dividends. According to the outcome model, dividends are paid because minority owners force insiders to do so. According to the substitution model, firms pay dividends to build up a reputation with minority shareholders, and this helps to issue additional equity. Empirical evidence from the 1990s tends to support the outcome model.

Historical data have also been used to test theories of dividend policy and to derive conclusions regarding the corporate governance system. In a seminal paper, Braggion and Moore (2011) use data from London around 1900 to evaluate the predictive power of various theories explaining the impact of dividend policy on stock prices. They show that dividend announcements disclose private information held by firm insiders to shareholders. A positive dividend announcement yields abnormally positive returns at the stock market, whereas a negative dividend announcement yields a negative return. Thus, investors take an announcement of a dividend change as information about the future cash flow of the firm. If this is indeed the case, a positive dividend announcement should be followed by higher earnings – and this is indeed the case. Moreover, Braggion and Moore investigate whether agency considerations are also relevant to understand dividend payments in Victorian Britain. Using the cross-sectional variation in the data, they find no effect. Dividend announcements have the same effect for all kinds of firms, leaving no room for competing explanations.

Campbell and Turner (2011) investigate whether dividend payments were used as a substitute for weak legal protection of shareholders in Victorian Britain. Using a sample of 823 companies listed in 1883, they demonstrate that pay-out ratios were similar in the cross section of firms. The only variable significantly related to pay-out ratios is firm size – large firms tend to pay relatively generous dividends. In addition, dividend policy (pay-out ratio or dividend-par value ratio) are positively associated with Tobin's Q.

Deloof et al. (2010) investigate dividend policy of Belgian firms between 1905 and 1909, with a special focus on the role of universal banks. Firms having a banker on board may not need to pay high dividends since the bank affiliation is already a positive signal to investors and since banks may provide capital. Yet, it might also be the case that bankers on board pressure firms to pay abnormally low dividends and to keep cash holdings, since this makes credit default less likely. At first glance, firms affiliated with a bank were more likely to pay dividends, their dividend yield was higher on average, they were more likely to continue dividend payments on an established level, and they had a higher pay-out ratio. In addition, bank-affiliated companies were more reluctant to cut dividend payments. In a multivariate setting, they provide evidence for the certification hypothesis. Bankers on board certify the good investment opportunities of firms (reflected in a high Tobin Q) having a higher pay-out ratio. But another explanation is possible: firms may need to pay higher dividends to compensate shareholders for the risk that bankers on board channel funds from owners to creditors. Yet, Deloof et al. demonstrate that this is most likely not the case, since a more intense relationship with a bank (i.e., reflected in several board members) does not result in higher dividend payments.

Guenther (2017) provides some evidence for Germany by looking at dividend announcements in 1895. For a sample of 166 firms, he finds statistically and economically significant positive abnormal stock market returns after a positive dividend announcement. Moreover, he finds that this effect is larger for relatively small firms and for firms providing relatively little financial information. Thus, we have some evidence for the dividend signaling hypothesis.

Boards

An extensive literature deals with the relationship of boards and corporate governance (Adams et al. 2010; Fear and Kobrak 2010). The literature based on historical data typically focuses on short periods of time and specific firms or events. In contrast, Lehn et al. (2009) has a broader scope by looking at the composition of corporate boards for 82 US companies during the period 1935–2000. He reports that board size is positively related to firm size (captured by market value) and negatively related to growth opportunities (reflected in the ratio of market-to-book value of assets). Large firms need more monitoring capacity and need to draw expertise from many different board members. Fast growing firms need smaller boards ready for quick action. Boards get larger, at least temporally, after mergers and acquisitions and during geographic expansion of corporations. Furthermore, the number of insiders declined by about two-thirds between 1950 and 2000 (Lehn et al. 2009). Using a 2SLS regression, Lehn et al. demonstrate that board size and board composition did not affect corporate performance once the factors driving board size and composition are accounted for.

The impact of bankers as board members on corporate performance has been investigated. In a classic paper, Ramirez (1995) looked at the function of J.P. Morgan for corporate investment in the USA around 1900. He compares 16 firms linked to J.P. Morgan to 30 unlinked firms between 1908 and 1912. The key question is whether being connected to J.P. Morgan mitigates cash flow restrictions. Ramirez estimates a standard cash flow to investment regression including firm fixed effects. It turns out that investment of firms not related to J.P. Morgan reacts negatively and statistically significantly to changes in cash flow, whereas cash flow played no role for investment of firms related to Morgan. Thus, monitoring by a banker alleviated capital market imperfections by reducing asymmetric information between investors and managers. Moreover, Simon (1998) shows that market valuation fell by 7% when bankers left corporate boards after passage of the Clayton Act in 1914. According to Simon, however, this decline is not an indication of monitoring services provided by banks, but an indication of declining market power. Bankers on boards of various firms from the same industry helped to establish collusion among firms. This coordination activity ended in 1914. The decline in stock market value thus reflects an increase in consumer surplus.

Recently, Frydman and Hilt (2017) used the Clayton Act to provide a causal interpretation of a classical question: did investment banks on corporate boards mitigate the problems of asymmetric information and help all shareholders or do

they exploit the additional information they get on the board to exploit rents from firms? If the monitoring role dominates, restricting board membership should lead to higher interest payments and less investment. If rent-seeking dominates, shareholder value should increase once bankers are removed from boards. In principle, the Clayton Act prohibited underwriters of railroad securities to sit on the board of the same railroad company. Thus, investment banks had to choose between underwriting a business and membership on its board. However, the relevant part of the Clayton Act was not implemented in 1914 and Congress postponed it until it went into effect in 1921. Nevertheless, the partners of J.P. Morgan & Co. announced immediately after passage of the Clayton Act that they were going to leave the boards of 30 companies.

Frydman and Hilt's empirical analysis was based on accounting, governance, and stock market data for 71 NYSE-listed railroads and 79 NYSE-listed industrials and utilities. Usually, railroads were linked to high-ranking investment banks, they had many interlocking directorates with other railroads, and they had a large number of shareholders. When it became clear that the act came into full force, the stock prices of the affected railroad companies reacted negatively, whereas returns of utilities and industrials did not decline. Looking beyond short-run returns, they show that Tobin's Q, investment rates, and leverage of affected railroad companies declined, whereas average interest payments increased. Thus, all proxy variables indicate a value to having bankers on board, a value that has been destroyed by policy intervention.

This difference-in-difference approach is supplemented by an instrumental variables regression. The strength of the railroad underwriter relationship in 1913 – before passage of the Clayton Act – is used as an instrument to causally explain changes taking place after 1920. Reassuringly, the instrumental variables approach confirms the earlier results (Frydman and Hilt 2017). The monitoring role of bankers on board has been especially relevant for railroads heavily using debt finance. Moreover, monitors from the leading investment banks created more value for railroads than did monitors from less prestigious underwriters.

A causal interpretation of board connections is also provided by Deloof and Vermoesen (2016). More specifically, they investigate the value of corporate boards for Belgian firms during the Great Depression, using it as an external shock allowing the identification of the causal relationship between board structure (as reflected in board size, presence of bankers on board, and the busyness of board members) and firm performance. During normal times, board structure is endogenous, since firms chose their board to maximize firm value. A larger board may provide more expertise, but the risk of free-riding is also larger. While bankers may provide debt finance, they may also ask for a low-risk firm strategy to make loan repayment more likely. Busy boards may offer many contacts to other firms, but busy officers may become too busy – in particular, during a crisis.

Using data for 150 firms for the period 1928–193,1 Deloof and Vermoesen (2016) estimate a random effects model to explain the market-to-book valuation of the firms. In principle, and with varying degrees of statistical and economic significance, all three indicators of board structure are positively related to firm valuation until the onset of the Great Depression, but these relationships turn negative during the Depression. The main driver during the Depression is board busyness. While the

effect of bankers and of board size is often insignificant, the effect of board busyness remains significant. In normal times, a busy board is value enhancing, but the effect turns negative during an extreme downturn.

Beyond bankers on board, politicians on board have become a focus of recent research. For example, Grossman and Imai (2016) provide evidence for a weakly negative association between board membership of members of parliament and valuation of banks. They collected data for all English and Welsh banks for the period 1879–1909 on biannual frequency. In particular, they collect balance sheet, stock market, and board composition data as well as firm fixed data, e.g., distance to London and year of foundation. One reason for the weak effect might be the stability of English and Welsh banks during this period. Managers simply did not need political connections when business was calm and successful. Board members are allocated to three groups: noble members, members of parliament (together, they form the group of politically connected board members), and other members. Between 1879 and the turn of the century, about 20% of the banks had a member of parliament on the board. Subsequently, the share increased to 35%. The share of noble directors increased steadily from about 5% in 1879 to 35% in 1909.

To assess the impact of board structure on stock market returns, Grossman and Imai (2016) calculate a fixed effects panel regression of all observations and they use a propensity matching estimator based on total bank assets to neutralize size effect. The latter method yields basically no significant results, whereas a cross-sectional regression approach provides some (rather weak) evidence of a positive association between board connections and stock market returns. Using a dynamic fixed effect regression, there is no effect of noble directors on stock market returns and even negative effects of MPs board presence on returns. This result obviously raises the question why banks put MPs on board. It turns out that some banks – namely small banks and those located fairly far away from London – profited from politically connected board members.

To account for potential selection bias, Grossman and Imai (2016) perform event studies for six general elections. They focus on election results where board members won or lost with a small margin. This indicates that the election outcome was not clear from the beginning and one may thus expect a financial market reaction to the outcome. However, no event had a significant effect on stock returns. Thus, they conclude that politically connected directors had no equity value for English and Welsh banks between 1879 and 1909.

Braggion and Moore (2013) search for value-enhancing effects of politicians and they provide evidence of a positive impact of political board members on stock market valuations for new-tech firms in late Victorian Britain. Election or reelection of a board member to the parliament results in an increase of stock market value of about 2%. Moreover, firms having a politician on board were more likely to make a seasoned equity offering. They use standard event-study methodology to uncover potential effects of MPs on stock market values. In particular, they look at the elections of 1895, 1900, and 1906 to measure potential effects. However, in most constituencies, election results were pretty predictable and should have been factored into stock prices a long time before the election. To detect potential effects, they focus

on those districts where results were rather unpredictable. While they still find no effect for all firms, they do find an effect for new-tech firms. In addition, they investigate whether politically connected firms raised more money by way of seasoned equity offerings or bond offerings. When all firms are considered, this is not the case. Yet, a positive impact of political connections for new-tech firms is detected.

Product Market Competition

Evidence regarding the interaction of product market competition, corporate governance, and firm performance is reviewed by Crafts (2012). Product market competition makes it easier to assess managerial performance since price signals from the market are more precise. Moreover, product market competition acts as a disciplinary device, fostering a decent performance of lazy managers. According to Crafts, dispersed ownership and restricted voting rights contributed to the weak productivity performance of UK railroads before World War I. In addition, the increasing tendency toward a separation of ownership and control after World War II and the absence of strong shareholders fostered managerial ineffectiveness in an environment with weak product market competition from the 1940s to the 1970s. The deregulation of financial markets and stronger competition on product markets changes this from the 1970s onwards.

The potential managerial failure at railroad companies during the nineteenth century has been investigated in detail by Campbell and Turner (2015). They look at the impact of competition on firm performance in the railway sector, controlling for ownership structure. Railways were incorporated with limited liability by special parliamentary acts, started in 1826. Frequency of travel and price regulation started with the 1844 Railway Act. This act also allowed the nationalization of lines authorized after 1844 and it allowed concessions for competing lines. The mid-1840s were also characterized by a boom and bust cycle in the railway sector, with railroad companies established after 1843 typically serving relatively sparsely populated areas. Campbell and Turner look at the ability and cost to passengers of choosing between competing lines and they investigate whether competition increased during the 1840s. In 1843, no substitute was available for two-thirds of the lines, whereas more than 80% of railroad lines could be substituted by travelling on other lines in 1850. In particular, competition increased on main lines connecting important cities. As a consequence, prices declined.

Building lines in sparsely populated areas and increased competition between lines might be reasons for declining financial performance of railroad companies during the 1840s. Managerial failure might be another reason. In a counterfactual analysis, Campbell and Turner (2015) evaluate the potential impact of three managerial strategies for established lines (i.e., railroad lines already in operation before 1844). The strategies are: no expansion and no mergers; no expansion, but mergers with other lines; expansion and mergers. The first scenario is correlated with the worst outcome, the last scenario with the best outcome. Since managers of established lines indeed followed an expansion and merger strategy, there is no

sign of managerial failure. Moreover, a regression analysis shows that "those firms which had the greatest potential exposure to competition were those which expanded the most" (Campbell and Turner 2015: 1267). Thus, there is little evidence for managerial failure of British railroad executives during the 1840s.

The relationship between product market competition and corporate governance has also been investigated by Burhop and Lübbers (2009). In particular, they evaluate the impact of the formation of the RWKS, a large cartel dominating the German coal market from 1893 until World War II, on productive efficiency of the cartelized firms. Reducing incentives from the product market should lead to declining efficiency of firms. However, shareholders might increase incentives by offering generous bonus payments to managers. Indeed, the executive board of cartelized firms received 3.6% of profits as bonus payments, whereas executives of non-cartelized firms received only 2.5%. Moreover, an econometric model demonstrates that an increase of bonus payments by 1% (730 Mark) reduced inefficiency by about 790 Mark. Thus, increasing managerial incentives is a good answer in face of declining product market competition. However, the numbers also suggest that executives received nearly the entire efficiency gain as bonus payment.

Conclusion

Our knowledge about historical corporate governance has substantially improved over the last decade. Theory-based data collection efforts and the application of modern econometric methods markedly contributed to this progress. Today, we can be quite sure that separation of ownership and control has been a feature of many – perhaps most – listed UK and US corporations before World War I. With respect to Germany and other countries, much more research is necessary. Moreover, ownership structures of US corporations before the 1930s are a somewhat under-researched area. Furthermore, the separation of ownership and control and its evolution over time is unrelated to the legal origins of countries. The contributions of other macro-theories explaining ownership structures seem also not to explain very much. Consequently, historical corporate governance research turned from cross-country toward cross-firm evidence. In addition, institutional differences across time and space have been used to go beyond associations and correlations and to uncover causal factors driving governance structures and outcomes. Future research may combine mirco-data from several countries to assess the potential impact of cross-country differences of corporate governance.

Government, Health, and Welfare

Anthropometrics

Richard H. Steckel

Contents

Abstract

This chapter describes the rise, evolution, and durability of the new anthropometric history, an interdisciplinary approach to assessing biological aspects of the standard of living in the past using measurements such as height and weight, which are abundant from numerous historical sources such as military muster rolls, identification systems, slave manifests, and prison records. By comparing anthropometric data with traditional sources used by economists, such as wages, income, and occupation, scholars have found intriguing similarities and differences in these approaches to assessing the standard of living or human welfare

broadly defined. The chapter provides a brief history of anthropometric measures as used by anthropologists and human biologists, and gives an overview of the methodology that is useful for interpreting anthropometric data used by social scientists. Much of the discussion considers applications of anthropometric evidence to topics such as slavery, inequality, industrialization, mortality, colonization, and economic development. It concludes with notes on possible pitfalls of using anthropometric data that are important to practitioners in the area and with identification of research frontiers.

Keywords
Health · Height · Weight · Living standards

Introduction

The word "anthropometrics" descends from the Greek *anthropos* ("man") and *metron* ("measure"), and so the term refers to the measurement of man, traditionally in a physical sense. Anthropologists take hundreds of measurements, and in the nineteenth century, they were consumed by dimensions of the head and their relationship to "race" (Gould 1996). Anthropologists have long since abandoned this approach to race or ethnic identity but the term endures.

In cliometrics, the term refers to the study of height and weight, mainly because these measures have meaning in human biology and they are readily available (particularly stature) in the historical record. One can find reports on shoe size, chest expansion, arm length, and so forth, but these are difficult to interpret in relation to biological aspects of the standard of living.

This chapter provides a brief account of anthropometrics in the study of economic history beginning with its earliest applications to the analysis of important historical questions, including the nature of slavery, dimensions of inequality, the consequences of industrialization, and the effects of colonization, among others. The list of applications is long and growing, in part because height records number in the tens of millions around the globe. Femur length and various lesions assessed from skeletal remains recently entered the laboratory of economic history.

Origins

Surprisingly, interest in the human body and its dimensions did not begin with anthropology or human biology but with art (Tanner 1981). Artists of the Renaissance sought to recover ancient knowledge of human form and function by taking detailed measurements of Greek and Roman statues with a goal of learning ideal body proportions. The first medical person to take an interest in measuring the human body may have been Johann Elsholtz (1623–1688) who originated the term "anthropometry."

The intellectual history of the two major approaches to measuring human welfare (national income accounts) and auxology (the study of human growth) have two things in common: the first substantial efforts occurred in the seventeenth and eighteenth centuries and early studies were sporadic, imprecise attempts made by individuals. Unlike national income, however, investigators could make useful anthropometric measurements on a small scale. Systematic national income data awaited government involvement and support in the twentieth century while important progress in auxology was made by the middle of the nineteenth century (Studenski 1958; Tanner 1981)

Table 1 charts milestones in anthropometry from the perspective of human biology. Researchers took initial steps in the seventeenth and eighteenth centuries, but progress was slow until the second quarter of the nineteenth century. The realization that environmental conditions systematically influenced growth stimulated interest in growth studies in the 1820s. Auxological epidemiology arose in France, where Villermé studied the stature of soldiers; in Belgium, where Quetelet measured children and formulated mathematical representations of the human growth curve; and in England, where Edwin Chadwick inquired into the health of factory children (Villermé and Golfin 1829; Quetelet 1835; Chadwick 1842). After examining the heights of soldiers in France and Holland and studying the economic conditions in their places of origin, Villermé concluded in 1829 that poverty was

Source: Extracted from Tanner (1981)

much more important than climate in influencing growth. In 1833, the English Parliament put these ideas into action in legislation using stature as a criterion in evaluating minimum standards of health for child employment.

The greatest strides in the modern study of human growth occurred beginning in the mid-nineteenth century with the work of Charles Roberts, Henry Bowditch, and especially, Franz Boas (Boaz 1898; Roberts 1876, 1878; Bowdotch 1877). Roberts raised the level of sophistication in judging fitness for factory employment by using frequency distributions of stature and other measurements, such as weight-for-height and chest circumference. Bowditch assembled longitudinal data on stature to establish the prominent gender differences in growth. In 1875, he supervised the collection and analysis of heights from Boston school children, a data set on which he later used Galton's method of percentiles to create growth standards. In a career that spanned several decades, Boas identified salient relationships between the tempo of growth and height distributions and in 1891 coordinated a national growth study, which he used to develop national standards for height and weight. Later he pioneered the use of statistical methods in analyzing anthropometric measurements and investigated the effects of environment and heredity on growth. The volumes by Phyllis Eveleth and Tanner (1976, 1990), *Worldwide Variation in Human Growth*, summarize the explosion of growth studies in the twentieth century.

Methodology

Generations of observers have sensed that stature reflects biological well-being because casual empiricism identified factors behind stunting. Farmers knew, for example, that animals required certain foods to thrive and to work, and that plants were most productive if they received adequate amounts of water and sunlight. Trial and error could readily identify these forces but careful scientific observation and measurement were required to sponsor the rise of epidemiological auxology, clinical practice, and human biology.

In recent decades, the study of human growth has become heavily interdisciplinary, delving into the sciences of nutrition, genetics, biochemistry, and epigenetics, the latter being the study of ways that gene expression (whether active or dormant) is influenced by environmental and biological factors, such as diet, exercise, disease, and age (Francis 2012; Launer 2016). Researchers now recognize critical periods of human development, the most sensitive to environmental conditions being the period in utero and especially the first trimester, when rapid cell division creates specialized organs and structures. This new material may be difficult reading for social scientists, but several publications provide accessible introductions (Tanner and Preece 1989; Ulijaszek et al. 1998; Cameron and Bogin 2012).

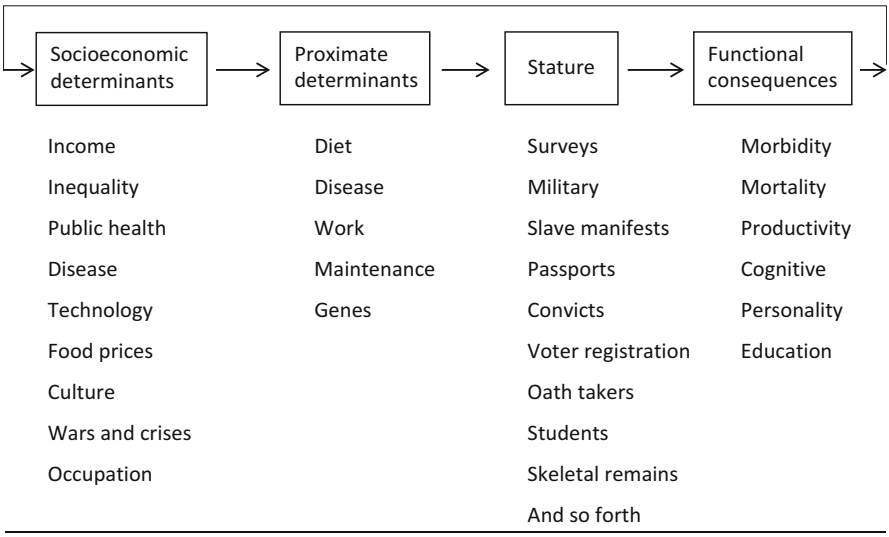
Although human biologists and physical anthropologists have known for some time that socioeconomic factors such as social class impinge on child growth and therefore adult height, a richer understanding of the relationship began to emerge when economists, historians, and other social scientists joined the conversation in the 1970s (Steckel 1998). Economic historians introduced new sources of data,

added several useful concepts, and discovered numerous puzzles or apparent anomalies in the past that elucidated the contribution of socioeconomic factors to growth. Because the historical record encompasses a rich variety of human experiences, their efforts helped to illuminate intergenerational influences on body size, measure the human capacity for growth following extreme deprivation, and expand the knowledge of cultural conditions that are ultimately expressed through proximate influences on growth.

In the late 1970s, economic historians formulated the concept of net nutrition (similar in meaning to nutritional status as used by nutritionists), which can be explained metaphorically by viewing the human body as a biological machine. Our machine operates on food as fuel (composed of protein, fat, micronutrients, and so forth), which it expends at idle (resting in bed), replacing depleted cells, and while fighting infection or engaging in physical activity. Diseases may stunt growth by diverting nutritional intake to mobilize the immune system that combatted infection or by causing incomplete absorption of food that is eaten. Similarly, arduous physical activity or work places a substantial claim on the diet, which makes it possible to lose weight or even starve on 3000 calories per day. For these reasons, average height reflects a population's history of *net* nutrition; growth occurs only if enough fuel is available after other expenditures, needed for survival, have been met. This is an adaptive mechanism that humans found beneficial for the survival of children, who have small stores of fat and muscle that can be converted into energy during dietary crises. If better times follow a period of deprivation, growth may exceed that ordinarily found under good conditions. Catch-up (or compensatory) growth is an adaptive biological mechanism that complicates the study of child health using adult height, because it can partially or completely erase the effects of deprivation. Between birth and maturity, a person may undergo several episodes of deprivation and recovery, thereby obscuring important fluctuations in the quality of life. Chronically poor net nutrition inevitably results in slow growth and stunting, which the National Center for Health Statistics formally defines as falling below the 5th percentile of modern height standards.

Figure 1 illustrates relationships involving stature. The arrows show that human growth is directly affected by diet and work, disease, and nutritional resources required for basal metabolism and replacement of worn-out cells. In turn, these variables respond to a host of environmental conditions, such as income, inequality, public health measures, food prices, technology, and the like, as shown in the figure. Social scientists are also interested in ways that stature influences demographic and socioeconomic outcomes, such as mortality, morbidity, labor productivity, cognitive development, and educational attainment. The figure shows that these variables shape various social outcomes, such as income, inequality, and technology used in the production process. This chapter explains and illustrates the links from socioeconomic conditions to stature via proximate determinants of growth and discusses ways that adult stature affects socioeconomic outcomes such as productivity and longevity.

Diet, disease, and work or physical activity are proximate or immediate determinants of growth that have been widely studied by human biologists. They also study genetic influences on growth, but the distinction between individual- and



Source: Adapted from Steckel (1995)

Fig. 1 A flow diagram showing determinants and consequences of stature. (Source: Adapted from Steckel (1995))

population-level outcomes is crucial. The vast majority of individual differences in stature are genetically or biologically regulated (Silventoinen 2003). Whether growth occurs under poor or good environmental conditions, how tall we become depends heavily on our inheritance from biological parents. At the population level, these individual differences tend to cancel such that average heights reflect primarily environmental conditions. Of course, this raises the question of whether systematic differences in growth potential exist around the world; that is, if populations of different continental ancestry lived under the same environmental conditions for several generations, would their average heights differ? DNA analysis may ultimately prove the most effective way to address the question, but the scientific community has yet to provide this answer.

We do know, however, that considerable convergence in average height has occurred around the globe where economic development has unfolded. In 1950, Japan had the shortest men of any industrial nation (about 160 cm) but young adult men today are approximately 173 cm, or roughly 5 cm below modern American height standards, and may well catch up within a generation (Honda 1997; Mosk 1996; Health Service Bureau 2009). While modest ethnic or ancestral differences in the potential for growth may exist, perhaps as much as a few centimeters, it is safe to say that environmental factors are known to have a much larger effect on average height differences around the world over the past two centuries. For example, in the early mid-nineteenth century, the average heights of young Dutch men were moderately small for Europe (about 164–165 cm), but today they reach 183 cm and are the tallest in the world (Drukker and Tassenaar 1997; Statline 2011).

Early Applications

Economists are familiar with the study of technological diffusion and most of them know the early work in the area by Zvi Griliches, who studied hybrid corn in American agriculture (Griliches 1957). He divided the process of technological change into three parts: (1) discovery of basic knowledge (also called invention); (2) application of this knowledge to the production process (also called innovation); and (3) diffusion of the new production process through an industry (also called spread). His work on hybrid corn mainly concerned diffusion, which he divided into three parts: origin, spread, and ceiling.

We can ask whether Griliches' framework may be useful for understanding the process of technological change in the industry of "research." If so, what are the parallels? In hybrid corn, the invention or discovery of basic knowledge was the method of hybridization, which crossed two inbred (self-pollinated) lines to create a new line that was more productive than either inbred line. In the rise of the new anthropometric history, there was no single, dramatic realization of the biology of human growth, parallel to hybridization, but rather an accumulation of knowledge over many decades, which economic historians realized with the guidance of the auxologist J.M. Tanner.

American Slavery

The first important application of this knowledge by economic historians concerned American slavery, and specifically the question of the average age at which young slave women could have had children, which Richard Steckel addressed in a paper he gave at the April 1977 St. Louis meetings of the Population Association of America (Steckel 1977a) and addressed again in his dissertation on slave fertility completed in the summer of 1977 (Steckel 1977b). The issue had lingered since the antebellum days of the slavery debates, which included claims by abolitionists of "breeding," that slave owners commonly forced women to have children at young ages. Based on plantation records (documents maintained by slave owners) and probate records (documents that often listed plantation assets such as slaves in family groups), and a procedure called the singulate mean, which is calculated using the share of women by age who had ever had children. By this method, the age of slave women at first birth was between 19.8 and 21.6 years, depending upon location and plantation size (Steckel 1977b, Table 33). If the maturation of slaves was substantially retarded due to malnutrition, however, it was possible that the age of menarche was high enough to prevent conception before the late teenage years, a result still consistent with widespread breeding.

Research in human biology shows that physical development occurs in a well-defined order, one feature of which is that on average, menarche occurs 1.0–1.5 years following the peak of the adolescent growth spurt (Frisch and Revelle 1969; Tanner 1966). Fortunately, there is a body of data known as slave manifests from which the

peak of the adolescent growth spurt can be estimated (Wesley 1942). These documents were required by law, beginning in 1808, to identify slaves transported in the coastwise trade to prove that they were not smuggled from Africa. Ship captains prepared duplicate manifests that described each slave by name, age, sex, height, color, and name of the owner or shipper. Steckel assembled a large sample of these records, which shows that the peak was about 13.3 years (Steckel 1977a). Therefore, menarche would have occurred by age 15 (2–3 years earlier than estimates for European populations of the era). Allowing a conservative estimate for the delay from menarche to first birth of 3 years would place the age at first birth of less than 18 years, if slave owners forced slave women to have children as soon as possible. It seems clear that owners in general did not manipulate fertility to this end. Possibly, owners tried to prevent early conceptions because infant mortality rates are relatively high if born to young women, or that unions of young slaves were unstable, resulting in costly labor force discontent. Whatever the explanation, to the extent that slave breeding may have existed, it was atypical.

Steckel (1979) reported that adult slave men were approximately 67.2 in. tall, which was about half an inch smaller than northern whites of the antebellum period as measured by Civil War muster rolls of the Union army. Thus, slaves did experience some nutritional deprivation, but on balance, their diet was reasonably adequate for the work effort and disease load they faced.

Subsequent research showed that children were remarkably malnourished – comparable in stature to the most disadvantaged groups of today's poor developing countries – a phenomenon that can be linked to seasonal growth retardation in utero, early interruption of breastfeeding, and a low protein diet (Steckel 1986a, b). In fact, young slave children were so malnourished that the typical child would have been cause for alarm in a modern pediatrician's office. Such deprivation would have created significant and permanent cognitive deficits among children and adults. Slave owners, however, were more interested in raw physical labor than developing skilled workers. Possibly, slaves with greater cognitive abilities would have been difficult to manage.

To economists, it may seem puzzling that slave children were greatly malnourished, despite the fact that planters owned all of their future expected net earnings. If owners invested in good nutrition for slave children, they would reap the benefits of taller and stronger slaves. On the other hand, there would have been costs in the form of meat protein (pork) and higher child-care costs. Well-nourished children are very active and would have required adult supervision, taking valuable labor away from field work. In sum, it was unprofitable to do so and therefore the children were not well-fed until they began working in the fields around age 10. This preadolescent boost in nutrition was enough to propel the slaves upward through the percentiles of modern height standards, in a process called catch-up or compensatory growth.

Thus, the nutritional circumstances of slaves were more varied and complex than anticipated by historians of the subject. Children had extraordinarily poor health, but adults were reasonably well-fed. The central role of stature in measuring and unraveling one of the important aspects of slave life was important in establishing a niche for anthropometric history.

Diffusion

Mortality

Diffusion of anthropometrics occurred in several directions. Cited by the Nobel Prize Committee in 1993, one of the most influential applications in the diffusion process was research by Robert Fogel on mortality (Fogel 1986; Fogel et al. 1983). Anthropometrics helped clarify explanations for the substantial long-term improvement in life expectancy that began in Europe after the middle of the nineteenth century (Mitchell 1978). The trends have inspired numerous hypotheses about the contributions of man and nature (McKeown 1976). Some scholars have advocated advances in medical technology while others pointed to the possibility of less virulent pathogens or greater immunity through natural selection. It seems clear that personal hygiene, public health, and improved diet were relevant. Through a process of elimination, McKeown assigned the most important role to an improved diet. He argued that changes in virulence or greater immunity through selection were implausible, that improved medical technology was largely irrelevant before the 1930s, and that advances in public health or personal hygiene were trivial before the end of the nineteenth century.

Fogel (1986) investigated McKeown's claims by using height data to measure the independent contribution of nutrition to the mortality decline. Knowing that ·heights are a proxy for net nutrition, he regressed mortality rates on heights and other factors to estimate the strength of the relationship. By applying changes in height observed over the period of declining mortality, he calculated that improved nutrition accounted for approximately 40% of the English mortality decline between 1800 and 1980.

Industrialization

The quality of life during industrialization has long been a staple of debate among scholars. Despite this interest, traditional sources, such as per capita income and real wages, have failed to resolve the debate. Often the raw data series are meager in quality, especially for the crucial early and middle phases of change, and traditional measures also fail to capture several important aspects of the quality of life. They ignore inequality, hours of work, work effort, health and safety while at work, and psychological adjustments to an urban-industrial way of life. In addition, the type and quality of goods available for purchase changed radically from the pre- to the postindustrial period, and it is hard to accurately measure changes in the cost of living over long periods of time.

Of course, stature is far from comprehensive, but everyone would agree that nutritional status is an important aspect of the standard of living. Moreover, the data are available for many countries as far back as the preindustrial period, providing a longer time series than is available for many other types of evidence. In addition, as a measure of nutritional status, stature avoids the consistency problems that distort traditional measures, such as real wages, compared over long periods of time.

The report on nutritional status and industrialization for Sweden was rather optimistic (Sandberg and Steckel 1980). Heights in that country increased with brief interruptions during the nineteenth century, providing a good nutritional foundation for worker productivity that was to follow, and moreover, heights continued to increase during the industrial phase of the late nineteenth century, contradicting claims by Marx and Engles.

Results for England and the United States were more pessimistic. In important work on the UK, Floud and Wachter (1982, 1990) found that the stature of London poor boys declined during the early and middle nineteenth century, suggesting that the poor became worse off during the heart of the Industrial Revolution. In the United States, a half-century height decline began for those born in the early industrial period (c.1830) and coincided with growing occupational disparities in average heights (Steckel and Haurin 1994; Margo and Steckel 1983; Costa and Steckel 1997). Verified in other studies and different data sources, the American pattern has given rise to what John Komlos has called the "early industrial growth puzzle" or in the American context the "antebellum puzzle" (Komlos and Coclanis 1997).

While height data did not resolve debates over the standard of living, they helped to focus thought on its meaning and they did identify episodes of deteriorating quality of life that were missed by conventional measures. Indeed, comparisons of this sort have become a small industry (see Steckel and Floud 1997). For example, the American heights challenged firm beliefs that the quality of life was improving unambiguously after 1830, which has sparked a debate over the aspects of life that were deteriorating, such as greater exposure to disease, higher food prices, and perhaps additional work effort. In England, the economic prosperity of the 1820s to the 1850s must be weighed against urbanization's negative impact on health.

Bodenhorn, Guinnane, and Mroz (2017) challenged the extent and possibly the existence of the antebellum puzzle, claiming it could have been an artifact of sample selection bias created by market wages that were rising relative to military compensation. Because wages increased with stature, in this line of reasoning, taller individuals opted out of the military in favor of civilian employment. Komlos and A'Hearn (2017) and Zimran (forthcoming) dispute the analysis and conclusions by Bodenhorn et al., the former on grounds that military pay during the Civil War rose relative to that in civilian labor markets. They also note that the Roy model they employ does not apply to occupational choice during a conflict in which patriotism rather than wages were paramount. Zimran reaches a similar conclusion by using a two-step semi-parametric sample-selection model to correct patterns in average stature for selection into military service on observable and unobservable characteristics.

These exchanges do not end the debate over the standard of living during industrialization as a general phenomenon, in part because the experiences of other countries must be considered. In this regard, it is useful to consult *Health and Welfare during Industrialization* (Steckel and Floud 1997) which compares the experiences of several countries. In Sweden, for example, industrialization had no adverse impact on health during the late nineteenth century (Sandberg and Steckel 1997), whereas health

declined during industrialization in Japan, Gail Honda argued, because the military absorbed resources that could have gone into public health (Honda 1997).

Inequality

Economists and historians have long-established interests in the fate of different social and economic groups in society. A high, persistent degree of inequality suggests that opportunities for social and economic advancement were limited, which in turn affected the willingness of individuals to save and invest in human or physical capital.

Despite great interest in inequality, estimates are often difficult to acquire and they often pose problems of interpretation. Unlike aggregate data on income, which might be estimated from census data on production, measures of income or wealth inequality must be estimated from data recorded for individuals (or families). Tax records, probate records, and census manuscript schedules have proven useful, but it is difficult to assemble consistent time series from these sources. In addition, cross-section measures of inequality, such as the Gini coefficient, do not measure variation in individual opportunities over time. The latter requires longitudinal data, which are even more difficult to obtain from historical sources.

Of course, height data do not resolve all the problems of measuring inequality in historical settings; they merely add new, useful information. The idea that average height reflects inequality was pursued first by Steckel in the 1970s. His regressions on American slave heights showed that biological inequality varied systematically by region of residence, gender, and color (Steckel 1979). In work eventually published a few years later (Steckel 1983), he demonstrated that a country's average height in the mid-twentieth century was a nonlinear function of average income and a linear function of inequality (measured by the Gini coefficient of household income). Average height is a sensitive barometer of the share of the population that lacks the basic necessities of life and therefore is a useful measure of human welfare. In very poor countries, the health of a large share of the population is significantly constrained by inadequate diet, poor housing, and meager medical care. As income increases, a growing share of the population acquires the basic necessities of life and average height increases. In rich countries, nearly everyone attains their genetic potential for growth unless there is considerable inequality, which limits opportunities for growth among the poor.

Fortified with expectations that height and per capita income were positively related, economic historians were surprised to discover that heights were higher in lower income regions and they declined during the early phase of industrialization of some early industrializers such as the UK and the USA small industry has emerged to explain the pattern using knowledge that height and income measure different aspects of the standard of living (Steckel 1995; Komlos and Coclanis 1997).

Differences in average heights by occupation, region, ethnicity, etc. are a measure of inequality in biological aspects of the standard of living. For example, class differences in stature exceeded 10 cm in the eighteenth century England (Floud

and Wachter 1982), more than twice the difference ever observed for the USA. In the late Colonial Period, heights were virtually identical across occupations (Sokoloff and Villaflor 1982), and in the midnineteenth century, they differed by less than 4 cm (Margo and Steckel 1983). This relationship to inequality measures can be explained by the declining additional nutritional intake as income rises at high levels – the Engel curve and the declining marginal product of nutrition on human growth (Komlos 1989).

Native Americans

Taken as a whole, the depictions of Native American life are arguably the most distorted and contradictory of any large ethnic group in American history. Several centuries ago, accounts of early explorers and missionaries merged with the primitivistic tradition of Western civilization to create an image of the noble savage, who inhabited an ideal landscape and lived in harmony with nature and reason (Berkhofer 1988). During the westward movement of the mid-nineteenth century, whites commonly viewed the Plains tribes as bad Indians – warlike savages who terrorized settlers, stole horses, and practiced barbaric rituals. Near the end of the century, these natives morphed into entertainers who parodied their former lives in Buffalo Bill Cody's wild-west shows. Early in the twentieth century stories in the *Saturday Evening Post* and later, western movies, caricatured their habits, customs, and superstitions (Marsden and Nachbar 1988). Beginning in the 1960s, a wave of publications viewed Native Americans sympathetically, as victims whose peaceful civilizations were decimated by Euro-American aggression and disease. With the rise of the environmental movement, some researchers proclaimed that natives were ecologically sensitive caretakers of their surroundings and therefore models to emulate for our time.

Faced with these diverse images and meager evidence, how can one discern the truth? How did these Native Americans actually conduct their lives and what was their standard of living? Three recent papers probe the latter issue for the equestrian tribes of the Great Plains using height data originally collected by Franz Boas near the end of the nineteenth century (Steckel and Prince 2001; Komlos 2003; Steckel 2010). Using data on individuals born primarily between 1830 and 1872, these papers establish that the equestrian nomads were taller than any national population living in the mid-nineteenth century – exceeding by roughly 1 cm the next tallest groups, which were European descendants living in America or Australia. Explanations center on a protein-rich diet based on bison, abundant micronutrients from various plant sources and from trade with agricultural tribes, relative equality in access to resources within tribes, and low population density accompanied by frequent movements that reduced exposure to parasites and pathogens.

These papers noted large height differences across the tribes. Cheyenne men reached 176.7 cm, about 1 cm below modern American height standards and nearly 9 cm more than the shortest tribe, the Comanche. A difference of this magnitude is large and functionally important, exceeding the increase in average height of native-born American men from the early 1700s to the present.

Fates of Children During Crises

Two strands of literature have emerged on the health of children during crises, the most numerous focusing on developing countries, where considerable height data have been collected since the mid-1980s. In this vein, papers have appeared on Cameroon (Pongou et al. 2006), Kazakhstan (Dangour et al. 2003), North Korea (Schwekendiek 2008b), Novi Sad (Bozić-Krstić et al. 2004), South Africa (Hendriks 2005), and Zimbabwe (Hoddinott 2006; Alderman et al. 2006). The growth of adolescent boys fluctuated seasonally with the supply of food in Czechoslovakia (Cvrcek 2006).

One might expect that seismic shifts or differences in political systems adversely affect the health and welfare of children. The stature of children in Nazi Germany stagnated from 1933 to 1938 following autarchy and market disintegration (Baten and Wagner 2003). North Koreans declined in health relative to the South in the late twentieth century (Pak 2004) and were poorly equipped to deal with a famine that appeared in the 1990s (Schwekendiek 2008b). Delivery of United Nations food aid, however, seems to have improved anthropometric outcomes (Schwekendiek 2008a). Eastern Europe and Russia during the transition in the 1990s were different, whereby life expectancy deteriorated, especially in Russia, but anthropometric data suggest children were protected (Stillman 2006). Apparently adults bore the brunt of declining socioeconomic conditions during and immediately after these regime changes.

Fetal Origins Hypothesis

Careful sifting of epidemiological evidence assembled for the UK in the 1980s led David Barker and colleagues to hypothesize that several adult diseases, such as hypertension, Type 2 diabetes, and some cancers, could be traced to health conditions in a critical formative period of early life, from conception through early childhood (Barker 1994). Although medical experts disagree on the biological mechanism by which health in early life extends into adulthood, the empirical regularity is well established and is sometimes called the fetal origins hypothesis, or the Barker hypothesis (Blackwell et al. 2001). Because early childhood conditions are important for adult height, several studies use stature as a marker to predict longevity and/or adult disease patterns (Christensen et al. 2007; Costa 2004; Jousilahti et al. 2000; Riley 1994; Murray 1997; Harris 1997). Of course, other measures of early childhood health have been used in this line of research, including body mass index (Henriksson et al. 2001; Linares and Su 2005), child mortality rates (Bozzoli et al. 2007), exposure to epidemic disease (Almond 2006; Almond and Mazumder 2005), and skeletal markers of physiological stress (Steckel 2005). Recently economists and other social scientists have investigated ways that early childhood health affects cognition and skill formation, which sheds light on the optimal design of public policy (Heckman 2006). Such policies should note the intergenerational consequences of a mother's reproductive fitness because healthier female children later have healthier babies (Osmani and Sen 2003).

Some economic historians are already putting the health-cognition ideas to good use by linking proxies for physiological stress in early childhood with numeracy, or the ability to recall one's precise age, in this case for census enumerators in nineteenth century Britain (Baten et al. 2008). Although the evidence is circumstantial, it is plausible to believe that grain prices and welfare subsidies under the Poor Law impacted early childhood net nutrition and cognitive development, and thus numeracy rates found among these children as adults. This type of study opens an entirely new dimension to height research for understanding the nutritional underpinnings of human capital acquisition, technological change, innovation, and economic growth.

Colonial Rule

An interesting application of height research concerns the welfare of populations that lived under colonial rule. Over the past decade, papers have appeared on India, North America, and Burma under the British, and Taiwan under Japan (Brennan et al. 1997; Komlos 2001; Morgan and Liu 2007; Olds 2003; Bassino and Coclanis 2008). Various working papers in this general area are underway for other countries. The results suggest that colonialism, often maligned as exploitative, had some positive welfare benefit, at least in these countries. Brennan et al. report a modest increase in the average heights in India under the British but suggest this might be attributed to greater engagement in world markets and expansion of the transportation system. With regard to Taiwan, Olds finds that heights of children improved under Japanese rule up to 1930, which squares with results of Morgan and Liu. Unlike Olds, the latter have evidence through 1945, which indicates that heights after 1930 were static, as they were in Japan. In Burma, the picture is more pessimistic; heights did increase after World War II, but this was apparently a recovery from an earlier height decline induced by land-clearing for rice cultivation in malaria-infested areas.

Komlos assembled evidence on heights from newspaper advertisements on American-born soldiers who deserted and on run-away apprentices (Komlos 2001), reporting a 0.5 in. decline in the first half of the eighteenth century followed by a substantial rise. By the end of the century, American men were as much as 6.6 cm taller than the English, and at age 16, the American apprentices were about 12 cm taller than poor children of London. If the British exploited the American colony, then other factors, such as abundant cheap land and low population density, more than compensated.

Research Frontiers

One important extension of anthropometric methods involves collaboration with bioarchaeologists, who excavate and analyze skeletal remains to gain insights into the quality of life in the past. With training in both medicine and archaeology, these scientists seek to collaborate with economists and historians because they gain knowledge of historical events and processes that are potentially useful in interpreting

health conditions founds on skeletal remains. Through this source, measures of health conditions may extend far into the past, going back to the origins of agriculture and creation of permanent settlements. Moreover, the measures available include not only stature (from long bone lengths) but interruptions of the childhood growth process, trauma, oral health, and infections such as tuberculosis and syphilis.

The Western Hemisphere was the focus of a project completed in 2002, based on the remains of 12,520 individuals, some of whom lived as long ago as 5000 BC (Steckel and Rose 2002). About one-half of the sample lived in pre-Columbian America and approximately one-half lived in North America. One of the most interesting findings in this project was the long-term decline in health prior to the arrival of Columbus, possibly explained by movement of the population to less healthy environments such as urban areas.

A second project of this type focuses on health in Europe since the late Roman era (Steckel et al. 2019). The results are based on the skeletal remains of 15,119 individuals who lived in what are now 17 modern European countries. Surprisingly, there was no substantial trend in health but rather a sequence of changes that were somewhat offsetting. Trauma, for example, declined following the late Middle Ages but oral health deteriorated. Climate (in the form of temperature) and settlement size (i.e., urbanization) had a large impact on health in Europe.

Conclusions

Once a niche subject widely disparaged by skeptics, over the past 40 years anthropometric history has shed new light on important subjects in the social sciences. Its success hinged on blending human biology with historical data to shed new light on questions in which there was already an established interest. Though not without challenges, prospects for the field are bright because historical records are superabundant and many scholars now believe the methodology is credible. Moreover, universities and many individual departments increasingly support interdisciplinary research, of which anthropometric history is a good example.

Wealth and Income Inequality in the Long Run of History

Guido Alfani

Contents

Abstract

This article provides an overview of current knowledge about economic inequality, of both income and wealth, in the very long run of history focusing on Western Europe and North America. While most of the data provided by recent research cover the period from the late Middle Ages until today, some insights are also possible into even earlier epochs. Based on these recent findings, economic inequality seems to have been growing over centuries, with phases of clear and marked inequality reduction being relatively rare and usually associated with catastrophic events, such as the Black Death during the fifteenth century or the World Wars in the twentieth. Traditional explanations of long-term inequality growth are found to be unsatisfying, and a range of other possible causal factors are explored (demographic, social-economic, and institutional). Placing today's situation in a very long-run perspective not only leads us to question old

assumptions about the future of inequality (think of current criticism of Kuznets's hypotheses) but also changes how we perceive inequality in the modern world.

Keywords
Wealth inequality · Income inequality · Distribution · Long run · Western history

Introduction

Recent years have seen a flourishing of studies on long-term trends in inequality.[1] Much of this new research has focused on the nineteenth and twentieth centuries, continuing a tendency that had been originally triggered by Simon Kuznets's seminal article published in 1955. However, significant advances have also been made regarding preindustrial times, which for a long period had remained basically uncharted territory for inequality studies. The first article covering long-run inequality trends for a European region (Holland) was published 40 years after Kuznets's opening salvo (Van Zanden 1995). It is only during the last 5 to 10 years, though, that research on preindustrial inequality has really intensified, thanks to a large degree to the activities of the ERC-funded project *EINITE-Economic Inequality across Italy and Europe 1300–1800*.[2] This research has added considerably to the amount of information available to explore the dynamics and the underlying causes of inequality change in the very long run – so much so that today, in some respects and at least for some European areas, we might know more about preindustrial inequality than about the changes in distribution of the last 50 or 60 years. Another important development is that inequality research shifted from an income focus to more attention to the inequality of wealth.

The recent findings about long-run inequality trends, of both income and wealth, have significantly changed how we look both at historical distributive dynamics and current inequality levels and tendencies. Placing today's situation in a very long-run perspective leads us to question old assumptions about the future of inequality – indeed, Kuznets's hypothesis about the existence of an innate tendency for inequality to decline after the achievement of a certain level of development has now been explicitly rejected by many scholars. But more generally, all traditional explanations of long-term inequality growth have been found to be unsatisfying (as they are unable to account for the new *facts* unearthed by economic historians), and consequently, a range of other possible causal factors have been explored. The debate over the causes and to some degree also over the consequences of long-term inequality growth is today particularly intense and sees the active contribution of many economic historians and cliometricians.

This chapter sets out to provide an overview of recent acquisitions on wealth and income inequality in history, focusing on the period for which we have at least some

[1]I would like to thank Peter Lindert for many helpful comments.

[2]www.dondena.unibocconi.it/EINITE

good-quality data (approximately from 1300 until today) but also providing glimpses into inequality levels and dynamics in even more ancient periods (from prehistory to the Classical Age). The second part of the chapter proposes an overview of the debate over different factors that might have contributed to shaping inequality trends in the long run, taking into account economic, social-demographic, and institutional factors. In the conclusion, some reflections are provided about what history can teach us about the future of inequality. For reasons of space, the focus will mostly be on Europe and North America.

How Economic Inequality Has Changed over the Centuries

As Kuznets himself had underlined, progress in our understanding of long-run inequality trends depends strictly upon our ability to collect good-quality data about income and wealth distributions in time. In fact, as the recent wave of research on inequality trends has demonstrated beyond doubt, distributional dynamics are so complex that they could not be simply inferred from other variables (say, trends in per capita GDP) but need to be measured as directly as possible. The nature of such direct evidence changes over time and across space, although usually it comes from fiscal assessments of various kinds. In section "The Medieval and Early Modern Period (from ca. 1300 to 1800)," the sources available to study inequality in preindustrial times will be discussed briefly, while for those that can be used for the nineteenth and twentieth century, I will refer to the excellent recent synthesis by Roine and Waldenström (2015).

The available studies provide us with standard measures of inequality, which almost invariably include the Gini index of concentration. The Gini is calculated using the following formula:

$$G = \frac{2}{n-1} \sum_{i=1}^{n-1} (F_i - Q_i)$$

where n is the number of individuals/households, i is the position of each individual in the ranking sorted by increasing income/wealth, Fi is equal to i/n, and Qi is the sum of the income/wealth of all individuals comprised between position 1 and i divided by the total wealth of all individuals (in other words, $F_i - Q_i$ is the difference between the share of the population up to position i in the wealth distribution moving from bottom to top and their share of the overall wealth). In this formula, the Gini index is standardized to vary between the value of 0, which corresponds to perfect equality (when each individual/household has the same income/wealth, $F_i - Q_i$ is equal to 0 for every i), and 1, which corresponds to perfect inequality (one individual/household earns/owns everything).

The Gini index is the best instrument we have to "summarize" the level of inequality in a given society. However, the same index value can correspond to different distributions. For this reason, it is important to couple it with other

measures that allow us to keep in check important changes in specific parts of the distribution. Usually this is achieved by providing information about specific percentiles of the distribution, for example, the poorest 10%, the richest 10%, and so on. In recent years, the share of the richest part of the population – the top 1%, 5%, or 10% – has become a very popular indicator on its own, partly because it can also be easily understood by those who do not have specific knowledge of inequality statistics and partly because what happens at the top of the distribution seems to be particularly relevant in explaining the overall tendency toward greater or lower concentration of income or wealth (see discussion in Atkinson et al. 2011; Alvaredo et al. 2013). For the sake of simplicity, in the following only the two most popular inequality measures will be used: the Gini index and the share of the richest 10%. Trends in both wealth and income inequality will be explored. For the preindustrial period, this will allow the comparison of more areas, as usually only one of the two has been reconstructed (note that, for most preindustrial societies and lacking more complete information, wealth inequality can also be considered a rough proxy of income inequality, as land was the main source of income for most of the population. On this point, see Lindert 2014; Alfani 2015; Alfani and Ammannati 2017). For the more recent period (1800–today), it will be possible to compare the dynamics in income and wealth inequality for each area covered.

The Medieval and Early Modern Period (From ca. 1300 to 1800)

While our knowledge of levels and trends in preindustrial inequality was extremely limited until recently, we now have good-quality, data-rich reconstructions of long-term trends in (mostly wealth, sometimes income) inequality for many parts of Europe before 1800 (e.g., for Italy, Alfani 2015, 2017; Alfani and Di Tullio 2019; for Spain, Santiago-Caballero 2011; for Portugal, Reis 2017; for the Low Countries, Van Zanden 1995; Ryckbosch 2016; Alfani and Ryckbosch 2016). Some of these reconstructions cover many centuries, with possibly the best case so far being the Florentine State (Tuscany) in Italy, where it has been possible to reconstruct the general inequality trend in the entire period from 1300 to 1800 (Alfani and Ammannati 2017).[3] This broad research campaign reached beyond Europe, as long-term inequality trends in preindustrial times were also explored for Anatolia under the Ottoman Empire (Canbakal 2013), for the prerevolutionary USA (Lindert and Williamson 2016), and for Japan in the late Tokugawa period (Saito 2015).

Most of these studies make use of fiscal sources to reconstruct wealth distributions. In particular for Southern Europe, the sources more commonly used are the property tax records – usually called *estimi* in Italy, *cadastres* in France, and similarly elsewhere – that contain information about the taxable wealth owned by

[3]Other recent research focused on single years when exceptional sources were available for specific areas, for example, Spain in 1759 (Nicolini and Ramos Palencia 2016) or Poland in 1578 (Malinowski and Van Zanden 2017).

each household. This always includes real estate (lands and buildings), which was by far the main component of wealth in preindustrial rural societies, and sometimes other items as well, like capital invested in trade. A limitation of these sources is that they only rarely include the propertyless, which are those households that had no taxable wealth. However, such households are usually very few (3–7% of the total); hence although their exclusion from inequality measurement leads to systematic underestimation of inequality levels, the distortion is very limited,[4] and more importantly, empirically we find that including the propertyless or not does not change the direction of the trend (see Alfani 2015, 2017 and Alfani and Di Tullio 2019 for further discussion).

Overall, the new research allowed the establishment of two fundamental "stylized facts" about preindustrial inequality in Europe in the period 1300 to 1800:

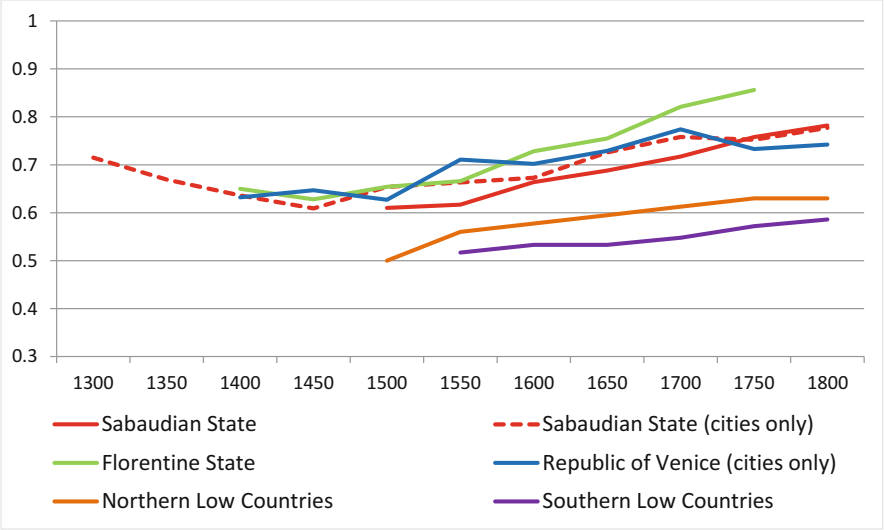
1. During the entire period, the only phase of sustained inequality decline was triggered by the Black Death epidemic, which spread through Europe from 1347 to 1351.
2. After this phase of decline, and beginning from ca. 1450 (with some regional variation), both income and wealth inequality tended to increase almost monotonically in almost all the areas for which we have evidence.

These stylized facts are clearly visible in Fig. 1a and b, which report the Gini index and the share of the richest 10% for some Italian states, the southern Low Countries (current day Belgium) and the northern Low Countries (current day the Netherlands). The measures refer to wealth inequality for Italy and to income inequality for the Low Countries – hence the trends, not the levels, should be compared (as wealth tends to be more concentrated than income, in the past as with today).

The longest series available for an entire state or region refers to the Sabaudian State (Piedmont) in northwestern Italy (cities only). There, before the Black Death the Gini index of wealth concentration equalled 0.715. By 1350, in the immediate aftermath of the Black Death, it had declined to 0.669. Decline continued in the following years, and the absolute minimum value reported for this area in the entire period 1300 to 1800 was reached around 1450, with a Gini of 0.609. After that, inequality growth resumed, continuing without interruption for about two and a half centuries. Indeed, only by the mid-seventeenth century, the pre-plague inequality levels were finally exceeded. Inequality growth stalled in the cities of Piedmont during the first half of the eighteenth century but became intense again in the second

[4]For example, in the city of Bergamo in the Republic of Venice, possibly the Italian community for which we have the most complete information about the prevalence of the propertyless over time, from 1537 to 1702, the distortion to the level of the Gini index varied from a minimum of 0.006 Gini points in 1640 (from 0.715 excluding the propertyless to 0.721 including them) to a maximum of 0.03 Gini points in 1610 (from 0.723 to 0.753) (Alfani and Di Tullio 2019).

a. Gini indexes



b. Share of the top 10%

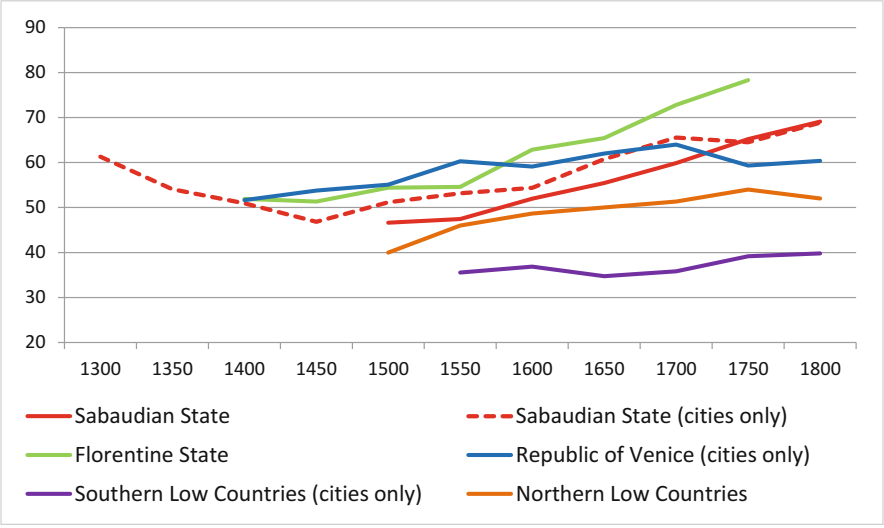


Fig. 1 Long-term trends in economic inequality in Italy and the Low Countries, 1300–1800. Notes: The series refer to wealth inequality for the Sabaudian State, the Florentine State, and the Republic of Venice (excluding those with no property) and to income inequality for the southern and northern Low Countries. (Sources: Alfani (2015) for the Sabaudian State; Alfani and Ammannati (2017) and Alfani and Ryckbosch (2016) for the Florentine State; Alfani and Di Tullio (2019) for the Republic of Venice; Van Zanden (1995) for the Northern Low Countries (Holland); Alfani and Ryckbosch (2016) for the Southern Low Countries)

half of the century, peaking at 0.777 by 1800 (if we look at the entire region, not just cities, inequality growth continued throughout the century). The same path is found looking at the share of the richest 10%, who owned 61.3% of all wealth in 1300, 46.8% in 1450, and 68.9% in 1800, as well as at the other Italian states (Alfani 2015, 2017). During the early modern period, (income) inequality growth is also found in the northern and southern Low Countries.

The distributive consequences of the Black Death are worthy of specific attention. For such an early period, evidence is relatively scarce, and to date it involves mostly the Sabaudian State (Alfani 2015), the Florentine State (Alfani and Ammannati 2017), and the southern Low Countries (Ryckbosch 2016). Although only for the Sabaudian State we have an aggregate series covering the pre- and post-Black Death, for each of these areas, we can observe some specific communities before and after this terrible mortality crisis. For all available cases, inequality declined immediately after the Black Death, with a tendency to continue for about 50 to 100 years, depending on the area. For example, in the city of Prato in Tuscany, the Gini index of wealth inequality was 0.703 in 1325, but by 1372 it had fallen to an all-time low of 0.591 (between the two dates, the share of the richest 10% declined from 65.7% to 48.1%, to the advantage of all other segments of the wealth distribution). Again in Tuscany, in the rural community of Poggibonsi, the Gini index was 0.550 in 1338 but only 0.474 in 1357, after the Black Death (Alfani and Ammannati 2017). Indeed, in the period following the terrible plague, we find the lowest levels of wealth inequality reported for preindustrial Europe – levels that, as will be seen, are not far from those found today. It should also be noted that inequality decline after this, which was probably the most terrible mortality crisis to have ever affected Europe (it killed up to 50% of the population on the continent), is the outcome that should be expected as it goes hand-in-hand with increasing real wages following the sharp reduction in the offer of labor, which contributed to reducing income inequality. Reduction in wealth inequality (and consequently, in capital income inequality) is also to be expected, as higher real wages provided a larger part of the population with the means to acquire property – in a context in which much more real estate than usual was being offered on the market, leading to cheaper prices (Alfani and Murphy 2017, pp. 332–334).

Regarding the dynamics characteristic of the early modern period, the almost monotonic inequality growth reported by almost all available cases continued in the following century, as will be seen in section "The Modern Period (From ca. 1800 Until Today)." Until now, Portugal is the only case for which has been found some evidence of (income) inequality decline during the early modern period, possibly as the consequence of "a long wave of agriculture-based economic expansion during which the demand for labour mostly ran ahead of that for land" (Reis 2017, p. 21). For the rest of Europe, however, a growing body of literature has been discussing the factors leading to inequality *growth*, as will be seen in the second part of this chapter. Before exploring the inequality trends characteristic of the last two centuries, it is useful to underline another stylized fact about preindustrial inequality: the ability of tendencies affecting the share of the top of the distribution (here, the richest 10%) to shape the overall inequality trend as

measured by Gini indexes (just compare Fig. 1a and b). This stylized fact is perfectly reproduced in contemporary societies (Atkinson et al. 2011; Alvaredo et al. 2013), as can be easily seen looking at the evidence provided in the following.

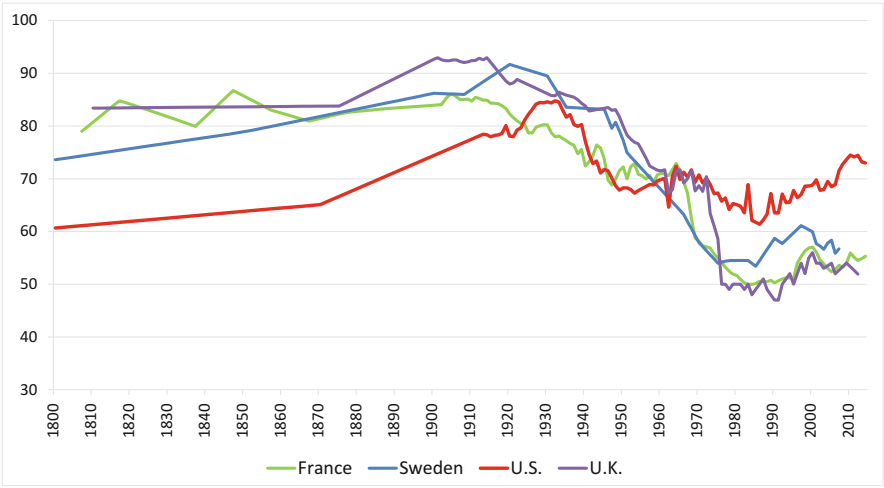
The Modern Period (From ca. 1800 Until Today)

The tendency for an ever-increasing income and wealth concentration that has been reported for the early modern period continued during the nineteenth century, with some signs of growing intensity over time. For this period, too, we have better information about wealth than income. According to all accounts and based on the data currently available, wealth inequality reached its historical maximum on the eve of World War I. For example, in France – probably the country in the world whose wealth distribution during the nineteenth century has been researched most thoroughly (Piketty et al. 2006, 2014; Piketty 2014) – in the immediate prewar years, the share of the richest 10% was about 85%, quite a bit higher (by 5–6 percentage points) than that found in 1807, which is the first year for which we have information. In the same time span, the share of the richest 1% grew even more, by more than 10 percentage points (from 44% to 54–56%).

In the early twentieth century, a continental European country like France was still characterized by a considerably more uneven distribution of wealth than the USA. In 1913, the richest American 10% owned 78.4% of all wealth, slightly less than the richest Frenchmen had owned a century earlier (the same is true looking at the richest 1%, whose share was 45.1% of all wealth in 1913 in the USA). Indeed, in that year the USA was characterized by less uneven wealth distribution than almost all European countries as, for example, the share of the richest 10% was 92.6% in the UK in 1913 and 86% in Sweden in 1908. This relatively egalitarian character of the USA – or more generally, of North America given that in Canada[5] in 1902, the richest 1% had 36.4% of all wealth compared to 53.8% in 1908 Sweden and 66.6% in 1913 UK – has been reported already for the eve of the Revolution. In fact, in 1774 the richest 10% owned "just" 59% of the overall wealth (measured as "net worth"), while the richest 1% had 16.5% (Lindert 2000, p. 188). The share of the richest tended to grow in nineteenth-century America, as the top 10% owned 65.1% of all wealth in 1870 and 78.4% in 1913. Unfortunately no in-between estimates are available, but it seems safe to presume that the overall tendency in the nineteenth-century USA was toward growing wealth concentration (also see Lindert and Williamson 2016, pp. 121–122). If we connect linearly the three dates, we get the tendency shown in Fig. 2a, which also makes it clear how the inequality gap between the USA and France tended to decline over time as a consequence of slower inequality growth in the second. A similar tendency for inequality to grow was found in the UK, where the richest 10% owned 83.4% of all wealth in 1810, 83.8%

[5]The estimate for Canada refers to the Ontario area only. Davis and Di Matteo 2018, p. 34.

a. Wealth share of the top 10%



b. Income share of the top 10%

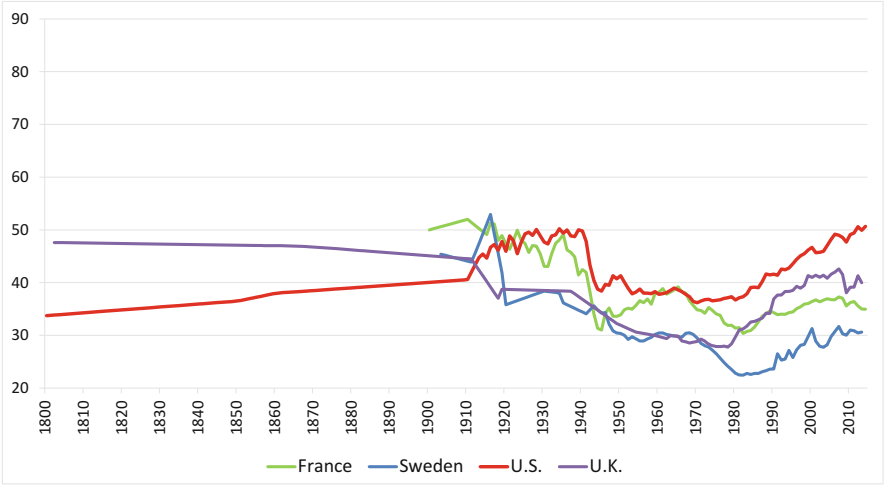


Fig. 2 Long-term trends in economic inequality in Europe and North America, 1800–2014. Notes: Data for wealth refers to households. Data for income refers to fiscal units and is pre-tax. (Sources: Wealth shares: for France, *World Wealth and Income Database* (WID); for Sweden, Bengtsson et al. (2018) for wealth shares in 1800, 1850 and 1900, and Roine and Waldenström (2015) for 1908–2007; for the U.S., Lindert (2000) for 1774, Sutch (2016) for 1870, and WID for 1913–2014 with some integrations from Roine and Waldenström (2015); for the U.K., Lindert (1986) for 1810 and 1875, and WID for 1900–1912 with some integration from Roine and Waldenström (2015). Income shares: for France, WID; for Sweden, WID; for the U.S., Lindert and Williamson (2016) for 1774, 1850, 1860, 1870, and 1910, WID for 1913–2014; for the U.K, Lindert (2000) for 1802, 1867 and 1911 (with some original elaboration), WID for 1918–2013)

in 1875, and 92.6% in 1913. These figures characterize the UK as the country where nineteenth-century wealth concentration was the highest, although admittedly the only other two cases for which we have some information since the early nineteenth century, Sweden and France, lagged just behind. These relative trends can be seen in Fig. 2a, which includes the four countries for which we have some indication of the share of wealth and/or income for the top 10% since the beginning of the nineteenth century (the notes on the figure provide the sources for the estimates discussed above and in the following).

We do not have estimates of the Gini index of wealth inequality for nineteenth-century France and the UK, and more generally, research on the last two centuries has focused more on measuring top wealth and income shares than on reconstructing complete distributions (which are required to calculate Gini indexes). For the USA we have an estimate for 1774, when the Gini equalled 0.694 (free households only). For Sweden, however, a recent study placed the wealth Gini index at 0.79 in 1750, 0.84 in 1800, 0.87 in 1850, and 0.91 in 1900 (Bengtsson et al. 2018). This trend matches perfectly that of the share of the richest 10% reported in Fig. 2a, which across the four dates grew from 68.7% to 73.6%, 78.9%, and finally 86.2% in 1900 – further confirmation of the fact that in most situations, the trend in the top share can be considered indicative of the overall direction of inequality change.

If we look at income, of the four countries included in Fig. 2, only for the USA and the UK do the data available give an impression of the overall trend in the century or so preceding World War I. In the UK, the top 10% concentrated 47.6% of the national income in 1802, 46.9% in 1867, and 44.5% in 1911 (Lindert 2000). In the USA, the share of the top 10% was 32.3% in 1774 (thirteen colonies), 36.5% in 1850, 38% in 1860, 38.5% in 1870, and 40.6% in 1910 (Lindert and Williamson 2016). For a few dates, we also have an income Gini index, which would have equalled 0.459 in the UK in 1759, 0.515 in 1801, and 0.530 in 1867 (Milanovic 2013, p. 12), while in the USA it would have been 0.441 in 1774 (13 colonies) and 0.511 in 1860 and 1870 (Lindert and Williamson 2016). Hence while in the USA the trend was clearly oriented toward inequality growth in income as well as in wealth, in the UK the picture is more mixed – which seems to fit the "Kuznetsian" idea of (income) inequality decline during a late phase of the Industrial Revolution, a process that had been spearheaded by England.

The two World Wars, as well as the troubled period between them, led to a very significant decline in the share of both wealth and income owned by the richest across Western countries. This can also be seen in Fig. 2 and in Table 1. Between 1900 and 1950, the richest 10% released their grip on 12.7% of the overall wealth in the UK, 11.7% in France, 8.9% in Sweden, and 6.1% in the USA. In the same period, across the four countries, the decline in the income share of the top 10% equalled 16.1 percentage points in France, 15 in Sweden, and 13.2 in the UK. Only in the USA do we find a slight increase – by 1.3 percentage points – but here, too, some decline would be found if we took as a comparison the very eve of the USA's entry in the war. This being said, the interwar period remains the moment when the USA finally caught up with continental European levels of wealth and income inequality, turning from being one of the most egalitarian among Western countries to the most *in*egalitarian.

Table 1 Share of wealth and income of the top 10% in Europe and North America, 1850–2010 (data clustered around 50-year breakpoints, with actual year – if different from breakpoint – in parentheses)

	Top 10% (wealth)					Top 10% (income)

For Germany in 2010, *Global Wealth Databook* 2017. For Italy, Brandolini et al. 2004 and *Global Wealth Databook* for 2010. For Sweden, Bengtsson et al. (2018) for 1850 and 1900, and Roine and Waldenström (2015) for other dates. For the U.K, Lindert 1986 for 1875, WID for 1900, Roine and Waldenström 2015 for 1950 and 1980, WID for 2009. For the U.S., (Sutch 2016) for 1870 and WID for other dates. For Canada, Davis and Di Matteo (2018), with some original elaboration for 1902 and 1950 (the figure for 1902 refers to the Ontario area only)

Income shares: WID for all countries and dates, exception made for the following. Lindert and Williamson (2016) for the USA in 1850 and 1910. Lindert (2000) for the UK in 1867 and 1911 (with some original elaboration)

Notes: Data for wealth refers to households (exception made for Canada 1950, which refers to adults) and is net wealth (exception made for the USA in 1870 for which only gross wealth estimates are available). Data for income refers to fiscal units and is pre-tax

The reduction in wealth inequality in this period – which also explains an important part of the reduction in overall income inequality, by trimming down disparities in capital income – seems to be due more to the damage suffered by large patrimonies than to a trickling of wealth from the top downward. Indeed, war hyperinflation and the stock market crashes of the 1920s destroyed financial capital; the wars, and especially World War II, significantly affected physical capital; many overseas properties and investments were lost (for a synthesis, see Piketty 2014, pp. 181–187). However after the end of World War II and for 30 years or so, wealth and income inequality remained relatively low, and in many cases, they fell further, at least in Europe. Looking at top income shares, this drop was particularly impressive in Sweden, where from 1950 to 1980, the top 10% lost 7.6 percentage points of the overall national income. In the case of wealth, the largest decline is found in the UK, where the top 10% saw their share drop by 29.9 percentage points. Indeed, by 1980 the UK, which had long been characterized by one of the highest levels of wealth inequality found in Western countries, had become relatively egalitarian, as can also be seen in Table 1, which includes information about the wealth and income share of the top 10% across a broader range of countries.

This overall tendency for a further reduction in income and wealth inequality came to an end from the late 1970s to early 1980s, partly as a consequence of tax reforms (see discussion in section "Institutions"). This is also the point when a difference seems to have emerged in distributive dynamics between English-speaking countries and other Western countries (if we focus on income) or between the USA and European countries (if we focus on wealth, see Fig. 2 and Table 1). In particular, the point has been made that, if we look at the income share of the top 1%, the main English-speaking countries (Australia, Canada, the UK, and the USA) followed a "U-shaped" curve during the twentieth century, with the income share of the top 1% growing quickly after 1980 and more than doubling by 2007, finally reaching or coming close to pre-World War I levels. Instead, continental European countries (plus Japan) followed an "L-shape" path, with much less tendency for income inequality to grow after 1980 (Alvaredo et al. 2013, pp. 5–6). Overall, this difference between continental Europe and English-speaking "Atlantic" countries is confirmed if we look at the income share of the top 10%, as, from 1980 to 2010, we see an increase of 12.4 percentage points in the USA and 10.8 in the UK, more than double what is found in countries like France or Finland, where the increase equalled 4.8 percentage points or Italy where it amounted to 6.7 percentage points. On the other hand, in Canada the increase in the income share of the top 10% was relatively low even by European standards (4.2 percentage points), while from ca. 1990, the OECD country that has been affected by the largest increases in inequality is Sweden. To a significant degree, this is due to (i) the growing importance of capital gains as a component of total income in Sweden, which is consistent with a picture of growing wealth concentration, as well as to (ii) the decreasing progressiveness of the fiscal system (OECD 2015; Waldenström 2009). The latter factor is probably one of the main culprits in the cross-countries increase in *both* income and wealth inequality detected for the post-1980 period. This point will be further discussed in section "How to Explain Inequality Change in the Long Run?" – but before, we need to complete our overview of very long-term trends in economic inequality by moving further back in time.

Glimpses into a More Remote Past: From Prehistory to the Classical Age

The new wave of research on inequality levels and trends in the past has also involved very early epochs. Although the evidence collected is inevitably less abundant and less precise than what we now have for the Middle Ages, it seems important to include here a brief account of recent contributions to our knowledge of economic inequality in the Classical Age and before.

Indeed, some authors have even tried to provide tentative estimates of economic inequality during prehistory. Their work relies upon both archaeological evidence and more detailed information about historical and current "primitive" societies, like the few surviving tribes of hunter-gatherers. Generally speaking, human groups that relied upon foraging were characterized by low levels of economic differentiation. However if we consider early farmers, we can already detect significant increases in economic inequality. There is, in fact, a continuum in inequality levels, from hunter-gatherers, to farmers and beyond: "substantial levels of economic inequality became characteristic of many (but far from all) populations only after the domestication of plants and animals, eventually culminating in the emergence of class societies and the hierarchical ancient states" (Bowles et al. 2010, p. 8). To give an idea of the implied changes in inequality levels, in a sample of contemporary and historical "small-scale societies," the average Gini inequality index of material wealth (including cattle, land, and other physical components of wealth) was 0.36 among hunter-gatherers, rising to 0.51–0.52 for pastoral and horticultural societies and to 0.57 for agricultural societies (Borgerhoff Mulder et al. 2009, Table S4). Wealth concentration, through the inheritance system, was key to reproducing and deepening inequality across generations – indeed, changes in the degree of inheritability of wealth seem to explain much of the variation in inequality levels detected both through prehistory (especially when comparing human societies before and after the so-called Neolithic Revolution, which began around 10,000–8000 BCE and was associated with the appearance of the first permanent settlements and the introduction of agriculture) and when analyzing the conditions experienced by different kinds of small-scale societies today (Borgerhoff Mulder et al. 2009; Bowles et al. 2010). Others underline the importance of a broad variety of "disequalizing factors" potentially leading early societies to grow unequal (as well as more socially hierarchical). Domestication of plants and animals is surely one such factor, along with resource scarcity and technological progress[6] (Scheidel 2017, pp. 33–39).

Further developments in early societies, and particularly the development of governmental institutions and the progressive formation of the first states, enrooted and deepened economic inequality: "premodern states generated unprecedented

[6]For example, there is archaeological proof that among the Chumash tribe living on the shores of California, the introduction of large oceangoing plank canoes able to venture relatively far from the coast, which occurred around 500–700 CE, led to the transition from an egalitarian society of foragers to one dominated by polygamous chiefs who controlled the canoes and organized economic, as well as military and religious activities (Scheidel 2017, pp. 34–35).

opportunities for the accumulation and concentration of material resources in the hands of the few, both by providing a measure of protection for commercial activity and by opening up new sources of personal gain for those most closely associated with the exercise of political power. In the long run, political and material inequality evolved in tandem" (Scheidel 2017, p. 43). As well during this period, the evidence of further inequality growth is mostly archaeological (although some useful written documentation survives) and involves early states like the Akkadian Kingdom from the twenty-fourth to the twenty-second century BCE, Babylon from the second millennium BCE to the sixth century BCE, or Egypt in various epochs (Diamond 1997; Scheidel 2017). It is only when we move a step further, into the Classical Age, whose starting point is conventionally placed around the eighth and the seventh century BCE, that the overall information we have allows for producing some more detailed – although still highly speculative in many respects – estimates of levels of economic inequality. For the sake of synthesis, I will focus on the case of the Roman Empire, which has been the object of a relatively large number of recent publications.

There are currently available two estimates of interpersonal inequality in the Roman Empire built from social tables. One refers to 14 CE, in the early empire period, when the Gini index was placed in the 0.364–0.394 range (Milanovic et al. 2007, p. 77). The second relates to year 150 CE, the apogee of the Roman Empire. By then, income inequality seems to have grown significantly, as the point estimate we have is a Gini of 0.413 (Scheidel and Friesen 2009; Scheidel 2017, p. 78). Both these estimates refer to the Roman Empire as a whole. More recently, an attempt has been made at integrating such measures of interpersonal inequality with new estimates of regional inequality in average income levels, to produce a tentative picture of inequality change across the Empire over a much longer period. Overall, this reconstruction suggests that income inequality grew from 14 CE to 150 CE, which was a period of growing prosperity and territorial expansion. Thereafter, from the high level of about 0.4, income inequality declined very significantly, to a bottom as low as 0.13–0.15 by the year 600 or 700, apparently going hand in hand with the empire's decline (Milanovic 2017, p. 12 and elsewhere).

We know much less about wealth inequality. The available evidence suggests that in this case, too, a first period characterized by increasing wealth concentration is to be found (from the second century BCE to the first century CE, hence covering the late Republican period and the first imperial phase), during which the size of the largest fortunes rose by a factor of 80, from 4–5 million to 300–400 million sesterces (Scheidel 2017, pp. 71–75). This tendency stopped when the Roman Empire began encountering difficulties and then entered a phase of decline. The final collapse of the state, which during the fifth century progressively lost control over its provinces in Europe and the Mediterranean area and in the end even over the core territories of Italy, led to a very substantial reduction in wealth inequality. To a large degree, this was the result of the breakdown of the "extensive networks of estates" that members of the Roman economic elite had owned across the Empire. We have evidence of this process in the abandonment of many country villas, but more importantly, archaeology offers some proof of a more general reduction in

inequality, involving as well the middle and upper-middle strata of society, through the analysis of the distribution of house sizes. In Britain, for example, the Gini index of house sizes fell from a level around 0.6 at the time of the Roman Empire to just 0.4 in the Early Middle Ages (Scheidel 2017, pp. 265–269). According to Walter Scheidel, this is proof of the leveling power of state collapse and more generally of large-scale catastrophes.

How to Explain Inequality Change in the Long Run?

From the data presented above, we get the clear impression that in the long run of history, wealth and income inequality have tended to grow almost continuously. In the last seven centuries – the period for which we have, at least for some world areas, detailed information about distributional dynamics reconstructed from archival or statistical sources or provided by reliable institutions – a significant decline in wealth and income inequality can be detected only after large-scale catastrophes: the Black Death in the fourteenth century and the two World Wars in the twentieth. If we include in the analysis the earlier period, for which we have sparser information, it seems that in the West in the last two millennia, the number of inequality-reducing catastrophes can be increased to three by adding the collapse of the Roman Empire during the fifth century. In all other periods (and allowing for some incertitude for the least-documented phases, in particular the Early Middle Ages), inequality seems to have been increasing almost monotonically. Given these historical dynamics, explaining inequality growth is somewhat trickier than accounting for inequality decline. Indeed, the factors able to determine inequality growth in the long run of history are currently the object of intense debates, which could not be covered in detail here – especially if one allows for the possibility that different forces were acting in different periods, that is, trends that seem similar across space and time might have deeply dissimilar underlying causes. The objective of this session is to provide an overview of these debates – a non-exhaustive overview, surely, but one aimed at making clear possible elements of continuity in the very long run of human history as well as at making explicit connections that research more narrowly focused on specific periods or areas has often failed to underline. As the distributive, inequality-reducing consequences of the main catastrophes have already been outlined in the first part of the chapter, the focus here will be placed on the factors leading inequality to increase during the other periods.

Economic Variables

As will be recalled from the Introduction, much of the research into long-term inequality trends has been triggered by the original contribution of Simon Kuznets (1955). Although there are strong reasons to argue that we should definitely move beyond Kuznets's approach (see below), it still seems useful to begin by briefly recalling his hypothesis, which focuses on economic development as the trigger of

inequality change during the industrial period. According to Kuznets, as well as to scholars who tweaked his analysis in the decades immediately following the publication of his seminal article (for a synthesis, see Brenner et al. 1991), income inequality followed an inverted-U path through the industrialization process (the so-called Kuznets Curve), with a rising phase at the beginning of industrialization. This path would be the consequence of economic development and particularly of the transfer of the workforce from a traditional (agrarian) sector to an advanced (industrial) one. Western countries would have experienced inequality growth during the late eighteenth and nineteenth centuries, and inequality decline from a certain point during the twentieth century. Kuznets's hypothesis referred to income inequality; however it stands to reason that it can also be applied to wealth (Lindert 1991, 2014). Indeed, some studies of Western areas reported an inverted-U path in wealth inequality during the Industrial Revolution, with a decline after the two World Wars. This is also clearly visible in Fig. 2a.

If Kuznets's argument still stands as a description of the historical path followed by inequality in Western countries, its broader implications have now been proven wrong, both if we look at the left side (the long preindustrial period) and at the right side (from ca. 1980 until today) of the Kuznets curve. Regarding preindustrial times, Kuznets seemed to imply that before ca. 1800 or 1750 at the earliest, inequality was relatively low and stable over time. However, as seen in section "How Economic Inequality Has Changed Over the Centuries," this was not the case. The first attempt at measuring inequality growth during the early modern period, involving Holland from the sixteenth to the nineteenth centuries, found evidence of continuous growth in income inequality (Van Zanden 1995; Soltow and Van Zanden 1998. Also see Fig. 1a, "Northern Low Countries"). Jan Luiten Van Zanden provided an interpretation of this phenomenon that was "Kuznetsian" in character. He argued that preindustrial inequality growth was even "over-explained" by economic growth and proposed different explanations for why economic growth could foster inequality growth: (i) urbanization (hence, transfer of workforce from a rural/backward sector to an urban/relatively advanced one), (ii) increasing skill premium, and (iii) changes in the functional distribution of income. He then argued that preindustrial inequality growth constituted only the first phase of a "super-Kuznets curve" that connected preindustrial and industrial economic growth. This interpretation was grounded in the specific context of the Dutch Republic, one of the most economically dynamic areas of early modern Europe. Recently, a similar view has been expressed by Bas Van Bavel (2016, pp. 192–193), who has connected inequality increase in this part of Europe to the development of market economies, which might have led to growth in inequality of both income and wealth through increases in the efficient scale of trade and production, growing opportunities for financial dealing and speculation, and growing investment opportunities (favoring the elites) in landed property and in shares of the public debt.

It is surely possible, even probable, that the inequality growth that has characterized the Dutch Republic during the early modern period was, at least in part, the consequence of economic growth. However, this argument could not be generalized to the rest of Europe, where income and wealth inequality growth were also found in

periods of economic stagnation, or decline.[7] This was, for example, the case in many Italian states (Alfani 2015; Alfani and Ammannati 2017; Alfani and Di Tullio 2019) as well as in the southern Low Countries (Alfani and Ryckbosch 2016), and, as will be seen, this is why much recent literature has been looking in other directions for an explanation of preindustrial inequality growth.[8]

If we now consider the right side of the Kuznets curve, it must be noted that the implication of the existence of an automatic mechanism leading to inequality decline after certain levels of development were reached involved the promise that the system itself would have provided a solution to the problems (social and other) caused by growing economic inequality in the early phases of the industrialization process. This is one of the fundamental reasons why, in Kuznets's view as well as in that of other scholars who recently associated inequality growth with economic development and welfare improvements (e.g., Deaton 2013), growing income concentration is seen as a relatively "benign" process, as it can be understood as a side effect of increasing prosperity and possibly just a temporary one. This view, however, is challenged by what we now know about long-term inequality trends. As seen above, the idea that increases in economic inequality are simply the result of economic growth is challenged quite directly by the historical experience of preindustrial Europe. The idea that inequality decline will follow development, instead, is challenged by what we have seen happening in recent times: "the recent increase [in income inequality] since around 1980… does not fit the [Kuznetsian] predicted earnings dynamics within the distribution. As an increasing number become skilled, the difference within the top should decrease, not increase as seems to be the case" (Roine and Waldenström 2015, p. 552). Moreover, the decline in income inequality in the first half of the twentieth century also does not easily fit the Kuznetsian paradigm, driven as it was, to a large degree at least, by the dynamics of capital income and not of labor income (Piketty 2006, 2014). From all the above considerations, the conclusion can be reached that "there is no mechanical relationship between inequality and industrialization or technological change. It is no more unavoidable that inequality increases in early stages of introducing new technology, than it is automatic that inequality eventually goes down" (Roine and Waldenström 2015, p. 552). For these and other reasons (but mostly simply due to the distributional trends that can be detected for the twentieth century), many scholars have argued that we should move definitely beyond the idea of the Kuznets curve – Peter Lindert, for example, has explicitly declared it to have now become obsolete (Lindert 2000, 2014).

It seems probable, however, that Kuznetsian arguments will continue to be present in the debate, at least for a while. Recently, Branko Milanovic (2016) offered an original perspective. He tried to reconcile the idea of the Kuznets curve with the

[7]This is also confirmed by comparing the available estimates of per capita GDP with the estimates of economic inequality in time: Alfani and Ryckbosch 2016; Alfani and Di Tullio 2019.

[8]Note that until now, the only European area for which we have evidence of a correlation between early modern economic stagnation and income inequality decline is Portugal (Reis 2017).

evidence now available about both the preindustrial period and the developments of the last 50 years or so. Milanovic argues that across history, we can detect a series of "Kuznets waves," that is, alternating phases of rising and then declining inequality, drawing a sequence of "inverted-U" curves. For example, an early wave would begin with pre-Black Death medieval inequality growth, followed by inequality decline only after that terrible pandemic. A second wave would have its ascending phase during the early modern period and would continue during industrialization, with a phase of declining inequality from 1914 onward. Finally, from the late 1970s, a third wave would begin, of which we are currently experiencing the ascending phase. According to Milanovic, this final phase of increasing inequality will also one day reverse, generating its own inverted-U. Leaving apart this forecast, which by definition is not the object of economic history (although history does remind us that earlier promises of inequality reduction have been disproved by real distributive dynamics),[9] there is reason to doubt whether we should label these movements, which are truly wave-like, "Kuznets waves" – as the factors leading to the swings in inequality during the preindustrial period are generally very different from those imagined by Kuznets.

An appealing characteristic of Kuznets's approach is its simplicity as well as its (at least in principle) generalizability. This characteristic is shared by Thomas Piketty's recent attempt at explaining inequality dynamics from the nineteenth century until today (Piketty 2014; Piketty and Zucman 2014). Piketty focused on wealth/income ratios as predictors of income inequality (the higher the ratios, the higher the expected income inequality). Moreover, he argued that as long as the rate of return to capital (r) is higher than the growth rate of national income (g) and as long as wealth stays highly inheritable, inequality (of *both* income and wealth) will continue to increase. Piketty argued that the relative dynamics of these two variables would reflect quite well the tendencies reconstructed by economic historians for the last two centuries, and made the forecast that without policy interventions, inequality will probably tend to grow indefinitely in the coming decades. Indeed, Piketty also provided some hints that his simple law would explain preindustrial distributive dynamics, too – as in a fairly speculative section of his now-famous book, *Capital in the Twenty-First Century*, he argued for r being constantly $>$ g across the world and throughout the period from year 0 to the eve of World War I (Piketty 2014, pp. 445–451). However, there are a number of problems when trying to apply Piketty's views to preindustrial times (note that admittedly, the preindustrial period *was not* Piketty's main focus). First, there is a problem with the supporting empirical evidence, as the available information about preindustrial growth rates of national incomes (g) is still highly hypothetical, while in the case of the return to capital (r), to my knowledge it has never been the object of systematic comparative studies for

[9]Admittedly, Milanovic's "optimism" only goes as far as hypothesizing that the current bout of inequality growth will one day peak, at a level lower than that reached in the early twentieth century due to the presence of "inequality stabilizers" like state pensions and unemployment benefits and will subsequently go down. That day, though, might be a long way off.

preindustrial economies. The most important problem, though, is that the view of a constantly growing inequality does not fit the empirical finding that the Black Death caused a century-long phase of significant inequality decline. Indeed, as this catastrophe destroyed human capital and only marginally physical and financial capital, the wealth/income ratio inevitably grew, which does not support, at least for this specific period, the view that such a ratio would be positively correlated to income and wealth inequality.

Piketty's ideas about the drivers of inequality growth have also been criticized for the nineteenth and twentieth century (and beyond) – indeed, as argued by Lindert, Piketty's arguments seem to encounter stronger support in data for the period 1810 to 1914, as for later periods "across countries, the levels and movements of the [wealth/income] ratio do not correlate well with those in income inequality" (Lindert 2014, p. 8). More generally, Piketty has been criticized for not defining in an entirely clear and satisfying way his concepts and the nature of the variables he uses, as well as for possible faults in his theory (see, e.g., Blum and Durlauf 2015).

It is beyond the aims of this chapter to discuss further the ample debate about Piketty's views – which, in the measure they are grounded in the large-scale (and very laudable) campaign of collection of new information about income and wealth inequality connected to the building of the *World Top Incomes Database* (now *World Wealth and Income Database*[10]), will surely continue to attract considerable attention by economic historians and cliometricians in the upcoming years. What, however, the apparent inability of both Kuznets's and Piketty's theories to fully explain the complexities of historical inequality dynamics seems to teach us is that probably we should look for complex and more case-specific explanations instead of trying to devise simple universal "laws." Again in the words of Lindert (and of Tony Atkinson before him), "[scholars] should invest in an eclectic approach that finds different causes for movements in different epochs" (Lindert 2000, p. 200) – a task that, it seems, economic historians are particularly well-equipped to accomplish.

Demography and Society

Among the many tentative explanations for long-term inequality growth, some have to do with demographic factors or with radical changes in social and social-economic structures. Explanations of this kind are particularly frequent in works focused on the early modern period, as many studies have hinted at a general connection between population growth and inequality growth, especially in cities (Van Zanden 1995; Alfani 2015; Ryckbosch 2016). The point here is not that cities were more unequal than villages and larger cities more unequal than smaller cities – a finding fairly well established in the literature (see for a synthesis Alfani and Ammannati 2017, pp. 1084–1085). It is instead the ability of population growth in a specific setting (a community urban or rural or a broader aggregate such as a region

[10] http://wid.world/data/

or state) to promote inequality growth within the setting that should be evaluated. However, looking at the larger possible aggregates – entire states – and on the basis of the available reconstructions of long-term inequality trends, it has recently been demonstrated that there is no automatic connection between population growth and inequality growth (Alfani and Ryckbosch 2016; Alfani and Di Tullio 2019). For example, in the Sabaudian State, the population stagnated during the seventeenth century – but wealth inequality continued its monotonic growth (Fig. 1a and Alfani 2015). Moreover, when large-scale mortality crises affected early modern populations (like at the time of the terrible plagues affecting Italy and other southern European areas, e.g., that of 1629–1631), they failed to cause significant inequality decline (Alfani and Murphy 2017; Alfani and Di Tullio 2019). As seen in section "How Economic Inequality Has Changed Over the Centuries," the fourteenth-century Black Death certainly did reduce inequality – but this was the result of its broader consequences on the land and labor market, mediated through a specific institutional setting in which a key role was played by the presence of unmitigated partible inheritance systems (instead, by when the seventeenth-century plagues took place, institutional adaptation affecting inheritance systems had occurred, aimed at protecting the largest patrimonies from undesired redistribution. See discussion in Alfani and Murphy 2017; Alfani and Di Tullio 2019).

More generally, it is not obvious why population change at the level of broader aggregates should affect inequality. One possibility is that this happens because demographic growth is positively correlated with economic growth – but this simply leads us back to the criticism of economic growth as the cause of inequality growth. Another possibility is that demographic growth is one of the causes of the waves of "proletarianization" that affected early modern Europe (see below). The trigger, in this case, would be population pressure on resources – which might explain why in the context of early modern Europe only population growth, and not population decline, is positively correlated to inequality. However, the reasons why demographic factors were able to shape inequality trends are more easily observed on a smaller scale: that of single communities, particularly cities. In fact, as early modern cities had a negative natural change (i.e., more individuals died in the city than were born there), growth in urban populations was possible exclusively through significant immigration from rural areas. Some micro-studies have shown how immigration acted as a kind of perpetual generator of inequality for cities, a process that became more intense after severe mortality crises, and – importantly – one that could occur even in the absence of economic growth, for example, simply because physical space to live in had opened within the city walls following a mortality crisis (Alfani 2010), as well as in the absence of growth in urban population/urbanization rates, as would be the case of a severe epidemic affecting cities but sparing rural communities. Note that these dynamics could fuel inequality of both wealth (as the newcomers tended to belong to the surplus rural population and usually had no property) and income (as the newcomers usually belonged to the low-skills workforce and consequently contributed to increasing the wage premium within the urban economy, as argued, e.g., by Van Zanden 1995). However, the evidence of community-level demographic growth actually explaining inequality growth at the *local* level in

preindustrial settings is currently inconclusive, as shown by econometric analyses of inequality in communities of the southern Low Countries from 1500 to 1900 (Ryckbosch 2016) and of the Florentine State from 1300 to 1800 (Alfani and Ammannati 2017).

The last, and in some regard the most important, demographic factor that has been considered a possible determinant of inequality change is urbanization. One reason for this is that, again, urbanization rates are often considered good indicators of economic growth while having some advantages over other indicators: they are easier to measure with actual direct archival data, and they are often available at a regional and subregional level. But urbanization rates are also relevant to assess the potential impact of "Kuznetsian" dynamics in preindustrial Europe. In fact, as argued by Van Zanden (1995, pp. 655–656), if we replace Kuznets's (1955) original distinction between an "industrial" and an "agrarian" sector characterized by different wage levels with that between an "urban" and a "rural" sector, also characterized by a steep wage differential (and there is little doubt that in early modern Europe, average wages were higher in the city than in the country), then "The gradual urbanization that typified . . . [the early modern] period probably contributed to a rise in income inequality through the mechanism described by Kuznets" (Van Zanden 1995, p. 656), i.e., as the simple consequence of the transfer of workforce from one sector to another (through migration from the country to the city), which is testified to by changes in urbanization rates. However, as for population at the state level, recent research could not find any clear correlation between changes in urbanization rates and inequality trends (Alfani and Ryckbosch 2016; Alfani and Di Tullio 2019).

As mentioned above, a mechanism through which population growth might have led to inequality growth is by leading to acute pressure on available resources thus triggering "proletarianization" – that is, the historical process leading a growing share of the European population to lose the ownership of the means of production, thus becoming dependent on selling their labor for wages. This view, which is clearly rooted in the Marxist tradition of economic history, in relatively recent times, has been strongly argued for by Tilly (1984). Many specific historical processes have been presented as a component of this overall tendency toward proletarianization, from the rural enclosures movement to the spread of the putting-out system. Its main aspect, though, is the crisis of small land ownership. If we focus on the areas for which we have reconstructions of long-term inequality, we find, for Italy, an ample literature detailing the crisis of small peasant property with the subsequent concentration of wealth in many areas, especially from the second half of the sixteenth century when population pressure on available resources became acute. Specifically, the crisis of peasant property has been singled out as a possible factor contributing to inequality growth in the Sabaudian State (Alfani 2015), while for the Republic of Venice, we have some evidence of proletarianization in the growing share of propertyless households throughout the early modern period (Alfani and Di Tullio 2019). Similar processes have been detected, too, in the southern Low Countries and in the Dutch Republic (Ryckbosch 2016; Alfani and Ryckbosch 2016). Differently from other possible explanatory factors like economic

growth or urbanization increase, proletarianization was a general, pan-European phenomenon (Tilly 1984, pp. 26–36; Van Zanden 1995, pp. 656–658; Alfani and Ryckbosch 2016), and consequently, it seems – at the very least – an important contributing cause to explaining inequality trends that were largely similar across the continent. However, as proletarianization was connected to population pressure and was triggered by acute phases of scarcity (especially continental-level famines), it tended to come in waves. This is why, although it was surely an important inequality-promoting factor, proletarianization seems to fail to fully account for a process that is found to be overall monotonic in practically all areas from 1500 to 1800. This is a reason to look for possible causes of inequality growth that exerted a more constant influence throughout the early modern period: as will be seen, institutional change affecting fiscal systems satisfies this requirement.

Demographic and socioeconomic-demographic explanations of inequality change are much less frequent when we move from the preindustrial period to the nineteenth and twentieth century. Surely, one reason for this is that economic variables can be observed more directly – hence there is no need to recur to such imperfect measures of economic development as population density and urbanization rates. Demography, however, is obviously part of those explanations that look at the growth rates of the workforce – or at its relative trends in different sectors – as the source of changes in income differentials between different components of the workforce. For example, in the UK and the USA during the nineteenth century, the demographic transition, which is associated with historically very high rates of population growth, promoted income inequality growth by widening the wage differential between skilled and unskilled labor, also due to the inability of the educational system of the time to allow for significant improvements in skills per worker. Later, when the demographic transition entered its second phase (characterized by shrinking fertility rates) and particularly in the first part of the twentieth century, labor income inequality tended to decline due to slower population growth as well as to a better ability of the educational system to allow for increases in the growth rate of workers' skills (Williamson and Lindert 1980; Williamson 1985). If we focus on wealth distribution instead, population dynamics are relevant as – in combination with inheritance systems – they contribute do determining whether the tendency is for wealth to become more or less concentrated as in general, the lower the rate of population growth, the higher the ability of the system to produce more wealth concentration over time through transfer of patrimonies to fewer inheritors (see, for a detailed discussion, Roine and Waldenström 2015, p. 552).

Institutions

Institutions play an important role in many possible explanations of the determinants of historical inequality trends. For example, as seen above, inheritance systems contribute to determining the distributive consequences of population growth from the early modern period until today (as they affect how wealth is transferred across generations), while educational systems contribute to explaining how demographic

dynamics can lead to changes in labor income inequality. Now the focus will be placed on a specific kind of institution: the fiscal systems. These are key to many explanations of inequality dynamics during the twentieth and twenty-first centuries and recently have been proposed as a fundamental cause or co-cause of the inequality tendencies found for the early modern period, too.

We are used to thinking of fiscal redistribution as something leading to lower inequality, of both income and wealth, as this is the common situation in most world countries today, including all the richest ones. In particular, taxation on income, which is usually progressive (hence those who earn larger incomes will pay proportionally more than those who earn lower incomes), reduces inequality in the short run, as by definition in a progressive fiscal regime, post-tax inequality is lower than pre-tax. Although these short-run effects may be small, they tend to accumulate over time, becoming potentially much more substantial in the medium and long run. Regarding wealth, for today's societies, the most important aspect to consider is the level and the structure of the inheritance tax, which directly affects wealth distribution (as personal or household wealth results from the combination of inherited and self-made wealth) and contributes in a crucial way to determining the degree of inheritability of wealth itself in a given society, with all that this entails for the expected long-term dynamics.

Generally speaking, fiscal redistribution seems to have been a major reason for the lull in inequality growth in the post-World War II decades. It is in this period that the progressivity of fiscal systems increased to levels never experienced before – or after (Atkinson 2004; Atkinson et al. 2011; Alvaredo et al. 2013). In 1975, the top rate on earned income was 83% in the UK, 70% in the USA, 72% in Italy, 60% in France, 56% in Germany, and 47% in Canada. Twenty-five years later, at the end of a long series of fiscal reforms that were initiated by President Ronald Reagan in the USA and Prime Minister Margaret Thatcher in the UK, the situation was inverted, with a top rate of 61% in France, 60% in Germany, 54% in Canada, 51% in Italy, 48% in the USA, and 40% in the UK (Messere 2003, p. 23). Top rates of inheritance taxes followed an entirely similar pattern. In 1980, the top rate was 75% in the UK, 70% in the USA, 35% in Germany, and 20% in France, but in 2013 the highest rate was found in France (45%), followed by the UK (40%), the USA (35%), and Germany (30%) (Piketty 2014, p. 644). By simply comparing these trends with the historical inequality trends presented in Fig. 2, we have strong hints that the progressive simplification of the Western fiscal systems[11] and the reduction in the top rates provided fertile ground for an increase in inequality. This was not just the consequence of a decline in the overall progressivity of the fiscal regime (hence in its ability to lead to a lower level of post-tax inequality compared to pre-tax), but probably also of how institutional change regarding taxation affected the pre-tax income distribution. It has been argued that lower top income rates favored

[11]The number of income "brackets" used by national personal income taxes has declined dramatically since 1975: in the case of the USA, for example, from 10 in 1975 to just 3 in 2000. Messere (2003), p. 23.

behaviors, for example, in wage negotiation, that led to increasing within-company wage differentials as higher potential net rewards favored more aggressive bargaining at the top, and this is independent from economic growth. Others favor a somewhat more optimistic picture, arguing that lower taxes stimulated economic activity, especially at the top of the income distribution (which, generally speaking, is the part of the distribution most advantaged by a reduction in top rates); hence the resulting inequality growth was in fact a collateral effect of quicker economic growth – although it has also been argued that there is no strong empirical evidence of a correlation between cuts in top tax rates and the pace of economic growth (for a synthesis, see Alvaredo et al. 2013, pp. 8–11). A final aspect to mention is that seemingly different fiscal developments contributed in a crucial way to determining the difference in the overall income inequality path followed, during the twentieth century, by English-speaking "Atlantic" countries (U-shaped) compared to continental European countries (L-shaped) (see discussion in section "How Economic Inequality Has Changed Over the Centuries" as well as Alvaredo et al. 2013).

If changes in fiscal systems seem to tell us much about the trends in economic inequality after World War II, there is reason to believe that they also played an important role in earlier decades, and in particular, that they contribute to explaining the tendency for inequality decline that was detected during the interwar period (at least for some countries and especially looking at wealth). Indeed, the interwar period was associated with the extension of the personal income tax. In the UK, for example, given the structure of exemptions, in 1912–1913 just 5% of all "tax units" were required to pay it. Already by 1930, the figure had risen to 40% of all tax units, and finally, by the end of World War II, the majority of the British population was required to pay it. In the same period, the top income tax rate rose from 8% to more than 40%. Across Europe, during the war and interwar period, the inheritance tax also increased significantly (Atkinson 2004; Piketty 2014). However, as seen in section "How Economic Inequality Has Changed Over the Centuries," arguably other factors played an even more important role in reducing economic inequality than the deepening of progressive taxation. For example, in the case of wealth, hyperinflation due to war (including during the years following the end of war itself) destroyed the real value of shares of the public debt, which had been owned mostly by the richest part of the population – a process that, in Piketty's words, was akin to expropriation through inflation (Piketty 2014, p. 184).

If during the twentieth century fiscal systems tended to become more progressive, prosecuting a tendency that had timidly begun during the nineteenth century, if we move further back in time, to the early modern period, we are faced with an entirely different situation as preindustrial fiscal systems were overall *regressive* – that is, the effective tax rates paid by those placed at top were lower (and considerably so) than those suffered by the bottom of society.[12] This was the consequence of a regime of

[12]Fiscal systems turned from being overall regressive and inequality enhancing to being progressive and inequality reducing at some point between the second half of the nineteenth century and the first decades of the twentieth. The exact timing is unclear because we lack specific studies of this fundamental transition.

systematic privilege, enrooted in law and institutions as well as in a culture that favored nobles over commoners, citizens over rural dwellers, and so on. With a regressive fiscal regime, post-tax inequality is higher than pre-tax inequality – and the greater the fiscal pressure, the greater the difference between pre- and post-tax distributions. Importantly, a continuous increase in per capita taxation is a distinctive feature of a fundamental historical process: the rise of the so-called fiscal-military state – that is, the emergence of the "modern" state with its deeper capacity and much greater ability to impose taxes on its subjects, chiefly to pay for the ever-increasing costs of war and defense. This process, which began in the sixteenth century, involved all European states independent of their economic conditions, as all had to play the same game if they were to protect themselves or to be able to project power outside their boundaries. For this reason, as a potential cause of the overall tendency for inequality growth reported for the early modern period, the increase in per capita taxation in the presence of a regressive fiscal system has the particularly desirable feature of being generalizable. For example, in the period ca. 1550 to 1780, per capita fiscal pressure rose by 70% in the Republic of Venice (where it was relatively high to begin with), more than trebled in the Sabaudian State, and increased sixfold in France and almost sevenfold in England and the Dutch Republic – thus increasing very significantly the ability of underlying regressive fiscal systems to foster inequality growth. Greater income inequality will produce, over time, more wealth inequality, too, by means of saving and investments. Consequently, the growth in the per capita tax burden during the early modern period can be seen as a co-cause of growth in inequality of both income and wealth (Alfani 2015; Alfani and Ryckbosch 2016; Alfani and Di Tullio 2019). This is even more clear if we consider that the main reason for collecting more and more resources – war – did not lead to inequality reduction as the consequence of state expenditure, differently from what we are used to today, when welfare and social spending represent the largest component of the public budget. Quite possibly, in preindustrial settings state expenditures further favored inequality growth, although further research on this specific aspect is much needed (for the redistributive consequences of public expenditure in the Republic of Venice, see Alfani and Di Tullio 2019).

Although it seems almost a certainty that during the early modern period the rise of the fiscal-military state played a very important role in favoring inequality growth across Europe (and beyond), this was surely not the only factor at work. Other common factors might have existed, for example, proletarianization, which, as seen above, probably played an important role in at least some specific historical phases. But more generally, it is probably wrong to focus research solely on identifying a single unifying cause of long-term inequality growth. In fact, as is arguably also the case for research on inequality trends in more recent epochs (Lindert 2000), we should openly recognize that the main causes explaining distributive dynamics can vary across space and time. As a consequence, we need to embrace complexity in explanations, pay great attention to context, and dig deep into available sources and information – that is, employ all the distinctive skills and good practices of economic historians. As an example of this way of proceeding, we can take the recent masterful study of inequality in the USA from 1700 until today by Peter Lindert and Jeff

Williamson (2016). Although they managed to provide an entirely convincing overall account of inequality dynamics over three centuries, for each specific period, they identified a range of concomitant causes able to explain the observed trends. For example, if we compare two phases of income inequality growth – 1800–1860 and 1970s–today – the proposed explanations are for 1800–1860: (i) rapid labor force growth that strained available resources (even taking into account the exceptionally high availability of natural resources in the USA compared to other advanced areas in the world in the same period) leading to rising prices of assets relative to wages, (ii) rapid technological progress favoring industries and cities and leading to widening North-South and city-countryside income gaps, and (iii) financial developments favoring the wealthy. Instead for the period 1970s–today inequality growth would be the consequence of: (i) political shifts leading to tax reforms of the kind described above, as well as to restricting of the welfare state, etc., (ii) skill-biased technological change, in particular the spread of automation, which determined a relative advantage for those with capital and skills, (iii) increasing competition in international trade (especially growing competition from Asia), which compromised wage gains at the bottom of the distribution, (iv) growing imbalances in levels of education, and (v) the rise of the financial sector favored by deregulation.

Conclusions: What Lessons from History?

This short overview of inequality trends in the long run of human history aimed to make explicit ways in which the remote past seems to shed light on recent developments, and vice versa, how the analysis of recent developments has led scholars to fruitfully explore the past with new eyes. A particularly important aspect is that the recently obtained better knowledge of the history of inequality in preindustrial times has changed how we perceive contemporary distributive dynamics by leading to the realization that the very long-run tendency has been for inequality to grow. The preindustrial period was not characterized by relatively flat distributive dynamics – on the contrary, the pace of inequality growth was probably comparable to that found in later epochs, with the possible exception of the phase of very quick income inequality growth experienced by a few countries since the 1970s. This common tendency, which is particularly clear when looking at the distribution of wealth, is interrupted only by two phases of inequality reduction, both triggered by large-scale catastrophes: the Black Death of 1347–1352 and the two World Wars of the twentieth century with the in-between troubles. If we expand the analysis to include, in a more tentative way, the first millennium, we can add to the list the progressive dissolution and ultimate "fall" of the Roman Empire during the fifth century.

The available historical evidence, then, strongly suggests that across two centuries and more, the overall tendency for inequality has been to increase, without, as it seems, any form of automatic rebalancing of the "Kuznetsian" kind. Admittedly, economic-historical research has underlined, for each period, different sets of potential causal factors leading to inequality growth – but what seems to be constant over time is that historically, it was much easier for inequality to grow than to decline,

as per inertia. Distributional developments in recent years lead us to think that this is what we should expect from the future, too. But is it really the case that only large-scale disasters were able to (temporarily) stop inequality growth? And hence should we be resigned to suffering growing disparities among human beings as the lesser of two evils? Luckily enough, history also offers some evidence that long-term inequality trends were heavily affected by human agency. The lull and even further decline in inequality after the end of World War II was also the effect of institutional innovations: the redistributive policies (in particular, strongly progressive taxation) and the development of welfare states from the 1950s to the early 1970s. It is only when those policies were weakened and that development was arrested (and at least in some countries, partially inverted) that inequality of both income and wealth found once again fertile ground to grow. In the opposite direction, the rise of the fiscal-military state, with the related increase in the per capita fiscal burden in a context of *regressive* taxation, fueled inequality growth throughout the early modern period.

The historical experience of Western countries does not necessarily teach us whether we should consider the current trend toward growth in economic inequality as an undesirable outcome or a problem per se (although there would be at least some ground to argue for that). What it does seem to teach us, though, is that altering that trend is entirely within our capacity, through our ability to change the institutions that in turn contribute to shaping our societies. At the same time, it teaches us that if we do not act, we have no reason whatsoever to expect that inequality will, one day, decline on its own. In other words, economic history allows us to identify quite clearly the boundaries of our playing field – but it is up to us to decide which kind of game we want to play.

Agricliometrics and Agricultural Change in the Nineteenth and Twentieth Centuries

Vicente Pinilla

Contents

Abstract

Before the industrial revolution, agriculture was the most important economic activity of traditional societies. The spread of industrialization processes, first throughout a large part of the western world and later across many more countries, gave rise to an abundance of literature on the role of agriculture in these processes. The initial perspectives offered by economic history, particularly for the British case, and the approaches of development economics specialists, largely based on previous studies by economic historians, became subject to

reconsideration when numerous studies emerged that, from a cliometric point of view, sought to evaluate the changes experienced by agriculture and their contribution to economic growth. In this context, the objective of this study is to use these contributions to analyze the profound transformations that have occurred in agriculture around the world over the last two centuries.

Economic history · Cliometrics · Agricliometrics · Agricultural production · Agricultural productivity · Technological change · Agricultural trade · Globalization · Agricultural policies · Agrarian institutions

Introduction

The agricultural sector has traditionally been a highly popular field of study among economic historians. Therefore, it is not surprising that since the emergence of new economic history in the 1950s, the cliometric approach has been frequently used in the analysis of the changes experienced by agriculture over the long term. Many researchers have used this methodology to explain the agricultural transformations, and in recent years a specialized forum has been created (Agricliometrics Conferences) in which cliometric agricultural historians are able to discuss their work. Three of these events have been organized to date (Zaragoza 2011 and 2015, Cambridge 2017).

This methodological approach, which is predominant in the universities of many developed countries today, has made a significant contribution to an in-depth and renewed vision of the principal changes that have taken place in the agricultural sector and the forces that have driven them. The use of explicit-theoretical approaches based on economic theory and the analysis of historical agricultural data with econometric techniques have enabled us to extend our knowledge substantially. For many regions, we have been able to establish not only by how much production has increased, but we are also able to explain whether this growth is due to a better use of inputs or improvements in productivity. It has also been possible to gain a thorough knowledge of the changes occurring in agricultural trade during the two waves of globalization and the forces that drove them. Finally, the agricultural policies, their effects, and the institutional changes have been examined from a new perspective aimed, mainly, at understanding the political economy that explained them and the reasons that enable us to understand them.

Furthermore, in publications providing an overall perspective of the agricultural change in the modern world, cliometric agricultural historians have summarized their previous contributions and renewed our understanding of the long-term evolution of the agricultural sector. Without a doubt, the most important study is the general overview by Federico (2005, 2014, and 2017) of the economic history of global agriculture in the nineteenth and twentieth centuries. Also from this perspective, views about the agricultural change in Europe (Lains and Pinilla 2009a), the global periphery (Pinilla and Willebald 2018a), or different regions of the world

(Hillbom and Svensson 2013) have been published. Moreover, economic history publications on certain relevant countries in the global economy which incorporate a study of agriculture have largely been undertaken by cliometric historians. Such is the case of the United States (Atacket al. 2000; Olmstead and Rhode 2000) and Great Britain (Allen 2004; Ó Gráda 1981; Turner 2004).

The interest of cliometric researchers in agriculture is not surprising. Until the beginning of the industrial revolution, agriculture was the principal economic activity of today's developed countries. There has been intense debate among economic historians about the role played by agriculture in the transformation of these countries from pre-industrial nations to advanced economies (Lains and Pinilla 2009b). Today, agriculture is still important in developing countries, and, although in developed nations, it has a very low weight in terms of production or the use of labor, it is still strategic as it produces the food essential for human beings. Furthermore, it is closely linked to the agri-food industry.

Within this context, the objective of this chapter is to offer a renewed vision of the changes that have taken place in global agriculture over the last two centuries in light of the research undertaken in recent decades by cliometric historians. Over the last 20 years, thanks to the surveys or joint volumes that have been published, this methodology has gone beyond the mere reporting of results in specialized academic journals. Nevertheless, it is still important to synthesize the principal results, as cliometric historians have tended to propose and verify new hypotheses while questioning some of the traditional ones.

The chapter is structured into five sections following this introduction. The first addresses the long-term evolution of agricultural production and productivity. An analysis of the technological change in agriculture is the subject of the second section. The third and fourth sections address the development of agricultural trade and the integration of agricultural product markets in the first and second globalizations, respectively. The final section analyzes some relevant aspects of the institutional change that has taken place in agriculture in the period studied in this chapter.

Long-Run Agricultural Production and Productivity

Increase in Production

The first difficulty faced by cliometric historians seeking to study the long-term changes in agricultural production and productivity was the absence of sufficiently consistent serial data for many countries. Therefore, the first task was usually to carry out a meticulous statistical reconstruction of annual agricultural production, particularly in the period leading up to the Second World War (i.e., GEHR 1991; Toutain 1992; Federico 2003a).

The availability of broad statistical series subsequently enabled the analysis of changes in production. From a global perspective, agricultural production has increased in the world as a whole over the last two centuries at a much faster pace than population growth. If we take into account that, due to the demographic

transition, population has increased at a very fast rate during this period, the capacity of agriculture to feed humankind should be recognized as an important achievement (Federico 2005).

It is obvious that the most complex estimates of agricultural production growth are those referring to the nineteenth century, given the lack of quality data or the difficulty in finding them. For example, in England there is considerable controversy surrounding the estimates carried out, and there is a lack of consensus (Allen 2005; Broadberry et al. 2015; Clark 2010; Floud et al. 2011; Muldrew 2011; Clark 2018). Kelly and Ó Gráda (2013) have examined the causes of these differences, proposing compromise estimates of agricultural output for the period of the industrial revolution, which show that the British population had broken the Malthusian ceiling as its agricultural production grew at a faster rate than population. Therefore, the food resources were clearly greater than those necessary for subsistence. Also, in Portugal and Sweden, agricultural production outperformed population growth substantially. In Scania, the granary of Sweden, agricultural production increased faster than in England between 1800 and 1850, with an annual growth rate of 1.77% (Olsson and Svensson 2010). Agricultural production also grew in Portugal in the first half of the nineteenth century at an appreciable annual rate of 0.7% (Reis 2016).

The only estimate carried out regarding the growth in agricultural production on a global scale highlights that, between 1870 and 1938, growth increased at an average annual rate of 1.3%. This growth was much greater until 1913 than during the interwar period, when it slowed down considerably (Federico 2004). The increase in production during this period varied greatly between the different regions, with faster rates in South America, the settler countries, and Europe. As production grew at a faster pace than the population, during this period agriculture contributed to improving nutritional levels, at least in those regions of the world where there was higher growth. However, this growth seems modest if we compare it with what came later. Between 1938 and 2000, world agricultural production grew at a higher rate, but particularly after 1950, it grew by more than 2% annually. Again, there was considerable regional dispersion as developing countries had growth rates of over 3% per annum after 1950, while developed countries grew more slowly, particularly during the final decades of the twentieth century (Federico 2005).

The greater availability of data for developed countries enables us to analyze the growth rate of their production in more detail (Table 1). The agricultural production of European countries grew throughout the nineteenth century until the First World War at an annual rate of between 0.5% and 1.5% with notable differences between countries. These rates remained at similar levels in the interwar period, although the dispersion across countries increased and some had rates higher or lower than the aforementioned range. The annual growth rates of settler countries were very high (usually above 6%) during the conquest of new territories and the displacement of the frontier westward. Once this process was completed, in the interwar period, the growth rate fell significantly (Federico 2004). After the war developed country growth rates accelerated considerably between 1950 and 1990, when they grew at an annual rate of over 2%. Since 1990, these rates have fallen considerably, to an annual level of less than 1%, or have stagnated.

Table 1 Rate of change in gross agricultural output, 1870–2000 (%)

	1870/1913	1913/1938	1938/1948–1952	1948–1952/1958–1960	1961/2000

Source: Federico (2004, 2005). Between 1870 and 1938, Asia includes only Japan, India, and Indonesia; Western Settlement includes Canada, Australia, and New Zealand; South America includes Argentina, Chile, and Uruguay. Asia between 1936–1938 and 1958–1960 does not include China. The World between 1936–1938 and 1958–1960 excludes the Socialist countries

For the second half of the twentieth century, it is possible to determine the growth rates of production and their regional differences with greater precision. In terms of the growth rates of production, a clear gap can be observed between developing countries and developed countries, as the former had higher rates while the latter had steadier rates in the expansion of their production (Alston and Pardey 2014; Pinilla and Willebald 2018b). Europe is an example of the developed countries. Its production grew very fast until the end of the 1980s, with annual rates of over 2%, but then it stagnated with minimum growth in the majority of the countries and negative growth in the old centrally planned economies (Martín-Retortillo and Pinilla 2015b). In developing countries the pattern is very different. If we take the case of Latin America, the figures show that the growth rates of agriculture remained relatively stable during the whole period (somewhat lower during the crisis years of the 1970s and 1980s), with very high levels at around 3% per year (Martín-Retortillo et al. 2019).

Growth in Productivity

Once the growth rates of production had been established, the most important contributions began to focus on analyzing the changes occurring in agricultural productivity and its determining factors. Two main strategies have been followed to approach this issue: calculating the total factor productivity (TFP) and partial productivities and principal labor productivity.

The emphasis on the study of TFP is largely due to the growing role that its improvement has had in the increase of production. According to Federico (2005), we can talk about a predominantly extensive model of agricultural growth until Second World War, based on the use of a greater amount of inputs and a small

contribution of an increased TFP, and an intensive growth model after the Second World War in which a more relevant role is attributed to the improvement in TFP. Many studies have been carried out estimating the historical growth of TFP, the majority of them for countries with currently high incomes. Although there is a clear spatial variability in the results obtained, some general trends can be drawn from them. First, the studies for Great Britain (i.e., Clark 2002; Allen 1994) or the United States (Craig and Weiss 1991) show that at the beginning of the industrialization processes, the TFP grew at an annual rate of around 0.5%. The most advanced European countries followed this trend in the second half of the nineteenth century, with higher annual rates, which in some countries exceeded 1% (Van Zanden 1991). Other European countries, such as France, Italy, Portugal, or Spain, had similar rates at around 0.7% (Grantham 1993; Federico 2003a; Lains 2003; Bringas 2000). In these countries, the TFP grew even faster during the interwar period, as the industrialization processes intensified. But without a doubt, the greatest growth acceleration of the TFP occurred during the decades following the Second World War. Agricultural economists have carried out the majority of studies for the second half of the twentieth century for short periods of time, which makes the comparison of their results difficult (Federico 2014).

Two recent cliometric studies for Europe and Latin America for the whole of the period 1950–2005 enable more robust conclusions to be drawn (Table 2). Therefore, the European case shows that the growth of agricultural production in European countries followed different paths but tended to converge. A model strongly based on increased efficiency was categorically followed by the more advanced countries from the early 1960s and by the more backward countries of the southern periphery from the early 1980s. The countries of Central and Eastern Europe had to wait for their transition to market economies in the mid-1990s before they could adopt a similar model. Latin America constitutes an interesting contrast, as the countries in this continent had medium and low incomes around 1950. In this case, efficiency gains made a rather modest contribution to the considerable increase in production,

Table 2 Annual growth rates of outputs, inputs, and TFP between 1950 and 2005/2008: the big European and Latin American countries

	Output	Labor	Land	Capital	TFP
Argentina	1.68	−0.23	1.13	3.66	−0.04
Brazil	3.97	0.28	2.23	4.57	1.90
Colombia	2.55	1.01	0.98	1.99	1.18
Mexico	3.67	0.89	0.77	3.22	1.99
France	1.48	−3.87	−0.14	2.43	2.31
Germany	1.24	−3.88	−0.22	1.00	2.48

although this contribution became increasingly larger over time and was highly significant between 1994 and 2008 (Martín-Retortillo and Pinilla 2015a; Martín-Retortillo et al. 2019).

The historical studies conducted on partial productivities highlight the wide variety of agricultural systems and their evolution. The studies conducted by O'Brien and Prados de la Escosura (1992) and Van Zanden (1991) for Europe from the end of the nineteenth century to the end of the twentieth century and the study undertaken by Hayami and Ruttan (1985) for six developed countries over a long time period from the end of the nineteenth century to the end of the twentieth century enable us to appreciate a wide variety of models. In all of them, over these 100 years, the increases in productivity of the land and of labor have been spectacular. In some countries, usually those with lower levels of land productivity, improvements in labor productivity were achieved mainly by increasing the number of hectares farmed per worker, with the United States being the most notable case. In other countries, such as Japan, it was largely the improvement in land productivity that contributed to the increase in labor productivity.

This variety in the agricultural development models can be generalized to the whole of the world, which also shows the existence of different trends in the second half of the twentieth century, particularly based on the improvement of land productivity in Asian countries or labor productivity in developed countries (Alston and Pardey 2014; Federico 2005).

Technological Change

A key study in the analysis of technological change in agriculture is, undoubtedly, the one conducted by Hayami and Ruttan (1985). It combines a theoretical proposal for its understanding, an international comparison between developed and developing countries and a historical-econometric analysis contrasting the cases of the United States and Japan. Based on Hicks' analysis of technical change, the authors proposed the theory of induced innovation to explain the technological change in agriculture, whereby the direction of this change depends on the relative prices of the factors. In the United States, as labor was a relatively scarce and expensive factor, the mechanization of agriculture was predominant in order to save on labor, while in Japan, where land was the scarce factor, biological innovations predominated. This is what Olmstead and Rhode (1993) call the "level approach" to technical change, meaning that even at constant relative factor prices, innovations try to save relative scarce factors.

Some studies seek to verify the key factors that determined the adoption of the new agricultural machinery. For the case of the United States, David (1966) concluded that the adoption of the harvester in the Midwest depended on whether certain economies of scale were obtained, which, in turn, critically depended on the variation of the relative prices of the factors. However, Olmstead (1975) pointed out that small variations in the values of the variables that intervened in the model had significant repercussions on the profitability threshold farm size for adopting

machinery and that the hire or joint purchase of machinery enabled this size to be reduced. In Europe, Reis (1982) concluded that in order to adopt the steam thresher in Portugal, the variation in the price of labor, the cereal yields, and the hiring or joint purchase of these machines were key factors. For Italy, the diffusion of the steam thresher from the 1870s was determined by the cost of the capital and was facilitated because these machines were purchased by specialized entrepreneurs, who in turn rented them to farmers and landowners (Federico 2003b).

An additional problem in the analysis of technological change in agriculture is the classification of the innovations as land or labor saving. Some of them can produce effects simultaneously in both directions (Federico 2005; Olmstead and Rhode 1995). For example, in the case of the United States, "tractorization" substantially reduced the land required to feed draught animals (Olmstead and Rhode 2001).

However, the analysis of technological change in agriculture must be more complex than studying the mechanical application of the theory of induced innovation, as shown in the in-depth review of the North American case carried out by Olmstead and Rhode (2008, 2015). They highlighted the importance that biological innovations (not mechanical) had throughout the nineteenth century and the first third of the twentieth century. Biological innovations were important for the country's major crops, particularly through the import of genetic material from other places and the growing capacity to combat plagues and insects that threatened harvests. Furthermore, one of the most important, though often overlooked, consequences for land productivity was the increasing capacity to control and eradicate epidemics suffered by animals for human consumption. Finally, they showed that the evolution of the relative prices of land and labor in the United States moved in the opposite direction as that forecast by Hayami and Ruttan. Throughout the nineteenth century and until 1910, the ratio between the value of land and agricultural wages increased progressively, i.e., there was higher growth in land prices than in labor prices (Olmstead and Rhode 1993).

Innovations designed to increase the productivity of land have also been important in European agriculture. Until the Second World War, the use of chemical fertilizers and pesticides substantially contributed to increasing the productivity of land (Van Zanden 1991). During the first decades after the war, European agriculture intensified its yields. In the case of arid or semiarid areas (not only in Europe), the extension and intensification of irrigation has also been fundamental. In Europe, the irrigated area increased from 8.7 million hectares to 19.1 million hectares, 10 million of which are located in Mediterranean Europe (Martín-Retortillo and Pinilla 2015a). The contribution of irrigation to the increase in agricultural production is remarkable. For example, Cazcarro et al. (2015) estimate that between 1935 and 2006, 45% of the increase in Spanish vegetable production was due to the increased area of irrigation, and 41% was due to increased productivity of irrigated land.

Several studies have sought to demonstrate the importance of both foreign and domestic demand in encouraging the adoption of technological innovations, which could increase supply without increasing prices. This is an important argument to explain the virtuous cycle that triggered the English industrial revolution, as the

demand for food from the cities played a fundamental role in the growth of agricultural productivity (Allen 2003b). In the case of European countries, Van Zanden (1991) highlights the importance of domestic demand and overall economic growth to explain the improvement in agricultural productivity. Also, in the case of Germany, agriculture reacted to urban and industrial development rather than shaping it (Kopsidis and Hockmann 2010; Kopsidis and Wolf 2012; Pfister and Kopsidis 2015). In the case of France in the first half of the nineteenth century, demand was the main driver of the improvement in productivity (Grantham 1989). In Sweden, institutional change and growing markets for agricultural products boosted agricultural production and productivity between 1700 and 1860 (Olsson and Svensson 2010). The same argument has been used to explain the growth in North American agriculture throughout the twentieth century, emphasizing the importance of labor market adjustments and the relocation of the agricultural labor force to the nonagricultural sector as the principal cause of increased productivity in agriculture (Gardner 2002). In general, both internal and external demand have been identified as being important factors for the development of European agriculture (Lains and Pinilla 2009a).

Supply factors also played an important role in the technological change and the improvement in productivity. Returning to Hayami and Ruttan (1985), it seems obvious that, with all the precautions that we have already indicated, relative prices were important for understanding the direction in which innovation was moving. Here we can add some other key factors. First, the role of the public research centres has been an important factor driving innovation, more so in some sectors than others (Ruttan 2002). Due to the difficulties in defining property rights of some innovations, the public sector organized an agricultural research system that has produced remarkable results, which are clearly reflected in the case of the green revolution. Therefore, organized public (and also private) investment in agricultural R&D was a primary driver of rapid growth in productivity in the second half of the twentieth century (Alston et al. 2009; Federico 2014). Furthermore, as we shall see later, the growth of agricultural cooperatives facilitated the diffusion of innovations. Finally, access to credit was a determining factor for adopting innovations, as many required large capital investments.

The First Wave of Globalization and the Growth of Agricultural and Food Trade

Market Integration and Agricultural Trade

The upsurge in trade, together with mass transoceanic migrations of workers and capital movements, were the essential components of the first wave of globalization from the early decades of the nineteenth century (O'Rourke and Williamson 1999). A strict definition of globalization such as that commonly used by economic historians requires an increasing integration of factor and product markets

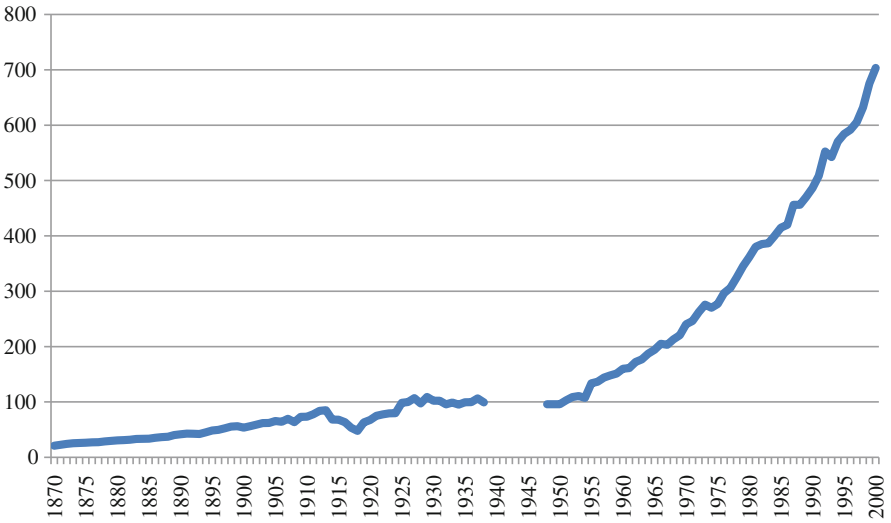

Fig. 1 International trade in agricultural and food products, 1870–2000 (constant prices, index numbers, 1934=100). (Source: Own elaboration based on Aparicio et al. (2009) and González et al. (2016))

(O'Rourke and Williamson 2002). In the case of goods markets, those with a greater weight in economic activity, such as textiles or grain, played a decisive role.

In the first wave of globalization, international trade in agricultural goods expanded rapidly (Fig. 1). The estimations performed by Lewis (1952, 1981) for primary products as a whole indicate an annual growth rate of 3.7% between 1850 and 1900. In the first third of the twentieth century, agricultural trade grew at an annual rate of 1.4%. However, this period was characterized by enormous contrasts. Until 1914, the growth rate of agricultural trade was similar to that of the nineteenth century. It subsequently fell during the First World War, recovered in the 1920s, and suffered a considerable decrease in the 1930s due to the Great Depression (Aparicio et al. 2009).

During the first wave of globalization, agricultural products were a key component of international trade, representing approximately half of the total. During this period, trade was essentially interindustrial, that is, the predominant tendency was the exchange of raw materials and food products for manufactured goods. Therefore, the Heckscher-Ohlin models based on comparative advantage usually provide a convincing explanation of the specialization trends and trade patterns.

During this first wave of globalization, the integration and formation of the agricultural product markets was essential (Federico 2018). The wheat market was fundamental, as wheat was a staple product and its trade accounted for a high volume of total agricultural trade.

There is an abundance of evidence suggesting that a massive international integration process of the wheat market took place between the end of the Napoleonic wars and approximately 1870, as measured through the convergence

of its prices and the reduction of its dispersion (Jacks 2006). The northwestern European countries led this process, reaching high levels of integration before any other region (Chilosi et al. 2013). The protectionist measures implemented after the "grain invasion" in the final decades of the nineteenth century partially reversed this integration process, which resumed at the beginning of the twentieth century. The domestic markets also partially experienced this integration process (Federico 2012a; Uebele 2011). In the case of integration between Asia and the international market, the process was more continuous until the First World War with no regression at the end of the nineteenth century (Chilosi and Federico 2015). After the First World War and during the 1920s, the dispersion in prices was once again very low, but the 1930s depression disintegrated the wheat market once more (Federico and Pearsson 2007; Hynes et al. 2012). In this process, at least in the European market, the contribution of the domestic and international markets to the long-run process of integration was similar. Its main drivers were political events, trade liberalization, and the fall in transportation costs (Federico 2011).

The European demand for wheat, mostly from Britain, was the key factor in the growth of its trade in the nineteenth century. The abolition of the Corn Laws in Britain in 1846 was one decisive factor in the liberalization process that took place (Sharp and Weisdorf 2013). However, at the end of the century, the situation for the European producers became complicated by the increasing imports of wheat from the East (the Russian Empire) and from the West (the United States), at prices which were lower than those usually seen in Europe. The largest countries, such as Germany, France, Italy, and Spain, reacted by imposing protectionist barriers, which gave a certain margin to their farmers to compete with foreign production, with the condition that they modernize their farms by introducing innovations such as chemical fertilizers or machinery. Less common was the practice implemented by countries such as the United Kingdom, the Netherlands, and Denmark, which decided to maintain their free trade policies. These different responses have been explained by the fact that the grain invasion implied different shocks in different European countries and also had different effects on income distribution depending on the importance of grain production and agriculture (O'Rourke 1997). The capacity of influence of the different sectors affected by the crisis in each country was, therefore, decisive in explaining the type of trade policy adopted (Lehmann and Volckart 2011).

Until the First World War, trade in wheat was characterized by the stability of demand from the European free trade countries, while that proceeding from the protectionist countries was highly irregular. The war and the decline of European production, together with the end of Russian exports, led to a growth in production in overseas countries, while in the rest of the world production decreased. Exports from those countries also increased significantly. In the 1920s, the market began to display unequivocal signs of saturation. During the 1930s worldwide exports of wheat decreased. This fall was approximately 65 million quintals between 1928–1932 and 1934–1938 (Aparicio and Pinilla 2019). The principal explanation can be found in the increasing self-sufficiency of the principal wheat consumers due to the increase in protectionist measures. From 1929 onward, the traditionally

protectionist countries increased their tariffs on wheat imports and, in 1932, adopted additional measures to reinforce their protectionist policies. In this latter year, even the United Kingdom abandoned its free trade policy and adopted some type of protective measures.

Market integration processes also took place in other agricultural and processed agricultural products. In the case of Mediterranean fruit and vegetables, which were hardly consumed outside of their area of production before the first wave of globalization, there was a strong increase in trade and intense international competition. As exports from Southern Europe increased, new producers entered the market, with California being the most noteworthy, seeking to win market share from the traditional producers (Morilla et al. 1999). Spain obtained a prominent leadership position when, over the first third of the twentieth century, it became the world's number one exporter, with its sales increasing more quickly from the end of the nineteenth century. Rising incomes in the more developed countries and technological change in agriculture specializing in these products were key to the growth of this trade. Spanish exporters also benefited from the increasing integration of international markets, especially through declining transport costs and, to a lesser extent, trade liberalization (Pinilla and Ayuda 2010). The results of the transatlantic competition between the Mediterranean countries and the new producers were varied. Thanks to its technological leadership, efficient marketing, and protectionist policies, California was able to seize the North American market from the Mediterranean producers. However, the latter retained the European markets, thanks to highly competitive prices despite a certain technological delay. Even so, the cost of losing the North American market, which had the highest growth rate in the world, was high. For Spain, which was the leader in the trade of these products, the cost was considerable. Considering only the orange market, in the counterfactual case of a nonexistent Californian product, Spain's GDP would have been 0.8% higher in 1910 (Pinilla and Ayuda 2009). In the case of raisins, the only example where the Californians eliminated the Mediterranean competitors, the cost was extremely high and their production in the old continent stagnated or decreased substantially (Morilla et al. 1999).

In other cases, the competition was mainly intra-European, such as the case of olive oil, where Italy specialized in the highest quality and value segment, while Spain dominated the lower-quality segment (Ramon 2000).

The trade of wine increased from the mid-nineteenth century (Anderson and Pinilla 2018). It grew strongly during the second half of the nineteenth century due to the increase in demand both in countries in the north of Europe that traditionally did not consume wine and in the destination countries of European Mediterranean emigrants. The arrival of the phylloxera plague in France led to imports of wine from Spain and other countries in order to supply its domestic market and maintain its exports. France ultimately took a leadership position as both an exporter and later as an importer of wine (Ayuda et al. 2018). The plague implied a progressive orientation in France toward the high-quality segment, while other Mediterranean countries drifted toward the low-quality segment of the market. French trade policy, which opened its duty-free doors to wine from its Algerian

colony, penalized the rest of the producers with high tariffs once the Algerian production was able to replace their exports beginning in the 1890s. The wines that entered France, the leading importing market, were highly sensitive to tariff policy. Each one percent increase in the tariff reduced the market share of imports by 1.8% in the long term (Pinilla and Ayuda 2002). From the end of the nineteenth century, new competitors entered the wine market from the new world, namely, Argentina, Chile, the United States, Australia, and South Africa. Before the last quarter of the twentieth century, the new competing countries did not threaten the European markets, but helped by their fierce protectionist policies, they were able to reduce the imports of European wines slightly. The use of gravity models to explain the determinants of wine exports has revealed their sensitivity to tariff increases (Pinilla and Serrano 2008). The wine market also shows how the end of the first wave of globalization was the result of deliberate measures taken by different countries to hamper trade flows. So the French, despite specializing in high-quality wines, suffered enormously from the tariff increases caused by the new Soviet State during the Depression and Prohibition in North America (Ayuda et al. 2018).

The textile fiber markets also operated on an international scale. In the case of silk, there were three main competing countries: Japan, China, and Italy. International demand grew, and the producers responded by expanding their supply, with Japan gaining the greatest market share. China fared the worst, due to its technological delay and poor competitiveness. The silk market illustrates how two of the three principal producers (Japan and Italy) took advantage of the opportunities of an expanding demand to improve their productivity and expand their exports (Federico 1997).

In other cases, such as the Anglo-Danish trade of butter, the integration between these markets took place extremely early (Lampe and Sharp 2015a).

Export-Led Growth

One of the most relevant consequences of the advance in globalization was a new division of labor on an international scale. In this respect, those countries of the world with a clear technological and industrial leadership position, such as Britain and other Western European nations, specialized in the production and export of manufactured goods. On the contrary, other regions of the world, such as the settler countries, Africa, and Asia, took advantage of the strong demand for agricultural raw materials and food to specialize their production and supply these goods to countries with higher levels of industrialization.

In order to be able to produce the products demanded by the industrialized world in the settler countries, the development of this specialization implied the displacement, confinement, or extermination of native peoples when they were colonized. In these countries, the agri-export sector acted as a driver of their economic development, and throughout the first wave of globalization not only did they spectacularly expand their frontiers and increase the size of their economies, but they also reached high levels of income per inhabitant. Before the First World War, Australia,

Argentina, Canada, and New Zealand were among those countries with the highest per capita income. However, the jump from this agri-export specialization to industrialization was not always straightforward, and the results were varied. The progress of Australia, Canada, and New Zealand after the First World War was clearly superior to that of Argentina and Uruguay. According to Willebald (2007), there was a positive relationship between higher degrees of inequality and production-trade specialization in goods of a low aggregate value and a lower capacity to absorb more advanced technology, which was a problem when industry became the leading sector. Therefore, in the second half of the twentieth century, the production structures, which had produced an undeniable success in the exporting era in some of these countries, limited the structural change and technological processes that were essential for the culmination of the industrialization and diversification of exports (Willebald and Bértola 2013).

Not all of the countries seeking to base their economic development on agricultural exports had the same success. Even expanding their exports, countries located in tropical areas of America, Africa, and Asia were not able to develop their economies sufficiently enough to close the gap with the industrial center of the world. The growth of exports was much slower, and the linkages with the rest of the economy were very weak. As a consequence, income levels remained low, and these economies did not experience far-reaching transformations (Aparicio et al. 2018).

Other countries combined the development of an export sector of agricultural raw materials and food with the beginning of their industrialization process. Therefore, some peripheral countries of Europe, such as Italy and Spain, combined an early specialization in the export of agricultural products to their neighbors in Northern Europe with the development of a slow industrialization process. Their position in the international markets of agricultural products was strong, and this sector made an appreciable contribution to their development (Federico 1994; Clar and Pinilla 2009)

Finally, the case of the United States is noteworthy. It experienced a rapid and far-reaching industrialization while simultaneously pushing its frontier ever westward to colonize an immense territory (Atack et al. 2000). This resulted in large increases in both grain and cotton production. The exports of only two products, cotton and wheat, constituted a substantial part of total US goods exported well into the nineteenth century (North 1966). This concentration of exports in only one or two products was also common in the settler countries (Anderson 2018).

Agricultural Trade in the Second Wave of Globalization

The Second World War dealt a harsh blow to trade, which had already been significantly affected by the Great Depression and the policies implemented during it (Hynes et al. 2012). South American agricultural exports contracted by about 40% during the war (Pinilla and Aparicio 2015). For the world as a whole, in 1948–1950, agricultural trade was still 4% lower than that of 1934–1938. At the beginning of the 1950s, trade once again exceeded the prewar level, although in 1952–1954, it had only grown by 9% with respect to the prewar level (González et al. 2016).

More important than the fall in the level of trade was that of the terms of trade, which experienced a considerable deterioration in the interwar period, during which there was a structural rupture in the series, and the improvement during the Second World War did not compensate for this decline (Ocampo and Parra-Lancourt 2010).

After the postwar recovery period, world agricultural trade displayed remarkable contrasts during the second globalization that started around 1950. On the one hand, it grew at an even faster rate than during the first wave of globalization, but on the other hand, it suffered a spectacular drop in its relative share of total international trade.

Agricultural trade grew faster in this period than during the first third of the twentieth century (Fig. 1). This growth was also higher than in the expansion phase during the second half of the nineteenth century, when it grew at an average annual rate of 3.7%, whereas in the second half of the twentieth century, it grew at a rate of 4.0% (Aparicio et al. 2009). A series of econometric studies have sought to explain the causes of this rapid growth with two different methodologies: time series and gravity models.

In the first case, the rapid growth of agricultural trade is explained mostly by the increase in income and, to a lesser degree, by the fall in real agricultural prices and exchange rate stability. Transport costs and tariff protection, measured through the nominal protection coefficient, remained stable in the long term without fostering agricultural trade (Serrano and Pinilla 2010).

The cliometric research based on gravity models provides us with richer information about this evolution. First, it offers a powerful explanation for the change in the composition of agricultural trade. The trend in trade shows a substantial loss in the relative importance of commodities, while processed and high-value products gained considerable weight. This explains why we can observe the home market effect in the processed and high-value products (not in commodities), which were closely related to the progressive concentration of the agri-food industry in the developed world. Therefore, the gravity equation has enabled us to verify that the increasing returns/product differentiation theory appropriately explains the growth in trade in high-value and processed products and that the homogeneous goods/relative factor abundance theory can explain trade growth in agricultural commodities. Finally, the group of high value-added products and processed foods benefited from greater trade liberalization, as we have seen. Thus, trade flows between high-income nations, where differentiated and reference-priced products were concentrated, benefited earlier from a progressive liberalization of regional markets. Beginning in the 1990s, these products enjoyed a more liberalized trade, with a new boost from regional trade agreements (RTAs) among economies of the South and liberalization, which the Uruguay Round produced for the food and drink industry. In contrast, the markets for traditional export groups and homogeneous goods, which characterize South-North trade flows, remained tightly controlled, and the GATT had no effect on the liberalization of their trade. This suggests that closed markets were a key factor in the decline in homogeneous goods trade flows, compared to the rise in the trade in differentiated products and reference-price goods (Serrano and Pinilla 2014).

In addition, the gravity model can be used to explain the important changes that have taken place in regional shares of agricultural and food product trade. A highly interesting contrast can be observed between Europe, particularly after the Treaty of Rome, and Latin America.

The European case is surprising from the outset. In the first wave of globalization, before the Second World War, Europe, led by England and the other industrialized countries, was the world's principal importer of agricultural products and food, accounting for approximately 60% of world imports. The share decreased steadily throughout the second half of the twentieth century, falling to less than 50%. By dividing these imports into inter-European and intra-European exports, we can observe two contrary trends. Trade between the member countries of the European Union (EU) began to grow quickly after the customs union was formed in the early 1960s. At the same time, agricultural imports from non-EU countries lost importance very quickly in relative terms, and at the end of the twentieth century, their percentage share of world imports was just half of what it had been in the 1950s. In absolute terms, these imports were much lower than those from EU member countries.

Before Second World War, Europe represented only 17% of world exports of agricultural and food products but by the end of the century accounted for almost 50%. Again, the explanation lies in the strong increase in trade between EU member countries (Pinilla and Serrano 2009). Gravity models once again help us to understand the causes of these trajectories. First, exports from EU countries from 1963 to 2000 were stimulated by their high concentration in products that had a home market effect, characteristic of a pattern of intra-industrial trade associated with the growing concentration of the international agri-food industry within the EU. The expansion of these countries' markets had a major impact. This proved to be even more important as a driver of exports than growth in their export markets as intense trade specialization in industrially processed agricultural and food products created economies of scale and generated a home market effect that increased export levels. Moreover, the development of the EU enormously affected the growth of imports from the countries joining it, and the slow growth of imports from outside countries was affected by the growing agricultural self-sufficiency of the EU. Models for intra-EU trade show that membership created trade between the partners (Serrano and Pinilla 2011a).

The evolution of the agricultural trade of Latin America constitutes a striking contrast to Europe. In the second half of the twentieth century, Latin American countries lost a substantial part of their share of worldwide exports of agricultural and food products. These countries specialized intensively in the export of commodities during the "first globalization," to the point where the excellent economic results achieved by some republics can be attributed entirely to export-led growth models (Martín-Retortillo et al. 2018). Disincentives for farm exports produced by import substitution industrialization (ISI) strategies followed by these countries partly explain the decline in Latin America's relevance as a partner in world trade.

Additional factors important in helping us understand what happened in Latin America have been identified by studies using gravity models. They highlight the importance of the profound regionalization of farm trade in this period. In addition, the failure of Latin American attempts to liberalize trade in the region delayed the

creation of trade until much later. Latin American countries failed to make any major changes in the composition of their farm and food exports until very late in the period, and as a result, they remained anchored to low-demand products. Moreover, the region's agro-export specialization fundamentally consisted of basic goods and did not benefit from any long-run home market effect. The high levels of protection facing Latin American exporters throughout practically the whole of the period made it difficult for them to perform better in their target markets. The exclusion of agricultural products from the GATT agreements until almost the end of the century imposed a high cost on countries specializing in farm exports. At the same time, the European customs union created a trade distortion that affected Latin American exports by removing trade barriers between EU partners and raising a tariff wall against outside imports (Serrano and Pinilla 2016).

Another important characteristic of the evolution of agricultural trade in the second wave of globalization is its loss of relative importance with respect to total world trade. While agricultural and food products accounted for 43.0% of total world trade in 1951, this share had shrunk to just 6.7% at current values by 2000. One of the most important reasons for this significant loss of importance is the relative fall in prices. This is evident when we consider the difference between the drop in agricultural trade in terms of value and the more moderate (albeit important) decline in terms of volume, which demonstrates an extremely serious fall in relative prices. The aggregate index of the real prices of agricultural and food products presents a structural break in the level (AO2) in 1976 and in the trend (IO2) in 1977, which suggests that they suffered the impact of the 1970s oil crisis with a lag. Thus, the deterioration in terms of the trade of agricultural and food products was strong and clear in the second half of the last century and especially impacted countries that specialized in the export of the most basic products (Serrano and Pinilla 2011b).

With regard to the causes of the loss of share in terms of volume, one reason was the generalized protectionism in the international markets for agricultural products (Anderson 2009, 2016). While other types of trade, such as manufacturing, enjoyed a greater multilateral liberalization of their markets, strong market intervention caused agricultural trade growth to be based on the proliferation and success of regional trade agreements, in addition to important changes in consumption patterns related to rising income levels. Therefore, the slower growth in farm trade had a lot to do with the significant fall in agriculture's share of world GDP. The smaller share of intra-industrial trade for the majority of agricultural products was also crucial. The home market effect for agricultural exchanges was weak, which explains why these markets grew less dynamically than those of manufactured goods and total trade (Serrano and Pinilla 2012).

Public Intervention in the Agricultural Sector

In the laissez-faire period, public intervention in the agricultural sector was scarce and highly focused on trade policy. Throughout the nineteenth century, the states adopted a fairly passive role with respect not only to agriculture but also in terms of

economic activity as a whole. One area where the states did take a hands-on approach was the creation of agricultural experiment stations, which appeared in several countries. The objective was for these centers to collaborate with agricultural producers, facilitating the adoption of the latest innovations. In some cases, their role was highly relevant.

In contrast, despite the liberal paradigm advocating free trade, there were varying degrees of tariff protection in many countries, particularly for wheat. In Europe, the first half of the nineteenth century was dominated by highly protectionist policies to safeguard national wheat production. The abolition of the Corn Laws and its effects on British agriculture aroused the interest of cliometricians.

Some studies indicated that the impact of these protectionist measures on British agriculture was only moderate until the 1840s. Williamson (1990) used a counterfactual model to argue that the protection of British grain markets had only a moderate impact on the domestic market. The liberalization arising from the abolition of these laws, within a context of robust demand, implied the rapid increase of exports to Great Britain from different countries. However, during the first post-abolition decades, prices remained more or less stable in the British market, although they tended to increase in the markets of the exporting countries (Gallego 2004). This demand was also favored by the fall in transport prices and trade liberalization (O'Rourke and Williamson 1999). However, some studies have given more importance to the trade liberalization processes or the reduction in other trade costs than the reduction in transport costs, at least until the last quarter of the nineteenth century (Jacks 2006). The trade liberalization processes, brought about through the signing of many trade agreements, were particularly important during that period (Lampe and Sharp 2015b). The technological innovations also contributed to a decrease in the production costs of the exporting countries and, from the end of the 1870s, grain from the Russian Empire, and the Americas began to arrive in Europe at prices that were lower than the production costs of the European farmers.

The so-called European grain invasion generated numerous responses across the continent, although the large countries, such as Germany, France, Italy, and Spain reacted by substantially increasing their tariffs on grain. However, other countries, such as the United Kingdom and Denmark, kept their markets open. The wide variety of responses has been explained, at least partially, by the fact that the shocks suffered due to the invasion were also very diverse, on both prices and income distribution (O'Rourke 1997). However, we should note that this protectionist reaction did not imply a general increase of tariffs on other agricultural products, nor was it essential for the survival of European agriculture (Federico 2005). The estimates of the nominal rate of assistance for several Western European countries show that the support received by farmers was very low until the First World War and only grew substantially in the 1930s (Swinnen 2009).

Until the 1930s, direct public intervention in agriculture was very low, although at the end of the nineteenth century, there were some cases that went against the laissez-faire policy, such as the federal intervention to control animal health in the United States, mainly through the creation of the Bureau of Animal Industry in 1884. This organization exerted substantial influence, and its actions to eradicate the principal

diseases that decimated the livestock population had considerable success (Olmstead and Rhode 2015). Interventions that sought to prevent price reductions were also carried out in the 1930s. These policies had far-reaching effects as a consequence of the Great Depression. The passing of the Agricultural Adjustment Act of 1933 marked a divide in the scale of public intervention in agriculture and had an enormous influence on future policies both in the United States and in other developed countries (Libecap 1998). On the other hand, the fixing of minimum prices for the purchase of produce from farmers required the restriction of this production and, therefore, implied a profound intervention, which completely distorted the functioning of the agricultural product market in the United States. We cannot find policies in any other country with such a high capacity to limit the role of the market in agriculture. However, regulatory policies also began to be extended, normally on a sectoral basis, as in the case of the regulation of wine production in France (Chevet et al. 2018).

The Second World War and the needs that it created for the warring parties increased government intervention in agriculture, and in many countries the regulatory measures of production, consumption, or prices were extended. These precedents are fundamental for understanding the policies that were designed after 1945, as the tendency to intervene persisted (Federico 2012b, 2017).

The North American policy implemented in 1933 was to have profound consequences for the functioning of the international market in agricultural products. Its objective in 1933 was to raise the purchasing power of most agricultural products to their 1909–1914 parity ratios (Olmstead and Rhode 2000). Gains in agricultural efficiency and output were not matched by a comparable advance in farm incomes. This farm income problem was soon perceived as structural rather than temporary, and intervention measures were implemented in order to raise and stabilize agricultural income (González et al. 2016).

Policy developments in rich countries over the period following Second World War tended to ignore the supply side and were mainly focused on raising farm returns through price supports. One paradoxical outcome of those policies was the stimulation of production, thus aggravating the problem of surpluses (Johnson 1987). The farm problem and the notion of an equitable income for those engaged in agriculture were at the heart of most policy statements in postwar industrialized countries. However, agricultural policy was also driven by other considerations. As Johnson has pointed out, these included national self-sufficiency or autarky for food, reducing balance of payment difficulties, and benefits to consumers in the form of an assured source of supply and stable prices.

As food shortages disappeared, price supports were maintained and even reinforced, thus revealing that the objective of sustaining higher incomes in agriculture was the major driving force behind policymaking. Of course, national farm policies strongly reflected the private and public interests underlying their national political economy systems. In the case of the United States, there is no doubt that postwar agricultural policy was deeply influenced by the farm lobby. These policies, which were traditionally justified as welfare policies for farm households, have been questioned in some cliometric studies. Spoerer (2015) has calculated that these

policies were much more beneficial to European agriculture than any welfare policy could have been. Rent-seeking behavior by agricultural lobbies emerged as a fundamental determinant of these policies.

International agricultural trade after Second World War was greatly distorted by domestic farm policies. Intervention was widespread among industrialized countries and was actually permitted by the set of international rules regulating trade. On the one hand, agricultural trade was severely restricted by import control measures, but on the other hand, it was actually expanded by the use of export subsidies and restitutions. World agriculture markets were in disarray because of the distortions in prices and trade, the substantial costs imposed on taxpayers and consumers, the inefficient expansion of farm output in the industrial countries, and its associated effects on developing countries (Tyres and Anderson 1992). In the GATT, which was the principal mechanism for reducing tariffs in the second half of the twentieth century, special rules were applied to agricultural trade, and agricultural protectionism was largely untouched. The GATT rules were adapted to the agricultural policies of the developed countries, particularly the United States. This meant that, in the European integration process, it was not necessary to adapt agricultural policy to international trade rules.

Countries tended to go from taxing to subsidizing agriculture depending on other sectors and the course of their economic development. Lindert (1991) identified the existence of two clear patterns. Developed countries tended to protect their agricultural sector with protectionist policies and direct intervention in the markets, regulating prices or establishing transfers to farmers (development pattern). Developing countries did just the opposite, taxing exportable-good agriculture and protecting import-competing agriculture (anti-trade pattern). This pattern has been quantitatively confirmed with the estimates of the nominal rate of assistance (NRA). The NRA is "the percentage by which government policies have raised gross returns to farmers above what they would be without government intervention, or lowered them, if the NRA is below zero" (Anderson 2009: 11). The figures are telling that the NRA was positive in weighted average terms in the developed world at least after 1955, the first year for which data are available. Thus, the public policies of developed countries increased farm incomes by 44% in Western Europe, 39% in Japan, and 13% in the United States in the years 1955–1959. In later years, support to farmers grew considerably, especially in Western Europe and Japan. The NRA estimates for European countries show a continuous growth from the beginning of the 1950s until they reached very high values after the implementation of the Common Agricultural Policy (Swinnen 2009). The pattern identified by Lindert has been verified econometrically as a quadratic relationship between the NRA and per capita GDP. In developing countries with low levels of income, an increase in income reduces the NRA, while for higher-income levels, the NRA increases (Anderson et al. 2010). During these years in developed countries, electoral regimes and coalition governments also influenced agricultural policies. The adoption of proportional representation in Europe is related to heavier support for farmers (Fernández 2016). In developing countries, however, the pattern after Second World War was the direct or indirect taxation of farmers due to the implementation

of import-substituting industrialization strategies, which led to the overvaluation of their currencies. The consequence was the depression of price incentives so that their farmers turned toward export markets (Anderson 2009).

Agrarian Institutional Change

The analysis of institutional change has been at the heart of the research of economic historians in recent decades, undoubtedly driven by the theoretical and empirical development proposed by Douglas North (1991, 1999). The agricultural institutions have experienced extensive transformations over the last two centuries. Even when the discussion addresses how much the institutional change has contributed to the increase in production, there is broad consensus regarding its significance (Wallis 2018). The configuration of a market economy in which the economic agents respond to the price signals is decisive in not only explaining the growth in agricultural output in Europe and other countries colonized by the Europeans since the beginning of the nineteenth century but also for understanding the processes of technological change, which enabled a substantial increase in productivity.

Property Rights, Agrarian Contracts, and Labor

In the case of agriculture, the redefinition of property rights over the land and transformations in agricultural contracts were highly important (Federico 2014; Libecap 2018). From the eighteenth century and throughout the nineteenth century, the majority of European societies considerably modified an institutional framework in which the property rights over land were not clearly defined or were shared and frequently limited the capacity of landowners to act. The long shadow cast by seigniorial rights still extended across many European countries. Therefore, one of the primary objectives of the liberal revolutions, beginning with France, was the establishment of an institutional framework characteristic of a market economy. In the case of land, this implied ending the partitioning of rights where this system still existed and ensuring the capacity of owners to freely dispose of their land and act according to their interests, with clarity regarding their ownership rights. Church property rights were undermined in Catholic European countries, resulting in large areas of land coming on to the market.

The agricultural contracts have also changed over the last two centuries, displaying an enormous spatial variability. The types of contracts that exist are endogenous to each society, and cliometric research has sought to explain them accordingly. It is well known that the establishment of market-economy-style institutions did not imply that agriculture would thereafter be organized principally through large companies using salaried workers. On the contrary, family farms not only survived, but they became the dominant form of organizing agricultural production. Even so, organizational forms were varied and benefitted from coexistence advantages. Large farms that used salaried workers coexisted with family-run farms

where the land was either owned or leased. Elsewhere, particularly in Africa and Asia, the plantations, usually owned by European colonists who employed local labor, gained considerable weight. However, after decolonization they began to lose significance and were replaced primarily by small family farms due to the combination of their inherent efficiency, a more level playing field in terms of policy support, and institutional innovations to coordinate their production (Byerlee and Viswanathanm 2018).

The study of lease contracts has attracted much attention. Decades ago this was seen as feudal survival and a type of inefficient contract. However, research has since revealed them to be perfectly rational, adapting to the circumstances and characteristics of the countries where they prevailed, such as the crop mix, the social environment, or the characteristics of the agents involved (Carmona and Simpson 2012; Garrido 2017). In short, agriculture has special characteristics derived from the difficulties of obtaining perfect information, the risks assumed, the supervision costs, and, in general, the transaction costs (Federico 2006). In this way, the choice of contract has been explored in different cliometric studies. In their study on the variety of contracts – wage payment, crop sharing, and land rental – in the south of the United States, Alston and Higgs (1982) concluded that their variations over time and space depended on the relative resource endowments of the contracting parties, the prevailing risk conditions, and the transaction costs of alternative contractual arrangements. Federico (2006) shows that the total share of tenant land, under both sharecropping and fixed-rent contracts, followed a significantly declining trend due to the combined outcome of economic motivations, institutional changes, and specific policies, such as the agricultural reforms implemented in the twentieth century. In Western Europe, this decline was particularly important, most of all during the second half of the twentieth century (Swinnen 2002).

The case of Spain also shows how the number of landless workers decreased as a result of the falling ratio between land prices and rural wages. This made plots of land cheaper for landless workers to rent and buy and led to a structural change that drained the rural population from the countryside (Carmona and Rosés 2012; Carmona et al. 2018). This process did not work that well in southern Spain where landless laborers continued to constitute a significant part of the agricultural population. In short, the modernization of agriculture, with changes in technology, the prices of factors of production, or the products themselves could also have contributed to the disappearance of sharecropping contracts that had prevailed for a long time.

Considerable social conflict surrounded the agricultural contracts and the existing pattern of land ownership. In some countries, criticism of the existence of large properties or tenants asserting their rights to be owners generated serious social conflict. During the interwar period and after Second World War, a variety of agricultural reforms were implemented in different countries, resulting in the transfer of land ownership from large landowners to small farmers, landless workers, or tenants (Federico 2005). Some had a significant impact due to the volume of land transferred, such as Mexico during the 1930s and Japan between 1947 and 1950, when almost 40% of the land changed hands (Hayami and Yamada 1991). However,

the most important land ownership transfer processes were the collectivizations that took place in the Soviet Union, the Eastern European countries after 1945, and China after the communist party came to power. The collectivization of Soviet agriculture was the first that was carried out, and it served as a model for the other cases to follow. Soviet leaders justified this as the inevitable outcome of the recurring procurement crises during the years of the New Economic Policy (NEP). Gregory and Mokhtari (1993), however, argue that they were really caused by state pricing policy. The accelerated industrialization as a major economic objective was another justification of this collectivization process, although in reality its contribution to economic growth was very small and could have been achieved under the NEP framework (Allen 2003a).

Another fundamental aspect in the institutional change in agriculture was the elimination of coercive ways of providing work. In Eastern Europe, serfdom still existed in the nineteenth century and was eliminated over the course of that century (Federico 2014). In Imperial Russia, this abolition produced substantial increases in agricultural productivity, industrial growth, and peasant living standards (Markevich and Zhuravskaya 2018). Outside of Europe, slavery was commonplace in many regions, though it was eliminated throughout the nineteenth century. The United States is not only the best case study but was a favorite subject for early cliometricians (Olmstead and Rhode 2018; Sutch 2018). One of the foundational studies of cliometrics (Conrad and Meyer 1958) broke with firmly established beliefs by arguing that slave labor in the Southern United States was a profitable activity. The investment in slaves provided returns that were comparable or higher than the alternative investments (Fogel and Engerman 1974; Yasuba 1961). Other studies reveal that there was no economic reason that would have led to the disappearance of slavery in the South (Sutch 1965), although the growth prospects of the southern economy were not promising due to their incapacity to foster innovation and economic diversification (Wright 2006).

Agricultural Cooperatives

The emergence and development of agricultural cooperatives from the end of the nineteenth century in western countries led to the practice of collective purchases of new innovations, such as fertilizers or machinery. Cooperatives also provided credit for their members and helped with the processing, marketing, and distribution of farm products. These new forms of cooperation sought to improve the competitive possibilities of the farmers in response to the technological change or the problems derived from the agricultural depression at the turn of the century. In this way, family-run farms sought to better adapt to the new economic conditions arising at the end of the nineteenth century.

Coperatives enjoyed highly unequal degrees of success and explaining that a variety has occupied the attention of many economic historians. Some have identified pre-existing social capital as the key to explaining the unequal performance of agricultural cooperatives (Fernández 2014; Guinnane 2001; Henriksen 1999). The

trust between farmers emerged as a decisive factor for understanding these differences, with a whole variety of factors that could determine it. The existence of networks that allow for social interaction may also have been favored by the existing common lands and irrigation communities, such as in Spain, providing the social networks that facilitated the building of mutual trust (Beltrán Tapia 2012). The existence of this previous social capital, however, is not a guarantee that cooperatives would emerge, as other factors could prevent this (Garrido 2014; Henriksen et al. 2015). Other factors that affected the performance of cooperatives include the existing institutional framework, the predominance of small- and medium-sized family farms, the existence of well-trained human capital, the density of production, and product specialization (Henriksen et al. 2012).

The characteristics of the products were also important for the spread of cooperatives. They were much more important in the production and marketing of butter in the north of Europe than in that of wine in the south. Fernández and Simpson (2017) explain this contrast by pointing out that while in some products cooperative production could improve product quality and competitiveness in high-value markets, wine cooperatives produced mostly low-quality wine due to environmental conditions and measurement problems. However, specializing in a certain type of production did not guarantee the success of cooperatives. The successful Danish case in butter production contrasts with the poor results in Ireland (Ó Gráda 1977). The existence of serious social and political conflict on the island generated distrust between potential partners, in contrast to the religious and cultural homogeneity of Denmark (O'Rourke 2007).

The Privatization of the Common Lands

Finally, to conclude this section, we will analyze the advances made in the understanding of the role played by the common lands in economic development. In early cliometric studies, the privatization of the communal regime was seen as a precondition to foster economic growth (McCloskey 1975; North and Thomas 1978). Private property rights were believed to be essential for stimulating innovation and investment and therefore generating growth. They also indicate that an inevitable consequence of the existence of common property regimes was resource overexploitation. However, since the 1980s, the essential points of these arguments have been thoroughly revised. Common property regimes can be efficient and sustainable, which, in turn, has led to the reassessment of the possible role that they have played in economic development (Allen 1982, 1992; Clark 1998; Van Zanden 1999; De Moor et al. 2002, De Moor 2009; Ostrom 1990; 2005).

As a result, the link established between the enclosures and the British agricultural revolution has also been questioned. Allen (1992, 1999, 2003b) reveals that before the parliamentary enclosures began, the agricultural revolution was already underway, and agricultural productivity growth had also taken place on open fields. He also notes that the privatization of the common lands deprived the lower rural classes of their rights of access, which, in many cases, gave rise to the worsening of

their standard of living, forcing them to migrate to the towns (Humphries 1990). It is also important to highlight how this series of more recent studies has emphasized the fact that the commons were not open-access resources. They were regulated by local communities by way of a series of formal and informal rules that guaranteed their sustainability (De Moor 2009; Beltrán Tapia 2016).

The case of privatization of the common lands in Spain has been used to highlight that this process did not promote the growth of agricultural productivity. In contrast, it is associated with deteriorating living standards of the poorest segment of the rural population (similar to the case of Great Britain), lower educational attainments due to the limited capacity of town councils to finance primary education, and the deterioration of social capital (Beltrán Tapia 2016).

Conclusion

The emergence of cliometrics in economic history revolutionized this discipline (Haupert 2015). From the beginning of the new economic history, research in agriculture has been important to this new methodological perspective. Although this rupture with the traditional methods used by agricultural historians emerged in the United States, it has since spread to other continents, particularly Europe, and since the 1990s has grown in importance. Today a large number of economic historians base their research on economic theoretical foundations and use econometric methodology. The organization of three international conferences over the last decade to discuss the progress made in this field has established agricliometrics as a growing field of study.

Cliometricians have addressed an enormous variety of topics in the study of agricultural history, but they have concentrated a good part of their efforts on a few main subjects, primarily the study of the evolution of agricultural production and the role played by the increased productivity in its growth. The studies carried out highlight the different speeds in the growth rates of production over the last two centuries and their regional differences. Furthermore, the increasing role of the gains in productivity increase is evident, particularly after the Second World War.

The relevance of the two waves of globalization and their effects on different economies help explain the interest generated by the analysis of agricultural trade and the articulation and development processes of the agricultural product and food markets. Agricultural products played a key role in the first wave of globalization, and the analysis focuses on the integration processes of the different product markets and the drivers of these processes. In the second globalization, although agricultural trade grew even more quickly, its relative weight with respect to total trade fell sharply due to the low elasticity of demand for agricultural products, the diminished importance of its intra-industrial trade, the lower degree of differentiation of its products, and the high level of protectionism, which contrasts with the strong liberalization experienced by manufactured products.

The growing role of public intervention from the 1930s oriented many studies toward the role of government both in relation to trade policies adopted and

agricultural policies followed. Trade policies were relaxed until the end of the nineteenth century and the grain invasion experienced by Europe, and consequently protectionism was increased. However, it was the Great Depression of the 1930s that led to the collapse of the first globalization and had a profound effect on international agricultural trade. The high levels of protectionism were maintained during the decades following the Second World War, and only at the end of the twentieth century were tentative attempts made to liberalize trade.

Finally, the analysis of different agricultural institutions, such as ownership, agricultural contracts, privatization of common lands, and cooperatives, has also constituted a fertile field for cliometric research. This work highlights the importance of institutional change and the reasons explaining the continuity or modification of certain agricultural contracts as well as the unequal growth of agricultural cooperatives.

Nutrition, the Biological Standard of Living, and Cliometrics

Lee A. Craig

Contents

Abstract

In much of the world today, populations are richer, taller, and enjoy longer healthier lives than their counterparts in the past. Cliometricians debate the extent to which this "health transition" was the result of nutritional improvements or other factors, such as the increase in public health infrastructure that followed mastery of the germ theory of disease. Although the long-run trend in health was positive, in the nineteenth century, many Western countries experienced cyclical downturns in the biological standard of living, the so-called antebellum puzzle. While the long-run trends in the growth of real GDP, income, and wages were positive, as the presence of the antebellum puzzle suggests, the onset of industrialization was accompanied by an increase in inequality, the stagnation of the expectation of life at birth, increases in morbidity, declines in mean adult stature, and an erosion in the consumption of net nutrients. Taken together, this experience has been labeled the "Malthusian squeeze."

Introduction: Nutrition and the Standard of Living

In the opening passage of his *Structure and Change in Economic History*, Nobel Laureate Douglass North states: "I take it as the task of economic history to explain the structure and performance of economies through time" (North 1981, p. 3). As an indicator of an economy's performance over time, economists typically use real gross domestic product (GDP), which is the value of final goods and services produced in an economy, usually on an annualized basis. The word "economy" in this context refers to the geographical boundaries of a nation state. Mathematically, real GDP is the sum of the product of prices (adjusted for inflation, which makes the measure "real") and the final quantities of goods and services produced; thus, GDP measures production rather than consumption.[1] Writing nearly a century and a half before the creation of the national income and product accounts, of which GDP is a key component, Adam Smith admonished his readers that, when it came to comparing the performance of one country's economy relative to that of another, "Consumption is the sole end and purpose of all production" (Smith 1976, vol. 2, p. 179). Here, Smith was grasping for a concept economists would subsequently refer to as the "living standard."

Since real GDP reflects aggregate economic activity, a geographically large, but poor, country might have a GDP that exceeded that of a small, but rich, country, thus masking the very performance North would have us explain. In response to this "size problem," economists use real GDP per capita as the typical indicator of the living standard within a modern nation state, and the growth of this measure is assumed to reflect improvements in the standard of living. Another Nobel Laureate, Simon Kuznets (1966) – referred to as the "patron saint" of national income accounting[2] – popularized the expression "modern economic growth," by which he meant real GDP growth that exceeded population growth by enough, and for long enough, that periodic downturns would not disrupt the long-run improvement in the standard of living, as measured by real GDP per capita. In Western civilization, before the onset of modern economic growth in the early nineteenth century, the long-run average annual compounded rate of growth of real GDP per capita was essentially zero (Clark 2007, p. 2). Only with the Industrial Revolution, so the argument goes, did the West escape from the Malthusian world in which short-run economic growth was eventually matched by population growth. In the United States, to offer one example of an early-developing country, real GDP per capita expanded at 1.3% annually from

[1]The difference between the production of goods and their consumption is captured, at least partly, by the "change in business inventories" component of GDP.

[2]Feldstein 1990, p. 10

1800 to 1860, 1.6% from 1860 to 1910, and it has grown at 2.0% annually over the past century.[3]

Despite the 30-fold increase in real GDP per capita over the past two centuries or so, Kuznets himself recognized that the use of GDP to measure the standard of living was not without its faults. Specifically, real GDP per capita failed to reflect the distribution of income, and it ignored many "quality-of-life issues."[4] In his Nobel lecture, Kuznets noted that industrialization, and the high rate of economic growth that came with it, could have a negative impact on the standard of living more broadly defined (1973, p. 257).

In the late 1970s, one of Kuznets's students, Robert Fogel, yet another Nobel Laureate, and some of his colleagues and students, began to explore the use of biological indicators of the standard of living, many of which were tied to nutrition (Fogel et al. 1979). Among the most prominent of these indicators were mortality and human stature. Survival, as captured by infant mortality rates and life expectancy, reflected the ultimate standard by which the quality of life could be judged. Stature represents a more subtle measure. The consumption of net nutrients, i.e., those beyond that exhausted during work or fighting disease, determines whether an individual will achieve a genetically programmed height potential and, more indirectly, life expectancy. Although like real GDP per capita, stature allows researchers to characterize economic performance, it differs from GDP in that stature more directly reflects consumption, specifically the consumption of nutrients, and the physical costs (i.e., work and disease) associated with the productive activities captured by GDP. As such, it better reflects the distribution of consumption and living standards.

Of course, the consumption of net nutrients is also affected by the time and intensity of labor, as well as by working and living conditions. Physically demanding occupations and those that require more intense effort increase these demands and thus leave fewer nutrients for growth. Disease also imposes demands on the body, and it spreads more easily in urban and industrial environments relative to rural and agricultural ones. It follows that mean adult stature offers a valuable indicator of a population's biological standard of living. In other words, it is a "cumulative indicator of net nutritional status over the growth years" (Cuff 2005, p. 10).

Today, as measured by real GDP per capita, populations in developing countries are richer, on average, than their counterparts in the past; they are taller; and they enjoy longer healthier lives. Fogel and Costa (1997) and Floud et al. (2011) characterize the increase in stature and the reduction in mortality that accompanied it as the product of the "techno-physio evolution," and Costa (2013) refers to the extension of the life span and improvements in health as the "health transition." This chapter reviews the research on nutrition's role in these important changes.

[3] Williamson 2013

[4] It also omits many types of economic activity, though this was not a point of emphasis for Kuznets.

Nutrition, the Health Transition, and the Techno-Physio Evolution

The expression "health transition" refers to improvements in a set of outcomes that exemplify the health of a population. One body of research on the transition has focused on the reduction in age-specific mortality, which resulted in an increase in life expectancy. From the late nineteenth century through the middle of the twentieth century, among the countries that experienced an increase in life expectancy, the largest decreases in mortality occurred at the youngest ages. As Haines and Steckel observe, "The reduction in mortality reflected largely a sharp decrease in mortality due to infectious diseases. . .the young, especially infants and children, who had suffered the highest fatality rates from many of these diseases, were the principal beneficiaries of the sharp reduction in their incidence" (2000, p. 647). Stolnitz (1955) was among the first to argue that, because the mortality declines were geographically widespread, at the macro-level, the mastery of the germ theory of disease, rather than nutritional improvements, must be among the causes of the decline. This led scholars who followed Stolnitz to largely attribute the increase in life expectancy to improvements in health-care technologies including both science-based medical care, such as vaccinations, and public health infrastructure (Preston 1975).[5] Subsequent micro-level research on clean water and sewer systems, to offer examples of the type of infrastructure likely to reduce mortality, supported this position (Troesken 2004). Deaton (2003, 2006) supports it further by noting that "it is clear that public health measures, particularly the provision of clean water and better sanitation. . .were the fundamental forces for mortality reduction during the century from 1850 to 1950" (2006, p. 110).

The mortality declines resulting from mastery of the germ theory of disease leave in question the net impact of these changes on the overall morbidity of a society. The early improvements in public health technologies largely eliminated infectious disease as a killer among the young, which, holding other factors constant, puts downward pressure on overall morbidity while increasing life expectancy. At the same time, the increase in life expectancy increased the incidence of chronic morbidity among the (now more numerous) elderly, leaving the net impact on morbidity ambiguous, a debate about which we will say more below.

In contrast to the view that the health transition was largely one of technological change in medical care and public health, which was supported primarily by public spending, McKeown (1976) points out that much of the decrease in mortality came before the major medical breakthroughs, and so he places a greater weight on the role of nutritional improvements, which occurred earlier than those associated with medical care, a point conceded, if grudgingly, by Deaton (2006, p. 110).[6]

[5]It was this article that generated the famous "Preston curve," which shows life expectancy as a function of income (or real GDP) per capita. The first derivative of the resulting function is positive, but the second is negative, suggesting that, beyond some point, increases in income do not lead to further increases in life expectancy.

[6]To be fair, Preston also mentioned nutrition as a causal element; to wit, "Income, food, and literacy were unquestionably placing limits on levels of life expectancy. . ." (1975, p. 240).

McKeown's position is supported by Fogel (2004) who emphasizes the "synergism" between nutrition and income: More net nutrition yields more productive workers, who in turn earn higher incomes, which are used to purchase more nutrition and so forth. Furthermore, as Floud et al. (2011) note, there is an intergenerational component to the synergism between nutrition and income, arguing that the nutritional status of one generation determines the life span and productivity (and hence income) of the members of that generation, which in turn determines, at least partly, the nutrition, life span and productivity of the next generation, and so on.

This "supremacy of nutrition" argument forms the foundation of the explanation in Floud et al. of the "techno-physio evolution." It is based on what Komlos refers to as *Homo sapiens*' "evolutionary advantage," which is humankind's capacity to "adapt to the availability of nourishment" (2012, p. 4). In short, Floud et al. and Komlos reject the Malthusian rhetoric that framed much of the earlier debate on these issues. The standard juxtaposition of a Malthusian world, with high death rates, no understanding of the germ theory of disease, and no public health spending or technologies to speak of, with a post-Malthusian world, with low death rates, a mastery of the germ theory, and extensive public works projects aimed at public health, is a false one. Nutrition is the key to the techno-physio evolution and health transition because death was not the only, or even the main, biological response to nutritional want. Rather than having a mass die-off in the face of want, humans could simply be smaller and less healthy.

Indeed, by detailed estimation of the supply and demand of nutrients in the past,[7] and the use of Waaler curves – which plot height, weight, and mortality risk – Floud et al. show that populations in the past adjusted their size to the availability of nutrients. But it is important to note that being smaller also meant being weaker, sicker, and more likely to die earlier. As one reviewer summarized this position, "In other words, smaller was not equal. Malthus was right to focus on the misery of past populations. His model just did not well reflect all of the dimensions of that misery" (Craig 2013, p. 114).

The late nineteenth- and early twentieth-century period was also one marked by Kuznets's modern economic growth, as well as the reasonably steady growth of agricultural production in much of the early-developing world. The synergy between these trends – which resulted in the reduction in morbidity and mortality, as well as the growth of labor productivity and incomes from the Industrial Revolution (and some scholars would argue an agricultural revolution that either preceded or accompanied it) – explains the techno-physio revolution and much of the health transition. However, a challenging "food puzzle" remains to be explained. According to Clark et al. (1995), the puzzle is that, between 1750 and 1850, a period during which the techno-physio evolution was underway, the British population and incomes increased much more rapidly than food production. In evaluating various explanations of the puzzle, Clark et al. focus on changing patterns in consumption. Specifically, they argue that as populations became more urban, they increased their

[7]Which involves allocating nutrition across various physical activities.

consumption of certain processed foods, including alcohol, tea, and sugar, and their solution to the puzzle rests on a combination of variations in the income elasticity of food and changes in the relative prices of various foods and beverages. In contrast, Floud et al. argue that the income elasticity employed by scholars looking at the puzzle is too high, because, during the early phase of industrialization, incomes increased more rapidly than the physically smaller populations at that time could increase their consumption of nutrients. That is, they were too small to consume enough additional nutrition to justify spending their – now higher – incomes on food. It follows that the high-earning urban workers and their families increased their consumption of other goods, including alcohol, caffeine, and sugar.

These issues have public policy implications. For those who place the weight on public-sector spending for scientific medical research and public health infrastructure, the government, rather than the market, is the key to increasing the biological standard of living. Easterlin notes that, in societies that eventually broke out of the Malthusian trap, historically, "free market institutions have functioned poorly to control major infectious diseases" and hence mortality (2004, p. 125). Floud et al. do not disagree that government played an important, and positive, role in improving the consumption of nutrients. They argue that from the dawn of the early modern era, famines in the West were "man-made rather than natural disasters." Nutritional crises occurred "not because there was not enough grain to go around, but because the demand for inventories pushed prices so high that laborers lacked the cash to purchase the grain."[8] Governments lessened the severity of the crises by intervening in the markets for food, primarily through price controls and the pooling of output in public granaries. Thus, the authors conclude that "By the start of the nineteenth century, famines had been conquered in England, not because the weather had shifted, or because of improvements in technology, but because [of] government policy. . . ."[9]

The Biological Standard of Living and the Antebellum Puzzle

The debates concerning the source of the techno-physio evolution and the health transition tend to focus primarily on the long-run trends in the underlying indicators. However, a number of Western countries experienced cyclical downturns in the biological standard of living during the nineteenth century. In the United States, for example, the mean adult stature of native-born white males declined by roughly 2.5 cm between 1800 and 1860 (Haines et al. 2003), a period during which real per capita GDP grew at a robust rate by historical standards (1.3% per annum). Mean stature further eroded after 1870, bottoming out in 1880 (Treme and Craig 2013). Margo and Steckel (1983) and Komlos (1987) were among the first to explore this

[8]Floud et al. 2011, p. 117

[9]Floud et al. 2011, pp. 116–118

deviation from the long-run trend in the biological standard of living, an event which Komlos and Coclanis (1997) labeled the "antebellum puzzle."

The discovery of the erosion of the biological standard of living in the United States during the early decades of the nineteenth century led scholars to explore the trends and cycles in other countries that were experiencing the onset of modern economic growth during the same period. These investigations found that, as was the case in the United States, the behavior of height was cyclical in many countries. A common pattern was that mean adult stature increased early in the nineteenth century, decreased mid-century, and began to increase again near the end of the century. The magnitude of the downturns varied from country to country. In the United Kingdom, the difference in adult stature between birth cohorts of 1810 and 1850 was almost 5.8 cm; the Netherlands experienced a downturn of 2.5 cm between 1830 and 1860; in Denmark the decline was 1.7 cm between 1820 and 1850; in Sweden the decline was 0.3 cm between 1830 and 1840 (Treme and Craig 2013, Fig. 1).[10]

Explanations of the antebellum puzzle focus on four factors: (1) a decline in the mean consumption of net nutrients, (2) a growing inequality in the distribution of income, (3) Kuznets's "negative results" associated with industrialization (including an increase in the intensity of work) and urbanization, and (4) a deterioration in the epidemiological environment resulting from improvements in transportation and urbanization.[11] The last two of these we consider below, in the section on technological change; however, items (1) and (2) we consider here.

With respect to the trend in net nutrition, in his path-breaking study of the nutritional status of West Point cadets, Komlos argued that "nutritional intake was declining [in the United States] in the late antebellum period. The availability of nutrients declined because food output did not keep pace with the demands placed upon it. . ." (1987, pp. 909–910). He estimated that the per capita consumption of nutrients declined by roughly 10% during the 1840s (1987, Table 8). That position was subsequently challenged by Gallman, who argued that "diet surely improved – and importantly – between the 1820s and the1850s" (1996, p. 199). Following subsequent debate in the literature, Komlos and Coclanis (1997) showed that an important feature of the period was a change in the relative prices of nutrients, which was caused by the commercialization of agriculture and which in turn caused households to substitute out of the consumption of meat, a key source of protein, and into carbohydrates. Evidence provided by Craig and Weiss (1997) on the commercialization of agriculture, and Craig and Hammond (2013) on the allocation of nutrients between free and slave populations, is broadly supportive of the Komlos and Coclanis argument.

As for the argument that the distribution of income became more unequal during the period, there are two related issues: First, did income in fact become more

[10]Interestingly, US slaves and the very rich did not experience a downturn in the biological standard of living (Craig and Hammond 2013; Sunder and Woitek 2005).

[11]This list is broadly consistent with, though not identical to, that found in Komlos (1987, p. 905).

unequally distributed, and second, if it did, then how exactly did that fact manifest itself in the erosion of the net nutrition of the US population? The evidence collected and analyzed by cliometricians would seem to support the proposition that wealth (and probably income) became less equally distributed over the course of the nineteenth century (Lindert and Williamson 1980, pp. 33–95). Of course, that observation still leaves one with the question of how the growing inequality led to the erosion of net nutrition for much of the population. Although the income elasticity of food tends to be relatively low, it is positive, and mean incomes and wealth were rising during the period; thus, food intake should have increased, as long as the food supply kept pace, which Komlos argues it did not. While that issue remains much debated, less controversial is the Komlos-Coclanis argument that changes in the relative price of nutrients, with that of meat and dairy products outpacing grains, caused farm families to substitute out of protein-laden products, which were more likely to promote adult stature, and into grains. In short, agricultural output was increasing; the prices of farm products were falling; and mean wealth and income, as measured by real GDP per capita, were rising, but this increase was disproportionately enjoyed by those in the richer tails of the distributions of wealth and income. For those further down the socioeconomic ladder, changes in the relative price of nutrients (increasing for protein-heavy foods, decreasing for carbohydrate-rich foods) caused the substitution effect to overwhelm the income effect and, for much of the population, led to a reduction of the net consumption of nutrients. Thus, the changing distribution of income and the changing relative price of nutrients together countered the positive impact of modern economic growth and led to the erosion of the biological standard of living.

Nutrition, Stature, and Income

Komlos's path-breaking microlevel study of the heights and weights of West Point cadets highlighted the relationship between nutrition, stature, and real output. Two important questions emerged from that study. One concerned the empirical relationship between net nutritional intake during the growth years and adult stature: Specifically, at the margin, how much net nutrition would be necessary to generate an additional centimeter in adult stature? The second was, again at the margin, how much additional real output would that marginal centimeter yield?

Unfortunately, the scarcity of data that would allow the matching of access to nutrients with individual consumers prohibits a detailed study of the type that would be ideal for answering those two questions. However, employing the sample of Union Army recruits compiled by Fogel et al. (1979) and microlevel data from the US Censuses of Population and Agriculture, Haines et al. (2003) were able to match the availability of nutrients in the county in which a recruit was born, and other variables, with the recruit's adult stature. Their argument was that recruits who grew up in counties that generated a "surplus" of food were more likely to have access to nutrients during their growth years and therefore should be taller as adults. The model they specified was:

$$\text{Height}_i = f(\text{Nutrition}_i, X_i) + \varepsilon_i \quad (1)$$

where Height_i is the adult stature of the ith Union Army recruit, Nutrition_i is the daily nutritional surplus generated in the county in which the recruit was born,[12] X_i is a vector of other location or individual-specific variables that would be expected to influence adult stature, and ε_i is an error term distributed $(0, \sigma^2)$.[13]

When it comes to generating stature, some nutrients are better than others. Baten and Murray (2000) show that protein is a particularly important component of the nutrition-stature relationship. Thus, Haines et al. focused on surplus protein production as their measure of access to nutrition. Their results suggest that being born in a county that generated a daily agricultural surplus equal to one-half of one standard deviation above the mean for US counties in 1840 (roughly 35 g of protein per capita, the equivalent of 120 g of beef or ten slices of whole wheat bread) would have yielded an additional 0.125 cm in adult stature (Haines et al. 2003, p. 405).

As for the relationship between income and stature, using national-level data, Steckel (1995, p. 1914) estimated the following equation:

$$\text{Height}_j = g(\text{Income}_j, Y_j) + \mu_j \quad (2)$$

where Height_j is the mean adult stature of the jth country, Income_j is per capita income in the jth country, Y_j is a vector of other country-specific variables, and ε_i is an error term distributed $(0, \sigma^2)$.[14]

The results indicate that, at the mean, the height elasticity of income is between 0.20 and 0.25. Craig et al. (2004) inverted this relationship to find the impact of stature on per capita income. Combining the coefficients from Haines et al. and Steckel, Craig et al. estimate that an additional 3.5 g of protein per capita per day, roughly a slice of whole wheat bread, would have generated an additional 0.0125 cm in mean adult stature, which would have in turn generated an additional 0.05% in national income (more than $2,000 per person in the United States today).[15] It is important to note that this estimate represents a permanent increase in income, not simply a one-time shock. The long-run impacts on the standard of living from these improvements in nutrition are arguably quite large by any reasonable comparison.

[12]As defined by Atack and Bateman (1987), this measure represents the surplus of nutrients beyond that consumed by the county's human and livestock populations.

[13]The other variables reflect the impacts of urbanization, the individual's occupation, the wealth of the region in which he grew up, and a dummy variable capturing whether or not the region had access to water or rail transportation.

[14]The other variables include or reflect the impacts of wealth, region, urbanization, and the age distribution of the population.

[15]Steckel estimated stature as a function of income; thus, this coefficient represents the inverse of his estimate.

Nutrition, Mortality, and Morbidity

A considerable body of research links the health transition with the mortality transition. Specifically, the expectation of life has increased dramatically in both early- and later-developing countries. (In the United States, for whites, it has gone from 39.5 in 1850 to 78.9 today, whereas in Mexico, to offer an example of a later-developing country, the figure has risen from 25.3 to over 70 today (Haines and Steckel 2000, pp. 696–698)). As noted, McKeown (1976) emphasized the role of nutrition in this improvement, and the findings of subsequent microlevel research indicate that historically there was a strong relationship between nutrition and longevity (Cuff 2005; Haines 1996). For example, US counties that generated agricultural surpluses, as defined above, had mortality rates that were 30% lower than those in deficit counties (Haines et al. 2003, p. 394).

Despite the unambiguous long-run positive trend in life expectancy, just as was the case with stature, life expectancy declined across many countries in the mid-nineteenth century. In the United States, life expectancy at age 20 declined by roughly 6 years during the first half of the century (Pope 1992), and, again, as was the case with stature, at least some of this decline was associated with the erosion in the consumption of net nutrients (Floud et al. 2011; Komlos 1987, 1996).

The scholarly work on trends and cycles in mortality should be reviewed in light of related work on morbidity. Research on morbidity tends to follow one of two paths. One path traces the mortality-disease nexus. Into the nineteenth century, outbreaks of infectious diseases were often serious enough and/or widespread enough to bring about substantial increase in death rates. According to Flinn, bubonic plague was the most effective and persistent killer, with outbreaks that "moved around Europe throughout most of the [early-modern] period. . .there were few years when the disease was not attacking somewhere" (1981, p. 51). Epidemics that resulted in an increase in the death rate tended to disrupt the economy directly through the labor market, in which the lost production of the sick and the dead reduced output. Thus, famine could follow plague, even without a harvest failure. Severe epidemics also disrupted trade. Disease often entered a region through port cities, and the subsequent damage to trade – primarily through lost labor, but also through the isolation that came from quarantine and fear – could be substantial (Craig and Garcia-Iglesias 2010).

The negative shocks of severe epidemics are relatively easy to identify, and on occasion, they could cause dramatic increases in mortality rates. However, by the mid-nineteenth century, other than the occasional local outbreak of, for example, cholera or yellow fever, food supplies were secure enough (and the appreciation of public health measures were widespread enough) that, at least in the West, disease- and famine-caused mortality crises were a thing of the past. As such, for most of the population, morbidity became a chronic, rather than an immediately life-threatening, concern. Using microlevel data from British friendly societies, Riley (1990, 1997) found that the prevalence of morbidity increased with the decline in mortality that accompanied modern economic growth. One interpretation of Riley's finding is that the decline in mortality was accompanied by longer – albeit, on an individual basis,

fewer – episodes of illness, as the health-care industry evolved to help workers better manage their illnesses. Thus, the implication of Riley's research is that overall, the health of Western societies has deteriorated over time as improvement in public and private health technologies have allowed the sick to survive illness that in the past would have killed them.

This conclusion is not without controversy. Not only does it conflict, at least qualitatively, with McKeown's argument that nutrition, rather than public health spending or improvements in the provision of private health care drove the health transition, it also conflicts with much recent empirical work on morbidity. For example, Dora Costa surveys a wide range of studies across several countries that, collectively, show an unambiguous improvement in the health of Western populations since the late nineteenth century. Comparing cohorts from the US Civil War with those from the late twentieth century, Costa (2000) and Costa et al. (2007) show that the incidence among the elderly of a wide set of conditions declined over time, and comparing early twentieth-century populations with those from later in the century, she notes that "mothers of the children born in the 1910s and 1930s were shorter, showed signs of malnutrition, had high blood pressure during pregnancy, and were more likely to be syphilitic than mothers who gave birth in the 1960s and in 1988" (2013, Table 3).

There is a fundamental mathematical element that lies at the heart of these positions, which, it should be noted, are not all mutually exclusive. If we think of disease as a state that lasts through time, then the prevalence of morbidity for an individual can be expressed as:

$$M_i = \int_0^T h(t)\, dt \tag{3}$$

where M_i is the amount of time over the course of the ith individual's life that she spends sick, h(t) characterizes her path of illness through time, and T is the length of her life. Assuming h can be expressed as a function of, among other things, nutrition and public and private health-care technologies, then McKeown's position can be summarized as follows: A decrease in h, largely caused by nutritional improvements, in turn led to an increase in T, leaving the net impact on lifetime morbidity, M, ambiguous. In short, over time, people ate better and lived longer, but that increased their exposure to disease. Riley's position can be interpreted as the long-run increase in T, a result of modern economic growth and improvements in health-care technologies, unambiguously increased lifetime exposure to morbidity. In short, as people lived longer, they spent more time sick, though the doctors got better at treating their illnesses. Finally, Costa's position can be interpreted as follows: Despite the increase in T, improvements in nutrition and health-care technologies unambiguously decreased the prevalence of morbidity. In short, people now enjoy longer *and* healthier lives than they did in the past.

In related research connecting morbidity directly to mortality, Alter and Riley (1989) offer an "insult accumulation model," in which exposure to disease – i.e., an

"insult" – weakens survivors in ways that cannot be easily erased through subsequent nutritional gains; thus, survivors are susceptible to future insults and higher mortality rates than would have been the case in the absence of the insult. Using microlevel data from the Union Army sample, Lee (2003) challenges this view. He finds that adults raised in locales with high childhood mortality rates, such as urban areas, had lower mortality rates while they were in the army than those from rural areas. This finding indicates that surviving prior insults gave one an advantage – rather than, as Alter and Riley suggest, a disadvantage – when faced with future insults.

Nutrition and Technological Change

Technological change has played an important, though often confounding, role in the techno-physio revolution and the health transition. At its most basic level, the nutritional access of a population is tied to the food supply from either domestic production or trade. Most of the world's population today no longer faces the food crises that kept population growth in check for millennia. The average annual compounded growth rate of the world's population over the past five centuries is an order of magnitude larger than it was over the prior 2000 years, 0.71% versus 0.03%.[16] This is largely the result of a series of technological changes in agriculture. Often referred to as "revolutions" in the literature, by some accounts, the first of these occurred before the Industrial Revolution and involved countless small-scale improvements by small-holding, open-field farmers. As evidence in support of this interpretation, Allen (1999) estimates that farm output in England doubled between 1520 and 1740. A second revolution, this one revolving around the mechanization of agriculture, occurred in the mid- to late nineteenth century. Craig and Weiss (2000) estimate that in the United States, average annual total factor productivity growth, a standard economic indicator of the pace of technological change, expanded from near zero in the two decades before 1860 to roughly 0.70% in the four decades after that date. Finally, in the twentieth century, the so-called Green Revolution, which was marked by the development and expanding use of chemical pesticides, herbicides, and fertilizers, increased agricultural output in much of the world. Whereas in 1500, the vast majority of the world's labor force was directly employed in the production of food and fiber; in modern developed economies, only 1% or 2% is so employed today, and in many countries, the most prominent nutritional problem is a surplus of food leading to an epidemic of obesity (Komlos et al. 2008).

Holding other factors constant, in the long run, the resulting increase in food production unambiguously reduced mortality and morbidity, though as the antebellum puzzle suggests, the positive trend was not without a cyclical component. Transportation improvements, also frequently referred to as a "revolution," proved to be an ambiguous influence on the relationship between the increase in food

[16]United Nations 1999, Table 1

production and the biological standard of living. Technological change in transportation reduces costs and results in an increase in the amount of goods shipped, which would tend to increase total consumption, including the consumption of nutrients. However, transportation also had two negative impacts on net nutrition.

As Komlos and Coclanis note, in the nineteenth century, transportation improvements were accompanied by urbanization, which increased the demand for food supplied to the market, which in turn impacted the nutritional status of both urban and farm populations. In urban areas, there were now more people purchasing food in the market, and although the per unit cost of transporting food declined, "a larger share of the population had to pay transportation costs in order to obtain its nutrients . . ." (1997, p. 448). On the farm, the commercialization of agriculture led to an increase in the production and export of cash crops, most notably cotton in the South, at the expense of a healthier more diverse diet that had previously been heavy in animal-based protein.

> The price of meat and dairy products rose with the distance from the point of production, thereby impinging on the amounts demanded. Hence, a decline in the number of livestock per capita implies that the consumption of an important determinant of nutritional status, animal protein, was declining . . . Cash, in other words, did not automatically translate into higher nutritional status in the early industrial era . . . . (1997, pp. 447–448)

So both urban and rural populations suffered nutritionally as a result of these changes.

The other problem transportation improvements caused for the biological standard of living was an expansion of the disease nexus. Urbanization, the expansion of which was facilitated by the industrial and transportation revolutions, was strongly correlated with increases in mortality rates and the erosion in other indicators of the biological standard of living. In their study of the antebellum puzzle, Haines et al. (2003) estimate that in the United States, 10 percentage point increase in a county's urbanization rate resulted in a 7.5% increase in the crude death rate, and US Army recruits from urban areas were, on average, an inch shorter than those from rural areas. Supporting that finding more broadly, Fogel (1986) estimates that urbanization explains approximately 20% of the US stature decline during the same time period.

In addition, these changes also led to an increase in the intensity of farm labor. Average hours at work in agriculture increased during the period in question (Craig and Weiss 2000). Recall that it is net nutrition that allows the body to prosper, and the body consumes nutrients while fighting disease and exerting the energy needed for work. The expansion of the disease nexus and the increase in hours at work associated with the commercialization of agriculture, all of which were at least partly dependent on improvements in transportation, led to an increase in the body's demand for nutrients at a time when, for much of the population, their supply was increasingly challenged.

There was one technological innovation that unambiguously led to an improvement in the standard of living, as traditionally measured by income, as well as the biological standard of living: mechanical refrigeration. The physics of refrigeration

had been well understood thousands of years before the widespread adoption of mechanical refrigeration in the late nineteenth century and early twentieth century. The first US patent for a mechanical refrigerator was issued in 1853. The early machines were too costly to build and maintain, and too unreliable, to be widely adopted. Only after a set of "rather mundane improvements in the machine-tool industry, related metallurgical improvements, the development of high-pressure seals, and the addition of the electric motor" were perfected and adopted was a low-cost refrigerator feasible (Goodwin et al. 2002). All of these changes came together near the end of the nineteenth century.

Refrigeration smoothed the seasonal price and supply swings that had plagued agricultural markets since time immemorial, but it also allowed farmers to maintain herds beyond the slaughter season, and without reducing slaughter rates, overall herd sizes could be increased: "In short, refrigeration did more than simply allow a farmer to hold a hog off the market today for future slaughter. It allowed the farmer to slaughter a hog today *and* hold another hog off the market for later slaughter" (Craig and Holt 2008, p. 111). This had an impact on the overall production of meat and dairy products, which together represented roughly 30% of total agricultural output, and agriculture was 25% of GDP in 1900. Craig and Holt estimate that the market value of agricultural output increased by 2.28% as a result of the adoption of mechanical refrigeration, which would represent a 0.17% increase in GDP. With respect to nutrition, Craig et al. estimate that mechanical refrigeration led to a 0.75% increase in the consumption of calories, a 1.25% increase in the consumption of protein, and a 1.26% increase in household incomes (2004, p. 333). Note that these were permanent additions to the long-run growth paths of these variables, not one-time increases. As Gordon (2000) observed, refrigeration was truly one of the "great inventions."

The debates surrounding the behavior of the biological standard of living during industrialization are part of a larger debate among cliometricians concerning the impact of the Industrial Revolution. Broadly speaking, scholars who focus on the long-run positive trends in the growth of real GDP, income, and wages have been labeled "optimists," whereas those who focus on the increase in inequality, stagnation of the expectation of life at birth, increases in morbidity, declines in mean adult stature, and erosion in the consumption of net nutrients have been labeled "pessimists" (Craig 2006). After several decades of cliometric debate, it is clear that a long-run view of these changes, where long-run here means a century or so after the onset of industrialization, leads to an optimistic conclusion. However, viewed from the perspective of many, perhaps most, of those who lived through the transition from the world of Malthus to the Gilded Age, there was probably a deterioration in the biological standard of living, an experience Haines et al. labeled the "Malthusian squeeze" (2003, p. 408).

Conclusion

Today, populations in the early-developing countries are richer, taller, and enjoy longer healthier lives than their counterparts in the past. Cliometricians have debated the extent to which the techno-physio evolution and the health transition resulted

from nutritional improvements or other factors, such as the increase in public health infrastructure that followed mastery of the germ theory of disease. Although the long-run trends in the growth of real GDP, income, wages, and the biological standard of living were positive, as the presence of the antebellum puzzle suggests, the onset of industrialization was accompanied by an increase in inequality, the stagnation of the expectation of life at birth, increases in morbidity, declines in mean adult stature, and an erosion in the consumption of net nutrients. Taken together, this experience has been labeled the Malthusian squeeze.

Whereas much of the cliometric research on nutrition focuses on its role in the techno-physio revolution and the health transition, modern developed societies face an entirely different nutritional issue: obesity. As Treme and Craig note, "There is a biological maximum to the mean stature of a population, and for those populations enjoying a surplus of nutrients, further consumption would merely lead to obesity" (2013, p. s131). Although the phenomenon is widespread among rich and not-so-rich societies, the United States offers perhaps the most striking example of the trend. Over the past 30 years, the incidence of obesity has doubled, and roughly one in three US adults is obese, as measured by BMI (Flegal et al. 2012). The social cost of this epidemic is enormous. Cawley and Meyerhofer (2012) estimate that more than 20% of US health-care expenditures are directly attributable to obesity.

Despite much recent study, the causes of mass obesity are not well understood. Cawley et al. (2010), employing cross-sectional econometric work with instrumental variables, show that income differences explain only a very small component of weight differences. This finding suggests that one possible culprit of the rise of obesity, the modern economic growth that helped developing countries generate the techno-physio revolution and escape from the Malthusian world, can be ruled out as the cause of obesity. Komlos et al. (2008) suggest that modern consumer technologies, such as the television and automobile, as well as labor-saving production technologies, explain the rising prevalence of obesity. In any case, the topic represents the next frontier in empirical research on nutrition and its economic and social impacts.

Improvements in Health and the Organization and Development of Health Care and Health Insurance Markets

Gregory T. Niemesh and Melissa A. Thomasson

Contents

Abstract

This chapter describes the gains in health in the twentieth century and the development of the markets of health care and health insurance. It first provides an overview of the literature documenting the gains in public health that led to mortality transition in the United States in the late nineteenth and early twentieth centuries. Clean water, sanitation and electrification helped reduce mortality, as did food and milk inspection, the elimination of parasites such as malaria and

hookworm, and food fortification. As the century progressed, advances in science and technology, combined with reforms in physician education and licensing led to improvements in medical care and health. These changes increased the cost of medical care and led to the development of health insurance markets.

Health care and insurance · Public health · Hospitals · Medical education

Introduction

In the late nineteenth and early twentieth centuries, infant mortality and life expectancy improved as mortality transitioned from infectious disease mortality to chronic disease mortality beginning in 1915 (Meeker 1972; Haines 2001). Early in this period, gains in longevity can be largely attributed to gains in public health. For the most part, medical care did not contribute to improved mortality because it was largely ineffective. A large body of research in economic history shows that gains in public health during this period led to significant improvements in health outcomes. Clean water, sanitation, and electrification helped reduce mortality, as did food and milk inspection. The eradication of parasites such as hookworm and malaria, and the fortification of foods to eliminate nutritional deficiencies also played roles in decreasing mortality and improving other outcomes.

In the first few decades of the twentieth century, advances in science and technology, coupled with improvements in physician education, led to improved health and quality of life. Discoveries such as diphtheria antitoxin, salvarsan for syphilis, and antibiotics led to more awareness of the effectiveness of medical care. As these discoveries increased the demand for medical care, they led to increases in medical costs and the development of the U.S. health insurance system. Occupational licensing of physicians and other medical professionals evolved both as medical schools sought to improve the quality of new physicians, and to protect consumers from unqualified practitioners. In this chapter, we focus on summarizing the literature in these different strands of research. We first discuss the literature on the improvements in health generated by public health initiatives, and then summarize studies that examine how changes in physician education and licensure affected the demand and supply of medical services. Finally, we provide an overview of studies that look at the emergence and impact of health insurance in the United States.

Improvements in Public Health

The definition of "public health" evolved with the changing health problems afflicting the population. The nineteenth- and early twentieth-century definition focused on the elimination of contagious infectious diseases (cholera, typhoid, dysentery) through "community action to avoid disease and other threats to the health and welfare of individuals and the community at large" (Duffy 1992, p. 1). Public

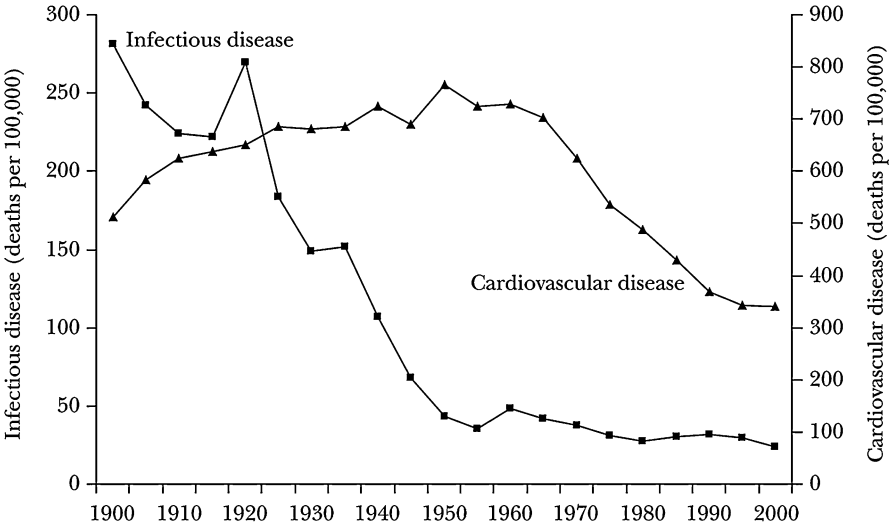

Fig. 1 Mortality from infectious disease and cardiovascular disease, United States, 1900–2000. (Source: Reprinted from Cutler et al. (2006). Data are from the Centers for Disease Control and Prevention, National Center for Health Statistics, and are age adjusted.)

health initiatives are often undertaken on the part of governments – local, state, and federal – and not through voluntary exchange in the health care market between physician and patient. The success of the early public health initiatives can be seen in Fig. 1: an initially high but rapidly falling mortality rate from infectious disease during the first half of the twentieth century in the United States. By at least the 1930s, the chronic diseases of old age had become the biggest killers. In response, the definition of public health expanded to include "actively promoting health rather than simply maintaining it" (Duffy 1992, p. 1), with a focus on the social determinants of health as a way to address mortality from chronic diseases. For example, poverty is viewed as an underlying cause of high mortality rates. Therefore, guaranteeing everyone a standard of living sufficient for a healthy existence became an aim for public health organizations.

It is important to emphasize the contributions of economic history to understanding the disease elimination aspects of the early public health movement. One of the main findings of the literature is that much of the improvement in health early in the twentieth century came from public health interventions. Early initiatives that nearly universally improved health included water purification and sanitation. Later in the century, nutritional fortification also improved health for Americans. Other public health efforts focused on eradicating parasites, such as hookworm and malaria.

Water Purification and Sewage Systems

Public health interventions such as water filtration, sanitation, refuse collection, and food inspection played a significant role in the decline of mortality in the early

twentieth century. Using city-level data, David Cutler and Grant Miller (2005) find that water filtration and chlorination account for almost half of the mortality reduction in major cities, 75% of the decrease in infant mortality, and two-thirds of the decrease in child mortality. Similarly, Werner Troesken (2004) finds that deaths from typhoid and other waterborne diseases were nearly eliminated by the expansion of public water and sewer services. Looking at Massachusetts, Alsan and Goldin (forthcoming) show that the combination of safe water and sewerage lowered child mortality by 26.6 log points and was more effective than either intervention alone. Joseph P. Ferrie and Werner Troesken (2008) find that reducing typhoid also led to a reduction in nonwaterborne diseases, including death rates from gastroenteritis, tuberculosis, pneumonia, influenza, bronchitis, heart disease, and kidney disease (known as the Mills-Reincke phenomenon).

While water purification systems reduced deaths from typhoid, they may have led to increased morbidity and mortality in cities that used lead pipes to deliver the water, depending on the age of the pipe and the acidity of the local water supply. In two studies, Troesken (2006, 2008) reports that lead resulted in increases of 25–50% for infant mortality and stillbirths in 1900 for the average Massachusetts town. As cities abandoned lead water pipes in the early 1900s, the deleterious effects of lead exposure on infant mortality were reduced, although a lack of data makes it difficult to estimate the size of the reduction. Karen Clay et al. (2014) follow up on this research and look at the effect of waterborne lead exposure on infant mortality in U.S. cities over the first two decades of the twentieth century. They use city-level variation in water acidity and the type of pipe used by cities (lead, iron or concrete), and confirm that lead pipes led to significant increases in infant mortality. Specifically, they find that increasing pH from the 25th percentile to the 50th percentile (since water becomes less acidic, it leaches lead more slowly) would reduce infant mortality by 7–33%.

Early public health improvements occurred nearly exclusively at the state and local levels (Preston and Haines 1991). State and local public health departments operated to reduce mortality in a variety of ways. Louis P. Cain and Elyce Rotella (2001) use data from 48 U.S. cities to examine the impact of sanitation expenditures on death rates. They find that spending on sewer systems and refuse collection reduced death rates from typhoid, dysentery, and diarrhea. Municipalities also engaged in street cleaning and the distribution of diphtheria antitoxin (Condron and Crimmins-Gardner 1978; Meckel 1990). State and local legislation was aimed at protecting food and milk and preventing the spread of disease. Mokyr and Stein (1996) state that by 1905, 32 states had laws preventing the adulteration of milk.

Several different types of laws were also enacted to stem the spread of tuberculosis. Between 1900 and 1917, state and local governments passed laws that required TB reporting. They also enacted disinfection laws, spitting bans, and common drinking cup bans (Anderson et al. forthcoming). Anderson et al. examine these laws and find that reporting laws led to a 6% reduction in the TB mortality rate, and that the establishment of a state-run sanatorium reduced TB by 4%. This finding is similar, but larger in magnitude to that found by Alex Hollingsworth (2013) in his study of sanitaria in North Carolina. However, a paper by Karen Clay et al. (2018)

suggests that community-based health interventions targeted at reducing tuberculosis did not reduce tuberculosis relative to control cities over time, although they did reduce infant mortality.

Scholars interested in examining state and local spending and their impact on outcomes can rely on several sources of data. At the state level, *Financial Statistics of States* provides similar information to that of *Financial Statistics of Cities* beginning in 1915. Richard E. Sylla et al. (1993) have published relevant data in State and Local Government Sources and Uses of Funds: Twentieth Century Statistics (ICPSR Study 6304). For municipalities, the *Bureau of Labor Statistics Bulletins* #24, 30, 36, and 42 (1899–1902) provide data on municipal finances for 1899–1902, and *Census Bulletin* #20 (United States Bureau of the Census 1904) provides similar information for 1902–1903. *The United States Census Bureau published Statistics of Cities* (1907, various years) to report annual data on municipal-level health related expenditures for cities over 30,000 between 1905 and 1908. *The United States Census Bureau also published Financial Statistics of Cities* (1909, various years), which provides similar information for the years 1909–1913, 1915–1919, and 1921–1930. The specific categories related to health include information on health conservation and sanitation cost payments; health conservation and sanitation outlays; charities, corrections, and hospital cost payments; and charities, corrections, and hospital outlays.

Public Health Education and Information

In addition to direct public health spending on refuse collection, infrastructure, and the passage of laws designed to facilitate the spread of disease, some public health initiatives revolved around educating families about hygiene and infant and child care. Grant Miller (2008) suggests that the enfranchisement of women led to large shifts in public spending on hygiene campaigns that led to increases in child survival. While Miller focuses on data from *Financial Statistics of Cities* (so that his mechanism about how public expenditures led to reductions in child mortality is a black box), other studies have used data on public health activities to identify the channels that were most effective in improving health outcomes. For example, Carolyn Moehling and Melissa A. Thomasson (2014) examine activities undertaken by public health authorities under the Sheppard-Towner program, in which the federal government gave matching funds to states to engage in infant and child care and hygiene. They find that the most effective interventions were those that provided one-on-one care, such as nurse visits and health centers, compared to activities such as classes, conferences, and demonstrations.

The Eradication of Parasites

In the early 1900s, up to 30% of the population was infected with malaria (Kitchens 2013a). The effects of malaria vary from stunted physical stature and impaired

cognitive development to death (Hong 2007; Bleakley 2010). Several New Deal agencies and programs contributed to the decline of malaria. By paying farmers to take land out of cultivation, the Agricultural Adjustment Act (AAA) led farm laborers to leave mosquito-breeding grounds (Humphreys 2001). Alan Barreca et al. (2012) estimate that this out-migration accounts for about 10% of the decline in malaria between 1930 and 1940. Carl Kitchens (2013a, b) examines the impact of other New Deal programs on malaria. Using county-level data from Georgia between 1932 and 1941, Kitchens (2013a) demonstrates that drainage projects constructed under the auspices of the Works Progress Administration (WPA) explain more than 40% of the observed reduction in malaria over the period.

Kitchens (2013b) finds different results when he looks at the construction of dams under the Tennessee Valley Authority (TVA). He uses county-level panel data from Alabama and Tennessee, and finds that the dams created a vast increase in coastline suited for mosquito breeding. Despite subsequent efforts of the TVA to control mosquitos, Kitchens calculates that the TVA led to a significant increase in loss of life due to malaria that reduced the fiscal benefit of dam construction by 24%.

Other public health efforts focused on eradicating another Southern parasite: hookworm. Transmitted through the soil, hookworm eventually lodges in the intestines of its victim. It causes lethargy and anemia, but is rarely fatal. Nevertheless, its effects can lead to decreased productivity and make it difficult for children to cognitively focus. For example, Garland Brinkley (1997) shows that the sharp decline in Southern agricultural output after the Civil War can be attributed to increased rates of hookworm infection.

In 1910, the Rockefeller Sanitary Commission (RSC) estimated that 40% of Southern schoolchildren were affected with hookworm. It engaged in an eradication campaign, and sent health care workers to dispense de-worming medication. Hoyt Bleakley (2007) finds that children living in areas with greater rates of hookworm infection prior to the RSC's campaign showed greater gains in school enrollment, attendance, and literacy than those living in areas with lower rates of infection. Thus, eradicating hookworm could account for closing up to half the literacy gap between the North and the South, and reducing the income gap by up to 20%.

Improvements in Diet

Nutritional insufficiency – whether stemming from parasitic infection or poor diet – is correlated with reduced economic outcomes. Numerous economists and historians have noted that nutritional improvements (measured by caloric and/or protein intake) are correlated with gains in both income and health (Higgs 1971; Fogel 1994; Steckel 1995; Floud et al. 2011). Most recently, Gregory Niemesh (2015) adds to this literature by measuring the impact of the first federal requirement in 1943 to fortify bread with iron. Iron deficiency in infants and children causes developmental delays and behavioral problems, and reduces productive capacity in adults. Niemesh uses pretreatment variation in iron consumption, and shows that the law led to increases in income and educational attainment in areas with lower levels of iron

consumption prior to the mandate. James Feyrer et al. (2017) similarly examine the impact of salt iodization in the U.S. in the 1920s on later cognitive outcomes. Their findings suggest that iodized salt raised IQ for those who were most deficient, but also increased thyroid-related deaths, particularly among older individuals. Karen Clay et al. (2018) examine the rise and fall of pellagra, a disease caused by niacin deficiency in the American South that is characterized by dermatitis, diarrhea, and dementia. They argue that cotton production in the South displaced local food production, leading to increases in pellagra rates. Using a difference-in-differences framework, they leverage the arrival and spread of the boll weevil to identify the relationship between cotton production and pellagra. They find that pellagra death rates fell between 23% and 40% more in high cotton counties than in low cotton counties after the boll weevil arrived. They also find that after 1937, state fortification laws helped to eliminate pellagra.

The Growth of the Market for Medical Care

Reforms in Medical Education and the Changing Public Perception of Hospitals

At the turn of the twentieth century, the formal health care market was much simpler than today and made up a smaller portion of economic activity. Consumer expenditures on medical care in 1900 (about $384 million) accounted for around 2% of Gross Domestic Product (Craig 2006; Sutch 2006), compared to around 18% in 2017 (Centers for Medicare & Medicaid Services 2018). Medical care was inexpensive because it was ineffective, so people did not need health insurance to pay for medical expenses (Thomasson 2002). Hospitals were generally shunned by people of means, and functioned as almshouse and places for those without families to care for them. Respectable people of means had physicians visit them in their homes.

At the turn of the twentieth century, physician training in the U.S. was largely substandard compared to medical education in Europe, but several medical schools had already made significant strides in reforming the quality of medical education. Johns Hopkins, Harvard, Michigan, and Pennsylvania had all increased admissions requirements, lengthened their terms, and moved from apprenticeships to a focus on clinical instruction. By the time Abraham Flexner (Flexner et al. 1910) published his well-known report on the quality of medical education in the United States, the reform movement was well underway (Moehling et al. 2018). A key component of modern medical education was the alliance between medical schools and clinical training in hospitals. As physician training moved to hospitals, so too did patients. At the turn of the twentieth century, few people even considered going to hospitals and preferred to have physicians visit their homes. This changed significantly as the public gradually became aware of scientific progress and visited physicians trained under the new regime. Although hospitals were considered second-rate and germ-ridden in 1900, by the second decade of the century, some products (such as Lysol) featured advertising boasting how they were used in hospitals. As news from Europe

during World War I showed doctors saving lives on the battlefield, the public perception of hospitals grew more favorable.

Occupational Licensing of Health Care Providers

While the first physician licensure laws in the United States were passed in the 1870s, most were very lax until the 1910s. For example, even as late as 1906, 13 states still allowed people who had not graduated from medical school to become physicians (Ludmerer 1985). Supporters of medical education reform had long pushed for stricter licensing requirements, but Flexner's report spurred legislators to implement higher standards to ensure that would-be physicians could meet new standards. States continued to ratchet up the entry and graduation requirements throughout the 1910s. Term lengths were lengthened to 4 years, and states began to require premedical education of at least 2 and sometimes 4 years. Many schools did not have the resources to invest in reforms, and subsequently closed or merged with other schools. In response, the number of medical schools fell from 160 in 1900 to 81 in 1922 (American Medical Association, Council on Medical Education 1922, p. 633).

Figure 2 displays the widespread adoption of stricter education qualifications for entry into medical school. No states required premedical education in 1907. By 1915, only 8 years later, 35 states had mandatory baccalaureate education as a requirement to admission to medical school. Figure 3 shows the simultaneous

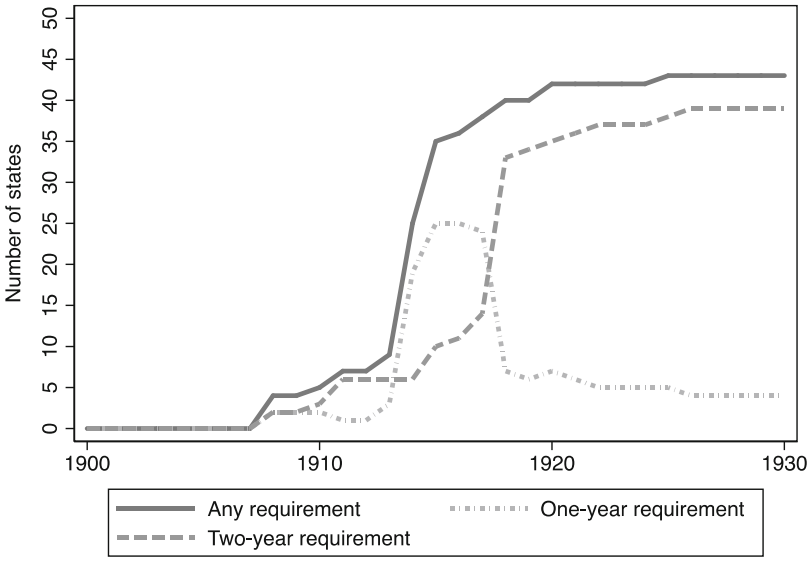

Fig. 2 States with premedical college requirements for physician licensure. (Source: "Medical Education in the United States," *Journal of American Medical Association*, Aug. 27, 1932: p. 746)

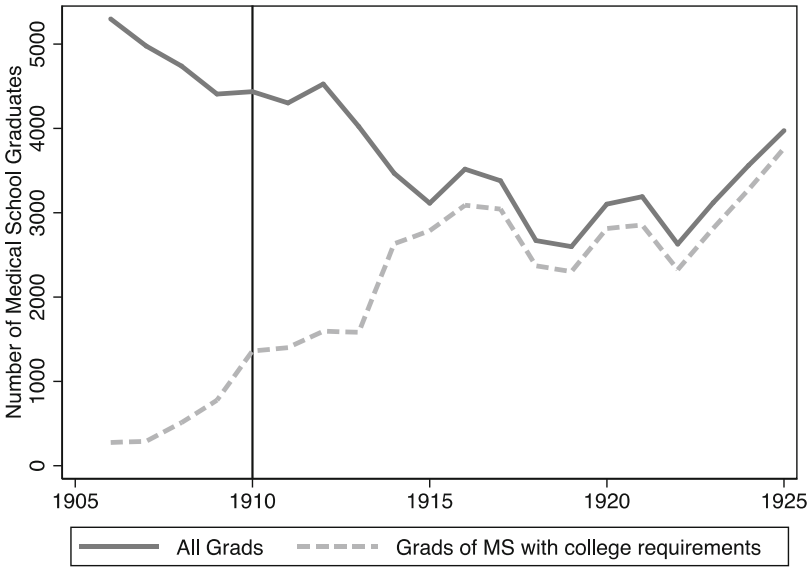

Fig. 3 Number of medical school graduates by college requirements. (Sources: Premedical college requirements are from American Medical Association Council on Medical Education (1919, 1923). Medical schools and graduates from American Medical Association Council on Medical Education (1905–1910, 1911–1914, 1915–1920).)

increase in the skill of new medical school graduates and the decrease in the supply. The number of new physicians produced by American medical schools had been gradually falling prior to the publication of the Flexner report in 1910, but the increased premedical education requirements accelerated the trend. As attending a medical school became increasingly more expensive – indirect costs from lost wages and direct costs from tuition of attending a baccalaureate institution – the number of medical school graduates declined. On the other hand, the skill of the potential entrants increased, measured as fulfilling the more strict premedical education requirements.

Economic historians have tried to explain the early adoption of occupational licensure laws by health professions, as well as the effect of widespread coverage of occupations across the various states. Their work focuses on the impact of licensing on supply, price, and quality, and they leverage their results to distinguish between two economic theories that explain the existence of occupational regulations. One theory is that professions are motivated by their own self-interest to lobby governments to enact occupational licensure requirements. As requirements for entry into the profession become stricter, competition for incumbent practitioners becomes more limited. Supply falls, so that prices and wages increase above what would have occurred in the absence of a license system. A related idea is that of regulatory capture, which occurs when practitioners take control of the licensing apparatus meant to regulate entry into an occupation. For example, physicians make up the

majority of members of state medical boards. With the licensing apparatus captured, boards could enact regulations in the interest of their profession (e.g., restrict supply and increase wages) at the expense of consumers (e.g., higher prices and less access). Underlying this view is that licensure provides no benefit to the consumer by increasing physician quality, or at least any quality gains that do occur do not fully compensate for the loss in welfare from higher prices and lower quantity of health services provided.

Alternatively, licensure might have emerged to solve an asymmetric information problem between the sellers of health services and patients. Physician quality may be unobservable. Since patients do not have the ability to discern "quacks" from good doctors, occupational licensure can help solve the asymmetric information problem by eliminating the low-quality providers from the market. Education requirements or an entrance exam to the profession proves a provider is of high quality. With the low-quality competition gone, the remaining high-quality providers may see an increase in wages. However, in contrast to the pure self-interest of regulatory capture, the consumers benefit on net from the quality increases in this case.

Physicians

Law and Kim (2005) document the effects of physician licensure laws on the supply and quality of doctors during the Progressive Era using licensure data spanning 1870–1930. They use cross-state variation in the timing of when specific parts of a licensure law were passed in a state-level decadal panel. In general, passage of a licensure law or an increase in entry requirements reduced entry to the profession and reduced the supply of doctors per capita. The requirements most related to declining entry were the implementation of 2-year and 4-year premedical education requirements; they find little evidence that the initial licensure statutes of the 1870s affected entry.

In addition, they find evidence that physician licensure may have reduced asymmetric information and improved patient outcomes. Using the same empirical framework, they find suggestive evidence that physician quality improved in response to the premedical education requirements during the 1910s. States with premedical requirements experienced relatively larger declines in maternal mortality and appendicitis mortality, negative outcomes that physician behavior might be able to mitigate during this period. However, the author's find no effect of greater licensure requirements on either overall mortality or the infant mortality rate.

Law and Kim (2005) provide additional evidence that that licensure reduced information asymmetry and improved quality. Professions that a priori one would expect to more acutely suffer from informational asymmetries were more successful in restricting entry (physicians, dentists, and veterinarians as opposed to plumbers, electricians, and barbers). Their results suggest this increased quality came at the expense of a reduction in entry into the profession.

Using panel data on medical school enrollments from 1906 to 1932, Moehling, Niemesh and Thomasson (2018) measure how medical school and state licensing

requirements may have differentially affected women physicians. They look at the effect of premedical college requirements at the school level on the percentage of female enrollment, and also include a third measure of reform: whether the school required graduates to complete an internship. In addition, they examine how state-level requirements affected enrollments. Their results indicate that as schools increased their standards for admission and required hospital internships, the shares of women enrolled fell (Fig. 4). Similarly, when a state imposed a hospital internship requirement for obtaining a physician license, the share of women in medical schools in that state decreased. These results run counter to the findings of Law and Marks (2009), who find no adverse effects of state licensing laws on the likelihood a woman reported herself as a physician in the census from 1870 to 1930. The differences may arise because Law and Marks do not examine the effect of the requirement to complete a hospital internship. In addition, they use individual level data from the IPUMS samples of the population censuses. While large from the perspective of historical data sets, the small number of women physicians during this period makes the variation used to identify the effects of changes in the licensing laws very small.

While these studies look at the effect of licensing on physician supply, focusing solely on the state-level supply impacts of licensure masks the geographic redistribution of physicians that may occur as the market for physician services adjusts to a new spatial equilibrium. Moehling et al. (2018) examine the rural/urban location choices of physicians in the first decades of the twentieth century to test whether they were related to the changes in medical education during the period. Physicians were becoming a more urban profession over the course of the early twentieth century, as was the population of the country as a whole. However, physicians trained in medical schools that required premedical education were significantly more likely to set up practice in an urban area than physicians that graduated from schools without premed education requirements. Physicians trained in "modern" medical schools were more strongly attracted to professional amenities located in urban areas such as hospital beds and larger physician communities than were physicians trained in lower quality schools. As states enacted increasingly strict admission requirements to medical school, not only did the total supply of physicians decrease, but the composition of new graduates was more likely to locate in an urban area. These two factors combined led a reduction in access to physician services in rural areas, increasing an already existing urban-rural divide.

Midwives

The studies above describe the effect of medical licensure on physicians. Yet during the Progressive Era, midwives also became more highly regulated. At the turn of the twentieth century, half of all births were attended by midwives, with the other half attended by physicians. Only 5% of births (mostly those by indigent women or unwed mothers) took place in hospitals (Wertz and Wertz 1989). Midwives during this period were (almost entirely) women who learned the craft through helping more

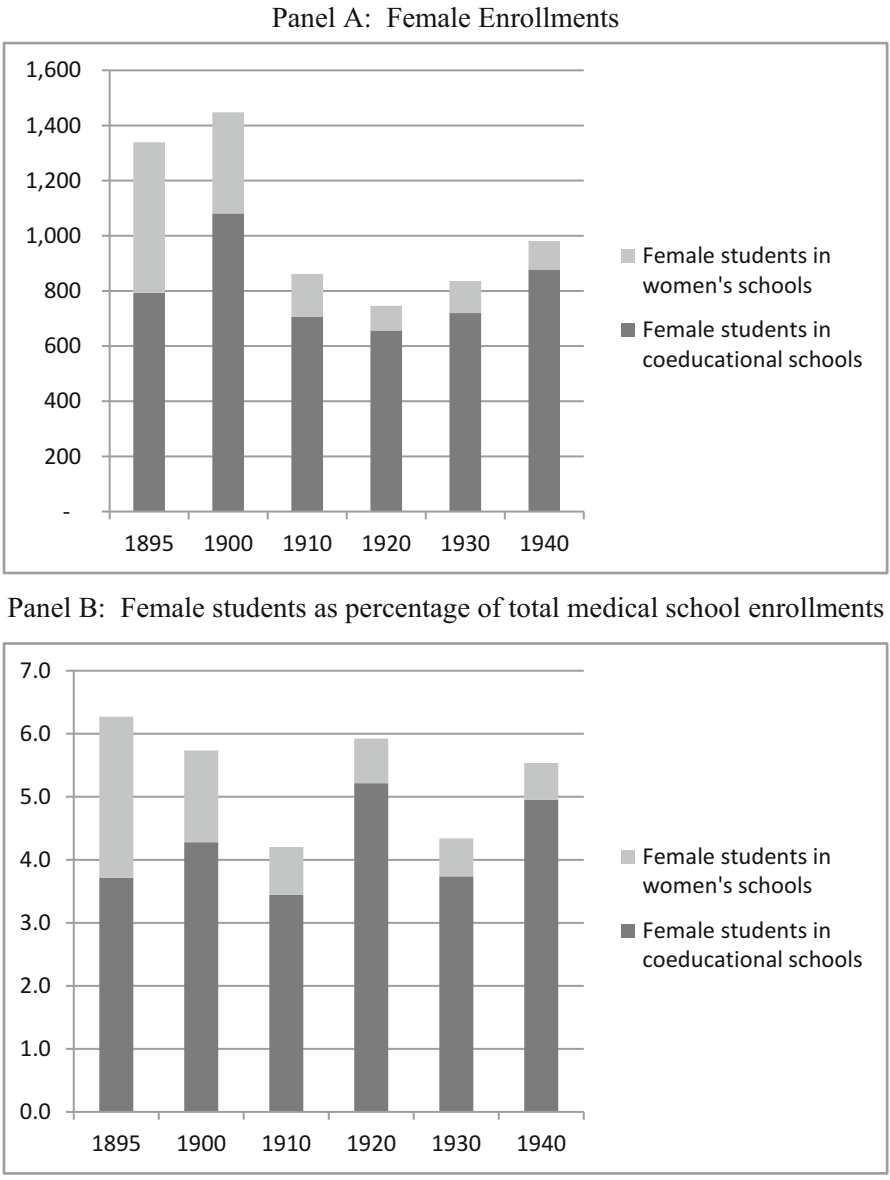

Fig. 4 Female medical school enrollment, 1895–1940. (Sources: United States Commissioner of Education (United States Commissioner of Education 1895 and 1900); American Medical Association Council on Medical Education (1910–1940))

experienced midwives. Formal training was not provided. Moreover, the market for midwives was wholly unregulated prior to a string of licensure laws enacted in the early twentieth century in an effort to increase the quality of midwifery services.

Anderson et al. (2016) analyze the supply and mortality outcomes associated with 22 states and at least a dozen municipalities enacting licensing requirements over the 1900–1940 period. The stringency of entry requirements varied tremendously across the states. "Applicants for licenses in Mississippi were judged based on their character, cleanliness and intelligence, but were not required to take an exam or graduate from a school of midwifery. By contrast, midwives in California, Washington and Wisconsin were required to graduate from a recognized school of midwifery and to pass an examination administered by their State Board of Medical Examiners" (Anderson et al. 2016, p. 3). The introduction of licensing requirements for midwives was associated with a 6–7% reduction in maternal mortality.

The Impact of Medical Care on Health

As medical education improved and medical care advanced, it became more effective. Thomasson and Treber (2008) show that the while medicalization of childbirth did not initially reduce maternal mortality, maternal mortality declined once sulfa drugs became available in 1937. Sulfa provided physicians with their first effective treatment against a range of bacterial infections. Jayachandran et al. (2010) show that in addition to reducing maternal mortality, sulfa use also reduced deaths from pneumonia and scarlet fever. They estimate that sulfa reduced overall mortality from 2% to 3%, and added 0.4–0.7 years of life expectancy.

Medical Costs and the Development of the Health Insurance Market

The fundamental function of any kind of insurance is to reduce financial uncertainty associated with catastrophic events by pooling risk. People pay a fixed amount of money over time, and receive a payout if they experience a loss. The market works because on average, the amount paid in premiums by the group is less than the amounts paid out in benefits. Prior to the late 1920s, health insurance in the U.S. did not develop for two reasons. First, the demand for health insurance was low. When medical care was inexpensive, people did not need health insurance to pay unexpectedly high bills (Thomasson 2002). Instead, wage earners needed to cover wage-loss associated with disability, so they obtained disability insurance (called "sickness" insurance) through their firms, unions, or through fraternal societies (Emery 1996; Emery and Emery 1999; Murray 2007). The lack of need for actual health insurance is reflected in the first failure of an attempt at health insurance reform during the Progressive Era. In 1916, the American Association for Labor Legislation (AALL) published a draft bill in which they proposed comprehensive sickness and medical benefits for low income workers. Under the plan, local mutual insurance companies would manage premium contributions shared by employers, workers, and the state. Employers and workers would each contribute 40% of the plan's premium, while the state would contribute the remaining 20% (Chasse 1994).

Entrenched interests, including insurance companies, druggists, and physicians opposed the bill, and popular support was lacking, as demonstrated by the results of a 1918 referendum in California in which the plan was defeated with 358,324 votes against to 133,858 in favor of the bill (Murray 2007).

The lack of demand for health insurance was joined by a lack of insurance companies willing to underwrite "health." Commercial insurance companies did not view health as an insurable product. In order for insurance markets to function well, two conditions must hold. First, the losses that insurance companies cover must be able to be measured and observed. Insurance companies wondered how they would monitor health and pay claims for ill health. Would they be able to tell who was really sick versus just malingering? If losses are hard to measure, they can result in moral hazard – when having insurance makes it more likely that an insured person would have a claim. Second, insurance companies can only offer insurance if they are able to measure the likelihood of someone having a claim. If policyholders have private information about their likelihood to have a claim, insurance companies will not collect enough money in premiums to be able to pay for losses. This problem, known as adverse selection, can prevent insurance markets from functioning. In the early twentieth century (and even today), insurance companies worried that they might not be able to tell who was likely to have a health claim and who was not, and as a result, they did not feel like they could profitably offer health insurance coverage.

The demand for health insurance did not rise until the overall cost of medical care increased and became more variable as medical treatment shifted to hospitals. By 1929, a nationwide study by the Committee on the Costs of Medical Care (CCMC) showed that the average American family had medical expenses totaling $108, with hospital expenditures contributing to about 14% of medical expenses (Falk et al. 1933). This average disguised significant variation; urban families with incomes between $2,000 and $3,000 per year had mean medical expenses of $67 without hospitalization but expenses of $261 if someone had been admitted to the hospital (Falk et al. 1933).

As the costs associated with hospitalization increased, some families had difficulty paying their bills. In response, hospitals began to organize payment plans, and in so doing, unwittingly mitigated the problems of adverse selection and moral hazard, and set the stage for the broad sale of health insurance. In 1929, Justin Ford Kimball, a former superintendent of schools, was an administrator at Baylor University Hospital. He worked with Dallas teachers to develop a plan, later known as Blue Cross, based on the principles of insurance to help them pay their bills: Baylor would provide each teacher with 21 days of hospital care for an annual fee of $6.00. These plans reduced adverse selection by selling insurance to groups of workers healthy enough to work. They reduced moral hazard because Blue Cross plans reimbursed hospitals directly and patients generally could not admit themselves to hospitals. During the Great Depression, more and more hospitals began to develop these plans as hospital occupancy rates – and revenues – fell.

Blue Cross plans also benefited from state-level legislation called "enabling laws" that allowed them to form as nonprofit corporations and enjoy tax-exempt status, as

well as being exempt from certain insurance regulations such as reserve requirements and assessment liability. Thomasson (2002) shows that these laws increased the amount of health insurance at the state level.

Although physicians were somewhat slower than hospitals to develop prepaid plans, the American Medical Association (AMA) feared national health insurance and attempted to forestall its development by encouraging state and local medical societies to form their own prepayment plans, which later became known as Blue Shield (Thomasson 2002). By 1940, 9% of the U.S. population was covered by health insurance, largely through the Blue Cross and Blue Shield plans (Thomasson 2003). After Blue Cross demonstrated, it had overcome the problems of adverse selection and moral hazard, commercial, for-profit companies began to move rapidly into the market.

In the 1940s, a series of factors led to the rapid expansion of health insurance. The National War Labor Board limited the ability of firms to raise wages to secure labor, even as the U.S. entry into World War II led to a shortage of workers. Health insurance was exempted from the ruling, and firms began to offer health benefits to attract workers. An administrative tax court ruling in 1943 (later codified under the 1954 Internal Revenue Code) exempted employer contributions to worker health insurance premiums from employee income taxes. Thomasson (2003) finds that the tax change increased the likelihood that a household would have coverage by 9%, and increased the amount of coverage purchased by 9.5%. By 1957, about 76% of the population held some form of private health insurance coverage.

The Impact of War on Poverty on Health Insurance

The development of employment-based insurance as a means to alleviate adverse selection and its accommodation by U.S. tax policy makes it difficult for people without jobs to receive health insurance coverage. The elderly, disabled, and unemployed often had a difficult time finding health insurance and paying for medical expenses. Their need for financial assistance was recognized in Congress. In 1950, amendments to the Social Security Act allowed the federal government to provide matching funds to states to pay doctors and hospitals for providing medical care to welfare recipients. In 1960, these "vendor payments" were expanded to include the elderly who were not welfare recipients (Moore and Smith 2005).

Despite the effort to support the elderly who could not afford medical care under the Medical Assistance for the Aged Act, Congressional hearings in the early 1960s concluded that ". . .increasing numbers of our older people are confronted with financial catastrophe brought on by illness" (U.S. Congress. Senate. Special Committee on Aging 1964). In 1965, Medicare became law. Under Part A, the elderly were automatically enrolled in the compulsory hospital insurance program upon reaching age 65. Part B provided insurance for physicians' services. Research on Medicare shows both its costs and benefits. David Card et al. (2008) demonstrate that because of Medicare, insurance coverage increases at age 65. By leveraging this discontinuous change, they are able to examine differences in health

care utilization and outcomes across different groups (such as educated whites compared to less educated minorities). They find that health insurance coverage does affect utilization of medical services, and find a small increase in self-reported health status. Looking at the impact of Medicare on mortality, Amy Finkelstein and Robin McKnight (2008) found that while Medicare did not reduce the mortality of elderly individuals, it significantly reduced their out-of-pocket expenses and financial risk.

Medicaid (Title XIX of the Social Security Act) was also enacted with Medicare to provide health insurance coverage to non-elderly populations in need of assistance with medical bills. In contrast to Medicare, which was federally funded and provided uniform benefits to all enrollees, states' participation in Medicaid was voluntary. States that participated in Medicaid received some federal funds to provide means-tested benefits originally to recipients of public assistance, although legislative changes over the years have expanded eligibility. While the federal government specified minimum standards for eligibility and benefits, states have the option to make eligibility for coverage or benefits more generous. Under the Affordable Care Act of 2010, the federal government provides additional funds to states seeking to expand Medicaid eligibility. There is a very large literature on the impact of Medicaid on both physical and financial health of enrollees. Thomas Buchmueller et al. (2016) provide a summary of the program and a very thorough review of the literature.

Directions for Future Research

This chapter enumerates a wide variety of studies that examine the effect of public health initiatives on health and well-being, as well as the development of health care and health insurance markets. Nevertheless, significant gaps in the literature point to areas where future research is needed. For example, we know little about the impact of vendor payments paid to hospitals and doctors on behalf of welfare recipients under the 1950 amendments to the Social Security Act, yet research suggests the effects may have been substantial. For example, work by Martha Bailey and Andrew Goodman-Bacon (2015) shows that Community Health Centers (rolled out as part of the War on Poverty) significantly lowered age-adjusted mortality among older Americans. Also of interest is more work in the area of the impact of both de jure and de facto racial segregation and prejudice. Douglas Almond et al. (2006) demonstrate that the elimination of segregation in Southern hospitals after 1964 reduced infant mortality among blacks. A 2018 study found that underrepresentation by blacks in the medical profession may lead to excess mortality among black men (Alsan et al. 2018), which echoes results from Alsan and Wanamaker (2018), who found that the exploitative Tuskegee Study contributed to racial disparities in health among its victims and those close to them. Both of these studies suggest that more work can be done by economic historians to examine the causes and effects of racial health disparities.

Cliometrics and the Great Depression

Abstract

The Great Depression was the worst economic disaster in American history. There were plenty of factors that helped cause the Depression, but there is still ample disagreement in the large literature on the topic as to how much weight to give each cause. In the early 1930s, the Hoover administration and congress nearly doubled federal government outlays, offered a wide range of loans, and sought voluntary efforts to combat the Depression. The economy continued to slide, and increases in tax rates in 1932 contributed to the slide. The economy finally began to grow again in 1933 as Roosevelt and a Democratic Congress developed the New Deal, a large number of new regulatory and spending

Price Fishback is the Thomas R. Brown Professor of Economics at the University of Arizona. I owe a great debt to the scholars, including numerous coauthors and students, who produced the valuable cliometric research that I survey here. Also special thanks are due to Michael Haupert and Claude Diebolt for their help in editing the chapter.

programs. The 1933 trough was so deep that unemployment rates remained high throughout the decade and real GDP per person did not reach its 1929 level again until around 1939 or 1940 despite rapid growth rates. A growing literature has been evaluating the impact of the New Deal programs, and the effects of several major programs are discussed here.

Great Depression · New Deal · Government policy · Fiscal policy · Monetary policy · Unemployment · Regulation

The Great Contraction

The Great Contraction was the worst economic disaster in American history. The unemployment rate (Table 1) skyrocketed from 2.9% in 1929 to nearly 16% in 1931 and then rose above 20% in 1932 and 1933. Except for during the 1930s, the annual unemployment rate has only been higher than 10% in one other year, 1921. A significant share of the population was not counted as unemployed because they became discouraged and stopped looking for work. People who kept their jobs often saw their average weekly hours (Table 2) decline by as much as one-fourth as companies tried to share work among more employees.

If anything, the output statistics were worse. In 1930, Americans produced almost 10% fewer final goods and services per person than in 1929 (Table 1 and Fig. 1). Outside of the 1930s, there were only two worse years in American history, during the 1907 Panic and during the military demobilization in 1946. Yet that was only the first year of the Great Depression. In 1931, the USA produced 16% less per person than in 1929, in 1932 27% less, and in 1933 roughly 29% less. It is hard to conceptualize such a drop in GDP. In 1932 and 1933, the drops were the equivalent of shutting down the entire economy west of the Mississippi River. The annual real GDP per capita did not reach its 1929 level again until 1939.

Meanwhile, the price level dropped like a stone. The price level fell 26% over 4 years. Some saw this "deflation" as good news. Workers who kept their jobs at the old wage could now purchase 26% more. But those who owed money, on homes or on the relatively new credit accounts, suddenly saw the values of the dollars that they had to pay back rise markedly. Lenders might have fared better with the more valuable repayments if so many people had not been forced to default on their loans. After taking into account the depreciation of buildings and equipment, the net investment in the USA grounded to a complete halt and then turned negative in one year. Total corporate profits were negative for the years 1932 and 1933. The small percentage of the population owning stocks saw the Dow Jones Stock Index (Fig. 2) fall by roughly 90% over the 4-year period. If you could sell your house in whatever market was left, you were likely to get 40–60% less in nominal terms than in the late 1920s in some cities.[1]

Sources and notes: Sources for per capita estimates in 2013 dollars for real GDP and federal government outlays, receipts, and surplus/deficit are described in notes to Fig. 1. The real GDP used to calculate the real GDP growth rates was constructed from the real GDP used to calculate per capita GDP. The unemployment rates are calculated from David Weir's estimates, series Ba473, Ba474, and Ba477 on pp. 2–82 and 2–83. The growth rate of the M2 money supply was calculated from series Cj45, pp. 3–605 and 3–606. The velocity was calculated by dividing the money supply by nominal GDP, and then the growth rate was calculated from the level which ranged from a high of 2.5 in 1920 to a low of 1.6 in 1932. The series are from Carter et al. (2006). The inflation/deflation rate is calculated from a series downloaded from Williamson and Officer (2014) at http://www.measuringworth.com/

Table 2 Labor and building statistics from the 1920s and 1930s

			Manufacturing			
	Share of civilian labor force		Earnings in 2013 dollars			
Year	Union members	Workers involved in strikes	Hourly	Weekly	Hours per week	Building permits (thousands)
1920	12.2	3.5	5.39	261.18	48.5	247
1921	11.2	2.6	5.46	247.75	45.4	449
1922	9.3	3.8	5.45	268.09	49.2	716

1937	13.4	3.5	8.89	342.97	38.6	332
1938	15.2	1.3	9.42	321.51	34.1	399
1939	16.3	2.1	9.56	359.09	37.6	458

Sources and notes. The number of union members is series Ba4783 (pp. 2-336, 2-337), civilian labor force is series Ba475 (pp. 2-82, 2-83), and workers involved in strikes is series Ba4955 (p. 2-354), hourly and weekly earnings are the National Industrial Conference Board estimates in series Ba4381 and Ba4382 (p. 2-279), and weekly hours were calculated by dividing the weekly earnings by hourly earnings. Building permits are series Dc510 (4-481). All series are from Carter et al. (2006). Earnings were converted to 2013 dollars using the GDP price deflator data downloaded from Williamson and Officer (2014) at http://www.measuringworth.com/

The statistics cannot do justice to how bad the economy was. Families ran through their savings and then still had to find ways to survive. As 2–3% of the nonfarm population lost their homes to mortgage foreclosures each year, some people moved in with extended family. A group of dispossessed lived in tent colonies or slept under newspapers renamed "Hoover blankets." Others wandered the countryside looking for work and food. The feature of American society that hit hardest was the optimistic spirit associated with the Horatio Alger stories. In the past, the watchword was to work hard and success would come your way. People who had worked hard all of their lives suddenly found themselves unemployed for long stretches of time. Pessimism about the future soon took hold, making it that much harder to spur a recovery.

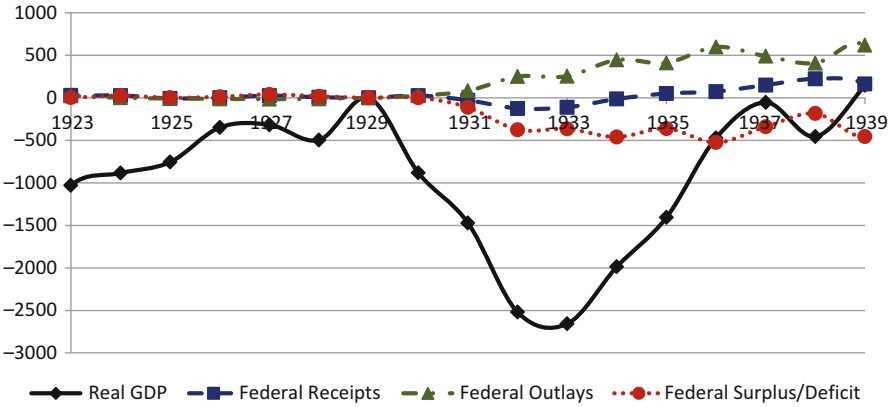

Fig. 1 Per capita gross domestic product and federal government revenue, outlay, and surplus/deficit value minus the 1929 value, (in 2013 Dollars), 1923–1939 (Source: Fiscal years ran from July 1 through June 30, such that the 1930 value covers the period July 1, 1929, through June 30, 1930. Federal government outlays receipts and the budget deficit/surplus are series Ea584, Ea585, and Ea586, and nominal GDP is series Ca10 from Carter et.al. (2006, pp. 5–80, 5–81, and 3–25). The deflator used to calculate the values for 2013 and resident population used to calculate per capita measures was downloaded from the Williamson and Officer (2014) website on October 10, 2014)

Fig. 2 Dow Jones Industrial Average Closing Price, October 1, 1928–December 31, 1933 (Source: Data downloaded from Dow Jones (2010) Historical Data on 4 June 2010)

Why?

Economists have plenty of answers but they do not all agree on how much weight to give each cause. The start of the Depression may have been a natural outcome of the boom and bust cycle in the economy. Investment expanded rapidly in the 1920s with the development and diffusion of new technologies like the auto, electricity, radios, and many new appliances. The boom in the stock market caused the Dow Jones Stock Index to rise from a low of 63 in 1921 to a peak of 381 in 1929. Construction of all types exploded. The number of building permits for housing in urban areas between 1922 and 1928 nearly doubled previous highs in the economy (Carter et al. 2006, pp. 4–481). The optimism that led to the investment boom was matched by the willingness of banks, insurance companies, and building and loans to lend. Stocks were sold on margin, consumers could buy new autos and appliances on installment plans, and mortgage loans expanded rapidly (Olney 1991). Some lenders packaged mortgages for resale to investors in mortgage-backed bonds. In many ways, the 1920s boom and the recession that started in 1929 match Joseph Schumpeter's (1939) description of increasing enthusiasm leading to overbuilding and over-investment followed by corrections that lead to recessions until the actual demand for goods catches up.

But such explanations can only really explain the start of the Depression. It makes sense, for example, that after the number of building permits (Table 2) peaked in 1925 at 937 thousand, nearly double the amount from any year before the 1920s, that number would fall back. By 1929, the number had nearly halved to a level that was still much higher than at the beginning of the 1920s. But what explains a decline to a low of 93 thousand in 1933? What explains an all-time high unemployment rate over 20% and the largest drop in output in history?

Since the Wall Street Crash occurred in late 1929, the timing seems to imply that the stock crash was a major cause of the Great Depression. The Dow Jones Stock Index (Fig. 2) peaked that year when it closed at 381 on September 3, 1929, soon after the recession had started in August. The most spectacular loss occurred when the Dow declined 24% from its previous Friday's close at 301 over Monday and Tuesday, October 28 and 29. It then dropped to a low of 198 on November 11. Stocks then recovered. By April 1930, the Dow was challenging the levels it had reached just before Black Tuesday. It then sunk in fits and starts to a low of 41.2 on July 8, 1932.

Most economists do not focus on the Stock Crash as a major cause of the Great Depression. One reason is that stock market values have fallen sharply on numerous occasions without consequent declines in the real economy. The spectacular drop in 1987 barely impacted the real economy and even the most recent decline of nearly 40% in the stock market in 2008 was followed by only one negative year of real output growth. Economists who assign the highest weight to the stock crash talk about how the crash led to greater uncertainty that caused consumers to cut back on purchases of durable goods like autos and refrigerators. Additionally, it created problems for stockholders who struggled to repay their loans or could no longer borrow, which in turn made it more difficult for banks to have enough funds to lend

for new investments. But a relatively small share of the population owned stocks at the time, so the vast majority had little invested in the stock market crash. One study of bond ratings found that investor confidence held up relatively well for a couple of years after the crash. The long length of the stock market's fall to its extremely low 1933 depth suggests that the market might well have been responding to the changes in the economy rather than being a cause of the decline in the economy.[2]

Explanations of the Depression's causes often lead to answers that still leave much to be explained. Speculations about a decline in consumption as a prime cause just pushed the question back one level because scholars know little about why consumers bought less. Others have focused on a series of negative productivity shocks on the supply side of the economy as causes. Yet, no one has had much success in identifying the exact nature of these shocks. Others point to increased uncertainty.[3]

Whatever was happening in the private economy, it was not helped by the economic policies chosen by the Congress, President Hoover, and the Federal Reserve Board. Nearly everybody agrees that the Federal Reserve Board's monetary policy helped turn a recession into a major Depression. The primary disagreements center on how much blame the Fed deserved and why they followed such an inadequate policy. The economy of the early 1930s was the Federal Reserve's first great test. Sadly, the Fed failed it.[4]

Through 1935, the Fed had two major tools for influencing the money supply. They could buy and sell existing bonds in "open market operations." They could also adjust the "discount rate" at which member banks borrowed funds from the Fed to meet reserve requirements. In response to bank failures in a panic or a general downturn, the Fed could increase the money supply and stimulate the economy by buying bonds and/or lowering the discount rate.

In making policy, the Fed also had to pay attention to the international gold standard. To remain on the gold standard, the Federal Reserve and US banks had to

[2]Peter Temin (1976) uses bond ratings to show that investor confidence held up well for a couple of years after the crash. Christina Romer (1990) and Frederic Mishkin (1978) of modern economists assign the largest role to the stock crash. For other readily readable discussions of the causes of the Great Depression, see Smiley (2002) and Randall Parker's (2002, 2007) volumes of incisive interviews with many of the leading economists who have written on the Depression.

[3]For the consumption arguments, see Temin (1976) and Romer (1990). For negative productivity shocks, see the work of Ohanian (2001) and Cole et al. (2005) and sources cited there. For uncertainty, see Flacco and Parker (1992).

[4]Friedman and Schwartz (1963) led the way in developing this monetarist argument. Bernanke (2000) provides additional arguments based on breakdowns in lending channels as the money supply shrunk. The argument was debated heavily in the 1970s and 1980s, and the debate is nicely summarized in Atack and Passell (1994). The monetarist analysis received support using dynamic general equilibrium analysis from a study by Bordo et al. (2000). Some challengers became more accepting of the argument when it was tied to reliance on the gold standard. Real business cycle economists tend to give less weight to the monetarist argument, but real business cycle economists Cole et al. (2005) assign as much as 33 % of the blame for the Depression internationally to monetary shocks. See also Chari et al. (2002). For a summary of more recent works from the 1990s and 2000s, see Fishback (2010).

stand ready to pay an ounce of gold for every $20.67 in Federal Reserve notes. This meant holding adequate US gold reserves to make the promise believable. If changes in the relative attractiveness of the dollar led the US supply of gold to fall below the appropriate level, the Fed was expected to take actions to make the dollar more attractive. At the time, the standard policies in response to gold outflows included raising the discount rate and selling (or at least reducing purchases of) existing bonds.

In an attempt to slow the speculative boom in stocks, the Federal Reserve policy in 1928 and 1929 aimed at slowing the growth of the money supply (Hamilton 1987). Over the next 4 years, there were a series of negative shocks to the money supply, including the stock market crash in 1929; banking crises in 1930–1931, 1931, and 1932–1933; and Britain's abandonment of the gold standard in September 1931. The Federal Reserve's response to these crises might best be described as "too little, too late," as it allowed the money supply to fall by 30%.

The policy makers at the Fed thought they had applied a great deal of stimulus to the money supply when they cut the nominal discount rate in eleven steps from 6% in October 1929 to 1.5% in 1931. The rates seem low but had little effect because rapid deflation raised the value of dollars that borrowers had to repay in ways that caused the real discount interest rate to rise as high as 10.5%. In the minutes of their meetings, the policy makers did not mention the impact of deflation on real interest rates as a concern (Meltzer 2003).

When Britain left the gold standard in 1931, the Fed felt that it had to stop an outflow of gold to Britain by raising the discount rate back to 3.5% in late 1931. Adjusted for deflation, the discount rate in real terms reached 14%. Even though the rate was lowered again, deflation left the real discount rate at 15.2% at one point in 1932. This is nearly triple the next highest real discount rate of 5.8% that has been reached since 1933. The deflation, itself a result of the fall in the money supply, made the discount rate a nearly useless tool for the Federal Reserve.

The Fed's other alternative was to make "open market purchases" of bonds. Its boldest move was an open market purchase of $1 billion in bonds over several months in the spring of 1932. By that time, output in the economy had sunk by 30% and the unemployment rate was over 20%. Had the Fed offset the banking crises in 1930–31 with a $1 billion purchase, the damage likely would have been limited and the murkiest depths of the Depression avoided.[5]

Why was the Federal Reserve so recalcitrant? In part, the Fed was following the same policies toward banks that they followed in the 1920s. Between 1920 and 1929, the Federal Reserve and state bank regulators allowed an average of 630 banks per year to suspend operations. Most of the banks were small and a good case could be made that they had made bad loans and investments that could not be salvaged. As the economy deteriorated between 1930 and 1933, banking problems worsened dramatically as bank runs led to a reduction in the number of banks from 25 thousand to 17.8 thousand. In

[5]This is the essence of Friedman and Schwartz's (1963) argument. See Christiano et al. (2003) for an analysis that emphasizes the role of monetary policy but not necessarily Friedman and Schwartz' "too little, too late" hypothesis.

many cases, the suspended banks looked as bad as the banks that failed in the 1920s. Fed policy was not uniform across the country. The Atlanta Fed had some success at staving off bank failures and declines in the southern economy by quickly providing large amounts of reserves to banks that faced runs. The quick backing allowed the banks to reassure all of their depositors, who then redeposited their money.[6]

The Fed's focus on keeping the USA on the gold standard also created significant problems. To combat the downturn, the Fed wanted to stimulate the money supply and thus the economy, but changes in international markets were forcing them to do the opposite to remain on the gold standard. Once the USA left the gold standard in 1933, the economy began to improve. The slow reaction to the bank panics during the 1930s was grouped with a series of policy blunders in other areas. The Hawley-Smoot Tariff Act of 1930 in the USA raised tariffs to levels that restricted US imports. Other countries responded by erecting their own barriers to trade, especially after Britain went off the gold standard in September 1931. The result was a downward spiral in world trade. In the USA, per capita exports and imports (Table 2) were cut in half by 1933. Tariffs led to a variety of inefficiencies in the economy, but the impact on real GDP per capita during the Depression was relatively small because exports were only about 6% of GDP in good times, while net exports were typically less than a half percent.[7]

Until the 1930s, wages and prices had typically declined during downturns. The declines in the past often had contributed to a surge in purchases of consumer goods and in hiring workers that helped turn the economy around. President Hoover held conferences in 1929 to ask leading manufacturers in the country to hold wages stable and run a job-sharing policy that cut weekly hours, so that workers would not lose their jobs. A number of large firms followed his dictate, waiting until the middle of 1931 before cutting hourly wages. In asking manufacturers to follow the job-sharing model, the Hoover administration hoped that keeping more workers employed with stable wages would leave them with enough buying power to keep the economy moving, despite their losses in weekly earnings. In 1932, he signed the Norris-LaGuardia Act, which outlawed several antiunion practices and gave unions more power to organize and hold the line on wages. Following their introduction, the economy continued to slide, and even union membership fell 11% over the next year.[8]

[6]Wheelock (1991) uses econometric methods to show that the statistical relationships between Fed policy instruments and the economic factors on which policy makers focused did not change between the 1920s and early 1930s. Wheelock (1991) and Richardson and Troost (2009) talk about differences in policies at the regional Federal Reserve Banks. For discussions of the declines in asset quality and bank suspensions, see Calomiris and Mason (2003).

[7]Irwin (2011) provides a detailed description of the political economy of the tariff and argues that the size of the tariff increase was not as large as many have stated.

[8]Ohanian (2009) argues that Hoover's jawboning was a major contributor to the Great Depression, arguing that employers followed the policies in part due to fears of the strength of unions. This is somewhat puzzling because union membership declined in the early 1930s, as seen in Table 2. See also Rose (2010) and Neumann et al. (2013) for more specifics about the Hoover policy.

Faced with increasing unemployment, President Hoover did not press for the federal government to start providing new welfare programs. Instead, he followed the path set by the long-term federal structure of governments. Since colonial times, responsibilities for caring for the poor and the disabled had resided in local governments. States began playing a bigger role after 1909 by establishing mothers' pensions, workers' compensation, aid to the blind, and old-age assistance.

Hoover also strongly believed in "voluntarism," as can be seen in his efforts to jawbone manufacturers into paying high wage rates. He thought the federal government should help organize efforts by others to resolve the problems. The government might help through loans. When faced by struggling farmers who demanded subsidies to control production and raise prices, the Hoover administration instead supported the provision of $500 million in loans through a Federal Farm Board. To aid the unemployed, he formed the President's Emergency Committee on Employment in 1930 to aid private organizations as they sought to help the poor. This group morphed into the President's Organization for Unemployment Relief in 1931. Eventually, in the summer of 1932, he signed a legislation to offer $300 million in loans to local governments to aid them in poor relief.

Faced with large-scale bank failures, Hoover convinced bankers to set up the National Credit Corporation (NCC) to aid troubled banks. When the NCC fell short, Hoover and the Republican Congress mimicked loan programs from World War I and created the Reconstruction Finance Corporation (RFC) in February 1932 to make loans to troubled banks, industries, and the farm sector. The bank loans were not effective at preventing suspensions because banks had to hold assets as collateral for the RFC loans and thus could not sell them to pay depositors if trouble arose. The RFC was more successful at saving the banks when it began taking short-run ownership stakes in the banks (Mason 2001; Calomiris et al. 2013). RFC ownership stakes set precedents for the moves by Treasury Secretary Henry Paulson and Fed Chair Ben Bernanke to take ownership positions in banks in the fall of 2008.

Hoover is often seen as a fiscal policy conservative. Compared to his Republican predecessors, however, he looks like a rabid spender. From 1921 through 1929, the Harding and Coolidge administrations had run budget surpluses (Fig. 1). They followed the standard pattern of repaying the debt run-up during World War I. In response to the worsening economy, Hoover and the Republican Congress increased real federal outlays per capita (Fig. 1 and Table 1) by 91% between 1929 and 1932. Herbert Hoover gets less credit for this rise than Franklin Roosevelt does for the New Deal because Hoover did not create new spending agencies, he just expanded existing programs by doubling federal highway spending and increasing the Army Corps of Engineers' river and harbors and flood control spending by over 40%.

Herbert Hoover believed in balanced budgets, as did Franklin Roosevelt during the New Deal. The debates between Hoover and the Congress in 1932 over how to raise taxes to balance the budget led to two major types of tax increases. The first was a "soak the rich" effort. Less than 10% of households earned enough to pay income taxes in the early 1930s. In the Revenue Act of 1932, the tax rate was raised for individuals earning more than $2,000 from 0.1% to 2%, and the rate rose from 0.9%

to 6% for incomes from $10 to $15 thousand. People with income over $1 million saw their tax rate rise from 23.1% to 57% (Carter et al. 2006, pp. 5–114).

The higher income tax rates did little to stem the drop in tax revenues between fiscal years 1932 and 1933 because receipts from income taxes and estate taxes fell to 37%.[9] Some of the fall was due to tax avoidance by the very rich and the rest was due to the continued deterioration in the economy. New excise taxes helped make up the shortfall in income tax revenue, so that per capita federal revenue stayed roughly the same in 1932 and 1933 (Fig. 1 and Table 1). The Revenue Act tacked on new excise taxes on oil pipeline transfers, electricity, bank checks, communications, and manufacturers – particularly autos, tires, oil, and gasoline 0020 (Commissioner of Internal Revenue 1933, pp. 14–15). Unfortunately, these new taxes contributed to retarding the development of some of the new industries that might have led a recovery.

As the economy dove toward the depths of the Depression, Herbert Hoover and the Republican Congress offered a variety of new policies to combat the problems. Some, like the Hawley-Smoot Tariff and the Federal Reserve's inaction, were disastrous, not only for the USA but for the world economy. The job-sharing policies were probably misguided and the efforts at voluntary organization floundered in the face of such a deep Depression. The Hoover administration offered a wide range of subsidized loans and even ramped up federal spending to shares of GDP not seen in peacetime. No matter what Hoover threw at the Depression, nothing stemmed the tide. In consequence, he and the Republican Congress lost power to Franklin Delano Roosevelt and the Democrats in a landslide during the 1932 Election.

Between Roosevelt's November landslide victory and his inauguration on March 4, 1933, the US economy's tailspin deepened. Industrial production, prices received by farmers and producers, real weekly manufacturing wages, and the share of corporations earning profits all bottomed out. Industrial production reached a low that had not been seen since the sharp recession in the spring of 1921 and since 1915 before that. The unemployment rate hovered around 25%, while average weekly work hours fell below 35 for the second time.

The banking sector went through another wave of failures as 633 banks suspended payments from December 1932 through February 1933. Roosevelt and Hoover disagreed over how to deal with the suspensions during the winter. Hoover pressed Roosevelt to agree to Hoover's recommended policies but would not act without Roosevelt's approval. Not wanting to be saddled with Hoover's policies, Roosevelt refused consent and decided to wait and set his own policies after the inauguration. Meanwhile, state governments had begun declaring bank holidays and restrictions on deposits paid out. By March 4, every state and Washington, DC, had imposed some type of restriction (Wicker 1966, p. 153). It remained to be seen what the new administration could do to turn the tide.

[9]Ellen McGrattan (2012) develops a model that shows the negative consequences of taxes on corporate income and dividends in the early 1930s.

The New Deal and Partial Recovery

"This Nation calls for action, and action now," Franklin Roosevelt declared during his inaugural speech on March 4, 1933.[10] Two days later, he announced the National Banking Holiday. Within 100 days, Roosevelt and the Democratic Congress had established a "New Deal for the American public" that developed into the largest peacetime expansion of federal government activity in American history.

Over the next 7 years, Roosevelt and the Democratic Congress tried government solutions to dozens of problems in the American economy. When they saw a problem, they tried to fix it with more spending or new government regulation. But in many cases, a policy designed to fix one problem contradicted the fix for another problem. For example, when they tried to raise prices in the farm sector by limiting production, they contributed to increased unemployment among farm workers while also raising prices for food for workers and the unemployed, leading to reductions in their standard of living.

Measuring the Recovery

The trough for the economy was so deep that growth rates coming out of the recovery were relatively rapid until a second-dip recession occurred in 1937–1938. In 1933, real GDP per person (Table 1 and Fig. 2) was about 29% less than its 1929 figure. Real GDP per person neared its 1929 level again in 1937 but fell back in 1938 before finally surpassing the 1929 level in 1939. An entire decade was spent with less output per person than in 1929. The shortfall was even worse when the long-run growth path is considered. Had real GDP per person risen at its long-run average growth rate of 1.6% per year, GDP per person in 2009 dollars would have been more than $1,000 higher than the $9,112 level reached in 1939.

One factor that might have taken its toll on the private economy was the high degree of uncertainty about what the government planned to do. The New Deal went through multiple phases, as the activities of the Agricultural Adjustment Administration (AAA) and the National Recovery Administration (NRA) were struck down by the courts in 1935 and the Roosevelt administration tinkered with the new regulations, new taxes were introduced then removed, and temporary agencies received new extensions. Such uncertainty can wreak havoc when businesses and workers are making longer-term decisions (Higgs 1997).

The unemployment rate did not recover as well as real GDP did. Table 1 shows two measures of the unemployment rate for the 1930s that differ based on whether people on work relief are categorized as unemployed or employed. Either measure shows unemployment rates during the New Deal that are among the highest in America's economic history. Since 1890, the unemployment rate has risen higher

[10]See the Inaugural Address of Franklin Delano Roosevelt (1933), downloaded on 10 June 2010, from http://www2.bartleby.com/124/pres49.html.

than 10% only during the Depression and in two other years, 1921 and 1983 (Carter, et al. 2006, 2–82 and 2–83).[11] Between 1933 and 1937, the unemployment rate dropped, but the Fed's increase of reserve requirements, the balancing of the federal budget deficit (Fig. 2), and a variety of other shocks to the economy contributed to a sharp spike in the unemployment rate in 1938. Not until 1942 did the unemployment rate fall into a more normal range.

One bright spot while digging out of the Depression was a surprisingly rapid rise in "productivity," a measure of output relative to the inputs put into the process. Alex Field (2003, 2011) has described the 1930s as "the most technologically progressive decade of the century." Partly, the rise in productivity came from the large public investments in roads, dams for electricity, highways, sanitation works, and airports that had begun earlier and been expanded under the New Deal. Many of these investments set the stage for greater productivity during World War II and the postwar boom. Some of the improvements came from firms faced with high wage rates and limited working time, finding new ways to organize their workers and raise output per man-hour. Some of the progress came from investments in research and development laboratories by businesses in the 1920s that bore fruit in the 1930s. Much of the research was based on basic science in chemistry and engineering that led to new uses of electricity, new fabrics, and new household appliances. The television, which dominated communications in the last half of the century, was being readied for commercial applications, but the War slowed the diffusion (Field 2003). In agriculture, new hybrid seeds, tractors, autos, trucks, and fertilizers began to diffuse widely. The usage was likely stimulated in part by farmers who sought to raise productivity on the acres that they had not taken out of production in response to the AAA payments.

In 1940 and 1941, the economy continued to recover. The USA may have benefited some from the disastrous war that had begun raging in Europe. Demand rose for US production of military hardware, food, clothing, and other necessities, as European production of many items was stunted by the Nazi invasions and the bombings in Britain (Gordon and Krenn 2010). Consumption in the USA was not growing as fast as output in part because the USA had begun shifting a number of factories to the production of munitions. The goal was to aid the Allies through Lend Lease and to prepare for the eventuality that the USA might enter the war. Once

[11]One of the thorniest issues for studying unemployment rates in 1930s is whether to define as employed or unemployed the people on emergency work relief programs, like the Federal Emergency Relief Administration from 1933 through 1935 and the Works Progress Administration from 1935 through 1942. The relief workers worked for their relief payments at hourly wages that were roughly half to two-thirds of the norm paid by other government projects. Since 1940, the unemployment statistics have treated people receiving unemployment benefits of similar size as unemployed and they have no work requirement. This suggests to me that the New Deal relief workers were worse off than modern people on unemployment insurance because they received the same benefits as the modern people but had to work for them. Thus, I believe the relief workers should be considered unemployed in comparison with modern unemployment rates. See Darby (1976) and Neumann et al. (2010) for more discussion of this issue.

Japan bombed Pearl Harbor, however, the American economy shifted swiftly to a wartime command economy.

Measuring the Success of the New Deal Policies

Roosevelt's New Deal led to enormous institutional changes that have carried into the twenty first century. The Federal Government took responsibility for insuring against a wide variety of potential crises, several emergency programs, new regulations, and social insurance programs. Economists and economic historians have been studying how much the economic policies contributed to the recovery and how they changed the structure of the economy.

Monetary Policies

Within 2 months of taking office, Roosevelt and the Federal Reserve had completely reversed the monetary policies of the early 1930s. Their goal was to shift expectations from continued deflation to anticipated inflation. Roosevelt announced the goal of higher prices for farmers and producers and higher wages for workers on numerous occasions. The National Bank Holiday closed all banks and thrift institutions temporarily, while auditors examined the banks. Banks declared sound were soon reopened. Insolvent banks were reorganized, some with Reconstruction Finance Corporation backing. These seals of approval for the reopened banks helped change expectations about the solvency of the bank system.[12]

By June, Roosevelt had taken the USA off of the gold standard and appointed Eugene Black from the Atlanta Fed as the Chair of the Federal Reserve Board. Under Black, who had saved many southern banks facing bank runs by flooding them with cash, the Fed began to focus on monetary expansion (Richardson and Troost 2009). Between April and May, the discount rate was cut from 3.5% to 2.5%. It then fell to 2% by the end of the year, to 1.5% in 1934, and then to 1% in 1937. The return of inflation meant that the real discount rate through 1937 was negative, a sharp contrast to the double-digit positive real discount rates during the Hoover era.

The move off of the gold standard and the devaluation of the dollar to $35 dollars per ounce of gold combined with political events in Europe to cause a flow of gold into America. The economy began to recover. This same pattern was repeated throughout the world. In country after country, as central banks sought to maintain the gold standard, their domestic economies continued to sink. As each left the gold standard, their economies rebounded.[13]

[12]For a description of the National Bank Holiday, see Mason (2001). For discussions of the reversal of policy to fight deflation, see Temin and Wigmore (1990) and Eggertsson (2008).

[13]Eichengreen (1992), Temin (1989), Temin and Wigmore (1990), and Kindleberger (1986) talk extensively about the move off of the gold standard.

The Fed's emphasis on raising the money supply lasted through three years of recovery, as real GDP per capita neared its 1929 level in 1937 and the unemployment rate fell toward 14% (Fig. 1 and Table 1). In 1935, the Fed gained control of an additional policy tool, "reserve requirements," the share of deposits banks were required to hold in reserve. Unfortunately, by August 1936 the Fed had begun to fear that banks were holding large excess reserves above and beyond the required reserves. Fearing that the banks would begin lending the excess reserves, raise the money supply, and create rapid inflation, the Fed doubled the long-standing reserve requirements in three steps on August 16, 1936; March 1, 1937; and May 1, 1937. The Fed had failed to recognize that the banks were holding so many excess reserves to protect themselves against bank runs. Their experience of the past decade had given them little confidence that the Fed would act as a lender of last resort. Therefore, the banks increased their reserves to make sure that they retained some excess reserves as a cushion above the newly doubled requirements. These changes were followed by a spike in unemployment to 19% in 1938 (Fig. 2) and a decline in real GDP per person back to its 1936 level (Fig. 1).[14]

Fiscal Policy

The myth that seemingly will not die is the idea that Roosevelt followed the doctrines of John Maynard Keynes in using government spending to stimulate the economy. In *The General Theory of Employment, Interest and Money* from 1935, Keynes (1964) argued that the economy can settle into an equilibrium at less than full employment, particularly when there are factors blocking wage and price adjustments. Increases in government spending and reductions in taxation that lead to larger budget deficits are methods for pushing the economy toward full employment. Because the New Deal ramped up government spending under the New Deal, people have mistakenly presumed that Roosevelt followed a Keynesian policy.

Although by 1939 the Roosevelt administration had raised real per capita government outlays by nearly 70% (Fig. 1), the per capita tax revenues rose at roughly the same pace. As a result, the budget deficits in Fig. 1 do not look much different from the deficits the Hoover administration ran in fiscal years 1932 and 1933. Economists and economic historians, including Keynes himself, have long known that Roosevelt did not follow Keynes' dictates. Keynes even wrote an open letter to President Roosevelt published in newspapers in late December 1933 saying that the increased spending was good but the increase in tax revenues was reducing the stimulative effect.[15]

[14]This description is based on Friedman and Schwartz (1963). For a view that puts less emphasis on the Fed's role, see Romer (1992). Calomiris et al. (2011) use data for individual banks to challenge the idea that the reserve requirement rise had a strong impact on the 1937–1938 recession. For a dynamic model of the 1937–1938 recession, see Eggertsson and Pugsley (2006).

[15]See Brown (1956) and Peppers (1973) for more sophisticated analysis showing that the New Deal did not follow the Keynesian policy. Barber (1996) describes the economic thinking of many of the New Deal advisors.

Both federal outlays and the size of deficits fell well short of the Keynesian recommendation, given the size of the shortfall in real GDP. The bottom line in Fig. 1 is the difference in real dollars between GDP per person in the year marked on the graph and in 1929. The GDP per person shortfall was $1,987 in 2013 dollars in 1934. Government outlays in that fiscal year were only about $436 per person more than they had been in 1929 and the deficit was only $455 per person more negative than it had been in 1929. To even begin to be close to the size of a Keynesian stimulative policy designed to get to full employment, the deficit would have needed to be at least 3 times as large and probably larger.

Roosevelt's tax rate policies made matters worse by chilling incentives for investors. After some minor tinkering in 1934, income tax rates were raised again for people earning over $100,000 in 1936. The top rate went from 57.2% to 68% for people earning over $1 million. The National Industrial Recovery Act of 1933 instituted a tax on capital stock, dividends, and excess profits that was collected through the rest of the 1930s. In 1936, a surtax was added on profits that were not distributed as dividends. None of these new tax rates generated a great deal of tax revenue, but they did create the wrong incentives for investment. Sadly, the companies least able to avoid the highest marginal rate of 27% on undistributed profits were smaller, faster-growing firms that were not yet able to obtain external financing (Calomiris and Hubbard 1993). Most of the growth in tax revenues came from natural increases in tax revenues as the economy recovered, a temporary processing tax on agricultural goods that ended in 1935, and the renewed collections of alcohol taxes after the end of Prohibition.

The Roosevelt administration's best tax policy was its relaxation of some of the tariff barriers imposed in 1930. The Reciprocal Trade Agreement Act of 1934 freed Roosevelt to sign a series of tariff reduction agreements with Canada, several South American countries, Britain, and key European trading partners. As a result, American imports rose from a 20-year low in 1932–1933 to an all-time high by 1940.[16]

Alphabet Soup

The New Deal combined expansions in federal spending and regulatory roles in a proliferation of acronyms for new agencies. Some were temporary, like the Federal Emergency Relief Administration (FERA), Civil Works Administration (CWA), and the Works Progress Administration (WPA) relief agencies, but the majority became permanent parts of the economic landscape.

The agencies that distributed the most grant money provided relief to the poor, built public works, and paid farmers to take land out of production. When the FERA was established during the first 100 days, the federal government took responsibility

[16]For historical comparisons of the impacts of tariff rates, see Irwin (1998). Kindleberger (1986, p. 170) and Atack and Passell (1994, p. 602) describe the international trade developments in the 1930s.

for the first time for aiding the poor and the unemployed.[17] The FERA provided both direct relief payments and work relief jobs through 1935, while the CWA lasted 4 months in the winter of 1933–1934. In 1935, the responsibility for "unemployables" was returned to the state and local governments and the WPA took over the provision of work relief. Meanwhile, the Public Works Administration (PWA), Public Roads Administration (PRA), and Public Building Administration (PBA) were new agencies that continued the federal government's role in funding the building of large dams, federal highways, federal buildings, and improvements to federal lands while also aiding the state and local governments in building their own projects.

A series of studies in the past 10 years show, on net, that the public works and relief spending were beneficial to the communities where they were built. Nearly all of the studies are based on panel data sets with multiple years of data for each location. The methods for identifying the effects typically examined the impact of changes over time within the same location after controlling for nationwide shocks to the economy. They used methods to avoid negative feedback effects that arose from the government providing more funds in areas where the economy was bad. An additional dollar of public works and relief spending in a state raised income in the state by between 67 cents and $1.09. Areas with more public works and relief projects saw increases in retail sales, drew more internal migrants, experienced less crime, and had lower death rates from infant mortality, suicides, and infectious disease. The one area where public works and relief spending had no positive impact was on raising private employment, which may help explain why the unemployment rate remained so high throughout the decade.[18]

The Social Security Act of 1935 established a new long-run set of social insurance institutions. The new old-age security pension program, what people now call social security, called for taxes on employers and workers to finance pensions for retired workers. Unemployment insurance (UI) required that employers pay into funds that would provide benefits when their workers became unemployed. Although many states had already set up programs to aid widows with children, the poor elderly, and the blind, the Social Security Act helped expand these programs by federal government-provided matching grants that improved benefits and gave states incentives to create the programs if they had not already. The states spent the most on the needs-based old-age assistance programs. These programs encouraged the elderly to live on their own and retire, although they did not have much impact on the death rates of the elderly.[19]

[17]The federal government had long provided benefits and disability payments for its administrative employees, soldiers, and veterans.

[18]See Wallis and Benjamin (1981), Benjamin and Mathews (1992), Fleck (1999), Fishback (2015), Fishback et al. (2007), Fishback et al. (2005, 2006), Fishback and Kachanovskaya (2015), Johnson et al. (2010), Neumann et al. (2010), and Garrett and Wheelock (2006). For a dataset with federal spending by state in the 1930s, see Fishback (2015). For datasets at the state, city, and county level, see Price Fishback's website at the University of Arizona Economics Department http://econ.arizona.edu/faculty/fishback.asp. For a general survey, see Fishback and Wallis (2013).

[19]See Costa (1999), Stoian and Fishback (2010), Parsons (1991) Balan-Cohen (2009), and Friedberg (1999).

In contrast, the AAA farm program was specifically designed to reduce output and raise farm prices with an aim to raise a farmer's incomes from a decade of doldrums. In the final analysis, the AAA led to a significant redistribution of benefits to landowning farmers away from consumers, farm workers, and some farm tenants. Large farmers were the chief beneficiaries of the payments and whatever price boosts occurred. The reduction in land under cultivation generally reduced the demand for labor and thus made it more difficult for farm workers and sharecroppers to find work. Recent estimates of the local effect of the AAA show that counties receiving more AAA spending saw no change or a negative effect on overall economic activity and experienced some out-migration.[20]

The financial disaster led to a variety of new financial regulations. Since the 1930s, the SEC has monitored the stock markets, set reporting requirements for firms issuing stock, combated insider trading, and enforced rules on market trades. To stem the tide of future bank runs on deposits, the FDIC and FSLIC provided federal government insurance of deposits in banks and savings and loans. Limits were set on the types of investments that could be made by commercial banks and savings and loans. Regulation Q prevented payment of interest on checking accounts.[21]

In the moribund housing sector, states had tried to prevent foreclosures with moratoria laws that allowed home and farm owners to delay payments on their mortgages. The laws had the unfortunate effect of raising the risk of making loans because lenders could not be sure the states would not prevent repayments again (Rucker and Alston 1987). The result after the moratoria were eliminated was higher interest rates and much more restricted lending during the recovery. The Home Owners' Loan Corporation (HOLC) bought over one million mortgages that were in danger of foreclosure "through no fault of" the homeowner and then refinanced them on generous terms. The purchases almost fully replaced the bad loans on the lenders' books while helping about 80% of the borrowers remain in their homes. Given the uncertainty about the program, the up-front subsidy to housing markets probably was as high as 20–30% of the value of the loans, although after the fact that the HOLC only had losses equal to about 2% of the loans. The program also helped stave off further drops in housing prices and homeownership.[22] In 1934, the Federal Housing Administration was formed to offer federal insurance for mortgage loans both for new and existing homes and for repair and reconstruction. In 1938, Fannie Mae was established as a government corporation to provide a secondary market for mortgage loans in which banks could sell the loans as assets and then use the funds to make new mortgages.

[21]For detailed accounts of the banking regulations, see Mitchener and Richardson (2013), Calomiris (2010), and Mason and Mitchener (2010).

[22]For analysis of the HOLC, see Courtemanche and Snowden (2011), Fishback et al. (2011, 2013), Harriss (1951), and Rose (2011).

The most controversial economic agency created by the New Deal was the National Recovery Administration (NRA). Between 1933 and 1935, when it was declared unconstitutional, the NRA fostered the development of "fair" codes of competition in industry. Industrialists, workers, and consumers in each industry were expected to meet and establish rules for minimum prices, quality standards, and trade practices. The workers were to be protected by minimum wages, limits on work hours, and rules related to working conditions in ways that looked like the job-sharing proposals Hoover had made earlier. Section 7a of the NIRA established a standard language for the codes that gave workers the right to bargain collectively through the agent of their choice. Once the code was approved by the NRA, the codes were to be binding to all firms in the industry, even those not involved in the code writing process. One of several goals was to prevent the "destructive" competition that some of Roosevelt's advisors believed had caused the deflation. The advisors expected that firms allowed to raise prices would sell more. Hour limits were put in place to allow more workers to remain employed, while the wages were raised to help reduce the losses in weekly earnings from the cut in hours.

The NRA might have had a beneficial macroeconomic effect to the extent that it contributed to shifting people's expectations from deflation to inflation.[23] However, from a microeconomic perspective, the NRA was the antithesis of antitrust policy at any other time in American history. The US law had always banned cartels and price-fixing agreements in restraint of trade. Suddenly, the federal government gave industry leaders antitrust exemptions and cartel-like powers to set prices, wages, and output. Many were written by industry trade groups with little input from unions, which were relatively weak at the time. Even worse, the federal government became the enforcer called on to prevent the natural tendency for firms to break away from cartel agreements. A recent study of the timing of the industry codes and their impact on the industries served to raise hourly wages and lowered hours worked in ways that cut the average weekly wage. When the Supreme Court struck down the NRA as unconstitutional in the Schechter Poultry case in 1935, no one was sorry to see the NRA go. Unlike the AAA, which was quickly reintroduced in a revised form after it was declared unconstitutional, there was little support for reenacting the codes of competition from many quarters and the Roosevelt administration let it die.[24]

After the NRA was struck down, the National Labor Relations Act of 1935 reinstituted the section 7A right of labor unions to organize and collectively bargain.

[23]See Temin and Wigmore (1990) and Eggertsson (2008, 2012) for this argument.

[24]Bellush (1975) offers a good administrative history of the NRA. Cole and Ohanian (2004) find that the high-wage policies and retrenchment in antitrust action associated with the NRA and the Roosevelt administration's post-NRA policies significantly slowed the recovery. Alexander (1997), Taylor (2007), and Vickers and Ziebarth (2014) discuss the problems the industries had in establishing the codes of "fair" competition and the reasons why businesses did not press for a new NRA when it was declared unconstitutional. Jason Taylor (2011) studied the impact of the NRA and the President's Reemployment Agreement on hourly wages, weekly wages, weekly hours, total hours employed, and industry output. Alexander and Libecap (2000) describe the different attitudes toward replacing the NRA and the AAA.

An employer was required to negotiate with a union if a majority of its workers voted to unionize. A National Labor Relations Board was established to monitor elections and arbitrate collective bargaining disputes. After the Act was affirmed as being constitutional in the spring of 1937, there was a surge in union recognition strikes, and the number of members rose from 4.2 million in 1936 to 8.3 million in 1938 (see Table 2).[25]

Conclusions

The Great Depression was the worst economic disaster in the American economic history. The annual output fell to 30% below the previous high and unemployment rates topped 10% for most of the decade and 20% in 4 years. Depression studies describe a variety of causes, including mistaken Federal Reserve policies tied to the gold standard and inadequate attention to deflation, uncertainty and damaged balance sheets related to the stock market crash, the Hawley-Smoot tariff, unexplained drops in consumption, negative productivity shocks, and labor market policies. Scholars still disagree on how much weight to give to each. In response to the contraction from 1929 to 1932, President Herbert Hoover and the Republican Congress nearly doubled real government outlays; distributed loans to banks, industry, and local governments; and tried several voluntary measures. Seeking to balance the budget in the fiscal year 1933, they sharply increased income tax rates and did not increase federal outlays any further, and the economy worsened even more.

Inaugurated in March 1933, President Franklin Roosevelt joined a newly elected Democratic majority in Congress to develop a large number of new regulatory and spending programs that they described as a New Deal for the American people. The USA left the gold standard and the reins on the money supply were loosened, although they were tightened again when the Fed doubled reserve requirements in three steps after 1935. The Roosevelt administration also roughly doubled federal government outlays but raised tax revenues at roughly the same pace and never really followed a Keynesian stimulus policy. Real output per person grew rapidly while climbing out of the deep trough hit in 1933, but was slowed by a second recession in 1937–1938. It finally reached the 1929 level after 1939. In spite of the output growth, unemployment rates remained above 9% until 1941.

The New Deal programs had a mixed record of success. RFC loans to banks in 1932 were not very effective at preventing bank suspensions, although more success was met when the RFC took ownership stakes in banks. Public works and relief spending contributed to the increases in economic activity and helped to reduce a variety of death rates and crime rates, but did not stimulate private employment. The AAA farm program that paid farmers to take land out of production aided farm owners, primarily large farm owners, but at the expense of a significant number of farm workers, sharecroppers, and tenants who lost their positions. The National

[25]For an economic overview of the changes in union policy, see Freeman (1998).

Recovery Administration seemed to help reverse deflationary expectations but had strong negative microeconomic effects. The HOLC helped keep about 800,000 people in their homes and helped stave off drops in housing values and home ownership rates at relatively low ex post cost.

The focus here has been on the emergency programs created during the New Deal. The New Deal also created many programs that are still in place today and programs that set precedents for current policy responses.[26] Cliometric research on the New Deal continues and I am willing to bet that the breadth and depth of New Deal research will increase greatly over the next decade.

Cliometric Approaches to War

Jari Eloranta

Contents

Abstract

This chapter is a review of the many perspectives from history, political science, sociology, and economics that economic historians have applied to the study of war. Here I first review some of the scholarship on the premodern period, especially the formation of European nation states and conflicts. It is fairly clear that Europeans emerged out of this period with a comparative advantage in violence, through technological innovations and repeated warfare. Fiscal innovation and expansion was a key part of this. The period of the revolutions and Napoleonic conflicts represented a change in the nature of warfare and the arrival of total war, as well as the industrial age. The period of the world wars represents perhaps the best represented area of study for economic historians as of late. New data and scholarship has shown the mechanics of mobilization and highlighted the importance of resources in deciding these conflicts. Conversely, the Cold War period has been relatively sparsely studied, at least from the perspective of conflicts or military spending. Given the availability of new data and the opening of many archives, it is highly likely that this state of affairs will change in the near

future. Economic historians have clearly made an impact in the study of long-run phenomena such as state formation, empires, and democracy. Cliometrics is well suited to the study of such topics, given the new panel and time series techniques, the rapid development of computing power, and the many new online databases.

Economic history · Defense Economics · Warfare · Cliometrics · Military spending · State formation

Introduction

The theoretical and methodological impact of the cliometric approach to economic history, embodying the application of economic theories and the use of quantitative methods, has been widely recognized in a number of studies which have brought modeling and quantification into the forefront of economic history analysis. In comparison, quantitative studies of war by economic historians are somewhat rare, although in the last 20 years or so, there have been many more such applications. If we take the world wars as an example, we can see how the approaches to the study of particular conflicts (or times of peace) have differed based on the scholar's theoretical and methodological leanings. Historians in general, especially diplomatic and military historians, have focused on understanding the origins of the world wars and the particular battles that took place – this has also applied to the study of other conflicts, big or small. Most of those studies have not paid adequate attention on the quantitative aspects of war; for example, Paul Kennedy's *The Rise and Fall of the Great Powers: Economic Change and Military Conflict from 1500 to 2000* (1989) contains no quantitative testing of the hypothesis of hegemonic overreach or credible numerical information to back up the findings (Eloranta 2003, 2005).

While economic historical treatments of the costs and impacts of wars have not been abundant, economists have not embraced the study of conflicts wholeheartedly either. For instance, the study of defense economics and military spending patterns is related to the immense expansion of military budgets and military establishments in the Cold War era. It involves the application of the methods and tools of economics to the study of government expansion in the post-Second World War era, and at least three features stand out: (1) the individuals and organizations involved (both private and public spheres of influence, e.g., in contracting); (2) the theoretical challenges introduced by the interaction of different institutional and organizational arrangements, in both the budgeting and the allocation procedures; and (3) the nature of military spending or, more correctly, national defense as a public good as well as its potential for destruction (Sandler and Hartley 1995). Most studies in the rather small field of defense economics have had a limited time span in their analyses, namely, from 1945 onward. The longer-run developments and historical issues have typically fallen outside the interest of defense economists, although many of the tools and theoretical insights are useful for long-run analysis too.

Political and conflict scientists, including peace sciences, often cover similar ground as defense economists, with a longer-run view of history, a focus on the causal factors behind the most destructive conflicts, and the determinants of state formation. One of the most significant efforts in these overlapping fields has been the *Correlates of War* (COW) project, which started in the spring of 1963. This project, and the researchers loosely associated with it, has had a big impact on the study of conflicts, not to mention its importance in producing comparative statistics (Singer 1979, 1981, 1990). Moreover, these contributions have had a lot to offer to the study of long-run dynamics of military spending and warfare. For example, according to Charles Tilly (1990), one of the key contributors in the study of state formation, *coercion* (a monopoly of violence by rulers and an ability to also wield coercion externally), and *capital* (the means of financing warfare) was the key elements in the European ascendancy to world domination in the early modern era. Warfare, state formation, and technological supremacy were all interrelated fundamentals of the same process.

In this chapter I review some of the applications of these interdisciplinary perspectives to the study of war, especially from the point of view of the findings that quantitative methods have brought forth. First, I analyze some of the scholarship on the Middle Ages and the early modern period, especially the formation of European nation states and conflicts. Then I review some of the perspectives on the French Revolution and Napoleonic Wars, in particular the changed nature of conflicts and the arrival of total war. I follow this by examining one of the most fruitful topics of study, especially from the perspective of quantitative approaches: the era of the world wars. Moreover, the Cold War period represents a relatively unexplored frontier for economic historians of conflict, although defense economists have done more work in this area. Finally, I discuss some studies of long-run processes, especially state formation, empires, democracies, and military spending.

Theme 1: Medieval and Early Modern Warfare

The emerging nation states of the early modern period were much better equipped to fight wars. On the one hand, the frequent wars, new gunpowder technologies, and the commercialization of warfare forced them to consolidate resources for the needs of warfare. On the other hand, the rulers eventually had to share some of their sovereignty to be able to secure required credit both domestically and abroad. The Dutch and the British were the best at this, with the latter creating an empire that spanned the globe on the eve of the First World War.

During the Middle Ages, following the collapse of the Roman Empire (or at least the Western half) and barbarian invasions, a system of European feudalism emerged, in which feudal lords provided protection for communities for service or price. After the first millennium ended, the command system was usually used to mobilize human and material resources for large-scale military ventures (France 2001). Most European societies, with the exception of the Byzantine Empire, paled in comparison with the splendor and accomplishment of the empires in China and

the Muslim world. However, it seems that the Christian Western Europe under the feudal system provided more stability and longer leadership tenures, which contributed to Europe's military resurgence (Blaydes and Chaney 2013). Furthermore, it was not until the twelfth century and the Crusades that the feudal kings engaged in larger-scale operations that required supplementing ordinary revenues to finance the conflicts. The political ambitions of medieval kings, however, were a precursor of things to come and led to short-term fiscal deficits, which made long-term credit and prolonged military campaigns difficult (Webber and Wildavsky 1986; Eloranta 2005).

Innovations in the waging of war and technology, especially gunpowder, arrived in Europe with a delay, which in turn permitted armies to attack and defend larger territories. This also made possible a commercialization of warfare in Europe in the fourteenth and fifteenth centuries as feudal armies had to give way to professional mercenary forces. The age of commercialization of warfare was accompanied by the rising importance of sea power as European states began to build their overseas empires. Portugal, the Netherlands, and England, respectively, became the "systemic leaders" due to their extensive fleets and commercial expansion in the period before the Napoleonic Wars. The early winners in the fight for world leadership, such as England, were greatly influenced by the availability of inexpensive credit, enabling them to mobilize limited resources effectively to meet military expenses (Thomas 1983; Modelski and Thompson 1988; Ferguson 2001; Eloranta 2003).

These earlier efforts at expansion of armies, nation states, and credit have been studied more and more recently by economic historians. While efforts such as the project and database constructed by Richard Bonney (see, e.g., Bonney 1999a)[1] and Philip Hoffman and Peter Lindert (see, e.g., Hoffman et al. 2002)[2] are illustrative of broader trends in fiscal development, they typically do not utilize econometric techniques or economic theory in the analysis explicitly. Rather, they offer data for others to use. One of the more interesting efforts that has looked at various episodes in history, including the medieval period, is the book by Brauer and van Tuyll, *Castles, Battles, and Bombs: How Economics Explains Military History* (2008), which argues that the events and outcomes in military history can be explained using logic derived from economic theory. Such explicit use of economic theory to explain military decision making has been rare in the literature so far. One of the issues they tackle is the location and layout of medieval and early modern castles. They use the concept of opportunity costs and sunk costs to explain the use of what were often inefficient armaments, since castles were often expanded outward, especially after the fourteenth century, as a response to the emergence of gunpowder weaponry. Moreover, they argue that diminishing marginal returns set in for bigger castles, although more remains to be studied in this respect.

What the existing literature suggests is that the newly emerging nation states began to develop more centralized and productive revenue–expenditure systems, the

[1]Coordinator of the *European State Finance Database*: http://www.esfdb.org/

[2]Founders of *The Global Price and Income History Group*: http://gpih.ucdavis.edu/

goal of which was to enhance the state's power, especially in the absolutist era. This also embodied a growing cost and scale of warfare. For example, during the 30 Years' War between 100,000 and 200,000, men fought under arms, whereas 20 years later 450,000–500,000 men fought on both sides in the War of the Spanish Succession. The numbers notwithstanding, the 30 Years' War was a conflict directly comparable to the biggest global conflicts in terms of destruction. For example, Charles Tilly (1990) estimated the battle deaths to have exceeded two million. Henry Kamen, in turn, emphasized the mass-scale destruction and economic dislocation this caused in the German lands, especially to the civilian population (Kamen 1968; Tilly 1990). In many ways this was total war, especially considering the high numbers of civilian casualties. Cliometricians have not yet really tackled the scale and scope of this conflict adequately, using modeling and other tools frequently utilized by demographers to assess the economic dimensions of this conflict. For example, did the war have similar impacts on the demand for labor as the Black Death epidemic?

Another issue pertains to the cost of Spain's empire and whether the funding model for the state's expansion was the root cause of long-run economic decline. With the increasing scale of armed conflicts in the seventeenth century, the European participants became more and more dependent on access to long-term credit, because whichever government ran out of money first had to surrender. For example, even though the causes of Spain's supposed decline in the seventeenth century are still disputed, nonetheless it can be said that the lack of royal credit and the poor management of government finances resulted in heavy deficit spending as military exertions followed one after another in the seventeenth century. Therefore, the Spanish Crown defaulted repeatedly during the sixteenth and seventeenth centuries and on several occasions forced Spain to seek an end to its military activities (Kamen 2004, 2008). But is this the whole story?

Douglass C. North (1990, 1993) has argued repeatedly that the institutional framework that was adopted early on in the newly unified Spain (the Reconquista was completed in 1492) became a hindrance in the long run, leading Spain to lose its competitive edge vis-à-vis emerging powers like France, the Netherlands, and Great Britain. However, Henry Kamen (2004) has taken a contrary point of view, emphasizing the unlike early success in Spain becoming an empire. Spain developed military expertise through empire building and lost its edge a lot later than North would contend, due to outsourcing its expansion to foreign banks and capital. Kamen did not accept the thesis of long-term decline, at least as outlined by scholars like North. It is hard to ascertain how large a role the recurring conflicts of the time period and the ensuing debt played in the decline. Cliometricians may be able to provide the most compelling arguments in this debate. The study of Philip II of Spain by Mauricio Drelichman and Hans-Joachim Voth (2011, 2014) shows that while the king defaulted several times, he was able to obtain more debt fairly soon after each default. According to their findings, the lenders were often able to thrive through the turbulent Spanish debt relations and that the contract structure in place offered opportunities for risk sharing between the parties. Therefore, Spain's decline may indeed be linked to its institutional framework, but it probably was not an irrational

pattern of development, but rather a mechanism that enabled the sovereigns to expand the empire in many ways for a long time.

Theme 2: Revolutionary and Napoleonic Wars

In the eighteenth century, with rapid population growth in Europe, armies also grew in size. In Western Europe, a mounting intensity of warfare with the 7 Years' War (1756–1763) finally culminated in the French Revolution and Napoleon's conquests (1792–1815). The new style of warfare brought on by the revolutionary wars, with conscription and war of attrition as new elements, can be seen in the growth of army sizes. For example, the French army grew to 650,000 men in 1793, more than 3.5 times its size in 1789. Similarly, the British army grew from 57,000 in 1783 to 255,000 men in 1816. The Russian army was a massive 800,000 men by 1816, a size they maintained throughout the nineteenth century. However, the actual number of Great Power wars declined in absolute numbers, as did the average duration of these wars. It was the *nature* of war that had changed (Eloranta 2005).

A key question for France, for example, was how to finance all these wars. According to Richard Bonney (1999b, c), the cost of France's armed forces in its era of "national greatness" was stupendous, with expenditure on the army by the period 1708–1714 averaging 218 million livres, whereas during the Dutch War of 1672–1678, it had averaged only 99 million in nominal terms. This was due to both the growth in the size of the armed forces and the decline in the purchasing power of the French currency. The overall burden of war, however, remained roughly similar in this period, at least as measured by budgetary share of military expenditures (see Table 1). Furthermore, as for most European monarchies, it was the expenditure on war that brought fiscal change in France, especially after the Napoleonic Wars. Between 1815 and 1913, there was a 444% increase in French public expenditure and a consolidation of the emerging fiscal state. This also embodied a change in the French credit market structure.

The military spending in the late eighteenth century was fairly consistent, representing the largest budgetary item for many European states (Table 1). And, whereas Prussia's defense share was continuously high, the English defense share went up and down, influenced by the various conflicts during this period. In turn, the revolutionary and Napoleonic Wars were truly total wars based on the methods chosen by the belligerents, which affected countries outside the direct fighting. The effects of the war spilled over to influence the relations between neutrals as well. Due to the fact that these wars had an impact on the trade relations of *all* nations, many countries scrambled to find new outlets and sources for their trade. As a result, the bargaining power of weak (United States) and/or smaller states (Portugal – which was both weak and small) increased albeit only temporarily (Moreira and Eloranta 2011).

Scholars have paid too little attention to the smaller players in times of war, often assuming that they occupied an insignificant role in conflicts. Moreira and Eloranta (2011) have argued this is an erroneous assumption, especially in the context of

Table 1 English, French, and Prussian defense shares in the seventeenth and eighteenth centuries

England		France		Prussia	
Year(s)	Defense share	Year(s)	Defense share	Year(s)	Defense share
1690	82	1620–1629	40	–	–
1700	66	1630–1639	35	–	–

major conflicts. For example, the United States was a weak state as well and for the most part remained neutral during this period due to its short existence and limited military power. Nonetheless, the United States played an important role in world trade prior to assuming the mantle of a hegemon after the Second World War. Ultimately, it is completely natural to focus most of the analysis on the great empires such as Great Britain and France. After all, it is staggering to conceptualize the evolution of an empire like Great Britain, from its humble beginnings in the sixteenth century, to the building of the navy and its first major victory against the Spanish Armada, to the multicultural, industrialized empire that ruled the world in the nineteenth century. Perhaps it was the intense nature of these rivalries and the total wars between the Great Powers that explains why they had to rely on alliances and often lesser powers to complement their war efforts and retain access to crucial strategic resources. Therefore, even a Great Power like Great Britain had to tolerate the activities of the neutral states, sometimes to the detriment of their own war efforts.

In recent years many scholars have analyzed the disruptions caused by major conflicts like the world wars. Reuven Glick and Alan Taylor (2010) studied the indirect economic effects of wars, in particular the First and the Second World War, with a large database, using an econometric gravity model. Their analysis, focusing on disruptions of trade and the subsequent economic losses, yielded clear results: trade was disrupted by such massive wars and did not return to prewar levels. Furthermore these economic disruptions affected even those countries that were not directly involved in the conflict. These findings may be applicable to other large-scale conflicts as well, even in the preindustrial era.

Furthermore, many scholars have doubted the efficacy of economic warfare, which can range from fairly benign policy measures and pressure to outright warfare

in the context of total war (O'Leary 1985; Førland 1993; Naylor 2001). Lance Davis and Stanley Engerman (2006) have studied one particular form of economic warfare, naval blockades, spanning several centuries. They also emphasize both the costs and challenges of sustaining a successful blockade. For example, during the Napoleonic Wars, the legalities of blockades were not that clearly agreed upon, especially the issue of neutrality. The success of a blockade, as they point out, is often difficult to assess as well (Crouzet 1964). Periods of actual warfare, even blockades, can bring substantial opportunities, as well as disruptions, for trade. As other scholars have argued, rising relative prices and substantial profits may be the answer to why such risky situations bring forth increases in trade (Thornton and Ekelund 2004). Moreover, recent scholarship, as represented by David Bell (2007), for example, certainly puts the revolutionary wars and the ensuing Napoleonic conflicts into the same category as the world wars. Finally, Kevin O'Rourke (2006) has provided cliometric insights into the revolutionary and Napoleonic Wars by focusing on the contraction of trade in particular. His results show that Great Britain was the least affected of the belligerents, whereas France and the United States suffered more. The welfare losses were around 5–6% for the United States, which could be classified as *substantial*.

Theme 3: World Wars

The last four decades leading to the First World War were a period of an intensifying arms race. As argued by Eloranta (2007), the military burdens incurred by the Great Powers also varied in terms of timing, suggesting different reactions to external and internal pressures. Nonetheless, the aggregate, systemic real military spending of the period showed a clear upward trend for the entire period. Moreover, the impact of the Russo–Japanese War was immense for the total (real) spending of the 16 states examined in Eloranta (2007), due to the fact that they were both Great Powers and Russian military expenditures alone were massive. The unexpected defeat of the Russians, along with the arrival of dreadnoughts, launched an even more intensive arms race (Hobson 1993). The basic parameters of the military spending by the most important participants are listed in Table 2.

In August of 1914, this military capacity was unleashed in Europe with horrible consequences, sparking the First World War, which lasted more than 4 years. Another total war had begun, now taking place in the industrial era. About 9 million combatants and 12 million civilians died during the so-called Great War, with property damage concentrated in France, Belgium, and Poland. There have been many new studies that have analyzed the war, in particular *The Economics of World War I*, edited by Stephen Broadberry and Mark Harrison (2005a). What do we know about the economic damages caused by the war? According to Rondo Cameron and Larry Neal (2003), the direct financial losses arising from the Great War were circa 180–230 billion 1914 US dollars, whereas the indirect losses of property and capital rose to over 150 billion dollars. According to Broadberry and Harrison (2005b), the

economic losses arising from the war could be as high as 692 billion 1938 US dollars. But how much of their resources did they have to mobilize and what were the human costs of the war?

The early phase of the First World War involved mobilizing the troops and the immediate economy for warfare. For Germany, the most viable strategy was one which could bring a victory quickly in the situation of geopolitical encirclement by the hostile powers (Ferguson 1999). The possibility that the conflict would be prolonged and Germany and its ally Austria–Hungary would have to fight a war of attrition on two fronts was not taken into serious consideration (Stevenson 2011; Strachan 2011). Great Britain serves as an example of state-directed industrial mobilization. The primary forms of state involvement were co-optation and coordination, not command and compulsion. By bringing in new manufacturers to war production, building new public factories, and buying munitions abroad, the government inadvertently promoted decentralization of the industry and sponsored competition among manufacturers. In a similar fashion, the market-based mechanism of transactions with raw materials had not disappeared; the governmental control in this sphere was accepted as a forced and a temporary measure. During the first 2 years of the war, the government essentially refrained from intervening in

food matters. Unlike all major continental countries, Britain never established a full monopoly on grain. The rationing of some other foods was introduced only 5 months before the end of war. To sum up, the British industry operated as a capitalist market economy, not an administered economy (Blum and Eloranta 2013).

Many of the features of a market economy fully applied to the wartime French economy. More than any other economic system, the French economy was an example of self-mobilization and self-organization of production. Although industrial mobilization was sponsored by the government, industrialists themselves came to play a primary role in organizing mass production of arms and munitions. French resource-allocation institutions, the consortia, represented a weak and temporary version of corporate organization. For about 3 years during the war, the French authorities limited themselves to very few measures of food regulation. What little regulation they imposed was mostly in the form of price controls on some foods. Because of large imports of food from overseas, more dramatic measures of food control did not seem necessary. The government introduced a grain monopoly and the rationing of bread late in 1917 (Blum and Eloranta 2013).

Allied Great Powers were also able to mobilize their resources more effectively during the war. Even though the Central Powers initially did quite well with the limited resources they had, the Allies were able to mobilize their far superior economic and military resources better both at the home front and on the front lines. Their more democratic institutions supported the demands of the total war effort better than their authoritarian counterparts, especially in terms of being able to mobilize their societies farther than their competitors. Therefore, the richer countries mobilized more men and materiel for the war, and their war industries proved quite capable of adapting to fulfill the needs of the war machine (Broadberry and Harrison 2005b).

Moreover, having a large peasant population turned out to be a hindrance for the production of food under wartime constraints. In poorer countries, and even in affluent Germany, mobilization efforts siphoned off resources from agriculture, and the farmers preferred to hoard food rather than sell it for low prices. As Avner Offer (1989) has argued, food (or the lack thereof) played a crucial part in Germany's collapse. Germany's problem was not so much that it was not able to mobilize resources for the war, but the fact that its main ally, Austria–Hungary, was a poor nation with limited resources and plagued by an inability to mobilize effectively. The collective mobilization of resources by the Allies proved too big an obstacle for Germany to overcome (Blum 2011, 2013; Blum and Eloranta 2013)

Ultimately, resources and mobilization were weaknesses of the Central Powers, and led to their defeat, after the overextension of their supply lines in the spring of 1918. After the ceasefire in 1918 and the Versailles peace treaty of 1919, Germany experienced political instability and economic turmoil. A complex process of interactions between a military defeat, an exhausted economy, the burden of reparations and war debt, and an uncertain political future laid the basis for three more turbulent decades. One consequence of the war and the war economy, which is believed to have contributed to the destruction of the Weimar Republic, was the hyperinflation experienced between 1921 and 1923. By 1923, the average price indices for food

prices and retailer prices were 198 billion and 166 billion, respectively, while wages rose disproportionally. Wage indices (1913 = 1 for all of them) for skilled workers in 1923 were 85 billion, while corresponding figures for unskilled and civil servants were 100 and 56, respectively (Blum 2013; Blum and Eloranta 2013). Despite the fact that hyperinflation was a stimulus for economic impulses, especially for the exporting sectors, and helped delete considerable amounts of internal and non-reparation foreign debt, the inflation's aggregate effect was disastrous; German GDP dropped by one third from 1922 to 1923.

Moreover, Albrecht Ritschl (2005) has argued that conditions for peace were simultaneously too lax and too strict, and the way Germany, especially the German public, perceived the end of this conflict was not realistic. He maintains that Germany's military was technically defeated, but Germany had not yet been invaded by Allied troops. German leaders had not been captured and the capital had not been besieged or conquered; in fact, German territory remained by and large unscathed and the Emperor managed to escape to the neutral Netherlands. Soon legends spread, saying that the lack of morale at the home front was sabotaging military strength – the birth of the *stab-in-the-back* legend. It was difficult to realize the inevitable defeat in the absence of obvious evidence; it took another coalition of Allied forces to complete this task in 1945. Illusions about the "true" reason for the lost war and financial disasters served right-wing propagandists to stir up hatred against ethnic and political minorities.

On the macroeconomic consequences, Feinstein et al. (1997) have identified four direct economic outcomes that arose from the conflict: (1) two immediate exogenous shocks, in terms of disruptions of supply and demand as well as excess mobilized production (and military) capacity after the conflict; (2) a more rigid economic environment, due in part to diminished wage flexibility; (3) a weaker financial structure, since the economies had to carry the new, increased levels of public spending as well as the acquired debts with mainly prewar levels of taxation; and (4) a fragile international monetary system. The "winners" of the war, at least in terms of economic growth effects, seemed to be the neutral states, such as the Nordic countries, who outperformed other Western states.

Ronald Findlay and Kevin O'Rourke (2007) have summarized the challenges brought on by the period of world wars in their aftermath for global trade and politics. First of all, there were three wartime adjustments that had serious consequences in the interwar period: (1) non-European producers who increased their role during the war and the subsequent price competition; (2) industrial expansion during wartime, which was difficult to redirect after the conflict; and (3) the boost in non-European industrialization. In terms of broader effects, they list the following: (1) the increased importance of turbulent domestic politics, (2) the legacy of the war debts, (3) the difficulties in returning to the gold standard, (4) the creation of new nation states, (5) the Communist revolution and state in Russia, and (6) the creation of instability and conditions as a result of the First World War that would lead to the Second World War.

There have been many studies of the interwar period, especially the disarmament and rearmament processes that took place. For example, studies on German

rearmament have typically focused on the war period. However, Max Hantke and Mark Spoerer (2010) have studied the hidden military spending of the 1920s, utilizing classic cliometric techniques such as counterfactual analysis. Their basic aim is to analyze the economic importance of the Versailles Treaty, i.e., reparations, on the German economy. In order to achieve this, they have devised a clever strategy. Their counterfactual framework attempts to see what the impact of "normal," unrestricted military spending would have been on the German economy without the treaty restrictions on their armed forces. In doing so, they conclude that the size of that spending, as well as its impact, would have been roughly equal and that the failure of the Weimar economy was due to domestic policies. At the heart of this failure were fiscal effects and constraints imposed by the loss of territory and industrial capacity. In terms of some of the techniques involved, Hantke and Spoerer showed considerable ingenuity in reconstructing the German budgetary figures for the turbulent 1920s. The discussion of reparations and their impact is also reminiscent of Eugene White's (2001) work on the Franco–Prussian war of 1870–1871 and its aftermath.

Moreover, one could ask why the League of Nations ultimately failed to achieve widespread disarmament, its most fundamental goal. Eloranta (2011) has shown that the failure of the League of Nations had two important aspects: the failure to provide adequate security guarantees for its members (like a credible alliance, e.g., the NATO) and the failure of this organization to achieve the disarmament goals it set out in the 1920s and 1930s. Thus it was doomed from the outset to fail, due to built-in institutional contradictions. In terms of economic theory and econometric analysis, the League of Nations can also be modeled and analyzed as a military alliance. Based on Eloranta's (2011) analysis, the results are fairly conclusive: the League of Nations did not function as a pure public good alliance, which encouraged an arms race in the 1930s.

In the interwar period, many countries maintained fairly high military spending levels, despite tendencies to disarm, particularly in the 1920s. The mid-1930s marked the beginning of intense rearmament, whereas some of the authoritarian regimes had begun earlier in the decade. Germany, under Hitler, increased its military burden from 1.6% in 1933 to 18.9% in 1938, a rearmament program combining creative financing and promising both guns and butter for the Germans. Mussolini was not quite as successful in his efforts to realize the new Roman Empire, with a military burden fluctuating between 4% and 5% in the 1930s (5.0% in 1938). The Japanese rearmament drive was perhaps the most impressive, with a military burden as high as 22.7% and greater than 50% defense share in 1938. For many countries, such as France and Russia, the rapid pace of technological change in the 1930s rendered many of the earlier armaments obsolete only 2 or 3 years later (Eloranta 2002).

Mark Thomas (1983) has analyzed the British rearmament using an adjusted version of input–output tables for the 1930s, which enabled him to examine the causal interdependencies in the economy. He argued that the rearmament helped alleviate the effects of the recession, essentially making a Keynesian argument about the government's fiscal policy. Crafts and Mills (2013) have challenged this recently,

making a case for a lower multiplier effect, in the range of 0.3–0.8. They also discuss at length the previous models of estimating the impact and note that the theoretical findings are, by and large, model dependent. Their choice is to use the more recent time series techniques, which take into account potential problems of endogeneity. This debate is far from resolved, which also applies to the debate over broader 1930s programs like the New Deal.[3]

In the Second World War, the initial phase from 1939 to early 1942 favored the Axis as far as strategic and economic potential was concerned. After that, the war of attrition, with the United States and the USSR joining the Allies, turned the tide in favor of the Allies. For example, in 1943 the Allied total GDP was 2,223 billion international dollars (in 1990 prices), whereas the Axis accounted for only 895 billion. Also, the impact of the Second World War was much more profound for the economies of the participants. For example, Great Britain at the height of the First World War incurred a military burden of circa 27%, whereas the military burden level consistently held throughout the Second World War was over 50% (Harrison 1998; Eloranta 2003).

Other Great Powers experienced similar levels. Only the massive economic resources of the United States made possible its lower military burden. The United Kingdom and the United States also mobilized their central/federal government expenditures efficiently for the military effort. In this sense the Soviet Union fared the worst, and additionally the share of military personnel out of the population was relatively small compared to the other Great Powers. On the other hand, the economic and demographic resources that the Soviet Union possessed ultimately ensured its survival during the German onslaught. On the aggregate, the largest personnel losses were incurred by Germany and the Soviet Union. They were many times those of the other Great Powers. In comparison with the First World War, the second one was even more destructive and lethal, and the aggregate economic losses from the war exceeded 4,000 billion 1938 US dollars. After the war, the European industrial and agricultural production amounted to only half of the 1938 total (Harrison 1996, 1998, 2000).

The Second World War has been extensively covered in recent economic history scholarship. *The Economics of World War II*, edited by Mark Harrison, is a good collection of such efforts. For example, although Britain and Germany had significantly different buildups to war, the war itself brought extreme economic activity where both nations had virtually zero unemployment and economies geared toward the production of armaments. From 1933 to 1944, Germany's GDP and GDP per capita rose every year. Naturally, the end of the war brought economic collapse to Germany, with a serious drop-off in both 1945 and 1946 (33% and 50%, respectively). Similarly, the United Kingdom experienced significant growth in its GDP and GDP per capita. By 1943, however, the United Kingdom's economic growth began to slow down and experienced a drop in both 1944 and 1945 GDP, though not

[3]See Fishback and Kachanovskaya (2010) as an example of this debate.

as devastating as the German economy's deterioration (Broadberry and Howlett 1998; Abelshauser 2000).

Moreover, Germany's total munitions output increased monthly for every year of the war, until September 1944, when production finally began to wane. However, German productivity in machine tools decreased throughout the war, falling to 79% of 1939 levels. Even the production of coal suffered a drop in productivity, falling to 75 t per shift per worker from the 1939 peak of 100 t. Some of this productivity loss was due to labor shortages or disputes. Though coal production in the United Kingdom fell, the agricultural sector experienced a seemingly miraculous increase in efficiency. Though losing a good portion of its experienced workers to the armed services and decreases in food imports of 70% or more, agricultural production was able to increase the calories per employee by nearly 77% from 1937 levels. Employment in the agriculture sector increased even with the loss of its experienced workers by using women, volunteer labor, and eventually prisoners of war. Ultimately, the success or failure of a sector varied wildly from industry to industry (Broadberry and Howlett 1998; Abelshauser 2000).

Finally, the war had immediate and long-term impacts on the economic development of these economies. In Germany, rationing began even before the war began. Furthermore, the cost of living steadily increased for the average family, particularly for food. By 1944, food prices had increased to 113% of 1938 prices, and clothing had risen to 141% of 1938 prices. As a result of these higher prices and rationing, the average caloric intake for a worker's family member fell from 2,435 cal in 1939–1940 to 1,412 by 1945–1946 (Abelshouser 2000). Of course, the dismantling of the German state and economy following the war left little doubt of the destructive power that the Second World War had on the economies of Europe. Even victors, such as the United Kingdom, experienced major losses. Based on physical capital, the British lost 18.6% of its prewar wealth (Broadberry and Howlett 1998). This left many concerned that the state planned to continue nationalizing industries (though that fear never materialized). In the end, every nation in Europe felt the economic pain of war.

Theme 4: Cold War and Beyond

The end of the Second World War brought with it a new global order, with the United States and the Soviet Union as the most dominant players in global security affairs. With the establishment of NATO in 1949, a formidable defense alliance was formed by the Western countries. The USSR, rising to new prominence due to the war, in turn established the Warsaw Pact in 1955. The war also meant a change in the public spending and taxation levels of most Western nations. Military spending levels followed increases in welfare and social spending and peaked during the early Cold War. The American military burden increased above 10% in 1952–1954, and the United States retained a high mean value for the postwar period of 6.7% (up until 1991). Great Britain and France followed the American example after the Korean War (Eloranta 2003).

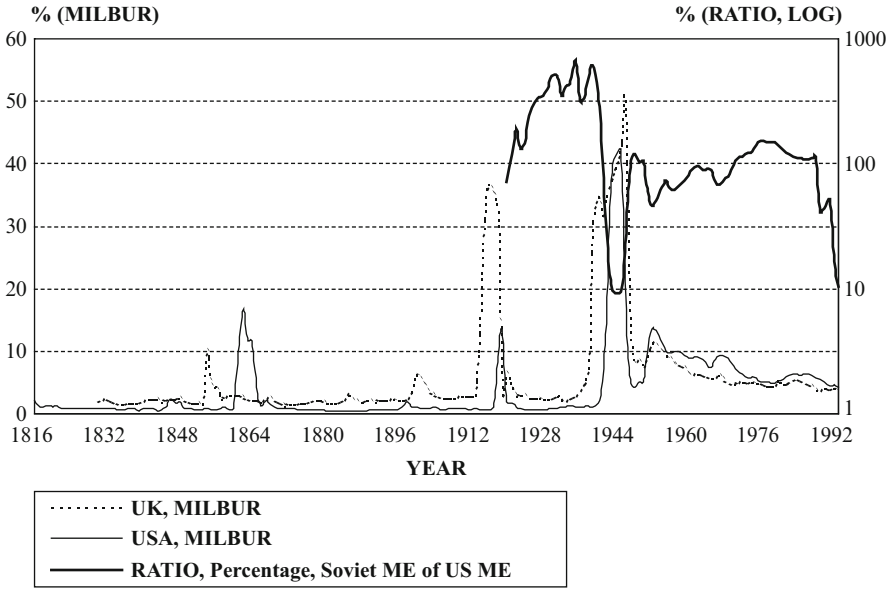

Fig. 1 Military burdens (= MILBUR) of the United States and the United Kingdom and the Soviet military spending as a percentage of the US military spending (*ME*), 1816–1993 (Sources: see Eloranta (2005) for details on the sources and methods of calculation)

The Cold War was tied to an extensive arms race, with nuclear weapons as the main investment item, with the USSR spending circa 60–70% of the American level in the 1950s, and the USSR briefly spending more than the United States in the 1970s (see Fig. 1). Nonetheless, the United States maintained a massive advantage over the Soviets in terms of nuclear warheads. Yet, the comparative spending figures suggest that NATO had a 2-to-1 lead in spending vis-à-vis the Warsaw Pact in the 1970s and early 1980s. Some of this armament race was due to technological advances that led to increases in the cost per soldier – it has been estimated that technological increases have produced a mean annual increase in real costs of circa 5.5% in the postwar period. However, the "bang for the buck" increased drastically with the introduction of nuclear weapons and other new weapons systems (Ferguson 2001; Eloranta 2005).

While the Second World War has been studied at length, the Cold War conflicts and military spending have not. However, some themes have been explored, for example, the so-called Military Industrial Complex (MIC), which refers to the influence that the military and industry would have on each other's policies. The more negative connotation refers to the unduly large influence that military producers might have over the public sector's acquisitions and foreign policy in particular, in such a collusive relationship. In fact, the origins of this type of interaction can be found further back in history. As Paul Koistinen (1980) has emphasized, the First World War was a watershed in business–government relationships, since businessmen were often brought into government to make supply

decisions during this total conflict. Most governments, as a matter of fact, needed the expertise of the core business elites during the world wars. In the United States some form of MIC came into existence before 1940. Similar developments can be seen in other countries before the Second World War, for example, in the Soviet Union. The Cold War simply reinforced these tendencies (Koistinen 1980; Harrison 2003; Eloranta 2009). Findings by example Robert Higgs (Trevino and Higgs 1992; Higgs 1994) establish that the financial performance of the leading defense contracting companies was, on the average, much better than that of comparable large corporations during the period 1948–1989. Nonetheless, his findings do not support the normative conclusion that the profits of defense contractors were abnormal.

The Cold War arms race has not been covered much by economic historians – most of the studies have been conducted by defense economists. Beginning with Mancur Olson and Richard Zeckhauser's path-breaking work on NATO (Olson and Zeckhauser 1966), there have been many testable hypotheses relating to the idea of collective security provision in an alliance and the implications of this provision on military spending. As the logic suggested by Olson and Zeckhauser implies, pure public good alliances are characterized by free riding by the smaller (or poorer) states since they have a reasonable expectation of military assistance from the larger nations under a cohesive defensive arrangement. For example, recent studies have found that the pure public good alliance concept describes NATO until about 1966, when a change in the strategic doctrine forced the members to rely more on their own military provision (Sandler and Hartley 1999).

Of course, as I would argue, the explanation resting on the foundation of the public good theory and the suboptimality of defense provision via the spillover effect has sound theoretical foundations. Indeed, Olson and Zeckhauser (1966) found a significant positive correlation, using Spearman rank correlation tests, between the NATO Allies' GNP and their military burdens in 1964, indicating clear free-riding behavior by the smaller Allies. Later studies specified the pure public good alliance to describe NATO until 1966, when the positive rank correlation between the variables ceased to be statistically significant (Sandler and Murdoch 1990; Sandler and Hartley 1999).

Another interesting field of debate is how the Cold War ended. It is obviously a topic that is fraught with political importance as well as scholarly debate. The list of possible explanatory factors is long indeed (see, e.g., Kegley 1994). Moreover, there is a big debate over the collapse of the Soviet Union. Economic historians have become involved in this debate too. For example, Mark Harrison (2002) has analyzed this issue by developing a simple model of costs and benefits to a dictator and producer of the command system. According to his findings, the command system was not necessarily inherently unstable; rather the stability was conditional, based on the equilibrium surrounding the level and application of coercion. In the case of the Soviet Union, the lessening of the threat of coercion that came with perestroika policies unraveled the system. Harrison used historical statistical and archival data on military spending to prove his assertions.

Nonetheless, despite these analyses, economic historians have not yet been very active in the debate over the scale and scope of the Cold War and the impacts of the

arms race. Economic historians have been more interested in the so-called Golden Age of Economic Growth (1950–1973), the evolution of the European Union, and the Marshall Plan (Maddison 1989, 2001; Berger and Ritschl 1995; Eichengreen 1995; Ritschl 2004). Most of this domain has been occupied by defense economists and political scientists. The opening of various archives and new data sources will certainly change this state of affairs in the near future.

Theme 5: Long-Run Analyses (Military Spending, Societal Structures, and Empires)

Economic historians have typically been more interested than economists in general in the long-run development of societies. Political and conflict scientists, as well as sociologists, have been interested in the same issues and even time periods, but not always from the same angle or using the same methods. However, even though some cycle theorists and conflict scientists have been interested in the formation of modern nation states and the respective system of states since 1648, they have not expressed any real interest in premodern societies and warfare (Wright 1942; Blainey 1973; Levy 1985, 1998; Geller and Singer 1998). Economic historians have continuously extended their reach back to earlier periods, especially since new data is now available to analyze, for example, state formation.

Political scientists are also in search of patterns of development, such as waves of development. According to George Modelski and William R. Thompson (1988, 1996), for proponents of Kondratieff waves and long cycles as explanatory forces in the development of world leadership patterns, the key aspect in a state's ascendancy to prominence is naval power. One of the less explored aspects in most studies of hegemonic patterns is the military expenditure component in the competition between the states for military and economic leadership in the system. It is often argued, for example, that uneven economic growth levels cause nations to compete for economic and military prowess. The leader nation thus has to dedicate increasing resources to armaments in order to maintain its position, while the other states, the so-called followers, can benefit from greater investments in other areas of economic activity. Therefore, the follower states act as free riders in the international system stabilized by the hegemon. A built-in assumption in this hypothesized development pattern is that military spending eventually becomes harmful for economic development, a notion that has often been challenged based on empirical studies (Kennedy 1989; Eloranta 2005).

There have been relatively few credible attempts to model the military (or budgetary) spending behavior of states based on their long-run regime characteristics. Here I will elaborate on three in particular: the Webber–Wildavsky (1986) model of budgeting, the Richard Bonney (1999a) model of fiscal systems, and the Niall Ferguson (2001) model of interaction between public debts and forms of government. Carolyn Webber and Aaron Wildavsky maintain that each political culture generates its characteristic budgetary objectives, namely, productivity in

market regimes, redistribution in sects (specific groups dissenting from an established authority), and more complex procedures in hierarchical regimes.

Their model, however, is essentially a static one. It does not provide clues as to why the behavior of nations may change over time, especially over long time periods. Richard Bonney (1999a) has addressed this problem in his writings on the early modern states. He has emphasized that the states' revenue and tax collection systems, the backbone of any militarily successful nation state, have evolved over time. For example, in most European states, the government became the arbiter of disputes and the defender of certain basic rights in the society by the early modern period. During the Middle Ages, the European fiscal systems were relatively backward and autarchic, with mostly predatory rulers (or roving bandits, as Mancur Olson (1993) has coined them). In his model this would be the stage of the so-called tribute state. Next in the evolution came, respectively, the domain state (with stationary bandits, providing some public goods), the tax state (more reliance on credit and revenue collection), and finally the fiscal state (embodying more complex fiscal and political structures). A superpower like Great Britain in the nineteenth century had to be a fiscal state to be able to dominate the world, due to all the burdens that went with an empire (Ferguson 2003).

While both of the models mentioned above have provided important clues as to how and why nations have prepared fiscally for wars, or survived them, the most complete account of this process has been provided by Niall Ferguson (2001, 2006). He has maintained that wars have shaped all the most relevant institutions of modern economic life: tax-collecting bureaucracies, central banks, bond markets, and stock exchanges. Moreover, he argues that the invention of public debt instruments has gone hand in hand with more democratic forms of government and military supremacy – hence, the so-called Dutch or British model. These types of regimes have also been the most efficient economically, which has in turn reinforced the success of this fiscal regime model. In fact, military expenditures may have been the principal cause of fiscal innovation for most of history. Ferguson's model highlights the importance, for a state's survival among its challengers, of the adoption of the right types of institutions, technology, and a sufficient helping of external ambitions. Typically, however, none of these models utilize extensive quantitative testing or methods in order to prove their assertions, which will make this field of inquiry a fruitful one in the future.

Cliometricians have already brought a lot to the table as well, especially concerning the long-run development of states, regime type, and financial/fiscal evolution. For example, Philip Hoffman (Hoffman and Rosenthal 1997; Hoffman 2011) has shown that it is possible to analyze the military sector and technology over several centuries, in fact before the industrial revolutions. He discovered, mostly based on the analysis of price data, that Western Europe developed a comparative advantage in violence long before 1800. European military industries exhibited tremendous productivity growth in the early modern period, which gave them the edge, particularly in gunpowder technologies. Hoffman (2012) has also introduced an interesting (and testable) model to explain where this comparative advantage came from, namely, the tournament model. In this model winning wars and

technological development to gain the edge with a country's competitors were intricately intertwined. And this led to giving the Europeans an edge in their military development and contributed to the building of empires.

Economic historians have also engaged heavily in the debate over the expansion, functioning, and profitability of empires, for example, the British Empire. Such critiques, of course, go back centuries, to such pivotal figures as Adam Smith (1776) or John Hobson (1965 reprint), who were very skeptical about the profitability of the British Empire and who ultimately benefited from the empire. More recently, several scholars, including Avner Offer (1993), Patrick O'Brien (1988), Lance Davis and Robert Huttenback (1982, 1986), and Niall Ferguson (2003, 2004), have weighed in on this question. The various tools of economic historians have been employed to tackle these questions. Davis and Huttenback maintained, on the basis of econometric exercises and modeling, that the profits from the empire were not sufficient to contribute to the overall economic growth of Britain and that the middle class incurred a larger share of the relative costs than the elites. In a related fashion, O'Brien argued, also along the lines of Smith and Hobson, that the empire was an unnecessary expenditure that dragged Britain to a multitude of conflicts, at high cost, and that the costs were borne unequally, mainly by mainland Britons. On the other hand, Offer has criticized some of these findings, especially the data solutions and the role that military expenditures have played in the building of the empire. He used alliance theories to explain the unequal allocation of expenditures within the empire. Ferguson, in a different fashion, has also attempted to highlight some of the benefits of the empire, for example, the ability to trade within a large area.

Another set of issues to which cliometricians have contributed heavily is the formation of states in the long run. Along with the scholars that I have already discussed, Mark Dincecco (2009, 2010; Dincecco and Prado 2012) has made some significant contributions to the debate over the fiscal revolution of European states. Typically employing newer panel data and related techniques, he found that centralization and limitations on political power led to higher revenues among European states, that premodern war casualties were correlated with fiscal institutions, that improvements in fiscal capacity possibly led to higher economic returns, and that Eastern and Western Europe, measured by the river Rhine, diverged institutionally after 1789. Moreover, in a similar fashion, David Stasavage et al., prominent political scientists, have discovered that between 1600 and 2000 the biggest factors in the rise and fall of the mass army were changes in transportation and communications technology and that mobilization for the needs of total warfare in the twentieth century led to the emergence of substantial redistribution of wealth and progressive taxation (Onorato et al. 2012; Scheve and Stasavage 2010).

In turn, Mark Harrison and Nikolaus Wolf (2011) have examined a different aspect of the development of states, namely, the development of democracies and warfare. The topic of so-called democratic peace, implying that democracies do not fight one another, is vast and very interdisciplinary (see, e.g., Russett 1993; De Mesquita et al. 1999; Choi 2011; Gowa 2011; Dafoe and Russett 2013). Harrison and Wolf (2014) argue that this widely accepted thesis may not always hold,

especially when analyzing the development of states from 1870 onward. They claim that trade and democracy do not always work to prevent conflicts, but can in fact lead to increasing the capacity for war and the frequency of conflicts. This entry has inspired some debate over the legitimacy of the democratic peace concept (Gleditsch and Pickering 2014; Harrison and Wolf 2014).

Conclusion

This chapter is meant as a review of the many of the perspectives from history, political sciences, sociology, and economics that economic historians have applied to the study of war, especially how theoretical and quantitative perspectives achieved in this fashion have enriched the debate over the causes, buildup, costs, and outcomes of conflicts. I would argue that economic historians, using a variety of techniques ranging from simple data tools to more complicated econometric exercises, have often broadened the scope of the debates, enabling both more comprehensive long-run analysis of conflicts and polities as well as deeper economic analysis of particular conflicts and periods.

Here I first reviewed some of the scholarship on medieval and the early modern periods, especially the formation of European nation states and the role conflicts played in these processes. I also returned to these themes toward the end of the review when looking at long-run processes. In sum, it is now fairly clear that Europeans emerged out of this period with a comparative advantage in violence, which they achieved through technological innovations and repeated warfare. Fiscal innovation and expansion was a key part of this. Then, I moved to the discussion of a pivotal period in history, namely, the period of the revolutions and Napoleonic conflicts. This period represented a change in the nature of warfare, the arrival of total war tactics and strategies in earnest, the emergence of new kinds of states, and the advent of the industrial age. The nineteenth century represented a period of globalization and relatively few conflicts, but it also set the stage for the destructive twentieth century.

The period of the world wars is perhaps the best represented area of study for economic historians of late. Many scholars have now delved into the economic dimensions and impacts of the conflicts, as well as the disarmament/rearmament of the interwar period. New data and scholarship has shown the mechanics of mobilization and highlighted the importance of resources in deciding these conflicts. Conversely, the Cold War period has been relatively sparsely studied, at least from the perspective of conflicts or military spending. Given the availability of new data and the opening of many archives, it is highly likely that this state of affairs will change in the near future. Economic historians have clearly made an impact in the study of long-run phenomena like state formation, empires, and democracy. Comparative studies are at the heart of these new scholarly efforts, and cliometrics is well suited to the study of such topics, especially given the new panel and time series techniques available, the rapid development of computing power, and the creation of many new online databases.

Abstract

In an essay exploring the role of cliometrics and economic history in the context of broader disciplines of history and economics, Claude Diebolt and Michael Haupert point out that:

> Perhaps the biggest challenge facing economic history is that in its attempt to pursue truth, economic history is at the same time too vast and too small. In a historical sense, we try to accurately compile all the facts relevant to a given topic of study. The smaller the topic, the

easier it becomes to gather and arrange all the relevant facts, and the more rigorous the result is likely to be. . . . But for the historian who aims to create general truths, the economic, like any other conventional division of the subject matter of history, is too narrow a conception. (Diebolt and Haupert 2018, 3)

The search for general truths is compounded by the tendency for scholars to stay within the confines of their academic disciplines. Military historians write military history, economic historians worry about problems of economic history and development, and cliometricians stay focused on the use of economic theory and statistical methods to predict the past with ever greater precision. Nowhere is this challenge more evident than in the study of war and economics in the twentieth century.

Introduction

In an essay exploring the role of cliometrics and economic history in the context of broader disciplines of history and economics, Claude Diebolt and Michael Haupert point out that:
