Clinical experience is another leg of the three-legged EBM stool that plays into our recommendation, but lack of experience with other modalities should not limit what we recommend. Ignorance of a procedure or treatment, or local unavailability of that option, does not absolve our duty to explore its usage during the option talk. In the case of SRT, a whole generation of dermatologists have been educated in an era when dermatology has been transformed from a medical specialty to a highly surgical specialty. During this time, dermatologists, standing on the shoulders of pioneers such as Leon Goldman and Ellet Drake, have developed a vast array of powerful yet specific laser systems and light-based therapeutic systems that target specific disorders selectively. Likewise, dermatologists have developed a very sophisticated and comprehensive set of procedures to deal with skin cancer based on the early adaptation of Mohs surgery from a fixed to a frozen tissue technique gaining universal acceptance through the leadership of Perry Robbins, Theodore Tromovitch, Sam Stegman, and others. Data for SRT goes back to the early 1900s with heavy continued use of this modality by dermatologists through the age of Phillip Mackee, the head of New York Skin and Cancer in the 1970s. Despite a temporary decline in the usage of superficial radiation therapy, our specialty developed, refined, and produced a vast amount of data that over the first half of the last century was transformed from empirical to practical and reproducible formulations to determine first the nominal skin dose, a reproducible number that could compare multiple fractionation schemas to the time-dose-fractionation (TDF) factors which allowed one to flexibly tailor dosage and fractionation schedules and compare and match their biological equivalency. No group played a greater role or had more clinical expertise in radiation than dermatologists and their treatment of innumerable skin cancers over the last century. As we will show in this chapter, multiple studies document its effectiveness and widespread usage by our predecessors.

The last leg of the three-legged EBM stool is "best available evidence." An assumption exists that best evidence means the exclusive use of randomized clinical trials. Since the aforementioned clinical experience has taught us that radiation should be used selectively, the use of a clinical trial which randomizes patients with severe medical comorbidities to surgery or young patients to radiation therapy and its long-term sequelae would be unethical. EBM specifically asks for the "best available" not "only the best" evidence, and there is a multitude of suitable studies to draw conclusions from.

Introduction

Superficial/soft radiotherapy (SRT) has over 106 years of research and development by dermatologists. Just 8 years after the discovery of X-rays by Wilhelm Conrad Roentgen on November 8, 1895, the first reported results using radiotherapy came from dermatologists in what was the precursor to the annual AAD meeting, "Rationale of and the Indications for Therapeutic Use of Rontgen Rays," 27th Annual Meeting of the American Dermatology Association, Washington, May 13 and 14, 1903. Today the procedure and technology have evolved with the manufacture and development of new SRT platforms that contain multiple built-in safety features and daily automatic calibration. Proper patient and tumor selection, tumor location, patient set-up, shielding, and histologic review of the tumor are critical for obtaining excellent outcomes and cannot be overemphasized.

Procedure Performance

The focus of this text is on the evidence involving the use of SRT for nonmelanoma skin cancer (NMSC); it is not intended to be a detailed tutorial on treatment delivery; nonetheless, two important concepts warrant further discussion. The half-dose depth (D1/2) concept and the time-dose-fractionation (TDF) factor have been used in dermatologic radiotherapy for selecting appropriate radiation qualities. For a detailed tutorial, we refer the reader to the book *Radiation Therapy for Skin Cancer*, chapter entitled "Superficial Radiation Therapy Treatment Planning" by Springer [6].

Half-Value Depth (D ½) Concept

The half-value depth (D ½) concept has served as an invaluable guideline in dermatologic radiotherapy and has been used for over 50 years in the treatment of skin cancer [7–10]. In lieu of confusing arithmetic computations based on depth dose charts with varying combinations of radiation factors, the dermatologic radiotherapist takes advantage of pre-set calibrations based on the D ½ (Fig. 36.1). The D ½ is the tissue depth in millimeters at which the dose is 50% of the surface dose. In treating NMSC, the goal is to deliver at least 50% of the surface dose to the tumors' deepest portion.

Time-Dose-Fractionation (TDF) Factor

In 1973, Orton and Ellis [11] developed the time-dose-fractionation (TDF) factor, building upon prior work of the nominal standard dose (NSD) concept. The TDF factor takes into account the time, dose, fractions, and the interval between fractions [7, 11–17].

$$\begin{aligned} TDF &= 10^{-3} \times NSD^{1.538} \\ &= Nd^{1.538} \left(T/N\right)^{-0.17} \times 10^{-3} \end{aligned}$$

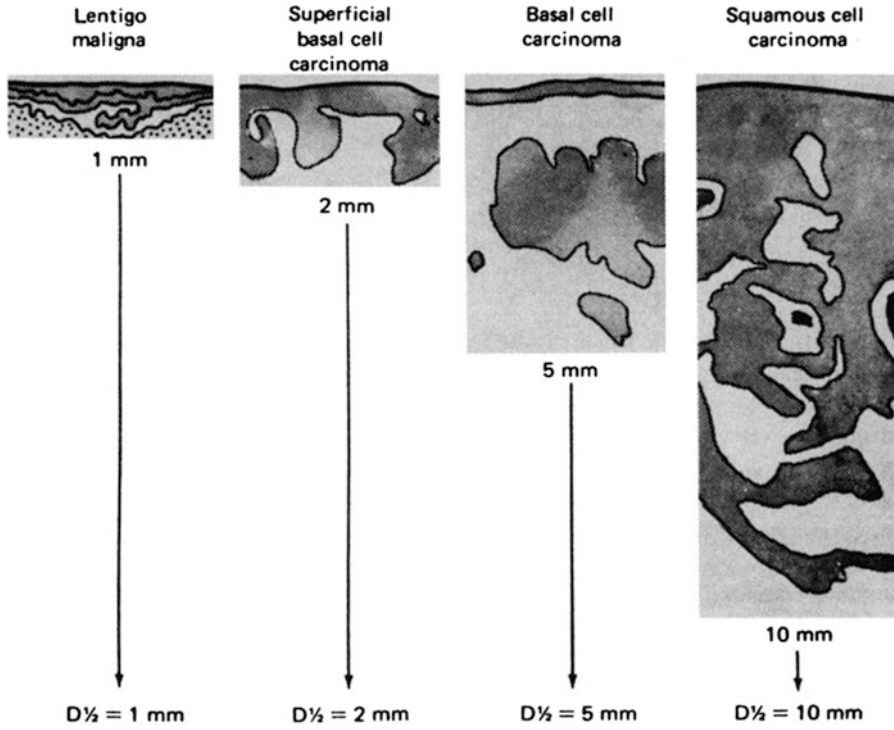

Fig. 36.1 Selection of D ½ for skin cancer treatment. (With permission from [87])

(NSD = nominal standard dose, N = number of fractions, d = dose per fraction, T = overall treatment time in days)

The culmination of their work are TDF factor tables which have been pre-calculated based upon the number of fractions/doses given per week. Treatment schedules comprise 1,2,3,4, and 5 fractions per week with the TDF factors based on dose (cGy) and total number of fractions. By using the TDF factor tables in treatment planning, it is possible to predict treatment outcome for cure, skin necrosis, and other effects. The optimal TDF factor for cure of epithelial skin cancer lies between 90 and 110 (Fig. 36.2) [8, 11–13, 15–17]. TDF factors less than 90 may result in underdosing, and greater than 110 increases the risk of complications such as skin necrosis.

Utilization of the TDF tables:

Step 1: The number of fractions delivered each week is selected (1, 2, 3, 4, or 5); we have selected the 3 fraction per week TDF table in this example.

Step 2: Select the total number of fractions for the overall treatment course.

Step 3: Locate the TDF factor between 90 and 100.

Step 4: Determine the dose in centigrays (cGy) of radiation to give with each fraction that correlates with the chosen TDF factor.

Note: New SRT platforms automatically calculate the TDF factor based on parameters entered into the software for the patient.

The number of fractions can be increased (lower dose per fraction) to decrease the late sequelae such as hypotrophic scarring, telangiectasias, and necrosis. Alternatively, the number of fractions can be decreased to deliver more radiation per dose if the patient is less concerned with cosmesis and wishes to have less treatments and travel.

In contrast to the TDF factor tables, radiation oncologists began using the linear-quadratic (LQ) model and biological effective dose (BED) as it was an easy way to convert dose-time frac-

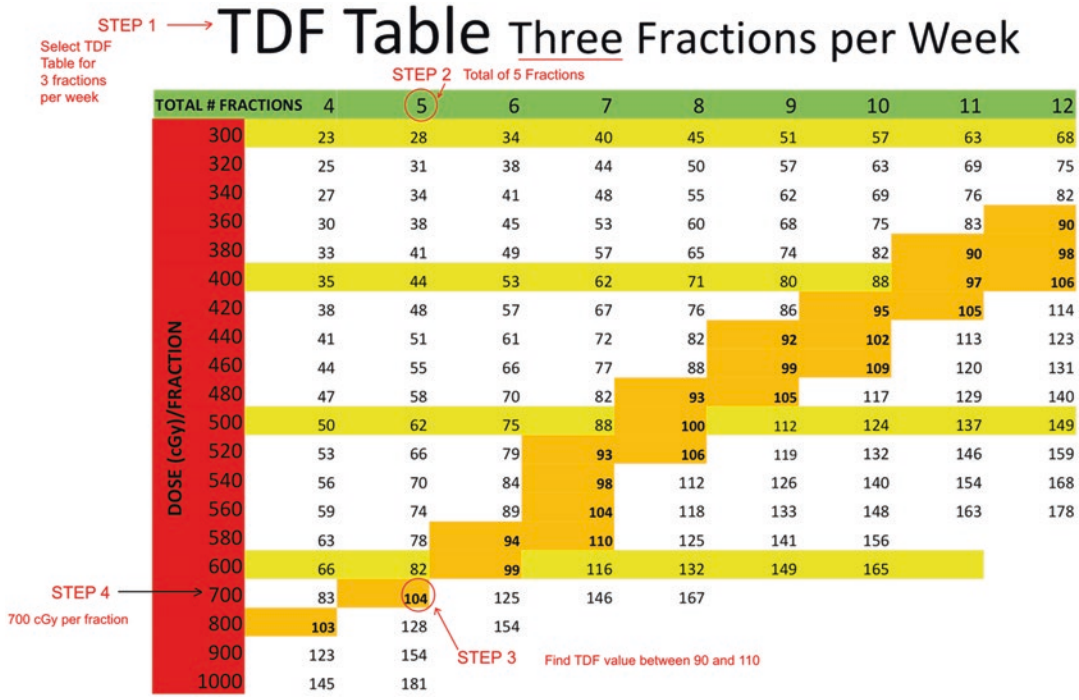

Fig. 36.2 TDF table utilization example. (Source: Modified from [11])

tionation schedules into a biologically effective dose, allowing for comparison between different radiation treatment schedules. This LQ/BED model depends upon α/β ratios obtained from experiments involving irradiated tissues in animal models.

An increase in dose per fraction relative to 2 Gy is termed hypofractionation and a decrease is hyperfractionation [18]. Most radiation oncology treatment schedules use hyperfractionated schedules of 2 Gy per fraction for 30 or more total fractions. Bentzen and Joiner [19] report that the LQ/BED model is only supported by data in the 1.0–5 Gy dose per fraction range, which is less than many dermatologic NMSC treatment schedules, making BED less reliable for comparison. They go on to note that even when dose ranges of 1–5 Gy are used, there is a lack of appropriate parameter estimates, or the available estimates have wide 95% confidence limits and that parameter estimates for clinical endpoints remain scarce [18, 19].

We feel that the NSD concept and TDF factors are most appropriate for comparing efficacy of different treatment regimens for NMSC in the dermatologic setting. As long as treatment schedules fall into the data range for which the TDF factor tables were originally calculated, they will be accurate in comparing treatment schedules. The TDF factors were derived from the following data ranges: dose per fraction 200–1000 cGy (2–10Gy), total number of fractions 4–40, and number of treatments per week 1–5. Treatment schedules for NMSC reported in the literature fall within these parameters [7, 20, 21].

Once SRT has been decided upon, appropriate lead shielding is placed to include eye shields, a thyroid shield, and the lead cutout for treatment of the tumor (Fig. 36.3). The lead cutout for the NMSC includes visible tumor plus a margin of at least 5 mm of surrounding normal tissue (Fig 36.4a,b). The patient is immobilized and the dose of radiation is delivered which takes approximately 60–120 s. In certain instances, intraoral and intraocular shielding is necessary depending on the treatment area (Fig. 36.5a, b).

Indications

The most critical aspect of SRT use is appropriate patient/tumor selection.

Though no formal appropriate use criteria (AUC) exist for SRT, the following indications and contraindications are generally accepted by experienced dermatology radiotherapists in the past and present for the treatment of basal cell carcinoma (BCC)/squamous cell carcinoma (SCC):

1. Location: central face, including the eyelids, nasal tip, nasal ala, ears, and lips [22–54].
2. Age ≥ 60 years: to minimize the synergistic effects of ultraviolet radiation [55–60].

Fig. 36.3 Lead shielding and patient set-up

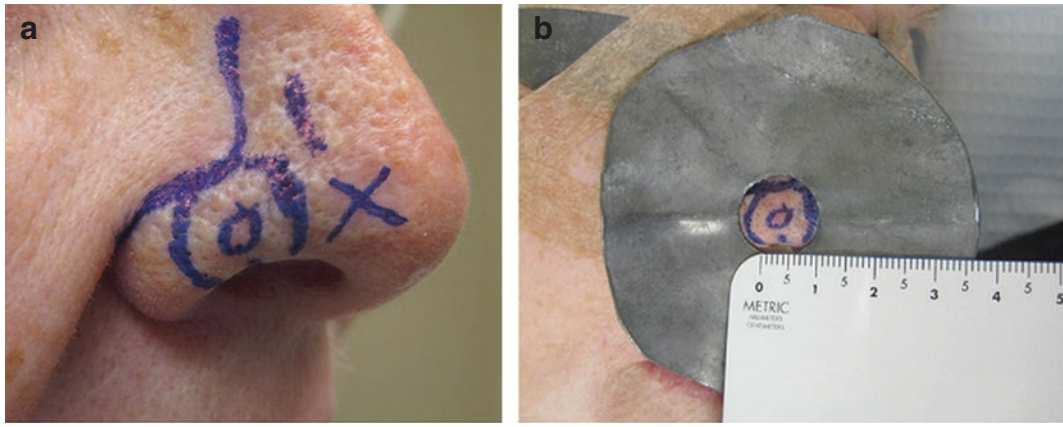

Fig. 36.4 (**a**, **b**) Lead cut out with 5-mm margin around NMSC

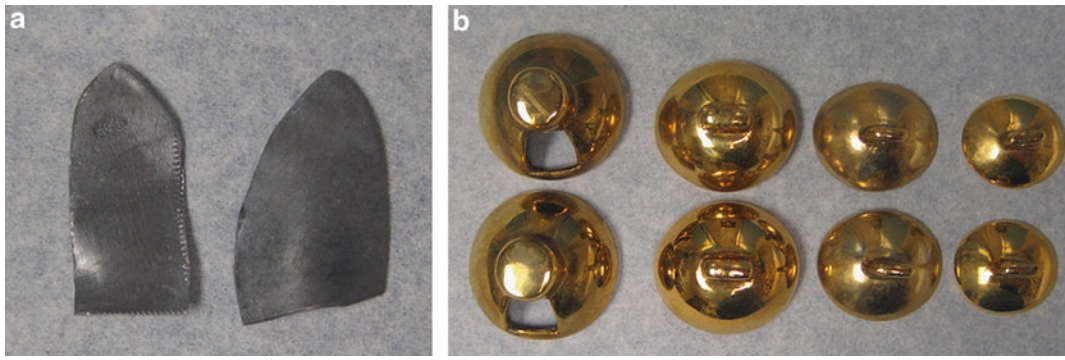

Fig. 36.5 (**a**, **b**) Intraoral and intraocular shielding

3. Tumor size. Medium-sized tumors up to 5 cm in diameter may be adequately treated with SRT [30, 61–65].
4. Tumor type/depth of invasion. Superficial and nodular BCCs, SCC in situ (SCCIS), and SCC that are nonaggressive are amenable to SRT [26, 62, 63, 66].
5. Frailty and medical status. Inability to tolerate surgery due to poor health, multiple comorbidities, or those on anticoagulant therapy may have a higher risk of adverse events. Eastern Cooperative Oncology Group (ECOG) performance status [67] (Table 36.1) may be used to document selection of radiotherapy over surgery.
6. Patient preference to avoid surgery may be a consideration and in cases where surgery will lead to skin graft or complex flap closure.

Table 36.1 ECOG performance status

Grade	ECOG performance status
0	Fully active, able to carry on all pre-disease performance without restriction
1	Restricted in physically strenuous activity but ambulatory and able to carry out work of a light or sedentary nature, e.g., light house work, office work
2	Ambulatory and capable of all selfcare but unable to carry out any work activities; up and about more than 50% of waking hours
3	Capable of only limited selfcare; confined to bed or chair more than 50% of waking hours
4	Completely disabled; cannot carry on any selfcare; totally confined to bed or chair
5	Dead

From Oken et al. [67]

Absolute (1–4) and relative (5, 6) contraindications for SRT:

1. Aggressive tumor histology: BCCs (sclerosing, morpheaform, infiltrative), SCC (perineural invasion, arising in previous sites of RT, burn scars, chronic ulcers, spindle cell carcinoma, poorly/ undifferentiated, or those secondary to osteomyelitis) [26, 62, 63, 66, 68–71].
2. Deep tumor invasion. Tumors that invade bone, cartilage, or arise within the mucosal surfaces (intranasal/intraoral) [72, 73].
3. Previously irradiated site. Increases incidence of late-term sequelae (ulcer, radionecrosis of cartilage and bone), results in unsatisfactory cosmesis, recurrence, and second primary tumors [68, 69, 74, 75].
4. Genetic anomalies. Nevoid basal cell carcinoma syndrome (NBCCS), xeroderma pigmentosum (XP), Garner's syndrome, Li-Fraumeni syndrome, and others with increased radiosensitivity or where radiation may induce new malignancies [76–83].
5. Organ transplant recipients (OTR). The mainstay of treatment is surgical excision or Mohs surgery.
6. Location trunk/extremities. Early pioneers of SRT recommended against the use of radiotherapy on the trunk and extremities due to late-sequelae changes (telangiectasias and pigmentary changes), lower oxygen saturation leading to potential decreased efficacy and wound healing issues, and the general ease and expediency of surgical removal. Recent studies also demonstrate the increased risk of non-healing ulcers of the lower extremities using RT[64, 84–90].

Additional considerations:

1. History of methicillin-resistant *Staphylococcus aureus* (MRSA) or other invasive infections.
2. Implantable pacemaker, defibrillator, intravascular device, artificial joint prosthesis that may serve as a nidus for bacterial or fungal colonization.
3. Current anticoagulant or antiplatelet use that cannot be discontinued prior to surgery.

Superficial/Soft Radiation Therapy for Basal Cell Carcinoma and Squamous Cell Carcinoma

Consensus Documents

National Cancer Comprehensive Network Guidelines (2a)

The National Cancer Comprehensive Network (NCCN) state their recommendations are category 2A unless otherwise noted, defined as "uniform NCCN consensus, based on lower-level evidence including clinical experience." NCCN guidelines recommend radiation therapy for non-surgical candidates in the form of megavoltage electron beam radiation therapy (RT), performed by radiation oncologists, a much more costly form of radiation therapy than SRT that requires the use of a linear accelerator in the treatment of BCC [68, 69]. Wolfe and Cognetta [91] performed a cost comparison of the various radiotherapy (RT) modalities used for skin cancer and found SRT in the outpatient setting performed by dermatologists to be the least expensive form of RT, $512 for SRT versus $7100 for electron beam RT. Recommendations for RT of SCC are the same as for BCC, with the recommendation to consider the addition of systemic therapy in conjunction with RT for local SCC with high-risk features (Table 36.2. Risk factors for local recurrence or metastasis SCC).

These guidelines fail to mention of SRT as a modality to treat NMSC. Of the 28 panel members that developed the NMSC NCCN guidelines, 16 are dermatologists (10 Mohs surgeons), 5 are medical oncologists, 5 are surgical oncologists, 1 is a pathology-trained dermatopathologist, and 1 is a radiation oncologist. To prevent perpetuating underlying bias introduced by members of original guideline panels, it has been suggested that periodic review by experts not involved with development of the initial guidelines be conducted [92]. Inclusion of dermatologists who utilize SRT as a treatment option may help prevent the exclusion of SRT as a treatment modality from future NCCN guidelines.

Table 36.2 NCCN risk factors for local recurrence or metastases SCC [69]

H & P	Low risk	High risk
Location/size	Area L <20 mm Area M <10 mm	Area L ≥20 mm Area M ≥10 mm Area H
Borders	Well defined	Poorly defined
Primary vs recurrent	–	+
Immunosuppression	–	+
Site of prior RT or chronic inflammatory process	–	+
Rapidly growing tumor	–	+
Neurologic symptoms	–	+
Pathology		
Degree of differentiation	Well or moderate	Poor
Adenoid (acantholytic), adenosquamous (mucin producing), desmoplastic, or metaplastic (carcinosarcomatous)	–	+
Depth: Thickness or Clark level	<2 mm or I,II,III	≥2 mm or IV, V
Perineural, lymphatic, or vascular involvement	–	+

Area H: "Mask areas" of face (central face, eyelids, eyebrows, periorbital, nose, lips [cutaneous and vermilion], chin, mandible, preauricular and postauricular skin/sulci, temple, ear), genitalia, hands, feet
Area M: Cheeks, forehead, scalp, neck, and pre-tibia
Area L: Trunk and extremities (excluding pretibial, hands, feet, nail units, and ankles

British Association of Dermatologists Guidelines

Basal Cell Carcinoma (2a) [93]

In 2008, British Association of Dermatologists (BAD) guidelines reported by Telfer et al. [93] state that RT is effective in the treatment of primary BCC, surgically recurrent BCC, as adjuvant therapy, and is probably the treatment of choice for high-risk disease in patients who are unwilling or unable to tolerate surgery. The authors assign the following quality of evidence I: evidence obtained from at least one properly designed, randomized controlled trial; strength of recommendation A: there is good evidence to support the use of the procedure.

The authors also note that poor long-term cosmetic results are much less likely following treatment using modern techniques. Fractionated treatment regimens generally produce superior cosmetic outcomes compared with single-fraction treatment. In the elderly, infirm patient, single-fraction regimens are still used, as the long-term cosmetic result of treatment is less of a concern. RT can be used successfully on many facial sites, and studies have reported good outcomes following treatment of BCC on the nose, lip, ear, and periorbital skin.

SCC (2a) [94]

Unpublished BAD guidelines for the treatment of SCC by RT reported by Motley et al. in 2009 [94] state that RT is generally contraindicated in the younger patient due to late effects in irradiated skin; in some circumstances RT will give a better cosmetic effect such as the lower eyelid, the inner canthus of the eye, the lip, the tip of the nose, and in some cases the ear. Areas that tolerate RT poorly include the back of the hand, the abdominal wall, and the lower limb, and surgical excision is preferable at these sites. The authors note that no long-term randomized trials have been conducted for the treatment of SCC and give no recommendation based on the level of evidence or strength of recommendation that was done with RT in the treatment of BCC and SCCIS; an update is in progress.

SCCIS (2a) [95]

BAD guidelines for the treatment of SCCIS by RT reported by Morton et al. in 2014 state that RT can be used to treat SCCIS in areas where surgical modalities are difficult. Level of Evidence 2+: extrapolated from well-conducted case-control or cohort studies with a low risk of confounding, bias, or chance; strength of recommendation D: a moderate probability that the relationship is causal.

Canadian Nonmelanoma Skin Cancer Guidelines Committee

Basal Cell Carcinoma (2a)

In 2015, Zloty et al. [96] published Canadian guidelines for the management of BCC with the recommendation that radiation therapy may be used in selected cases for treatment of high-risk primary BCCs when surgery is contraindicated or could be disfiguring. The authors define high-risk BCC as those arising on the eyelids, nose, lips, ears, fingers, toes, periorbital, and periauricular locations; size >2 cm all sites or ≥1 cm on cheeks/forehead/temples/scalp/neck/chin; histology morpheaform/sclerosing, infiltrative, micronodular, basosquamous, mixed subtype BCCs (should be treated as the highest-risk form); recurrent, perineural involvement, and poorly defined (level of evidence moderate, strength of recommendation weak).

Squamous Cell Carcinoma (2a)

In 2015, Sapijaszko and colleagues [97] published Canadian guidelines for the management of recurrent or high-risk SCC and primary low-risk SCC, including SCC in situ and keratoacanthomas with the recommendation that they may be treated with radiation therapy in selected patients with contraindications to surgery, when surgery would be disfiguring, or when radiation therapy is needed for palliation (level of evidence moderate, strength of recommendation strong).

Adjuvant radiation therapy may be added to the surgical treatment of high-risk SCCs, such as those with perineural invasion (level of evidence moderate, strength of recommendation weak).

High-risk SCC was defined as those arising on the external ears, lips, and scalp; size ≥2 cm, depth ≥0.2 cm or Clark level IV–V; poorly differentiated, Broder grade 3–4; etiology other than ultraviolet radiation, immunosuppression, perineural involvement, recurrent, rapid growth, and those originating from a wound or scar. The Canadian guidelines used for classifying and rating evidence are found in Tables 36.3 and 36.4.

Table 36.3 Canadian guidelines: Level of evidence classification system used

The Grading of Recommendations Assessment, Development and Evaluation (GRADE) system for classifying quality of evidence	
Level of evidence	Definition
High	Further research is very unlikely to change our confidence in the estimate of effect
Moderate	Further research is likely to have an important impact on our confidence in the estimate of effect and may change the estimate
Low	Further research is very likely to have an important impact on our confidence in the estimate of effect and is likely to change the estimate
Very low	Any estimate of effect is very uncertain

Table 36.4 Canadian guidelines: Definitions for rating the strength of recommendations

Strength of recommendation	Definition
Strong	Desirable effects Outweigh undesirable effects
Weak	Desirable effects Probably outweigh undesirable effects

American Academy of Dermatology Position Statement

The American Academy of Dermatology (AAD) March 2014 Position Statement on SRT for BCC and SCC is that surgical management remains the most effective treatment, providing the highest cure rates. The Academy supports consideration of superficial radiation therapy as a secondary option for the treatment of BCC and SCC, for use in special circumstances, such as when surgical intervention is contraindicated or refused and after the benefits and risks of treatment alternatives have been discussed with the patient. Unfortunately, the AAD still maintains the position that SRT is in need of research on long-term outcomes despite the numerous reports and research dating back to the late 1900s.

Dermatologists were the first radiation oncologists applying SRT to treat skin disease as early as 1897, shortly after the discovery of X-rays by Wilhelm C. Roentgen in 1895 and decades before the specialties of radiology and radiation oncology emerged and then diverged. Pioneers in radiotherapy, dermatologists authored, and more recently coauthored with radiation oncologists, textbooks that have been in continuous publication since 1921 on the use of SRT and radium in skin disease [6, 87, 98–102]. The first reported results using radiotherapy came from dermatologists in what was the precursor to the annual AAD meeting, "Rationale of and the Indications for Therapeutic Use of Rontgen Rays," 27th Annual Meeting of the American Dermatology Association, Washington, May 13 and 14, 1903.

Defining Radiation Modalities

Before commencing a review of the evidence for RT, it is important to define what constitutes SRT. By definition, SRT involves the emission of photon radiation from an X-ray machine cathode and classically involves kV energies ranging from 10 kV to 150 kV and less than 250 kV, with a source to surface distance (SSD) of ≤30 cm and a D1/2 of 1–30 mm. For the purpose of this text, energies ≥250 kV range (utilized by radiation oncologists) are not SRT and fall into the range of orthovoltage RT. We have not included Grenz ray therapy as newer SRT machines are just now being developed to deliver RT with these parameters but may do so in future editions of this text. Table 36.5 classifies RT based on several param-

Table 36.5 Radiation therapy methods

Classification of radiotherapy methods based on energy/voltage/generator						
Type	Sources & synonyms	Type of generator	kV	SSD[a] (cm)	$D^1/_2$ mm tissue	Surface dose (%)[b]
Megavoltage electron therapy	Electron beam Radiation	Linear accelerator (LINAC)	>1000 (6000–9000)	80	90% Isodose method used for electrons[c]	78–86
Megavoltage photon therapy (not routinely used to treat NMSC)	Megavoltage X-ray	Linear accelerator (LINAC), Betatron	>1000	80	150–200	6–30
Supervoltage therapy	Gamma (γ)-ray	Isotope teletherapy machines (60Cobalt)	400–800	50–80	80–110	40–90
Orthovoltage therapy	Deep X-ray	X-ray machine cathode	250–400	50–80	50–80	100
Intermediate therapy	*Half-deep therapy*	*X-ray machine cathode*	*110–249*	*30*	*30*	*100*
Contact therapy	*Ultrashort distance (Chaoul)*	*X-ray machine cathode*	*50–60*	*1.5–3.0*	*4–30*	*100*
Superficial X-ray therapy[d]	*Pyrex (glass) window (older units),*	*X-ray machine cathode*	*60–100*	*15–30*	*7–20*	*100*
Soft X-ray therapy[d]	*Beryllium window (modern units)*	*X-ray machine cathode*	*20–100*	*10–30*	*1–20*	*100*
Grenz therapy	Ultrasoft therapy, Supersoft therapy	X-ray machine cathode	5–20	10–15	0.2–1.2	100

Adapted from Goldschmidt et al. [21]
Bold = SRT range included in review
[a]SSD: Source to surface distance
[b]Surface dose is the percent of radiation dose delivered to the skin surface
[c]90% Isodose method is used by radiation oncologists for electron beam radiotherapy
[d]Superficial/soft X-ray therapy is the type most often utilized in dermatology office-based radiotherapy for SCC, SCCIS, and BCC

eters and identifies the types that fall within the realm of SRT.

Systematic Review of Randomized Controlled Trials (1a)

In 2004, Bath-Hextall (1a) [103] and colleagues conducted a systematic review (SR) of randomized controlled trials (RCT) on interventions for BCC. The authors searched the Cochrane Library and used standardized search engines to search Medline (from 1996 to December 2003), Embase (from 1980 to December 2003), the Cochrane Skin Group (December 2003), and the Cochrane Library (2004, issue 1) and manually searched cited references from identified trials and recent review articles. Twenty-five studies were identified, two studies involving RT. The authors conclude that little good-quality research has been done on the treatments used to treat BCC and that surgery and RT seem to be the most effective treatments.

Avril and colleagues (1b) [104] compared RT (n = 173) to surgery with frozen section margin control (n = 174) for the treatment of primary BCC of the face measuring less than 4 cm. The primary endpoint was failure rate (persistent or recurrent disease) at 4 years of follow-up. Of the RT group of 173 patients, 95 were treated with brachytherapy (implanted radioisotopes), 57 with 50 kV close-contact SRT, and 20 with 85–250 kV SRT. Brachytherapy was used for the smallest lesions (8.4 mm), close-contact 50 kV SRT for medium-sized lesions (12.9 mm), and 85–250 kV SRT for the largest lesions (15.5 mm). Failure rates were the highest for brachytherapy (8.8%), and lowest for the SRT subgroups, 6.6% for 50 kV close-contact SRT, and 5.0% for 85–250 kV SRT (Table 36.6. RT subgroup analysis). The 4-year failure rates for combined RT were 7.5% and surgery 0.7%. Actuarial failure rates were estimated with the Kaplan-Meier method.

Table 36.6 RT subgroup analysis

Method of RT	Number	BCC size mm	4-year failure rate (%)
Interstitial brachytherapy	95	8.4	8.8
Contact SRT (50 kV)	57	12.9	6.6
SRT (85–250 kV)	20	15.5	5.0

Data extracted from Avril et al. [104]

The second RT study included in this SR was a small study of 93 patients with BCC, comparing SRT to cryotherapy by Hall and colleagues (2b) [105]. RT was applied using 130 kV X-rays; tumors less than 1 cm were treated with 5 fractions of 700 cGy in 5 days or with 3 fractions of 650 cGy Monday, Wednesday, Friday for week 1 followed by 4 weekly fractions of 700 cGy. Lesions >1 cm were treated with 375 cGy in ten treatments over 12 days. Cryotherapy procedure involved using a thermocouple to record target temperatures of −25 °C and −30 °C beneath the tumors for two 1-min freeze-thaw cycles. At 2 years, 93/105 (89%) were available for follow-up; 47/49 (96%) of the SRT group and 27/44 (61%) of the cryotherapy group were disease-free.

Randomized Controlled Trials

Similar to Mohs micrographic surgery, the vast majority of research that has formed the foundation of dermatologic radiotherapy has come from retrospective analysis of patients chosen for SRT. From these studies we have gained an in-depth understanding of optimal dosimetry based on tumor characteristics and patient factors [22–29, 31, 32, 34–54, 65, 84, 88, 101, 106–128].

Randomized trials for the treatment of skin cancer are near impossible to undertake. To blindly assign patients to various modalities today would significantly increase the risk of recurrence, morbidity, and even mortality. For NMSC invading bone and orbital structures, it would be unethical to randomize a cohort of patients to Mohs surgery and another to RT; neither would be an appropriate choice based on the knowledge we have today, most of it from retrospective studies. As such selection bias is a factor in much of the literature.

In addition to the two studies in the prior section by Avril [104] and Hall [105], one additional

Table 36.7 RCT: TDF factor comparison

High dose (TDF 123)	Number treated	Recurred	Cure rate (%)
BCC	144	14	90
SCC	24	4	85
Overall	168	18	89
Low dose (TDF 106)			
BCC	148	12	92
SCC	20	1	96
Overall	168	13	92

Data extracted from Landthaler and Braun-Falco [15]

RCT was uncovered which involved the comparison of two TDF factors in SRT by Landthaler and Braun-Falco in 1988 (2b) [15] involving 319 patients with 142 BCC and 24 SCC placed in the high-dose (TDF 123) group and 148 BCC and 20 SCC in the low-dose (TDF 106) group, all followed up for 3 years. The results are shown in Table 36.7. The authors note that the age distribution of patients was identical in both treatment groups with the peak age of 70 years, the majority of tumors were located in sun-exposed areas in both groups with no significant differences in local distribution, and that 70% were located on the forehead, periocular region, nose, and lips. It is important to note the design is that of a randomized trial; however, the publication preceded recommendations outlined in Consolidated Standards Of Reporting Trials (CONSORT) first published in 1996 [129].

Systematic Review of Cohort Studies (2a)

A systematic review (SR) by Thissen and colleagues (2a) [130] included cohort studies reporting 5-year recurrence rates for seven treatment modalities for primary BCC. The study was limited to prospective cohorts completed after 1970 that included at least 50 lesions. Eighteen of 298 studies met the authors' inclusion criteria with 9930 primary BCC. This SR included one study of SRT by Silverman and colleagues (2b) [107] of 1288 biopsy-proven BCC treated by X-ray therapy between 1955 and 1982, including 862 primary BCC and 211 recurrent BCC. SRT was delivered using 29–50 kV with a D ½ between 2 mm and17 mm for a total of 5 fractions of 680 cGy. The 5-year recurrence rates were calculated using the modified life table method; for primary BCC the recurrence rate was 7.4% (64/862) and for recurrent BCC 9.5% (20/211).

Prospective Cohort Studies (2b)

In addition to the prospective cohort studies including Silverman and colleagues(2b) [107], one additional prospective cohort study by Avila and colleagues (2b) [23] reporting 3-year cure rates comparing surgery to RT for carcinoma of the ear (pinna) was identified. The surgery group included 50 patients, 5 treated with electrocoagulation, 39 treated with "V" excision, and 6 with partial amputation. The RT group included 44 treated with SRT 40–200 kV range and 1 patient with Cobalt RT (400–800 kV range). The 3-year cure rate was 96% (48/50) for the surgery group and 86.7% (39/45) for the RT group.

Classical Analytic Retrospective Cohort Study (2b)

Pampena and colleagues (2b) [131] compared two different treatment schedules for orthovoltage RT which included kilovolt levels in the SRT range, 50 kV up to 300 kV. The authors compared a one fraction per week (weekly) hypofractionated regimen to a standard daily regimen with the primary aim to compare overall survival, disease-free survival, and cosmetic outcome using life table analysis, Kaplan-Meier survival analysis, and multivariate Cox regression model to determine whether the one fraction per week schedule would be appropriate for elderly disabled patients.

The authors retrospectively enrolled 385 consecutive patients with 436 tumors. Group A consisted of those treated with one 525 cGy fraction per week for 7 weeks. Group B was treated with the standard daily 300 cGy/fraction for 15 consecutive daily fractions. Mean age for Group A (one weekly fraction) was 81.3 years and included

181 BCC, 93 SCC, and 1 mixed tumor; recurrence rate at 32 months was 5.5% (15/275). Group B mean age was 73.3 and included 128 BCC, 31 SCC, and 2 mixed tumors; recurrence rate at 32 months was 3.7% (6/161). The authors conclude that the one fraction per week regime seemed more appropriate for the elderly disabled patients in their cohort.

Distinguishing Case Series from Descriptive Cohort Studies

The Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) initiative was developed to improve the quality of reporting in observational studies, specifically cohort studies, case-control studies, and cross-sectional studies [132, 133]. These study types are classically defined according to epidemiological analytical principles where the aim is to determine the incidence or natural history of a disease together with the risk factors for the disease or outcome of interest [134]. While these descriptions are useful in epidemiological studies where the aim is to determine disease associations and risk factors, these descriptions fall short when attempting to classify studies involving therapeutic interventions which can lead to difficulty differentiating case series from cohort studies [135, 136].

Nijsten and colleagues [134] provide a basic definition for cohort studies and case series which are in agreement with basic texts on the subject. Cohort studies are defined as analytical, observational studies, based on data, from a follow-up period of a group in which some have had or will have the exposure of interest, to determine the association between that exposure and an outcome. Case series were defined as descriptive observational study of a series of cases, typically describing the manifestations, clinical course, and prognosis of a condition [134]. Furthermore, a comparison group is not a necessary or defining feature of a cohort study [135–141].

A cohort study is a research design where a group of subjects is identified on the basis of exposure (intervention) and followed over time for the occurrence of the outcome of interest (recurrence). As a comparison group is not a defining feature of a cohort study, when it is absent the design is more accurately described as a "descriptive" cohort study and like classical analytic cohort studies they can be retrospective, prospective, or both [136, 141]. A central feature of cohort studies is that they enable an absolute risk estimate for the outcome, or incident rate calculation. For descriptive cohort studies, the exposure is the intervention, and the outcome of interest is recurrence, from which an absolute risk estimate (recurrence rate) can be calculated and in the absence of a comparison group can be likened to "exposed" arm of analytic epidemiology cohort studies (Fig. 36.6. 2 × 2 Table for etiologic research, retrospective descriptive cohort absolute risk calculation) [135].

Dekker and colleagues [135] have proposed guidelines for distinguishing cohort studies from case series stating that a cohort study is one in which sampling is based on exposure (intervention), follow-up is part of the study, and absolute risks can be calculated. A case series is described as a study in which only patients with the outcome of interest are sampled (disease or recurrence) without regard to exposure (intervention), which does not permit calculation of an absolute risk. The Oxford Centre for Evidence-Based Medicine 2009 Levels of Evidence in which a case series may be considered a collection of individual case reports which contain detailed information about the individual patients. An absolute risk estimate (recurrence rate) cannot be obtained from a case report or group of case reports (Fig. 36.7. 2 × 2 Table for etiologic research, case series).

Much of the dermatologic literature on therapeutic interventions, to include Mohs micrographic surgery, radiation therapy, destructive modalities, and targeted therapies, should be labeled descriptive retrospective cohort studies level of evidence 2b according to the Oxford Centre for Evidence-Based Medicine 2009 Levels of Evidence, rather than relegated to level 4 evidence, the reflex reaction when a comparison group is not reported. According to STROBE guidelines [132, 133] and epidemiologic text-

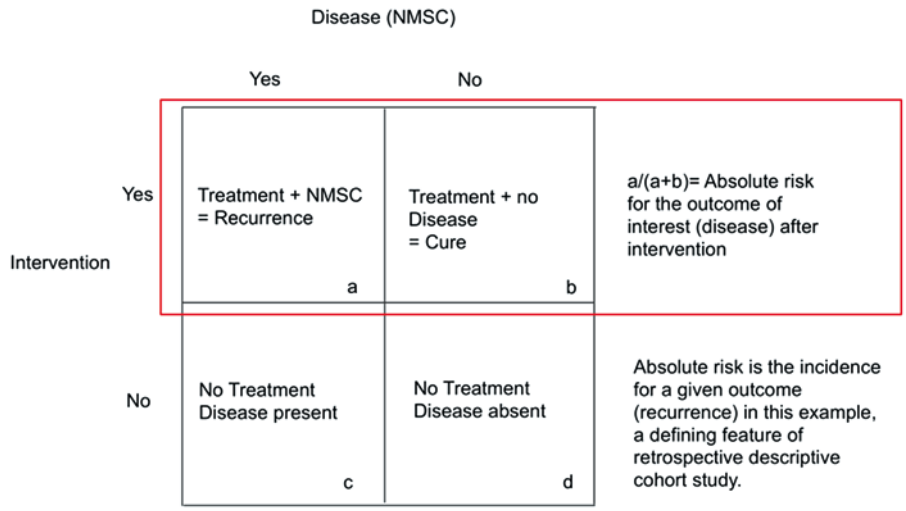

Fig. 36.6 2 × 2 Table for etiologic research, retrospective descriptive cohort absolute risk calculation

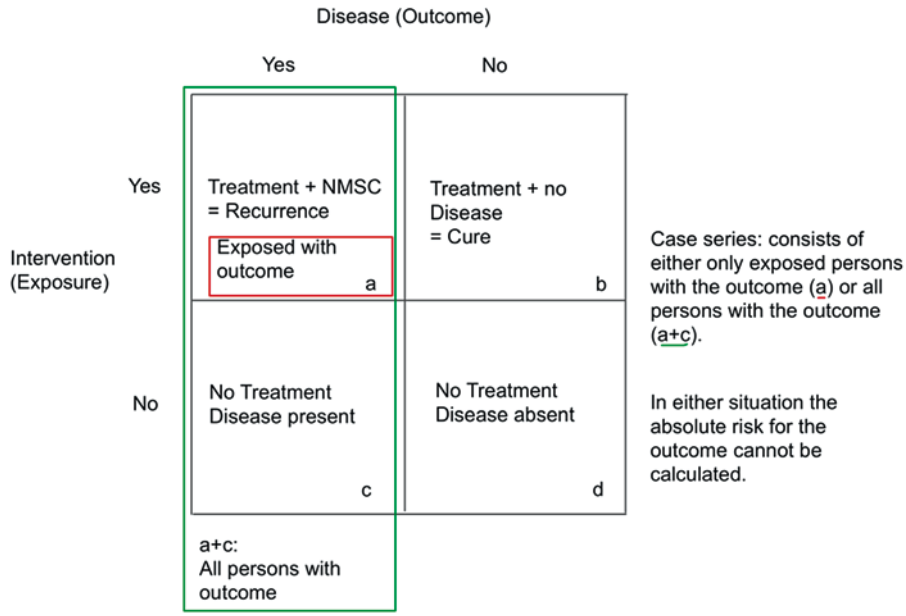

Fig. 36.7 2 × 2 Table for etiologic research, case series

books [137–140], these studies are indeed cohort studies because patients with a common exposure (intervention) are followed over time from a well-described inception point, which can be retrospective, for the outcome of interest (presence of disease or recurrence) and they need not have a comparison group. We have assigned a level of evidence of 2b "descriptive cohort study" when sampling is from exposure (intervention) to outcome (recurrence).

Conflicting definitions of what constitutes a case series are reported in the literature. We will report studies as case series as suggested by Dekkers and colleagues [135] when sampling is on the basis of both exposure and the presence of the outcome, for example, only patients who

undergo Mohs surgery (exposure) that have myocardial infarction (outcome) are described. The second type of case series involves the patients being sampled by the outcome under study (myocardial infarction) regardless of exposure characteristics (see Fig. 36.7).

Retrospective Descriptive Cohort Studies (2b)

A veritable mountain of research exists in the form retrospective descriptive cohort studies in dermatology involving SRT. For the purpose of summarizing the data, we have included tables for which data on SRT have been extracted based on the number of NMSC treated with SRT (Tables 36.8, 36.9, 36.10, 36.11, 36.12 and 36.13). Where research was conducted in the early years of medical literature where the widespread use of statistical analyses to account for patients lost to follow-up was not commonplace, we have included those studies that have accounted for all patients in the specified follow-up period with direct observation and have reported less than 5% lost to follow-up as retrospective descriptive cohorts (level 2b); those that report more than 5% lost to follow-up and do not include statistical analyses to account for them will be categorized as level 4 evidence (poor quality cohorts, poor quality case controls, case series), although this is not the only reason such studies will be labeled as "poor quality."

Poor Quality Cohort Studies and Case Series (4)

A retrospective cohort study by Griep and colleagues (4) [153] examined the recurrence rates and cosmetic outcome of 389 histologically confirmed NMSC either treated with SRT or electron beam RT from a single institution from 1980 to 1989. SRT was delivered at 600–1000 cGy/fraction for 6–10 fractions with a margin of 0.5–1.0 cm around the tumor. Recurrence rate for SRT was 6.9% with average follow-up of 32 months and 15.3% for electron beam RT with 24 months average follow-up (Table 36.14. SRT vs Electron beam RT).

In another retrospective cohort study of patients from a single center in Finland from 1963 to 1973, Nordman and Nordman (4) [154] examined the cure rates for BCC of the eyelid comparing SRT to radical excision. All patients were followed up for a minimum of 2 years, cure rate for SRT was 82% (65/79), and radical excision was 90% (27/30). The authors used a 1-mm margin around the tumor site, whereas it is common practice to use a minimum of 5 mm today which may account for the lower cure rate during this time period. A summary of the remaining level 4 studies is found in Tables 36.15, 36.16 and 36.17.

Safety of Superficial/Soft Radiotherapy

Safety issues were once a concern in the early years after the discovery of radiation as a potential treatment for various ailments. Realizing the need to protect the public and environment from unrestricted and unlicensed sources of ionizing radiation, the United States (US) government created the Energy Act of 1954 and later the Energy Reorganization Act of 1974. Since that time, federal and state regulatory requirements have continued to address safety concerns associated with the use of RT. Modern radiation platforms are manufactured with numerous safety mechanisms and systems of redundancy to minimize radiation accidents. All X-ray machines require annual calibration and certification providing ongoing oversight usually conducted at the state level.

In the 1940–1950s, ionizing radiation was used to treat benign conditions such as tinea capitis and acne resulting in radiogenic carcinoma development, on average 30 years later, likely from the combined effects of ultraviolet radiation (UV) as reported by Shore and colleagues [55, 56]. The total doses used to treat these conditions were in the order of 800–900 cGy [55, 56, 165], whereas the total dosages used to treat skin cancer are much larger, 3500–6000 cGy. Radiogenic

Data from Griep and colleagues [153]

carcinomas in these settings likely developed from smaller non-lethal, yet mutagenic, anti-inflammatory doses of radiation combined with the effects of UV radiation. In a follow-up study by Shore and colleagues [166] (3b), 2224 children receiving RT for tinea capitis were followed up for up to 50 years to determine cancer incidence compared to a control group of 1380 patients receiving only topical medication. The relative risk (RR) for BCC was 3.6 (95% confidence interval 2.3–5.9) among irradiated Caucasians (124 RT cases, 21 control cases) in response to a scalp dose of 475 cGy, no melanomas, and only a few SCC occurred. The authors note that 25% of both the treatment group and control group were African-American, with only 3 BCC in the RT group highlighting the importance of UV radiation as a cofactor.

In contrast to these reports, Lindelof and Ekklund [167] analyzed information from the Swedish Cancer Registry, Stockholm (1958–1981) for radiogenic carcinoma formation following Grenz ray therapy for benign conditions such as psoriasis, tinea, and hand dermatitis. In all 14,140 patients had received Grenz ray therapy, and only 8 radiation-induced SCC were uncovered at the Grenz RT sites using a latency period of ≥5 years from RT to tumor development as criteria for radiogenic carcinoma. Grenz ray is less penetrating, with an average D ½ penetration into skin of 0.2–1.3 mm, whereas SRT used for treating tinea in the studies by Shore and colleagues penetrated deeper, 7–20 mm, which in addition to other factors may account for the difference between these studies.

Ehring and Gattwinkel [116] in a study of 2005 patients irradiated for BCC report only one second tumor occurring 40 years after initial RT. Bart and colleagues [26] in a series of 500 patients treated with RT for skin cancer report only three possible radiogenic carcinomas. Landthaler and colleagues [168] examined the records of 2746 patients undergoing RT and uncovered 612 RT sites receiving a minimum dose of 1200 cGy with follow-up period of at least 10 years. The authors considered radiogenic carcinoma those that arose after a lag time of 10 years and uncovered 12 BCC and 9 SCC arising in RT sites (3.5%). Caccialanza and Cuka [169] examined the records of 5875 patients treated with SRT by dermatologists from 1970 to 2007 and discovered no radiogenic carcinoma (0%) using a latency period of 5 years from RT onset. Halpern [170] reports the incidence of radiogenic carcinoma using dosages to treat skin cancer to be less than 0.3% and attributes this to refinement in radiation and calibration techniques and the availability of more efficacious radiation modalities. Nevertheless, the recommendation of the NCCN guidelines and general consensus of most dermatologic radiotherapists is to use RT in those ≥60 years of age to minimize late sequelae.

Cost Comparisons

Previous cost comparisons of RT for the treatment of NMSC in the dermatologic literature have not differentiated dermatologic office-based RT (SRT) from radiation delivered by radiation oncologists in the hospital setting. Rogers and Coldiron [171], Kauvar and colleagues [172], and Zitelli and Cook [173] all report RT to cost between $2591 and

CPT Common Procedural Terminology, *APC* Ambulatory Payment Classification

$4558 at the time of their publication. We calculated and reported the costs of RT delivered in the outpatient dermatologic setting with SRT, the hospital setting using orthovoltage (250 kV) or megavoltage RT, as well as electronic brachytherapy using 2015 Medicare fee schedule national payment amount for physician services and the national Ambulatory Payment Classification rates paid to hospitals (Table 36.18. Cost comparison of RT modalities). RT delivered by dermatologists in the outpatient setting is the least costly form of RT in treating NMSC. Large-scale studies with more complex analyses are warranted that specifically examine SRT in the outpatient dermatologic setting; to date none exist.

Conclusion

SRT has over 106 years of research and development by dermatologists. One of the first reports on the use of radiotherapy came from dermatologists. Randomized trials, innumerable retrospective cohort, and several prospective cohort studies support the use of SRT in the treatment of NMSC. Calling on more than 70 specialty society partners including the AAD and ASTRO, the American Board of Internal Medicine (ABIM) Foundation launched "Choosing Wisely," a campaign to prevent unnecessary medical tests, treatments, and procedures through the promotion of conversations between clinicians and patients. The campaign is based on four tenets to help patients choose care that is (1) supported by evidence, (2) not duplicative of other tests or procedures already received, (3) free from harm, and (4) truly necessary. The key to "choosing wisely" with SRT is to select therapy based on patient age, infirmity, comorbidities, tumor type/depth, and patient choice. In line with choosing wisely, prospect theory is a concept applied to health values which considers a patient's baseline functionality when determining risk-to-benefit for an intervention, acknowledges uncertainty, reflects patient's values, and allows for treatment which may not necessarily achieve the highest cure rate but an acceptable one.

Chhabra and colleagues [174] in a viewpoint piece in the Journal of the American Medical Association (JAMA) entitled "Surgical Decision Making: Challenging Dogma and Incorporating Patient Preferences" discuss three recently published randomized trials which questioned the primacy of surgical management. These three randomized trials compared the established surgical gold standard to less aggressive operations or nonoperative alternatives. In all three trials, neither treatment was superior across "all outcomes." An example used by the authors to illustrate this point involves diverticulitis; colectomy was more effective in preventing the outcome of reoperation, whereas laparoscopic lavage was more effective in preventing the outcome of

stoma formation. Within the patient-centered framework, the modality that is "best" is determined by which outcome the patient values most. Informed consent represents an opportunity to understand a patient's values; the onus rests on us to understand which outcomes are most important to them and communicate the risks and benefits of each potential treatment option and the associated trade-offs, as Chhabra and colleagues state "patients are the ones who must live with the consequences."

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: Quality of evidence
SRT is indicated for the treatment of NMSC of the central face, nose, periorbital, ear, periauricular, periorbital locations	A
SRT should be limited to patients over 60 years of age	B
NMSC up to 5 cm in diameter may be treated with SRT	B
Better cure rates may be obtained by limiting SRT to the treatment of nonaggressive SCC, BCC (Tis-T2, N0, M0, TNM classification)	A
Aggressive histologic subtypes of BCC are a risk factor for recurrence	A
Aggressive SCC are a risk factor for recurrence: T3, T4, depth >2 mm, Clark level ≥IV, poorly differentiated, undifferentiated, perineural, lymphatic, or vascular invasion	A
SRT should not be used at sites of prior RT, chronic ulcers, or burn scars	A
SRT is associated with poorer cosmetic outcomes on the trunk and extremities	B
Frailty and poor overall health are reasons to consider SRT over surgery	B
Genetic anomalies associated with radiosensitivity are a contraindication to RT	A
Anticoagulant or antiplatelet use that cannot be discontinued prior to surgery is a consideration for SRT over surgery	B
SRT is associated with better cure rates than interstitial brachytherapy for the treatment of BCC	A
SRT has significantly higher cure rates than cryotherapy for BCC	A
SRT can be efficacious in the treatment of recurrent BCC	B
Hypofractionated once weekly fractions of SRT may be as effective as daily fractions of SRT for the elderly and disabled	B
Optimal TDF factors for the treatment of NMSC are between 90 and 110	B
The appropriate parameters should be chosen so that at least 50% of the depth dose (D ½) is at the base of the NMSC	B
Morpheaform BCC may be treated with SRT if surgery cannot be done	B
SRT is more effective than electron beam RT and megavoltage photon RT in the treatment of NMSC	B
SRT may be used for recurrent BCC (other than prior RT) if surgery cannot be done	B
SRT titrated to clinical response with additional fractions delivered may be associated with improved cure rates	B
SRT is associated with lower recurrence rates compared to electron beam RT	B
Planning an RT field with less than a 5-mm border around the tumor may be associated with increased risk of recurrence	B
Radiotherapy-induced carcinoma (radiogenic) are extremely rare when RT is delivered at dermatologic doses	A
SRT is the least expensive form of RT and less expensive than RT delivered by radiation oncologists and electronic brachytherapy	B
SRT is a viable treatment for NMSC in the elderly and infirm	A
Hypofractionated schedules of SRT 5–12 fractions are as effective as multiple protracted daily fractions in the treatment of nonaggressive NMSC	B
SRT is a treatment option for large SCC >2 cm in patients unable to undergo surgery	B

Self-Assessment Questions

1. Superficial/soft radiation therapy is most appropriate for basal cell carcinoma and squamous cell carcinoma in which of the following locations?
   (a) Extremities
   (b) Trunk
   (c) Neck
   (d) Hands
   (e) Nose

2. SRT is suitable for treatment of squamous cell carcinoma in which of the following situations?
   (a) SCC arising in a burn scar on the forehead of a 70-year-old
   (b) SCC on the hand of an organ transplant recipient
   (c) SCC in situ on the malar cheek of a 45-year-old patient
   (d) SCC on the nasal tip, Breslow depth 1 mm, in a 65-year-old on dabigatran for history of deep vein thrombosis
   (e) SCC arising on the foot of a diabetic patient with chronic osteomyelitis

3. Time-dose-fractionation factor tables are most useful for
   (a) Determining how much time to wait between fractions of radiation
   (b) Determining the maximum dose that should be given with each fraction of radiation
   (c) Deciding on the appropriate radiation treatment schedules to prevent over- and underdosing
   (d) Determining the optimum overall length of the radiation treatment schedule
   (e) Determining the appropriate amount of lead shielding to use on patients

4. The best cure rates in the treatment of basal cell carcinoma using SRT are obtained for which of the following histologic subtypes?
   (a) Nodular basal cell carcinoma
   (b) Morpheaform basal cell carcinoma
   (c) Infiltrative basal cell carcinoma
   (d) Multicentric basal cell carcinoma
   (e) Basosquamous carcinoma

5. All of the following are true except:
   (a) SRT is less expensive than electron beam radiation therapy.
   (b) SRT has better cure rates than cryotherapy and electrodessication and curettage.
   (c) The risk of radiogenic carcinoma is extremely low when used by dermatologists to treat skin cancer.
   (d) The risk of radiogenic carcinoma with the use of Grenz ray therapy for benign conditions is extremely low.
   (e) The appropriate TDF factor to aim for when selecting radiation parameters is between 150 and 170.

Correct Answers

1. e: Nose
2. d: SCC on the nasal tip, Breslow depth 1 mm, in a 65-year-old on dabigatran for history of deep vein thrombosis
3. c: Deciding on the appropriate radiation treatment schedules to prevent over- and underdosing
4. a: Nodular basal cell carcinoma
5. e: The appropriate TDF factor to aim for when selecting radiation parameters is between 150 and 170 (between 90 and 110, although some studies go up to 130).

Fat Transplantation

37

Dana L. Ellis and Lisa M. Donofrio

Abstract

The changes that happen as an intrinsic part of aging occur deeper in the subcutaneous tissues and are atrophic in nature (Donofrio, Dermatol Surg 26:1129–1134, 2000). This volume loss can be corrected through several means, including tissue repositioning, implants, synthetic fillers, or autologous tissue (Modarressi, World J Plast Surg 2(1):6–13, 2013). More recently, autologous fat grafting has come to be considered an ideal filler, as fat grafts are biocompatible, nonallergenic, nontoxic, easy to obtain, and synergistic with natural skin (Sinno et al. Plast Reconstr Surg 137:818–824, 2016). Neuber first reported the technique in 1893, followed by Illouz who then pioneered liposuction in the 1980s. In the modern day, Coleman demonstrated techniques for long-term fat graft stability (Sinno et al. Plast Reconstr Surg 137:818–824, 2016). Its first indications were for aesthetic surgery of the face, and more recently in hands (Modarressi, World J Plast Surg 2(1):6–13, 2013). Fat grafting is also useful for tissue loss due to an accident, operation, congenital disease, or lipodystrophy. In addition to a volumizing effect, the injected fat leads to neoangiogenesis, thereby improving the cutaneous elasticity. This technique is also used for wound healing, scar reduction, treatment of radiodermatitis, correction of acne scars, and breast reconstruction and augmentation in plastic surgery (Modarressi, World J Plast Surg 2(1):6–13, 2013).

Indications for Fat Transplantation

The changes that happen as an intrinsic part of aging occur deeper in the subcutaneous tissues and are atrophic in nature [1]. This volume loss can be corrected through several means, including tissue repositioning, implants, synthetic fillers, or autologous tissue [2]. More recently, autologous fat grafting has come to be considered an ideal filler, as fat grafts are biocompatible, nonallergenic, nontoxic, easy to obtain, and synergistic with natural skin [3]. Neuber first reported the technique in 1893, followed by Illouz who then pioneered liposuction in the 1980s. In the modern day, Coleman demonstrated techniques for long-term fat graft stability [3]. Its first indications were for aesthetic surgery of the face, and

more recently in hands [2]. Fat grafting is also useful for tissue loss due to an accident, operation, congenital disease, or lipodystrophy. In addition to a volumizing effect, the injected fat leads to neoangiogenesis, thereby improving the cutaneous elasticity. This technique is also used for wound healing, scar reduction, treatment of radiodermatitis, correction of acne scars, and breast reconstruction and augmentation in plastic surgery [2].

The main advantages of fat grafting include a long-lasting result, especially in comparison to the synthetic resorbable products, avoidance of granulomatous and allergic reactions that are often provoked by the more permanent (synthetic) products, a natural consistency, and improvement of cutaneous and subcutaneous trophicity [2].

Lipoaugmentation has become a staple in aesthetic medicine and surgery, and new technologies are continuously being introduced that support current clinical fat grafting efforts [3].

Effectiveness of Fat Transplantation

Autologous fat transfer offers many qualities of an ideal soft tissue filler. The success of fat grafting is thought to provide an abundant source of regenerative pluripotent cells, specifically adipocyte-derived stem cells (ADCs) [2]. These cells are able to integrate into host tissue and secrete important cytokines and growth factors including vascular endothelial growth factor (VEGF), hepatocyte growth factor (HGF), insulin-like growth factor (IGF), platelet-derived growth factor (PDGF), and transforming growth factor-beta (TGFβ) [4].

Transplanted fat requires contact with living tissue, and these grafts survive by diffusion until the process of neovascularization occurs. As such, one of the major drawbacks to this technique is a somewhat unpredictable long-term survival rate. Long-term results have been documented by operators practicing atraumatic harvesting and multilayer microdroplet infiltration [1]. However, there is difficulty in assessing longevity. First, there are no good objective measurement criteria available. We rely on photographs, but they are a two-dimensional representation of a three-dimensional result and are purposely chosen for their outcome. Second, patients who start with augmentation often supplement their results with other rejuvenation procedures, confounding the effect. Lastly, patients continue to age over the time they are in follow-up [1]. Lasting augmentation is most likely due to neovascularization of the adipocyte grafts; however, volume enhancement may also be caused by replacement fibrosis [1]. Although fat transplantation by structural principles presents a rationale for increased survival, it can occasionally prove to be unreliable, and patients need to be made aware of the often unpredictable nature of fat transplantation [1].

There is a single prospective study on the topic of fat graft longevity to the midface [5]. In this study, 66 patients were grafted with an average of 10 cc of fat using the modified Coleman technique. Using 3D image technology, the authors noted that 32% of the fat grafted to the midface was present at 16 months and concluded that the volumes required to make a visible change in midfacial rejuvenation are considerably less than originally anticipated (4) [5].

This unpredictable long-term survival rate has led to investigations into methods and techniques to increase fat viability and longevity [3].

Preoperative Evaluation

Assessment of the areas of facial atrophy is best accomplished while examining a young photograph. Since the idea that patients need to be filled and not cut is new, it helps to show them visually how they have aged [1]. The areas of future augmentation should be mutually agreed upon and documented. Patients with coagulopathies, a history of deep vein thrombosis, or warfarin intake are excluded. Connective tissue disease warrants caution since theoretically, transfer of an autologous material may stimulate an inflammatory response; however, this has not yet been described [1]. Patients must also be in overall good health with realistic expectations and

acceptance of the gradual sequential nature of the improvement [1]. The procedure works best in patients 30–50 years of age with enough anchoring recipient tissue. Patients with extreme atrophy or advancing age may have limited results or may require numerous transplant sessions [1]. Overweight patients with jowl and neck adiposity may need additional suctioning [1]. The patients should be educated on sun avoidance and textural and pigmentary alterations secondary to photodamage treated with appropriate modalities [1].

Azithromycin 500 mg is initiated on the day before the initial extraction/transplantation procedure and continued at a dose of 250 mg/day for 4 days. All nonsteroidal anti-inflammatory drugs should be discontinued 1 week prior, as well as vitamin E, St. John's Wort, and gingko biloba supplements. Patients should wear dark, loose clothing and bring a snug undergarment such as biking shorts for postoperative compression [1].

Best Techniques and Performance

The donor site should be picked from an area that can benefit cosmetically from fat removal. The outer thighs, buttocks, and abdominal fat have shown to possess the greatest lipogenic activity, and a concerted effort should be made to harvest from these sites [6]. Despite anecdotal reports of differing fat graft quality based on donor site, there are data to suggest no difference exists, as measured by a 2,3-bis-(2-methoxy-4-nitro-5-sulfophenyl)-2H-tetrazolium-5-carboxanilide (XTT) assay, in grafts harvested from four of the most common donor sites: the abdomen, thigh, flank, and knee (4) [7]. Another study reviewed 73 patients who underwent fat grafting for breast reconstruction and showed no difference in longevity between fat harvested from the abdomen or thigh based on three-dimensional imaging (4) [8].

Fat extraction takes place with purely tumescent anesthesia using a modified Klein solution [1]. After prepping and draping the donor area, tumescent anesthesia is infiltrated by hand or pump in a manner previously described [9]. It is best to wait 20–30 min to allow even dispersion of the tumescent fluid and maximum anesthesia. Current practice suggests that the amount of lidocaine used be kept to a minimum, since it is toxic to adipocytes [10]. In actuality, the data regarding the effect of local anesthesia on adipocyte biology is somewhat conflicting. Lidocaine, used for local anesthesia, has been reported to inhibit the growth of adipocytes in culture and slow down glucose transport and lipolysis as evaluated by D-[U-carbon 14]-glucose and spectrophotometric determination of glycerol for lipolysis [11]. Prior studies also suggest that local anesthetic may slow adipocyte metabolism, growth, and viability. These findings only persisted while lidocaine was present. Once the lidocaine was removed, so too were its inhibitory effects [11]. More recent studies show no difference in fat treated with infiltrative anesthetic by counting the number of living fat cells in a 100× field (4) [12].

The cardinal principle of structural augmentation involves the atraumatic and gentle harvesting of intact fat cylinders. This is accomplished with a 3-mm open-tipped cannula attached to a 10-ml syringe. Most dermatologic practices avoid the use of suction machines in this procedure because they generate damaging negative pressures [1]. However, there is evidence to suggest that no difference exists in cell viability between syringe aspiration and liposuction-assisted aspiration. One study using human fat, grafted into severe combined immunodeficient mice, argued that there was no difference between a 10-cc syringe or a Byron liposuction pump when comparing the specimen weights and metabolic assays of 12-week-old graft explants (4) [13].

When using a syringe, the plunger of the syringe is withdrawn slowly 1 ml at a time. The to-and-fro motion of the open-bore cannula is enough to fill the syringe with clean yellow fat tissue. A total of 10–20 syringes are filled in this manner, depending on the projected volume and number of transplants required. The collected 10-ml syringes are then spun down in a centrally sterile centrifuge for 20 s to separate the fat cells from the triglycerides and tumescent fluid. Once done, the watery infranate is released from the syringe, and the fat is transferred to 1-ml syringes

with a 16-gauge female-female adapter, stopping short of the oily supernate [1].

The reported rates of fat cell survival vary greatly in the medical literature (10–90%). Different techniques of harvesting and processing the fat cells are so claimed to be responsible for these differences, without any agreement concerning the best way to process [2]. Various studies have assessed the impact of centrifugation on fat transfer, and most have concluded that, unless conducted at very high speeds, in vernal centrifugation does not adversely affect adipocyte viability (3b) [14, 15] Coleman et al. suggest 3000 rpm for 3 min, but 1 min of centrifugation is as efficient with less harm to fat cells [16].

Although many authors may advocate for one fat preparation protocol over another, there are no objective data to support these claims. There is in fact evidence to suggest no difference in graft outcome between several fat preparation protocols. Of note, a previously cited study found no difference in end graft survival of fat without treatment, with centrifugation, with washes of normal saline, with washes of lactated Ringer solution, and with combinations of centrifugation and washes, where graft survival was estimated using explant weights and with an XTT cell viability assay (3b) [13].

Many properties of fat begin to change after processing. Glycerol-3-phosphate dehydrogenase activity, which is a measure of adipocyte destruction, increases linearly until 4 h [3]. Stem cells can be harvested up to 4 h at room temperature and up to 24 h at 4 °C [17]. Therefore, although fat preparation protocols may vary from one operator to another, there is evidence to support the notion that fat transfer should be undertaken as soon as possible after harvesting [3].

After extraction and preparation of the fat, the patient is placed in an upright position and the areas requiring augmentation sketched onto the skin with a sterile marking pen. The face is then prepped with an antiseptic wash and the table reclined. Facial anesthesia is in the form of blocks and local infiltration to effectively cover all the planned areas of augmentation. Entry sites are most often made with an 18-gauge Nokor needle tip in areas affording access and are best hidden at the hairline and in the base of rhytides. All infiltration is by way of a blunt cannula [1]. The large diameter ensures that the fat may pass in intact tissue parcels, and the blunt end prevents perforation or tearing of underlying structures [1]. There are experimental data supporting the notion that low-shear devices maintain fat structural integrity. Specifically, one study used computed tomographic (CT) volume measurements at 4 weeks to show a significantly increased fat viability and significantly lower lipolysis with a low-shear device [18]. This same study noted significantly higher fat volume retention in addition to healthier appearing fat on histologic evaluation in an animal model after delivery through a low-shear device (5) [18].

Optimal cannula diameter for fat injection is a minor topic of debate. One particular study found viability to be greatest with use of a 2.5-mm (~10–11 gauge) cannula compared with smaller cannulas as evaluated by counting live cells using a hemocytometer under 40× magnification [18]. The authors concluded that by increasing the diameter of aspiration and injection cannulas, trauma is minimized and viability and graft survival are improved (5) [18]. Another study stated the best results were achieved with the no. 14 cannula, as compared with smaller ones [19]. A third study found no difference between 14-, 16-, and 20-gauge cannulas. In this study, viability of the fat grafts was evaluated by fat cell isolation with collagenase digestion and staining and subsequently counted with a hemocytometer (5) [20].

During injection, the fat is deposited in minuscule strands of less than 0.1 ml amounts on the withdrawal phase of the motion [1]. The fat is woven in a three-dimensional design starting at the most stable plane (next to bone when available) and working up through the subcutaneous fat. Every attempt should be made to place the fat in virgin tunnels, avoiding excessive positive pressure on the syringe and globular deposits [1]. If at any time the infiltrator becomes clogged, it should be withdrawn and cleared. The purpose of this is to anchor the fat and allow enough room

between adipocytes for survival through respiratory diffusion [1].

Safety

Patients need to consent to all possible developments before the procedure. Expected sequelae are bruising and edema lasting 2–10 days, depending largely on the aggressiveness of the augmentation. Pre-icing as well as post-icing of the face and intramuscular betamethasone decrease this side effect. Other possible complications include local infection, asymmetry, lumpiness and fat cysts, entry site scars or discoloration, perforation of the orbital septum, marginal mandibular injury, parotitis, and reabsorption of fat. Most if not all of these can be avoided with experience and conservative, meticulous technique [1].

Postoperative Care and Follow-Up

Since the conditions favorable to fat cell survival are poorly understood, repeat staged transplants give an added advantage by providing more chances for the fat to take, and healing from initial treatments may increase vascularity and fibrosis in the recipient tissue [1].

Initial transfer procedures use 15–30 ml of the freshly harvested fat. The extra fat syringes are then labeled with name, date, and social security number and stored in a plasma freezer at 30° C. Patients return for additional augmentation procedures at 4–6-week intervals over the course of a year. At these visits, 8–12 ml of fat is placed in areas requiring further augmentation, adhering to the placement principles described above. There is usually no downtime from these smaller treatments, and the patient can put on makeup right after the session and return to work. Viability of thawed adipocytes has been previously demonstrated, and many believe that frozen fat "takes" better than fresh fat [10]. This may be due to dehydration of the tissue with freezing, leaving a more concentrated adipocyte suspension [1].

Alternative Procedures and Modifications

Animal models have proven that a number of tissue scaffolds can improve the longevity of grafted fat. One group of authors used a recently reported protocol to suspend harvested fat in Growth Factor-Reduced Matrigel (BD Biosciences, San Jose, Calif.) [21]. This biological matrix has been shown to improve early angiogenesis [22]. It has also been hypothesized that suspending the purified cells in the resorbable matrix helps to optimize graft viability by meeting the high metabolic demand of lipocytic tissue. This procedure was tested in a murine model that compared harvested fat alone to harvested fat suspended in Growth Factor–Reduced Matrigel. The matrix-assisted fat showed greater maintenance of volume and adipocyte cellularity at 3 months (5) [21].

Although there are numerous studies that focus on improving the harvest and preparation of fat, the recipient site is often forgotten when attempting to optimize the outcome. Microneedling has been proven beneficial in increasing skin vascularity and skin quality, but there have been few studies specifically investigating whether this technique is beneficial for increasing fat graft survival [3]. However, one study showed significantly more vascularity, higher graft survival, and better graft integrity with less fibrosis (by histomorphometric and immunohistochemical evaluation) after preconditioning with microneedling 1 week before grafting in an animal model (5) [22].

Again, there is no consensus concerning the best way to process the harvested fat before reinjection. Based on the recent literature, adding platelet-rich plasma (PRP) to fat preparation may be a means of improving fat survival and rendering a more predictable result [2]. Platelets work via the degranulation of their α-granules, which contain synthesized and prepacked growth factors [3], the most potent ones being PDGF, TGFβ, IGF, VEFG, and endothelial growth factor (EGF). Released growth factors stimulate angiogenesis, cell differentiation, and proliferation, leading to

the reconstitution of the tridimensional matrix that allows the rearrangement of adipocytes into the correct 3D organization. This approach is completely autologous and immediately employed without any type of in vitro preconditioning or media complement [2].

The benefit and safety of PRP are documented in more than 5000 studies where the authors observed enhancement of bone regeneration [23–25], wound healing [26–28], tendon and cartilage healing [29–31], corneal healing [32], and skin rejuvenation [33]. PRP is so used more and more often in the plastic, reconstructive, and aesthetic surgery fields [34–36].

In a series of in vitro studies, it has been demonstrated that PRP increases fat cells' survival rate and stem cells' differentiation [34, 37]. One study showed that fat graft survival rates were significantly increased in rats treated with PRP (4) [38]. There are also some successful cases of facial reconstruction with fat grafting and PRP [39], and this association has also been described for aesthetic cases [2].

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	Grade score: quality of evidence
Evidence does not support that abdominal fat demonstrates superior viability to that of other anatomic areas	C
Evidence does not support that infiltrative anesthesia affects the viability of fat from donor sites	C
There is limited evidence to support that liposuction pump aspiration yields fat as viable as that by syringe aspiration	D
There is no evidence to support that washing or centrifugation of fat improves graft survival	B
Evidence does not support an optimal cannula or needle diameter for fat reinjection	C
There is some evidence to support that injecting fat with a low-shear device preserves fat integrity	D
There is evidence to support that fat should be injected as soon as possible after harvesting	D
There is some evidence to support that the viability of thawed adipocytes is better than that of fresh fat	D
There is evidence to support the long-term efficacy of fat grafting to the midface	C
There is evidence to support tissue engineering techniques for improving fat longevity	D
There is some evidence to support that preconditioning the recipient site improves fat graft survival	D
There is evidence that demonstrates that PRP increases fat cell survival rates	C
There is no gold standard that exists for quantifying fat viability after transplant	N/A

Self-Assessment Questions

1. Which of the below is false?
   Repeat staged transplants give an added advantage by:
   (a) Providing more chances for the fat to take
   (b) Increasing vascularity in the recipient tissue
   (c) Increasing fibrosis in the recipient tissue
   (d) Increasing elasticity in the recipient tissue
   (e) Decreasing fibrosis in the recipient tissue
2. Which of the below are true?
   The main advantages of fat grafting include:
   (a) A long-lasting result
   (b) Avoidance of granulomatous reactions
   (c) Avoidance of allergic reactions
   (d) A natural consistency
   (e) Improvement of cutaneous and subcutaneous trophicity
   (f) All of the above
3. The success of fat grafting is based largely on the provision of an abundant source of regenerative stem cells, specifically:
   (a) Embryonic stem cells
   (b) Pluripotent stem cells
   (c) Hematopoietic stem cells
   (d) Epidermal stem cells
   (e) Epithelial stem cells
4. Lasting augmentation is most likely due to:
   (a) Fibrosis of the adipocyte grafts
   (b) Neovascularization of the adipocyte grafts
   (c) Stimulation of neoadiposity
   (d) Nature of underlying facial anatomy
   (e) Inosculation of the grafts
5. Which are absolute contraindications to autologous fat transfer? (Can pick more than one)
   (a) History of coagulopathies
   (b) History of deep vein thrombosis
   (c) Current use of warfarin
   (d) Current use of statin drug
   (e) Diabetes

Correct Answers

1. e: Since the conditions favorable to fat cell survival are poorly understood, repeat staged transplants give an added advantage by providing more chances for the fat to take, and healing from initial treatments may increase vascularity and fibrosis in the recipient tissue.
2. f: The main advantages of fat grafting include a long-lasting result, especially in comparison to the synthetic resorbable products, avoidance of granulomatous and allergic reactions that are often provoked by the more permanent (synthetic) products, a natural consistency, and improvement of cutaneous and subcutaneous trophicity.
3. b: The success of fat grafting is based largely on the provision of an abundant source of regenerative pluripotent cells, specifically adipocyte-derived stem cells (ADCs). These cells are able to integrate into host tissue and secrete important cytokines and growth factors including vascular endothelial growth factor (VEGF), hepatocyte growth factor (HGF), insulin-like growth factor (IGF), platelet-derived growth factor (PDGF), and transforming growth factor-beta (TGFβ).
4. b: Lasting augmentation is most likely due to neovascularization of the adipocyte grafts; however, volume enhancement may also be caused by replacement fibrosis.
5. a, b and c: Patients with coagulopathies, a history of deep vein thrombosis, or warfarin intake are excluded from autologous fat grafting procedures. Connective tissue disease warrants caution since theoretically, transfer of an autologous material may stimulate an inflammatory response; however, this has not yet been described. Patients must also be in overall good health with realistic expectations and acceptance of the gradual sequential nature of the improvement.

Soft Tissue Augmentation (Temporary Injectable Fillers) of the Upper Face (Cheeks, Brow, Forehead, Ear)

Sue Ellen Cox and Christie Regula

Abstract

Facial aging is a multifactorial process that is caused by changes in the skin, fat compartments, and underlying bony elements. Temporary injectable fillers are commonly used to improve the appearance of the aging face by restoring lost volume, smoothing rhytides, reducing skin laxity, and improving facial contouring. These fillers include hyaluronic acid, poly-L-lactic acid, and calcium hydroxyapatite. Filler selection is important for a successful treatment outcome, as is the pre-treatment evaluation, procedure technique, and follow-up care. This chapter specifically reviews the use of temporary injectable fillers for treatment of the upper face including the cheeks, brow, forehead, and ear. A thorough understanding of upper facial anatomy and other specific considerations are important to maintain a good safety profile and obtain excellent results in this region.

Indications for Soft Tissue Augmentation

Temporary injectable fillers are most commonly used to add volume to the upper face. Here, they can restore lost volume, smooth rhytides, reduce skin laxity, and improve facial contouring. In most cases, the changes we wish to correct are secondary to facial aging. Facial aging is a multifactorial process that is caused by changes in the skin, fat compartments, and underlying bony elements. Understanding these individual changes is important to effectively use injectable fillers for facial rejuvenation.

Skin

A decrease of types I and III collagen is a characteristic feature of aged and photodamaged skin [1]. This loss of fibrillar collagen leads to skin laxity and rhytides. Cross-linked hyaluronic acid, poly-l-lactic acid, and calcium hydroxyapatite, common dermal filler components, have all been shown to stimulate collagen synthesis, partially

restoring dermal matrix components that are lost in aging and photodamaged skin [2–4].

Adipose

Cadaver dissections have shown that the facial adipose system is divided into discrete anatomic compartments that are separated by fibrous membranes [5]. Volume loss and redistribution of fat within the compartments, and migration of these compartments, contribute to the aged appearance [6]. These differential changes are quite noticeable in the periocular and cheek regions.

The orbital septum holds two upper eyelid fat pads (nasal and central) and three lower eyelid fat pads (nasal, central, and lateral) in place within the orbit. Superiorly, the retro-orbicularis oculi fat pad (ROOF) lies under the brow (Fig. 38.1). Inferiorly, the suborbicularis oculi fat pad (SOOF) lies over the malar eminence and is separated from the lower eyelid fat pads by the orbitomalar ligament (Fig. 38.2). Soft tissue is lost along ligaments as one ages; loss along the orbitomalar ligament at the infraorbital rim creates a depressed tear trough. As the orbital septum weakens, the periocular fat pads can herniate forward, resulting in a puffy lid and accentuation of the tear trough.

The cheek has both superficial and deep fat compartments. The superficial fat compartments include five fat pads: the lateral-temporal, middle cheek, medial cheek, nasolabial, and labiomandibular, which are separated by retaining ligaments. The suborbicularis oculi, malar, maxillary, and buccal comprise the deep fat compartments. These are listed superficial to deep, with the deepest lying on the buccinator muscle. Computed tomographic scans examining the midfacial fat compartments reveal that over time, the deep fat compartments, namely the medial cheek and buccal, lose volume. Additionally, an inferior shift of both the fat within these compartments and the compartment itself leads to contour changes of the face and a "bottom heavy" appearance [6].

Bone

The skeletal morphology of the face changes with age, namely by an overall decrease in

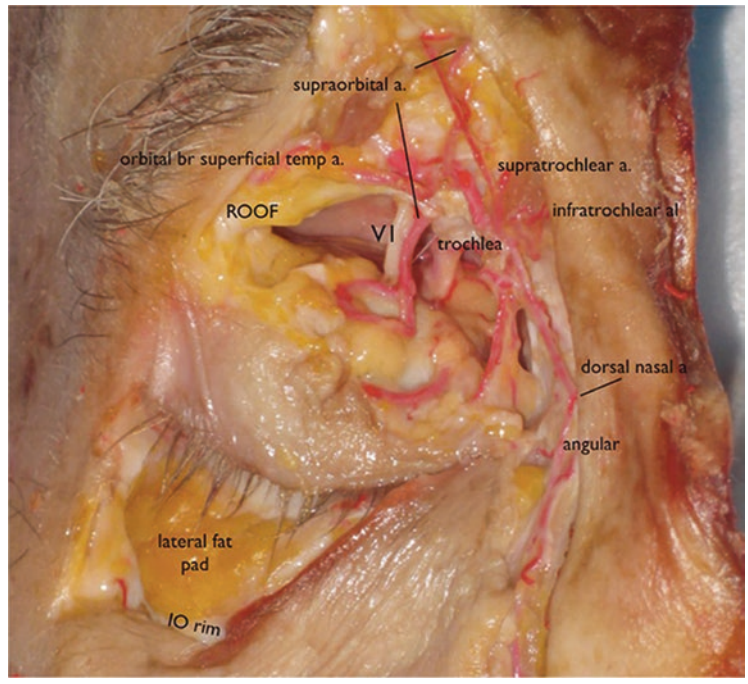

Fig. 38.1 Dissection of the supraorbital region revealing fat pads, vasculature, and innervation. (Anatomical figure courtesy of Julie Woodward, MD)

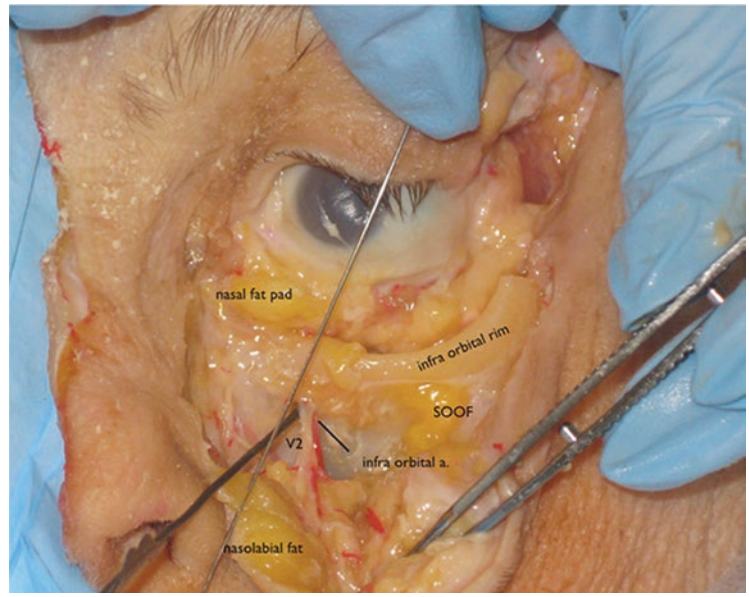

Fig. 38.2 Dissection of the infraorbital region revealing fat pads, vasculature, and innervation. (Anatomical figure courtesy of Julie Woodward, MD)

volume. Computed tomographic scans of 120 subjects objectively characterized these specific changes [7]. The superomedial and inferolateral aspects of the orbital rim resorb over time. This loss of bony volume results in a change of brow position and contributes to the formation of a nasojugal groove. The glabellar angle also decreases, due to bony resorption of the frontal bone and may contribute to brow ptosis and lateral orbital hooding. Results also showed a decreased maxillary angle, which represents a decrease in the height of the maxilla. This volume loss and decreased angle may be responsible for downward and forward movement of the medial and middle cheek fat pads. Overall, the loss of facial skeletal volume results in decreased structural support and projection of the overlying soft tissue.

Effectiveness of Soft-Tissue Augmentations

In 1981, bovine collagen was the first filler to gain FDA approval, and it remained the only FDA-approved filler for over two decades. In several formulations, it was used to treat fine lines, shallow scars, and fill deeper rhytides and folds. It also had several drawbacks including two prerequisite skin tests to minimize allergic reactions and a short duration of less than 3 months. These prompted the development of newer filler materials; most collagen fillers have not been available in the United States since 2010.

In 2003, the first hyaluronic acid (HA) filler was approved for use in the United States. Hyaluronic acid is the most prominent glycosaminoglycan in the skin and, therefore, has a very low allergic potential. It also effectively restores volume loss and is longer lasting than collagen fillers. In fact, since 2003 more than ten hyaluronic acid fillers have been approved by the FDA.

In 2005, poly-L-lactic acid (PLLA) was FDA approved for the treatment of HIV-associated lipoatrophy. This is a synthetic, biodegradable, immunologically inert peptide polymer that serves as a dermal stimulating agent [8].

In 2006, calcium hydroxyapatite (CaHA) was approved for the correction of HIV-associated facial lipoatrophy and in 2009 for correction of facial rhytides and folds in non-HIV patients. This product contains 30% CaHA microspheres and approximately 70% gel carrier. This combination of CaHA provides a filling effect as well as scaffolding for new collagen formation [9].

All of the above mentioned filler materials have been shown to stimulate new collagen formation [4]. This stimulation contributes to the effectiveness of dermal fillers in the upper face, as does the type of filler and injection technique. We will discuss the specific uses, effectiveness, and duration of individual fillers later in this section.

The choice of filler to be used in a particular area influences the effectiveness of the treatment. The three most common fillers, as mentioned previously, are hyaluronic acid, calcium hydroxyapatite, and poly-L-lactic acid. The distinction between these fillers is not only the material that they are made of but also the biophysical properties of the filler. Rheology is the study of flow-related properties and helps us better characterize and understand the differences between fillers.

Several rheologic properties of fillers are important to consider when choosing the appropriate filler for a specific purpose. G prime (G') is the elastic (storage) modulus, which is a measurement of gel stiffness and its ability to resist deformation. The higher the G', the less the filler deforms under pressure which is useful for areas where a "lift" is desired. Viscosity (η) measures the filler's ability to resist shearing forces, those that occur both during and after filling. The lower the viscosity, the less force the filler takes to inject, the easier it flows through the skin, and the easier and more likely it is to spread/mold. For example, lower viscosity filler is useful for filling the nasolabial folds. Cohesivity relates to the cross-linking of the filler molecules and the gel's ability to resist vertical compression to maintain the shape of the gel. Fillers with high cohesivity are especially useful in the midface because they can maintain the outward projection of the cheeks and have a low risk of filler migration. The cohesivity of hyaluronic acid (HA) fillers can also be described as monophasic or biphasic. Monophasic fillers contain homogenous microspheres, while biphasic fillers contain a range of microsphere sizes. Monophasic HA fillers are more cohesive and may not migrate as much following injection. A comprehensive rheologic summary of common fillers is found in Table 38.1.

Effectiveness of Individual Fillers

Hyaluronic Acids

Restylane®

Restylane® and Restylane-L® are FDA-approved for correction of nasolabial folds and lips. A split face study comparing the efficacy of Restylane® to collagen in correcting the nasolabial folds included 138 subjects and showed Restylane® provided superior results in the majority of patients [10]. This result persisted the entire duration of the 6-month study. Restylane® can also be effective off-label in treatment of the temples, glabella, and infraorbital folds [11–18].

Restylane® Lyft

Formerly marketed as Perlane®, Restylane® Lyft was originally FDA-approved in 2010 for correction of moderate to severe facial folds and wrinkles, such as the nasolabial folds. It has more recently also been approved for cheek augmentation and the correction of age-related midface contour deficiencies. A split face study including 68 patients comparing the efficacy of Perlane® to collagen in correcting the nasolabial folds showed Perlane® provided superior results in the majority of patients through 6 months [19]. The first study ($n = 40$) looking at the efficacy of Perlane® for treatment of midface volume and contour correction showed a 97.5% initial response rate [20]. An open-label, evaluator-blinded, randomized controlled trial examined the efficacy of Restylane® Lyft for correction of midface volume deficit or contour deficiency in 200 subjects. Periosteal injections of the midface were performed with 89% of treated subjects having initial improvement in the midface and 85% of treated subjects maintaining a global aesthetic improvement at 12 months [21]. Restylane® Lyft has also shown to be effective in off-label treatment of the temples and tear toughs [22, 23].

Restylane® Silk

Restylane® Silk was FDA-approved in 2014 for lip augmentation and correction of perioral rhytides. The original clinical trial of 221 subjects showed improvement in lip fullness and perioral rhytides at 8 weeks with the majority of patients maintaining an improvement at 6 months [24]. Off-label use of this product has been anecdotally reported in the forehead, periorbital rhytides, glabella, and infraorbital hollows [25].

Restylane® Refyne

Restylane® Refyne was FDA-approved in 2016 for the treatment of moderate to severe facial wrinkles and folds. In the pivotal clinical trial of 170 patients, Restylane® Refyne was used to correct moderate to severe nasolabial folds. At 6 months, improvement in nasolabial folds with Restylane® Refyne was observed in 78.8% of subjects. At 1 year, 62.3% of treated folds maintained improvement [26]. An 18-month follow-up, randomized comparison between Restylane® Refyne and Restylane® in treatment of the nasolabial folds showed no difference in the effectiveness, safety, or patient preference between the two fillers [27].

Restylane® Defyne

Restylane® Defyne was FDA-approved in 2016 for the treatment of moderate to severe, deep facial wrinkles and folds. In the pivotal clinical trial of 162 patients, Restylane® Defyne was used to correct moderate to severe nasolabial folds. At 6 months, improvement in nasolabial folds with Restylane® Defyne was observed in 77.1% of subjects. At 1 year, 69.7% of treated folds maintained improvement [28].

Juvederm®

The Juvederm® family of fillers was first approved in 2006 for the correction of nasolabial folds; this included Juvederm® Ultra and Juvederm® Ultra Plus. A multicenter, double-masked, randomized trial of 439 comparing both fillers to Zyplast collagen for correction of nasolabial folds showed both Juvederm® products to be effective in correcting the nasolabial folds, and 81–90% of those treated with Juvederm® Ultra and Juvederm® Ultra Plus maintained their results for 6 months or more [29, 30].

Juvederm® Voluma

Juvederm® Voluma XC was FDA-approved in 2013 for deep injection for cheek augmentation. In a multicenter, single-blinded, controlled study

of 235 subjects treated with Juvederm® Voluma for midface augmentation, 85.6% of the treatment group had significant improvement at 6 months, and nearly half of the subjects maintained correction for 24 months [31, 32]. This filler has also been described for off-label use in forehead reflation [33].

Juvederm® Volbella

Juvederm® Volbella was FDA-approved in 2016 for lip augmentation and correction of perioral rhytides and was shown to last up to 12 months in a prospective, multicenter, open-labeled study ($n = 60$) [34].

Belotero Balance®

Belotero Balance® was approved by the FDA in 2011 for the correction of moderate to severe facial wrinkles and folds. Two original studies showed the superiority of Belotero Balance® to collagen in correction of nasolabial folds. The first study showed correction to be maintained at 6 months ($n = 118$). The second long-term, open-label study ($n = 95$) showed that the effects of Belotero Balance® persisted in the majority of subjects without repeat treatment for at least 48 weeks [35, 36]. Belotero Balance® has also been shown to be effective off-label in treating the infraorbital folds, fine lines of the perioral region, and glabella [37].

Poly-L-lactic acid (PLLA)

Poly-L-lactic acid (PLLA), Sculptra®, was FDA-approved in 2005 for the treatment of HIV-associated lipoatrophy and in 2009 for the correction of nasolabial folds and facial rhytides. Its effectiveness in panfacial re-volumizing and correction of the nasolabial folds can last up to at least 2 years [38–41]. It has also been effective off-label in correction of hill and valley acne scarring, cheeks, and temples [42, 43].

Calcium Hydroxyapatite

Calcium hydroxyapatite (CaHA), Radiesse®, was approved by the FDA in 2006 for the correction of HIV-associated facial atrophy based on an open-label 18-month trial of 100 subjects that showed 100% of the patients had improvement at 3 months and 91% had improvement at 18 months [44]. In 2009, it was also approved for correction of moderate to deep lines and folds, such as nasolabial folds, based on a pivotal trial that compared Radiesse® to collagen ($n = 117$). At 6 months, 82% of CaHA patients showed improvement compared to 27% of collagen patients [45].

Preoperative Evaluation

Patient selection and evaluation is the first step in obtaining a successful outcome. Patients with variable amounts of bone and fat loss who maintain good skin elasticity are better candidates than those with severely sun-damaged skin or extreme skin laxity. The latter may be better suited for skin resurfacing or surgery. The patient interview and clinical examination are used to identify appropriate candidates for treatment. The assessment should begin with a review of the patient's medical history including history of previous fillers (temporary or permanent), prior cosmetic procedures, bleeding disorders or immunosuppression, current medications (particularly anticoagulants), allergies, and history of anaphylaxis. Contraindications should be reviewed; these include active infection near the treatment site, allergy to product components and pregnancy. With the longer-lasting fillers such as those with Vycross technology (Voluma, Vobella, Volift, Allergan Santa Barbara, Ca), a history of recent or near future dental work, chronic infections, or any procedure that potentially sheds bacteria into the bloodstream should be ascertained as this has been implicated as a potential risk factor for soft tissue fillers [46, 47].

During the consultation, the medical history regarding both prescription and over-the-counter medications and herbal and vitamin supplements should be reviewed. Substances that are known blood thinners such as aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) should be discontinued 7–10 days in advance to help diminish the risk of bruising. Supplements to be avoided for 1 week prior to injections include garlic, ginger, ginseng, gingko biloba, kava, celery root, fish oils, St John's Wort, vitamin E

(1,000–2000 IU /day), and glucosamine/chondroitin [48]. The patient should avoid these medications for 4–5 days post procedure if bruising is visible within 48 hours post procedure. Moderate doses of alcohol have been associated with inhibition of platelet activation and vasodilatation, so it should also be avoided pre- and post procedure [49]. In regard to therapeutic use of known anticoagulants, such as patients with a history of heart attack, stroke, or blood clot, it is recommended that these patients stay on their medications as the risk of going off outweighs the potential for a bruise [50]. Medications that may reduce bruising including Arnica, Arnica Montana, bromelain, and vitamin K topically should be at the discretion of the treating physician. Evidence is anecdotal and studies have been inconclusive [51–53].

The author (SEC) recommends that the patient curtails exercise for 48 hours after injections to help diminish bruising and swelling. Additionally, patients should be encouraged not to schedule treatments when they have important social functions within 7–10 days in case of bruising. Patients are asked to present to the clinic with a clean makeup-free face on the day of the procedure, so that the photographs are consistent and show the patient's natural appearance. This is also important for appropriate skin prep to minimize the potential for implantation of foreign material into the skin, which could increase the risk of infection or biofilm [54].

Photography and skin prep are important preprocedural considerations. Pre- and postprocedural photographs should be taken to document the clinical improvement for the physician's chart records and to demonstrate the improvement to the patient. The physician only has one opportunity to obtain an excellent pretreatment photo, so this is of critical importance. This photograph will be used as the standard to which all future treatments are compared. It will also document any pre-existing asymmetries. These photos need to be standardized and should be taken with the same camera, at the same angles, at the same distance with the same lighting to reduce any variables. Physicians may choose to implement three-dimensional photography as it allows the patient and physician the ability to visualize the shadows and contours that are corrected with fillers.

Skin prep is important with the advent of longer lasting fillers. To date, there have been no data with specific, universal guidelines on the appropriate method of prepping the skin for injections of soft tissue fillers. Benzalkonium chloride has been recommended [55]. Without data specific to soft tissue fillers, it is useful to consider prior publications regarding clinical experience with surgical procedures [56]. A prospective study of 849 patients undergoing nonfacial, "clean-contaminated" surgery (GI, urologic, and gyn) showed that chlorhexidine-alcohol was more effective than povidone-iodine [57]. General guidelines for reduction of healthcare-associated infections include skin antisepsis using 2% chlorhexidine gluconate in 70% isopropyl alcohol [58]. Chlorhexidine should not be used in the periorbital area due to the risk of keratitis and ocular injury. Avoidance of facial skin exposure to tap water in the periprocedural time frame is also prudent. Rodriguez et al. reported cases of *Mycobacterium chelonae* infection after cosmetic dermal injections of hyaluronic acid. The root of infection was traced to ice cubes used at the injection site. The organisms grown from the patient's culture matched the isolates from the faucet and tap water at the clinical site [59]. Patients can be instructed to wash their face with cleansing wipes, not in the sink, and to avoid reapplication of makeup for several hours posttreatment [60].

Anesthesia can be adequately achieved either with topical or regional nerve blocks. Topical products are used in our office with application 10–15 min prior to injections. SEC prefers Pliaglis (Galderma, Fort Worth TX) as it is the one of the few prescription-strength topical anesthetic creams that is currently FDA-approved. It contains a eutectic mixture of 7% lidocaine and 7% tetracaine and forms a pliable peel on the skin when exposed to air. Many physicians use the compounded higher concentration products, such as BLT (benzocaine, lidocaine, tetracaine); however, there have been reports of lidocaine toxicity when using high concentrations of compounded

products when applied to larger areas. Compounding may decrease product consistency depending on the compounding pharmacy. Less commonly, regional nerve blocks can also be used to achieve adequate anesthesia. A full discussion of the relevant anatomy and injection technique is found in another chapter in this text.

Informed consent is an important aspect to the pre-procedure process. Realistic expectations for treatment outcomes must be thoroughly discussed with patients. Optimal patient satisfaction is dependent on fulfilling the patient's expectations and the technical skill of the injector. This is particularly relevant with soft tissue fillers since the amount of product used can substantially affect the results. Informed consent should detail the risks, benefits, alternatives, and potential complications associated with treatment. The relative infrequency of specific complications should be communicated, but the consequences of complications should not be minimized.

Immediately after the procedure, the most common side effects include slight redness and swelling at the injection sites. Patients should also be reminded that bruising may occur, and we instruct them to avoid exercise for 1–2 days to help minimize this bruising and swelling. We also offer pulse dye laser to help expedite the resolution of the bruise. Follow-up visits are done at 2–4 weeks post procedure for photographs and potential "top off" filler to attain complete correction. Additional future visits will be scheduled depending on the longevity of the filler.

Best Techniques and Performance

The only upper face area that is FDA-approved for injection is the midface, including the anterior cheek, the lateral zygoma, and the submalar hollows. Aging of the midface is characterized by volume loss of the lower eyelid and cheek complex. The lower eyelid region is often referred to as the tear trough or nasojugal fold. This area is contiguous with the upper cheek; therefore correction of both cosmetic units is necessary for harmony of the upper face. Injection practices vary depending on the injector, the filler, and the area to be corrected. It is helpful to have a 3D mental picture of what you are trying to accomplish with reinflation. Experienced injectors will choose high G' fillers using a vertical supra-periosteal depot technique (VSDT) (Fig. 38.3) or the tower technique (TT) (Fig. 38.4) along the lateral zygoma to achieve maximum projection. Treatment of the anterior cheek is best accomplished with a cannula to help prevent intravascular injection. Below the infraorbital rim, the infraorbital artery and nerve exit 8–9 mm beneath the infraorbital rim between the pupil and the medial aspect of the iris. The same high G' product is used to give lift to the anterior cheek. A

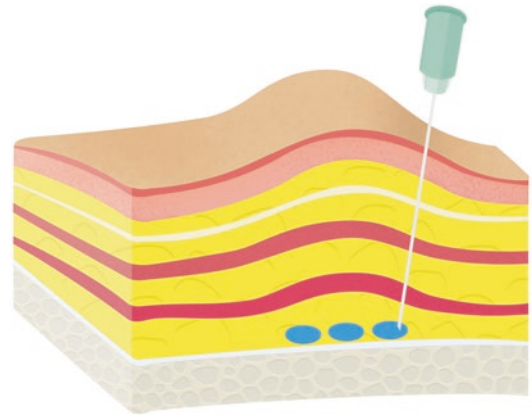

Fig. 38.3 Vertical supra-periosteal depot technique

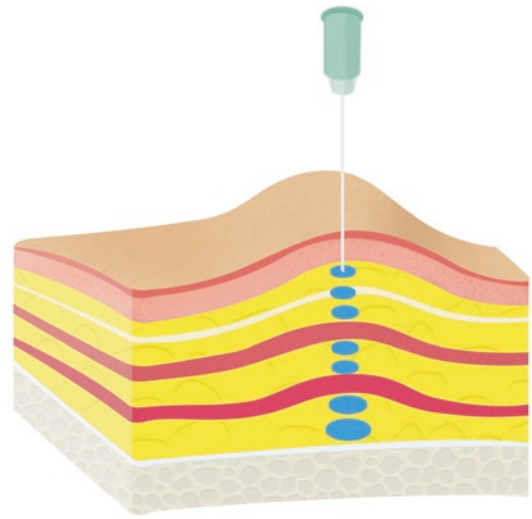

Fig. 38.4 Tower technique

pre-periosteal approach is the preferred depth, and resistance may be felt as the cannula pops through the zygomatic-cutaneous ligament. After the ligament is partially released, a layer of filler is injected beneath the muscle on the periosteum. The final cheek unit to be injected is the submalar hollow. This area is best injected with a lower G' product or reconstitution of the same product with saline to achieve enhanced spread. A longer needle or cannula using a fanning technique subcutaneously can help avoid contouring irregularities. According to the global aesthetic consensus group, no single injection technique, needle vs cannula, ensures complete safety. However, panelists recommended blunt cannulas in areas at higher risk for vascular complication [58]. (CR,PS) Injection of volumizers in the midface has changed the paradigm of facial injections. Replacing lost volume in the cheek area has led to improvement in the lower eyelid region and the nasolabial folds.

Tear trough depression or nasojugal folds are often improved with cheek injection; however, additional augmentation with soft tissue fillers may be necessary to eradicate the unwanted shadows. With the aging process, expansion of the anterior orbital aperture occurs along with atrophy of the orbitomalar ligament and periorbital fat atrophy, hypertrophy, and herniation [61]. Injections are usually done in the pre-periosteal plane along the orbitomalar ligament. A low G' filler that is not hydrophilic is the recommended product of choice. Hylacross technology (Allergan, Santa Barbara, CA) is to be avoided as it has a tendency to produce edema [58]. Injections are done with the patient in a neutral gaze. Upward gaze will produce prolapse of the fat pads and distort the area to be injected. Needles or cannulas can be used when injecting; the lower lid skin can be retracted to reveal 3–5 vertically running veins that should be avoided. Placement horizontally on the pre-periosteal plane can be done either antegrade or retrograde. Others prefer to inject from a point beneath the infraorbital rim fanning the product in a vertical fashion [62].

The brow or ROOF, retro-orbicularis oculi fat, can be re-inflated if it is atrophic. This will result in a beautiful full brow contour and anterior projection in appropriate patients. Care must be taken to inject conservatively to prevent the appearance of a heavy brow. The orbital branch of the superficial temporal artery courses through or above the brow to anastomose with the supraorbital artery. Cannulas may be preferred in this area to avoid the artery [62].

The superior sulcus becomes hollow as fat atrophies in the superior orbit in some patients. "A-frame deformity" refers to atrophy that occurs under the superior-orbital (SO) notch. Aliquots of 0.1–0.2 cc of hyaluronic acid filler placed with a cannula directly under the SO notch is considered an advanced technique [63].

Temples are often injected to produce a youthful facial frame. Temporal volume loss creates a skeletonized shadowing. Poly-L-lactic acid (PLLA) Sculptra® (Galderma Laboratories) and longer lasting HA fillers such as Juvederm® Voluma (Allergan, Irvine, CA) and Restylane® Lyft (Galderma Laboratories, Fort Worth, TX) are often used off-label to treat this area. There are a number of techniques described for filling this area; however, the most important point for safe injection is to inject in a supra-periosteal plane deep to the temporalis muscle. The frontal branch of the superficial temporal artery anastomoses with the supraorbital artery in a subdermal plane. The middle temporal vein (MTV) runs above the temporalis muscle therefore injections must be deep to the temporalis muscle to minimize a potential intravascular injection which could result in blindness [64]. Jung et al. investigated the course and diameter of the middle temporal vein by dissecting 18 cadaver hemifaces [65]. Based on this study, they concluded that the safest area for filler injection in the temporal fossa is one finger width above the zygomatic arch. Additionally the MTV was located superficially in the subcutaneous space; this provides additional rational for supra-periosteal injection [65]. Swift's technique of "1 up 1 over" refers to identifying the temporal fusion line and the lateral supraorbital rim and treating at the intersection 1 cm lateral to the temporal fusion line and 1 cm superior to the supraorbital rim [68]. Palpate to make sure the injection is not

occurring over the arterial pulse. The needle is then inserted perpendicular to the skin penetrating to the periosteum. Aspiration is recommended [58] although the lack of visible blood in the syringe does not rule out an intravascular placement because thin vessels can collapse upon retraction [66]. Typical volume of filler needed will depend on the muscle and fat wasting. Blunt cannulas can be used if a subcutaneous approach is performed; however, irregularities of the skin surface may be more likely with this approach [67]. An additional benefit of re-volumizing the temple is lateral eyebrow elevation.

The forehead is an often under-recognized area for filler injections. Volume loss in the glabella and forehead combined with brow and eyelid ptosis produce a fatigued appearance. Often these patients chronically elevate their frontalis muscle to enhance their visual field, and this produces deep horizontal forehead lines. A youthful female forehead is slightly convex, 12 degrees off vertical [68]. This may be achieved by re-volumizing the supra-brow concavity with a highly cohesive low G' filler that spreads along the periosteum in the subgaleal plane below the level of the frontalis muscle [69]. Volumizing the glide plane in the glabella and medial forehead can lift the medial brow. This "support" along the periosteum allows the frontalis to relax, leading to softening of the horizontal forehead lines. Pertinent anatomy in this area includes the supratrochlear and supraorbital arteries. To identify the location of these vessels, have the patient look straight ahead and mark the medial aspect of the iris. The supraorbital vessel comes out of the skull as a notch in 80% and a hole in 20% and is within 1 mm of the medial aspect of the iris and is deep. The supratrochlear vessel is 8–12 mm medial to the supraorbital vessel. It is easily identified by asking the patient to frown as it is found directly under the glabellar creases. If filler is necessary to efface deep glabellar lines, then it is important to inject in the dermis and not in the subdermal space to avoid intravascular injection. The supratrochlear and supraorbital arteries become subcutaneous 15–20 mm above the superior orbital rim. Filling in this location should be performed deep on the bone and can be done either with a needle or a cannula.

Earlobe rejuvenation with filler is another under recognized anatomic region. As women age, they often find it difficult to wear earrings due to earlobe atrophy. The earlobe typically comprises 20% of the length of the ear and the average length of the lobe is 18 mm [67]. The "deflated" lobe can be significantly improved with injectables. This is one of the easier areas to inject as it often only requires 0.2–0.5 cc of HA injected in the subdermal plane while stretching the skin.

Injection technique will vary according to the filler preparation used, area to be injected, and the experience of the injector. The six most commonly used techniques include vertical supraperiosteal depot, the tower technique, serial puncture, linear threading, fanning, and cross-hatching (Figs. 38.3, 38.4, 38.5, 38.6, 38.7, and 38.8). The glabella, fine lines, and nasolabial folds lend themselves to the serial puncture or linear threading technique. Serial puncture is performed by making multiple injections sequentially along the wrinkle or crease. Linear threading involves inserting the full length of the needle into the skin, and the filler is injected in a linear fashion as the needle is withdrawn (retrograde) or while the needle is being advanced (antegrade), forming a channel of products. The vermillion

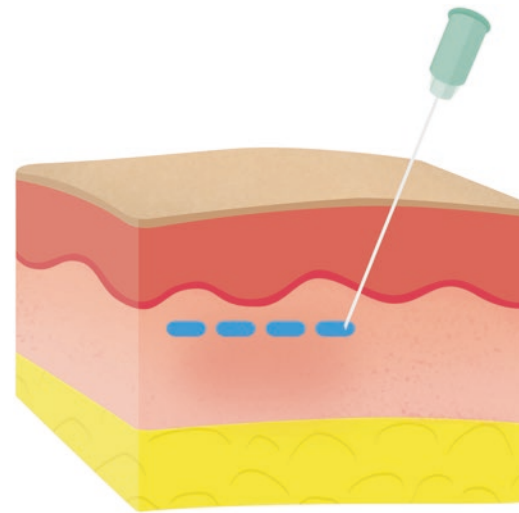

Fig. 38.5 Serial puncture

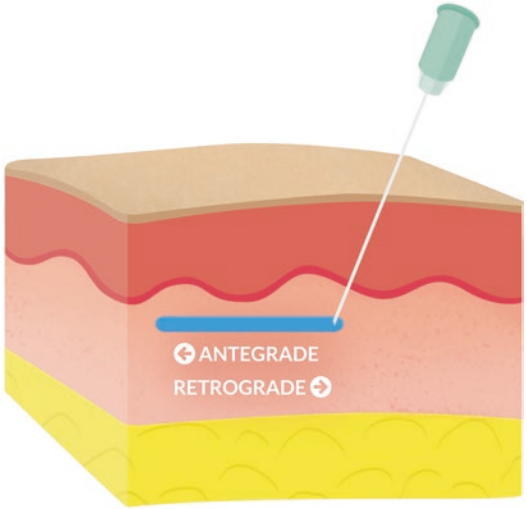

Fig. 38.6 Linear threading

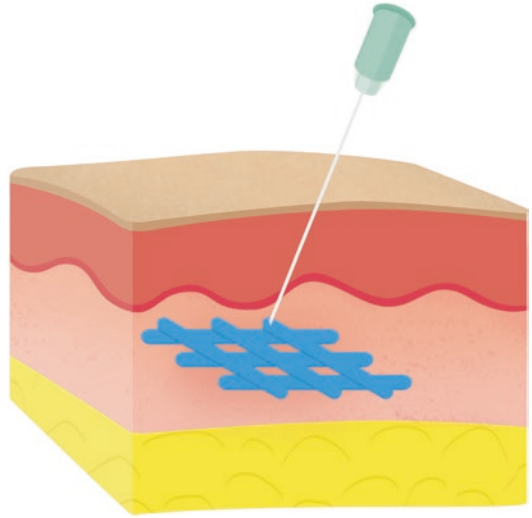

Fig. 38.8 Cross-hatching

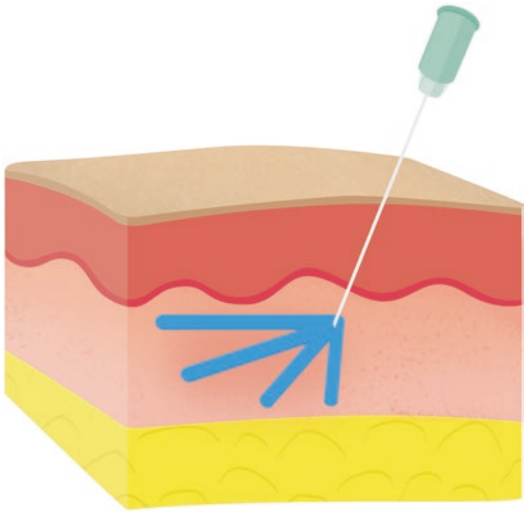

Fig. 38.7 Fanning

border of the lip responds excellently to antegrade injection. For larger areas like the cheek, cross-hatching or fanning can be very effective. Cross-hatching entails making a series of linear threads evenly spaced in a progressive grid and then smoothed together. Fanning is performed by inserting the needle in a similar fashion to linear threading but before it is withdrawn it is advanced in a different direction (clockwise or counterclockwise). This allows the injector to fill a peripheral area from the same injection site.

Vertical supra-periosteal depot (VSDT) involves a perpendicular injection down to the periosteum and placement of the filler on the bone to provide lift and support to the area. Because of the presence of the underlying bony support, very little filler is required for significant correction. The malar eminence is an excellent choice for this form of injection. The tower technique described by Gerhard Sattler is typically used in similar locations but involves the release of the product as the needle is being withdrawn in multiple columns to support the overlying skin [70]. Glogau and Kane found in a randomized, prospective, blinded, controlled study of 283 patients that injection techniques can contribute to the occurrence of adverse events [71]. Techniques that increased adverse events included dissection of the subepidermal plane (i.e., fanlike pattern), increased speed of injection, and high-volume injections [71].

Safety

Soft tissue filler demand continues to increase due to its high safety profile and high rate of physician and patient satisfaction. However, adverse events (AEs) do occur, and as the number of procedures and injectors increases, there

is likely to be an increased incidence of filler complications. Injectors must know how to recognize and manage impending complications. The vast majority of AEs are fairly commonplace and not severe. These tend to be related to the injection itself or the injector's technique and include swelling, erythema, bruising, and lumps or bumps due to too much filler or too superficial placement. Suboptimal product choice or product placement can also result in suboptimal results. Rohrich et al. propose that complications should be categorized as early (less than 14 days), late (14 days–1 year), and delayed (greater than 1 year), and these time points correlate with the underlying etiology [72]. Early complications would include acute inflammation, infection, or ischemic events. Late and delayed may overlap and refer to granuloma formation and biofilm [73].

The true incidence of complications is difficult to ascertain since most available data is based on small case series (Evidence level 4) [54]. Current statistics on fillers and associated complications can be obtained from the FDA (US Food and Drug Administration), manufacturer database, national societies, and from the Physicians Coalition for Injectable Safety. A few other studies deserve mention. A retrospective medical record review from 2007 to 2011, including 1,047 HA patients, 811 PLLA patients, and 231 CaHA patients, revealed 14 complications (Evidence level 2b) [74]. Another retrospective data review over 68 months, with 4,702 treatments with 11,460 ml of Juvederm® Voluma (Allergan, Pringy, France) showed a 0.5% incidence of delayed nodules. The median time from injection was 4 months; the median time to resolution from onset was 6 weeks [75]. One other retrospective review of vascular occlusion cited an incidence of 3 in 1000 to 3 in 10,000 depending on what product was used [76]. Finally, there is a multicenter prospective cohort study of procedures performed using lasers, energy devices, and injectables, among eight geographically different institutional and private practices with 23 dermatologists and a sample size of 20,399 cosmetic procedures. The aggregate AE rate for injectable fillers was 0.52% and mainly attributable to nodules and purpura.(Evidence level 1a) [77].

An excellent comprehensive recent review of soft tissue filler complications can be found in Facial Plastic Surgery journal [73]. The following information will synthesize some of the most important features of both common and uncommon but potentially serious complications. Bruising is a common side effect of soft tissue fillers. It can be minimized by discontinuing anticoagulant medications and vitamin and herbal supplements 7–10 days in advance of injections. Bruising can be minimized by using blunt-tipped cannulas, small gauge needles, slow injection, small aliquots of product, limited number of puncture sites, and injecting using the depot technique at the pre-periosteal level when appropriate. Swelling in the immediate post-procedural period is common and will vary with the agent used and the location of filler placement. The lips and periorbital area are the most common sites of swelling. Pronounced transient swelling of the lips may occur within hours after lip augmentation (Fig. 38.9). This swelling is generally a type 1 hypersensitivity reaction (IgE-mediated immune response that subsides fairly rapidly with antihistamine and oral steroids). Overcorrection and too superficial placement of fillers (Tyndall effect) (Fig. 38.10) are injector-related AEs. Nodules are categorized as non-inflammatory and can be treated with

Fig. 38.9 Immediate hypersensitivity reaction to hyaluronic acid lip filler

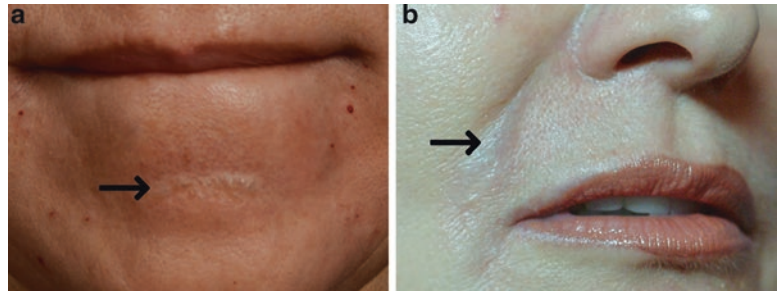

Fig. 38.10 **a** and **b** Tyndall effect

hyaluronidase. Rarely, inflammatory nodules can occur with acute infection, which is due to skin contamination and inadequate preparation of skin. These infections are often secondary to *Staphylococcus aureus* and respond to first-generation cephalosporins. Late onset (>2 weeks) may be due to less common bacteria such as atypical mycobacteria. A third type of inflammatory nodule is a biofilm. These are complex collections of bacteria that secrete a protective adhesive matrix that adheres to the surface of the filler and give rise to a low-grade chronic infection and is often resistant to antibiotics. Distinguishing inflammation due to a bacterial biofilm from a low-grade hypersensitivity reaction is difficult. The incidence of biofilms as a result of filler is not known. The treatment is removal of the material, and in the case of HA, hyaluronidase is used to dissolve the product. In addition, a recent global consensus on prevention and management of AEs with HA recommended empiric therapy with clarithromycin 500 mg daily plus moxifloxacin 400 mg bid for 10 days, ciprofloxacin 500–750 mg bid for 2–4 weeks, or minocycline 100 mg daily for 6 months [58]. The terminology of delayed hypersensitivity reactions to injectable fillers is confusing. The clinical appearance of a hypersensitivity reaction (Fig. 38.11) can mimic a biofilm and appear as firm, tender, red papules, nodules, or plaques that are culture negative. They appear after a latent period often several months after the injection. The mechanism is unknown, and one can speculate idiosyncratic reaction that may be triggered by an unrelated event. Lack of uniform morphology, low case numbers, difference in temporal onset, and deficiency of confirmatory scientific evidence such as skin test or circulating antibodies make it difficult to diagnose [78]. Treatment of HA filler hypersensitivity includes hyaluronidase, IL, or PO corticosteroids and IL 5-fluorouracil and low-dose triamcinolone.

Fig. 38.11 Delayed hypersensitivity reaction to high-concentration hyaluronic acid midface filler

Ischemia/Necrosis

Intravascular injection of fillers can lead to devastating side effects, such as tissue necrosis and rarely vision loss. One recent retrospective review cited an incidence of 3 in 1000 for calcium hydroxyapatite to 3 in 10,000 for hyaluronic acid products [54, 76]. Vascular occlusion occurs in areas which are supplied by only a single artery such as the glabella. In the facial area, injections in the nasolabial fold area can cannulate the angular artery, producing ischemia

and possible necrosis to the skin that it supplies. Vascular infarction can resemble a herpetic outbreak, and these should not be confused. Precautions include aspiration before injection, slow injections, minimal pressure on the plunger, small quantities of filler, and in-depth knowledge of underlying anatomy. Cannulas are advocated by some; however, a recent article by Yeh L, Fabi S and Welsh K et al. describes intra-arterial injection with a blunt-tip cannula [79]. An algorithm from the consensus guidelines for the treatment of intravascular injections includes immediate cessation of the injection, hyaluronidase, warm compresses, and massage. Liberal doses of hyaluronidase (200–300 U) should be injected immediately if signs and symptoms are present. Those signs would include livedo reticularis-like appearance (Fig. 38.12), well demarcated erythema, pain, and blanching. Patients should be reassessed every 24 hours and hyaluronidase should be repeated for a minimum of 2 days. Other strategies (without proven efficacy) include topical nitroglycerin (1%) paste, systemic steroids, aspirin, low molecular weight heparin, and hyperbaric oxygen. Measures to improve retinal perfusion include immediate ophthalmologic consultation, ocular massage, timolol eye drops, hyperbaric oxygen, diuretics, corticosteroids, anticoagulation, and needle decompression of the anterior chamber [80].

Alternative Procedures and Modifications

Successful rejuvenation of the upper face requires a combination of minimally invasive modalities to fill hollows, resurface rhytides, improve dyschromia, and smooth mimetic muscles. Unfortunately, there are few studies discussing combination therapy for rejuvenation of the upper face. Most of the studies are case reports; small pilot studies; retrospective, single center studies; and literature reviews combined with clinical experience [81–84]. Commonly performed complementary procedures with upper and mid face fillers include botulinum toxin, laser, intense pulsed light (IPL), microfocused ultrasound (MFUS), and microneedle fractional radiofrequency. There is little data discussing treatment order when doing combination therapy. Clinical studies have shown that hyaluronic acid filler in the nasolabial folds is unaffected by non-ablative laser, monopolar radiofrequency, and IPL treatments [82]. A porcine model revealed that HA-based fillers are unaffected by non-ablative and superficial ablative treatments, but more aggressive deeper laser treatments can produce some filler interactions [85]. Based on the above information, it is possible to administer facial filler before non-ablative laser, light, and MFUS treatments. The author's (SEC) main concern when performing complementary treatments is to avoid injectables on the same day as a device that may produce swelling. Botulinum toxin (BoNT) should be done at a separate session as a procedure that typically produces swelling such as non-ablative fractionated laser because of the concern that the BoNT could migrate down the supraorbital and supratrochlear nerve sheath and into the orbital tissues to cause ptosis or diplopia [86].

Conclusion

Facial aging is a multifactorial process proven to result from changes in the skin, adipose tissue, and bone. Injectable fillers are effective in correcting these changes of the upper face and stimulating new collagen formation. Evidence exists

for treatment of the forehead, temples, infraorbital hollows, periorbital rhytides, glabella, earlobes, and cheeks. Results have been shown to last from 6 to 24 months depending on the specific filler and amount used. Understanding a patient's goals, preoperative examination, discussion of expectations, and clinical photographs are important for patient satisfaction. There are numerous injection techniques that vary among injectors and areas being injected. High-level evidence is not present for any specific injection technique; choice of technique may be based on individual comfort and safety. Temporary fillers used in the upper face have a very good safety profile. The vast majority of adverse events are mild and include swelling, bruising, and lumps or bumps. The incidence of severe complications is more difficult to determine. These complications include type 1 hypersensitivity reaction, Tyndall effect, biofilm, and intravascular injection (leading to tissue necrosis and/or blindness). Injection technique and location can be altered to minimize the risk of these complications. The growing use of injectable fillers to correct facial aging has led to an increased development of new fillers, FDA-approved indications, and reports of non-FDA-approved indications. The evidence for these new fillers and areas for use must be critically examined to best implement them in clinical practice.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Temporary injectable fillers: evidence for FDA-approved and non-FDA-approved indications

Product (Manufacturer)	FDA-approved indications	Evidence level (FDA-approved indications)	Non-FDA-approved indications	Evidence level (Non- FDA-approved indications)	Duration
Restylane-L® (Galderma Laboratories, LP)	Mid-to-deep dermal implantation for the correction of moderate to severe facial wrinkles and folds, such as nasolabial folds	1b/A	Temples Glabella Infraorbital hollows	4/B 1b/B 4/B	6 months
	Submucosal implantation for lip augmentation	1b/B			
Restylane® Lyft (Galderma Laboratories, LP)	Implantation into the deep dermis to superficial subcutis for the correction of moderate to severe facial folds and wrinkles, such as nasolabial folds	1b/A	Temples Mandible Chin	4/B	6 months
	Subcutaneous to supra-periosteal implantation for cheek augmentation and correction of age-related midface contour deficiencies	1b/A		4/B	
Restylane® Silk (Galderma Laboratories, LP)	Submucosal implantation for lip augmentation and dermal implantation for correction of perioral rhytides	1b/A	Forehead Periorbital rhytides Glabella Infraorbital hollow	4/B 4/B 4/B 4/B	6 months
Restylane® Refyne (Galderma Laboratories, LP)	Injection into the mid-to-deep dermis for correction of moderate to severe facial wrinkles and folds, such as nasolabial folds	1b/B	Lips Periorbital hollows	5/D 5/D	6–12 months

(continued)

Product (Manufacturer)	FDA-approved indications	Evidence level (FDA-approved indications)	Non-FDA-approved indications	Evidence level (Non- FDA-approved indications)	Duration
Restylane® Defyne (Galderma Laboratories, LP)	Injection into the mid-to-deep dermis for correction of moderate to severe, deep facial wrinkles and folds, such as nasolabial folds	1b/B	Cheeks	5/D	6–12 month
Juvederm® Ultra XC (Allergan, Inc)	Injection into the mid-to-deep dermis for correction of moderate to severe facial wrinkles and folds, such as nasolabial folds	1b/A	Hands Submalar	5/D 5/D	6–12 months
	Injection into the lips and perioral area for lip augmentation	1b/B			
Juvederm® Ultra Plus XC (Allergan, Inc)	Injection into the mid-to-deep dermis for correction of moderate to severe facial wrinkles and folds, such as nasolabial folds	1b/A	Temples Cheeks	5/D 5/D	6–12 months
Juvederm® Voluma (Allergan, Inc)	Deep (subcutaneous and/or supra-periosteal) injection for cheek augmentation to correct age-related volume deficit in the midface	1b/A	Forehead Temple Mandible Chin	5/D 5/D 5/D 5/D	24 months
Juvederm® Volbella (Allergan, Inc)	Injection into the lips for lip augmentation and for correction of perioral rhytides	1b/B	Periocular rhytides Infraorbital hollows	5/D 5/D	12 months
Belotero Balance® (Merz Aesthetics)	Injection into the mid-to-deep dermis for correction of moderate-to-severe facial wrinkles and folds, such as nasolabial folds	1b/B	Infraorbital hollows Perioral rhytides Glabella Forehead Periocular rhytides Neck-horizontal rhytides	4/C 4/C 4/C	6 month
Sculptra® (Merz Aesthetics)	Indicated for use in people with healthy immune systems as a single regimen for the correction of shallow to deep nasolabial fold contour deficiencies and other facial wrinkles in which deep dermal grid pattern (crosshatch) injection technique is appropriate	1b/A	Acne scarring Cheeks Temples Marionette lines Chest Arms Buttocks Knees	4/C 4/C 4/C 4/C	12–24 months
Radiesse® and Radiesse® (+) (Merz Aesthetics)	Subdermal implantation for the correction of moderate to severe facial wrinkles and folds, such as nasolabial folds	1b/A	Cheeks Mandible Chin Nose	3/B	12 months
	Hand augmentation to correct volume loss in the dorsum of the hands	1b/A

Self-Assessment Questions

1. All of the following contribute to aging of the upper face EXCEPT:
   (a) Migration of facial fat pads
   (b) A decrease in types I and III collagen
   (c) Fat redistribution
   (d) Thickening of the frontal bone
   (e) Soft tissue loss along the orbitomalar ligament
2. What rheologic property of fillers is a measurement of gel stiffness and its ability to resist deformation?
   (a) Cohesivity
   (b) Viscosity (η)
   (c) Elastic (storage) modulus (G')
   (d) Concentration
   (e) Cross-linking
3. Which supplement(s) should patients avoid 1 week prior to filler injection to help diminish the risk of bruising?
   (a) Garlic
   (b) Vitamin B3 (nicotinamide)
   (c) Ginseng
   (d) a and b
   (e) a and c
4. Where is the safest injection point for filling of the temple?
   (a) Two finger widths above the zygomatic arch in a supra-periosteal plane deep to the temporalis muscle.
   (b) One finger width above the zygomatic arch in a supra-periosteal plane deep to the temporalis muscle.
   (c) One finger width above the zygomatic arch in the superficial fat.
   (d) Two finger widths above the zygomatic arch in the superficial fat.
   (e) Two finger widths above the zygomatic arch in a periosteal plane above the temporalis muscle.
5. What is an example of a late to delayed complication from filler injection?
   (a) Bruising
   (b) Biofilm
   (c) Inflammation
   (d) Infection
   (e) Ischemia

Correct Answers

1. d: Bony resorption, not thickening, of the frontal bone contributes to brow ptosis and lateral orbital hooding. Facial aging is a multi-factorial process and includes changes in the skin, adipose tissue, and facial bones. These include a decrease in types I and III collagen, volume loss and redistribution of fat in facial fat pads, downward migration of individual fat compartments, weakening of fibrous membranes, and resorption of the frontal bone, orbital rim, and maxilla.
2. c: G prime (G') is the elastic (storage) modulus, which is a measurement of gel stiffness and its ability to resist deformation. The higher the G', the less the filler deforms under pressure which is useful for areas where a "lift" is desired. Cohesivity relates to the cross-linking of the filler molecules and the gel's ability to resist vertical compression to maintain the shape of the gel. Viscosity (η) measures the filler's ability to resist shearing forces, those that occur both during and after filling. Concentration represents the concentration of hyaluronic acid in hyaluronic acid fillers. This does not directly influence gel stiffness. Cross-linking is the process by which individual chains of hyaluronic acid are bound together in the filler and can influence the duration of the filler.
3. e: a and c. Supplements that patients should avoid 1 week prior to filler injection include garlic, ginger, ginseng, gingko biloba, kava, celery root, fish oils, St John's Wort, vitamin E (1000–2000 IU /day), and glucosamine/chondroitin. These can all increase the risk of bruising, and patients should also avoid these medications for 4–5 days post procedure if bruising is visible within 48 hours post procedure.
4. b: The frontal branch of the superficial temporal artery anastomoses with the supraorbital artery in the temporal region in a subdermal plane. In this area, the middle temporal vein (MTV) also runs above the temporalis muscle. To avoid intravascular injection into these vessels, filler injections must be in a supra-periosteal plane deep to the temporalis muscle and one finger width above the zygomatic arch.
5. b: Biofilms are a late to delayed complication of filler injection (>2 weeks). They are complex collections of bacteria that secrete a protective adhesive matrix that adheres to the surface of the filler and give rise to a low-grade chronic infection and are often resistant to antibiotics. The treatment is removal of the material and in the case of HA, hyaluronidase is used to dissolve the product. In addition, empiric therapy with clarithromycin 500 mg daily plus moxifloxacin 400 mg bid for 10 days, ciprofloxacin 500–750 mg bid for 2–4 weeks, or minocycline 100 mg daily for 6 months has been recommended.

Soft Tissue Augmentation (Temporary Injectable Fillers) of the Lower Face and Neck (Lips, Perioral, Nose, Neck)

Amelia K. Hausauer and Derek H. Jones

Abstract

Soft tissue augmentation with injectable fillers is one of the most popular aesthetic procedures performed in the USA (US; V/B) (Ahn CS, Davis SA, Dabade TS, Williford PM, Feldman SR. Dermatol Surg 39(9):1351–9, 2013; Tierney EP, Hanke CW. Dermatol Surg 35(9):1324–33, 2009). The goal of these treatments is to either restore age- or disease-related volume loss or enhance and contour existing features, and the lower face is frequently an area of concern. In the aging face, bony remodeling, weakened retaining ligaments, and descent of atrophic fat pads contribute to the development of wrinkles and folds around the mouth, at the jawline, and at the chin. The nasolabial folds deepen; the lips thin; and the oral commissures turn down, delving into marionette lines. Bony resorption also makes the jawline less defined with a receding chin (Richard MJ, Morris C, Deen BF, Gray L, Woodward JA. Ophthal Plast Reconstr Surg 25(5):382–6, 2009; Rohrich RJ, Pessa JE. Plast Reconstr Surg 119(7):2219–27, 2007; Rohrich RJ, Pessa JE, Ristow B. Plast Reconstr Surg 121(6):2107–12, 2008; Shaw RB Jr, Katzel EB, Koltz PF, et al. Plast Reconstr Surg 127(1):374–83, 2011; Mendelson BC, Jacobson SR. Clin Plast Surg 35(3):395–404; 2008). Soft tissue augmentation seeks to soften these changes, particularly as part of a multimodal management plan with neuromodulators, resurfacing devices, and topical therapies (Carruthers J, Carruthers A. Dermatol Surg 42(Suppl 2):S89–93, 2016). On the flip side, younger patients also seek lower face enhancement, usually to correct genetically determined deficits such as nasal contour irregularities, to alter their face shapes, or to augment their features such as lips. This chapter evaluates the most commonly used injectable fillers in the USA to better understand the evidence-based literature supporting their safety and efficacy at the lower face, including the nasolabial folds, lips and perioral region, jawline and chin, nose, and neck and décolletage.

Introduction

Soft tissue augmentation with injectable fillers is one of the most popular aesthetic procedures performed in the USA (US; V/B) [1, 2]. The goal of these treatments is to either restore age- or disease-related volume loss or enhance and contour existing features, and the lower face is frequently an area of concern. In the aging face, bony remodeling, weakened retaining ligaments, and descent of atrophic fat pads contribute to the development of wrinkles and folds around the mouth, at the jawline, and at the chin. The nasolabial folds deepen; the lips thin; and the oral commissures turn down, delving into marionette lines. Bony resorption also makes the jawline less defined with a receding chin [3–7]. Soft tissue augmentation seeks to soften these changes, particularly as part of a multimodal management plan with neuromodulators, resurfacing devices, and topical therapies [8]. On the flip side, younger patients also seek lower face enhancement, usually to correct genetically determined deficits such as nasal contour irregularities, to alter their face shapes, or to augment their features such as lips. This chapter evaluates the most commonly used injectable fillers in the USA to better understand the evidence-based literature supporting their safety and efficacy at the lower face, including the nasolabial folds, lips and perioral region, jawline and chin, nose, and neck and décolletage.

Nasolabial Folds

Nearly all currently Food and Drug Administration (FDA)-approved soft tissue fillers first sought an indication for the correction of nasolabial folds, so there is a robust body of literature supporting their use in this anatomic area.

Photonumerical Scales

Photonumeric scales are metrics designed to ensure standardized, reliable, and reproducible grading of severity and response to treatment. Each is unique and proprietary. Some of these scales were developed and validated in the context of clinical trials, as required by the FDA, while others were devised independently or preemptively and have yet to be attached to a specific study. The Wrinkle Severity Rating Scale (WSRS) was the first novel tool presented to the FDA for assessment of primary efficacy in the Restylane® pivotal trial in 2003 (see below). Its validation involved five clinicians evaluating 30 photographs of the lower face over two separate sessions. They ranked the right and left nasolabial folds independently according to a five-point scale. Inter- and intrarater agreement was excellent (weighted kappa, 0.77 and 0.75 for the left and 0.81 and 0.78 for the right, respectively), results suggesting the WSRS is a reliable tool for analyzing nasolabial wrinkles (1a) [9].

Since that time, other photonumeric scales have been published or used in conjunction with other dermal fillers such as the Lemperle Rating Scale with Radiesse® or the six-point Wrinkle Assessment Scores (WAS) scale with Sculptra Aesthetic® (1a) [10–14].

Hyaluronic Acid

Hyaluronic acid (HA) is an endogenous glycosaminoglycan, naturally comprising a large portion of the dermis in all mammals and tissue types. Its anionic structure avidly binds water to produce a gel that hydrates, lubricates, and volumizes [15, 16]. Differences in HA concentration and manufacturing techniques contribute to each product's unique qualities, but on the whole, this class of fillers has become the most popular, completely supplanting collagen injectables, because of HA's increased longevity, good safety profile without the need for prior skin testing to rule out hypersensitivity, as well as reversibility with the enzyme hyaluronidase that degrades bonds within the HA chains to allow for quick metabolism. Treatment of the nasolabial folds was the first on-label indication for nearly all HA-based fillers, and each product has been evaluated independently rather than as a single class of agents. The pivotal trials critical in securing

FDA approval for Restylane®, Restylane Lyft®/Perlane®, Juvederm®, and Belotero Balance® were all of similar design—6-month, split-face, blinded, randomized, controlled, multicenter phase III trials comparing the new HA agent in question to Zyplast® bovine collagen, which is no longer available in the USA and, hence, will be discussed only in comparison to the more commonly used products.

Restylane® was the first to gain FDA approval in 2003 based on the results from a randomized, controlled, multicenter trial of 138 participants with moderate or severe nasolabial fold creases treated with Restylane® versus Zyplast®. Efficacy results from this double-blinded, split-face design suggested that HA required smaller volumes to correct deficits and that at 6 months, the investigator-based WSRS and Global Aesthetic Improvement Scale (GAIS) were superior for HA in 56.9% and 62.0% compared to in 9.5% and 8.0% of bovine collagen-treated subjects, respectively. Moreover, only 29% of Restylane®-augmented sites returned to baseline compared to 67% of those receiving Zyplast®. HA also had a better long-term safety profile, with 26.8% of participants experiencing adverse reactions versus 39.1% status post Zyplast®. Interestingly, Restylane® injection did result in more post-procedural swelling (87% for Restylane® vs. 73.9% for Zyplast®)(1b) [11]. Soon thereafter, an extension trial sought to better assess the duration of correction. Seventy-five patients with moderate to severe nasolabial folds received Restylane® at baseline with retreatment at one side after 4.5 months and at the other after 9 months. Both groups showed similar improvement lasting up to 18 months, irrespective of retreatment schedule, results confirming that repeat injection is safe and extends the duration of correction (1b) [17]. Subsequent studies presented to the FDA had a 6-month primary efficacy endpoint; then patients entered a retreatment phase if clinically indicated. Only the initial Restylane® product had two separate trials for this purpose.

Restylane Lyft®, previously named Perlane®, has the same chemical properties as Restylane® except for a larger particle size (20,000 particles/ml compared to 100,000 particles/ml), which makes it more suitable for treating deeper wrinkles and folds. It received FDA approval based on cumulative data from five studies. A split-face, double-blinded, randomized, controlled, multicenter trial among 180 patients comparing Restylane Lyft®/Perlane® to Hylaform®, a lower concentration HA filler no longer marketed in the USA, confirmed that the Restylane® family product also provided a durable correction with 75% of subjects having at least a 1-point improvement on the WSRS compared to 38% of those treated with Hylaform®. Incidence of injection-related complications, such as swelling, erythema, and pain, was also higher (41.3% for Restylane Lyft®/Perlane® vs. 21.3% for Hylaform®). It is thought that the increased viscosity of the product allowed for more durable correction and better lifting capacity but required larger gauge needles for injection, which produced more minor side effects (1b) [18]. A larger randomized, controlled study enrolled 283 subjects who received Restylane® at one nasolabial fold and Perlane® at the contralateral with a primary efficacy endpoint of change in WSRS from baseline at 12 weeks and secondary endpoints at 2, 6, and 24 weeks. At 12 and 24 weeks, both groups showed improvement, and there was no statistically significant difference between improvement seen with Perlane® versus Restylane® (at least 1-point improvement in WSRS, 12 weeks, 87% with Perlane® and 77% with Restylane®; 24 weeks, 63% with Perlane® and 74% with Restylane®)(1a) [19]. Consequently, Perlane® is considered non-inferior to Restylane®. Since this time, Restylane® Refyne and Defyne have also been FDA approved based on clinical data showing non-inferiority to a commercially available HA(1b) [20–23].

In 2006, Juvederm® Ultra and Ultra Plus entered the market. These products contain higher concentrations of more crosslinked HA than Restylane®. To determine safety and efficacy, the pivotal split-face, double-blinded, randomized, controlled, multicenter trial enrolled 439 participants with moderate to severe nasolabial creases who received either Juvederm® 30,

Ultra, or Ultra Plus at one side of the face and Zyplast® bovine collagen at the other. Juvederm® provided greater improvement and patient satisfaction at 6 months (1b) [24]. Additional post-study surveillance provided long-term efficacy data with 78% of subjects after Ultra and Ultra Plus, maintaining correction for over 1 year (1b) [25].

Belotero® Balance gained approval for correction of facial wrinkles such as the nasolabial fold in 2011. It is the only available product using cohesive polydensified matrix technology to yield a nonparticulate gel with different density zones that integrate into the dermis without causing bluish discoloration from the Tyndall effect [26]. Like the other HAs, Belotero® outperformed bovine collagen in a split-face, blinded, randomized, controlled, multicenter trial of 118 subjects. WSRS, GAIS, and visual analog scale were determined at baseline, 2, 4, 8, 12, and 24 weeks, with changes in WSRS at 12 weeks as the primary outcome measure. Overall, there was a significantly greater change in nasolabial fold grade after Belotero® compared to collagen at 6 months, and this result held true using the other metrics at other follow-up time points. Of the 107 participants who completed satisfaction questionnaires, 85 or 79.4% preferred the HA ($p < 0.001$; mean improvement rating 74.7% vs. 66%). Adverse events were common regardless of product (116 out of 118), but the majority were mild or moderate, resulting from injection technique rather than the actual product (1b) [26]. After 6 months, 95 of the subjects opted to participate in an open-label extension study. They received repeat injection and were assessed similarly at 32, 48, 72, and 98 weeks. As with the original trial, touch-ups were allowed to achieve optimal effect. Both sides of the face showed improvement at all time points, but it was greater after Belotero® than collagen fold. Mean GAIS ranged from improved (grade 2) to much improved (grade 3), and 80% of participants held their correction without repeat treatment for at least one interval of 48 weeks. Despite the high rate of injection-related side effects in the primary phase III trial, only one was reported in the extension. Moreover, a subset analysis of pre- and posttreatment serum antibodies confirmed Belotero's® low immunogenicity, which eliminates the need for skin hypersensitivity testing, routine before bovine collagen augmentation but not necessary for *any* of the HA products, since they are derived from tissue and species nonspecific matrix substance (1b) [27].

In March 2017, the FDA approved Juvederm® Vollure XC for the treatment of moderate to severe facial wrinkles and folds. It is the first product manufactured using Vycross™ intended for this indication and in clinical trials and had a duration of up to 18 months compared to the 12 seen with other available HA products (1b) [28].

With the exception of Belotero®, all HA fillers are now premixed with lidocaine. A prospective, split-faced European study of 60 patients injected with Juvederm® Ultra Plus 0.3% lidocaine versus Juvederm® Ultra only and a second of 126 patients injected with Juvederm® Ultra Plus 0.3% lidocaine versus Restylane® documented significantly less pain experienced by those receiving the HA plus anesthetic without change in filler efficacy (1b) [29]. Subsequently, in 2010, the FDA approved Juvederm® Ultra and Ultra Plus XC and Restylane-L and Restylane Lyft®-L, all of which contain premixed lidocaine.

Calcium Hydroxylapatite

Calcium hydroxylapatite (CaHA), Radiesse®, gained FDA approval for treatment of moderate to severe facial folds and wrinkles such as the nasolabial folds in 2006. Prospective randomized controlled trials have compared Radiesse® to collagen and hyaluronic acid fillers. In the pivotal, split-face, blinded, randomized, controlled study, 117 patients received Radiesse® to one randomly assigned nasolabial fold and human collagen to the other. Up to three injection sessions occurred every 2 weeks until achieving optimal correction. Blinded evaluators rated the aesthetic outcomes seen with Radiesse® on photographic imaging as superior to those seen with collagen at 6 months, and correction required

half the volume (mean 1.2 ml for Radiesse® vs. 3.4 ml for collagen) [14].

When compared to nonanimal stabilized HA (Restylane®), CaHA appeared to provide a more durable response; 79% of Radiesse® and 43% of HA-injected sites maintained acceptable nasolabial fold fill among 60 patients using the WSRS and GAIS at 12 months (1b) [30, 31]. However, these results differ from those seen in the follow-up phase III trial designed to assess longevity of effectiveness after Restylane® where 97% of subjects maintained at least a 1-point improvement in WSRS compared to baseline and 57% improved by 2 points or more at 18 months (1b) [17]. Each study included touch-up injections, so this practice cannot explain the divergent findings. Currently, manufactures of both Radiesse® and Restylane® claim that their products may persist for a year or more depending on anatomic location and patient characteristics.

In addition to randomized controlled trials, there are several notable cohort studies and case series that provide insight into the safety, efficacy, and longevity of CaHA. This filler contains 25–45 micron spheres of calcium hydroxylapatite, the major constituent found in the bone, suspended in an aqueous gel carrier. A pilot study of three patients injected with 0.1 ml CaHA at the postauricular area and bilateral nasolabial folds sought to better understand how the body reacts and processes these microspheres. At 1 and 3 months, 3 mm punch biopsies were obtained for histopathology and electron microscopy. The investigators saw no evidence of inflammatory cell reaction, fibrosis, ossification, and/or granuloma formation. Furthermore, a collagen matrix formed early around the implant and persisted for at least 6 months postinjection, results suggesting that CaHA appears to remain in the body for long periods of time without significant adverse events (4) [32].

The persistence and safety of CaHA were analyzed further over 4 years in a large study of 1000 subjects. Patients received filler most commonly at the nasolabial creases but also at marionette lines and other facial areas. More than 80% reported persistent correction at 12 months, and the rate of complications was low. The most frequent adverse events included: redness, swelling, itching, and bruising. A total of 1.7% of patients developed nodules after CaHA injection into cutaneous facial folds (4) [33].

Because of its similarity to bone and teeth matrix, there was initial concern that injection of CaHA would obscure the interpretation of radiographic images. A year-long prospective study of 58 subjects treated at the nasolabial folds or for human immunodeficiency virus (HIV)-associated lipoatrophy helped better characterize these effects. The CaHA implant was visible on both x-ray imaging and CT scans but did not appear to interfere with interpretation. CT scanning was more sensitive and specific with better filler characterization (4) [34].

Poly-L-lactic Acid

Originally approved for the treatment of HIV-related lipoatrophy, poly-L-lactic acid (PLLA) filler, marketed under the name Sculptra Aesthetic®, gained expanded FDA clearance in 2009 to treat nasolabial fold contour deficiencies in immunocompetent patients. In the phase III trial, Narins et al. described improvement in Wrinkles Assessment Scores (WAS) at 13 months from baseline for 116 participants treated with PLLA and 117 treated with collagen at the nasolabial folds during up to four sessions over 9 weeks. There was also an extended follow-up period of 25 months for the PLLA group only to assess longer-term duration of efficacy. Patients corrected with PLLA showed significantly better outcomes at months 3 through 13 compared to collagen, and these effects persisted for up to 25 months without additional treatments. Moreover, despite similar efficacy at 3 weeks post-injection, the difference was striking by 13–25 months with overall improvement above 85% for PLLA but only 6% for collagen. The percentage of subjects who developed nonvisible and visible papules and/or nodules was higher for Sculptra® than for control, and they were often delayed in onset and persistent, resolving either spontaneously over time or with intralesional

TAC injection (1b) [13]. Secondary reports from this same trial found that over 80% of patients continued to rate their PLLA treatment highly after 25 months; however, satisfaction declined 84% between week 3 and month 3 among collagen-treated subjects (1b) [35, 36].

Lips and Perioral Lines

Photonumeric Grading Scales

There are several unique, patented schemas intended to grade different qualities of the lips and perioral region. Some but not all were devised for pivotal trials presented to the FDA. In 2012, Medicis Aesthetics published their 5-point Medicis Lip Fullness Scales (MLFS) for upper and lower lips, which were used when obtaining approval of Restylane® for lip augmentation. During the two-part validation process, five dermatologists and plastic surgeons assessed 85 images at two separate sittings (photograph-to-photograph comparison), then three of these evaluators graded 39 live subjects followed by a repeat photographic rating of the same subjects 14 days later (live-to-photograph comparison). This two-phase approach made the scale suitable for photographic as well as live evaluation (1a) [37].

The Allergan Lip Fullness Scale is a more recent photonumeric tool used in the pivotal trial of Juvederm® Ultra XC for lip augmentation. It was initially a 4-point scale but was revised at the request of the FDA to a 5-point scale, encompassing a wider spectrum of facial features including grades for *marked* and *very marked* lip fullness as seen among African-Americans. Eight clinicians rating 55 live subjects validated the first iteration; then 21 aesthetic dermatologists and plastic surgeons graded three-dimensional images from 144 subjects at 2 different time points more than 2 weeks apart. Some of these images included participants before and after lip augmentation to determine clinically meaningful differences (1a) [38].

Melomental grooves, also known as marionette lines, and perioral rhytides are other deficits for which there are multiple photonumeric scales, some of which have yet to be attached to the phase III study. Other validated, proprietary scales include: the Marionette Lines Grading Scale; the Merz Lower Face Scales; and three Allergan scales—the Perioral Lines at Rest (POL), Oral Commissures (OCS), and Perioral Lines at Maximum contraction (POLM) Severity Scales (1a) [39–41].

Hyaluronic Acid

Currently, HA-derived fillers are the most common products used for lip augmentation, with Restylane® being the first to gain FDA approval in 2011. One hundred eighty patients participated in a blinded, randomized, controlled, multicenter trial comparing injection of up to 1.5 ml per lip of Restylane® or no treatment, since there were no previously licensed injectable for this anatomic location at that time. The upper and lower lips were rated independently at 8 weeks according to the MLFS. Overall, Restylane® augmentation resulted in more lip fullness than did the control (93% and 29%, respectively, for combined upper and lower lips, $p < 0.001$) with 97% of subjects at 8 weeks and 74% at 24 weeks, four reporting improved global aesthetic appearance (vs. 0% in the no-treatment group throughout; $p < 0.001$). Mild to moderate swelling (58%), bruising (44%), and pain (22%) were common side effects of the treatment (1b) [42]. Following a near-identical protocol, small-particle HA with 0.3% lidocaine, sold as Restylane-L®, was also found to be superior to no treatment for lip augmentation and perioral rhytides at 8 weeks among 199 subjects (1b) [43]. A small open-label study out of Sweden recently tested the efficacy and safety of a new HA filler, Restylane Lip Volume®, over 9 months. Eighty-six percent of the subjects and 97% of independent evaluators reported improvement according to the MLFS and GAIS (1b) [44]. Notably, this product is not currently available in the USA.

Juvederm® Ultra XC is indicated for lip augmentation as of 2015. Dayan et al. published results from the single-blinded, randomized,

controlled, multicenter phase III trial of 213 subjects who received lip injections with Juvederm® Ultra XC versus no treatment. 79.1% of those treated and 26.1% of controls had at least a 1-point increase in lip fullness, measured by the Allergan 5-point Lip Fullness Scale. These effects persisted for 12 months in more than half (56.4%). Improvement in marionette lines/oral commissures and perioral rhytides—secondary outcome variables—hovered between 40% and 50% at 3 and 12 months. The authors hypothesized that these percentages may have underestimated the actual degree of correction due to the more restrictive 4-point scales used when rating the perioral areas (validated Allergan Perioral Lines and Oral Commissure Severity Scales) (1b) [45]. Juvederm® Ultra XC outperformed Belotero Balance® in the randomized controlled treatment of perioral lines. At 6 months, a significantly higher proportion of participants had at least a 1-point improvement in the Allergan Perioral Lines Severity Scale after Juvederm® (87%) over Belotero® (72%). The Juvederm® group also experienced less treatment-related pain, likely because that product contains lidocaine, which is not premixed into Belotero Balance® (1b) [46].

Instead, Belotero® may be better suited to filling true fine lines rather than volume deficits, as it can be injected intradermally without producing blue discoloration. A new blinded, randomized, controlled trial of Belotero® for etched-in, fine lines at the forehead, cutaneous lip, melolabial folds, nasolabial folds, and/or radial cheeks found that all areas maintained statistically significant improvements at 26-week follow-up according to the Merz Aesthetic Assessment Scales and Lemperle Facial Wrinkle Scales (>1-point improvement for each site; $p < 0.001$). For the perioral regions only, over two-thirds of subjects reported greater than 50% correction, and all (100%) would repeat the treatment if necessary [47].

Juvederm® Volbella with lidocaine is a more recent dermal filler to gain FDA approval in September 2016 for lip augmentation and correction of perioral fine lines based on data from European and American, prospective, double-blinded, randomized, controlled, multicenter studies. Among 280 participants, Volbella® was non-inferior to Restylane-L® at 3 months according to the Allergan Lip Fullness, Perioral Lines, and Oral Commissures Severity Scales. The blinded investigators preferred Volbella® for correction of perioral and oral commissure rhytides (77.3% vs. 61.3%, $p = 0.0292$; 69.9% vs. 58.7%, $p = 0.0126$, respectively), although subjects did not appreciate significant differences. They were, however, more satisfied with the Volbella®, mainly due to less short-term, acute swelling (severe swelling, 22.1% for Volbella® versus 49.1% for Restylane-L®) (1b) [48, 49]. The US pivotal trial enrolled another 224 patients who were randomized to receive Volbella® ($n = 168$) or Restylane-L® ($n = 56$) into the lips and perioral region in a 3:1 ratio. Volbella® again was non-inferior at 3 months, and the majority of subjects maintained a clinically significant improvement in lip fullness (≥ 1-point change from baseline) at 1 year. Of note, seven participants developed lumps, bumps, or swelling weeks to months after treatment (1b) [50]. Similar delayed inflammatory reactions have been reported with all HA fillers produced by Vycross™ technology, Juvederm Voluma®, and Volbella®, which contain both high- and low-molecular weight particles [51, 52]. The short polysaccharide chains in these smaller molecules form more crosslinks and provide a greater lifting capacity and longevity [53] but may also act as a better immune stimulus in a subset of patients[52].

Calcium Hydroxylapatite

In contrast to the relatively low rate of nodules and papules in the skin, there is a significantly higher incidence when CaHA is used in the lips. One large-scale cohort reported papules after 5.9% of lip injections compared to 1.7% of cutaneous injections. Incidence declined over time, perhaps as the clinicians' experience increased. Based on this data, many experts consider Radiesse® contraindicated at the lips (1b) [33].

Jawline and Chin

None of the currently available soft tissue fillers has FDA approval for augmentation of the jawline and chin. However, there are ongoing studies for these indications.

Photonumeric Scales

Merz and Allergan have both sponsored the development of validated grading systems for the regions of the mandible that could severe in future phase III trials. Developed by a multidisciplinary team of experts, the Merz Aesthetic Scale for Jawline is the first quantitative metric to evaluate changes in facial shape, such as loss of oval (1a) [40]. The Allergan 5-point Chin Retrusion Scale is a photonumeric grading system designed to facilitate objective comparisons of chin projection before and after augmentation. Based on the responses from expert raters evaluating 298 patients during two sessions 3 weeks apart, a 1-point difference in rating reflected clinically significant differences in chin retrusion. The scale does not account for 3-dimensional projection, shape, contour, volume, or texture of the chin (1a) [54].

Hyaluronic Acid

Single and multicenter clinical trials for the safety and efficacy of Juvederm Voluma® at the chin and jaw are underway (1b) [55, 56]; however, existing evidence primarily comes from case series or in the context of full facial volume restoration. A consensus statement published by Matarrosso et al. found that 4% of experts reported chin and jawline as their second most common site of HA injection, whereas another 6% rated this region their least comfortable site for treatment (5) [57].

To ensure better outcomes and higher patient satisfaction, it is important to determine first who is a candidate for surgical versus less invasive chin augmentation. The authors of a retrospective review of 345 cases of microgenia with sagittal deformities proposed a decision-making protocol for optimal management. In their cohort, 135 patients underwent sliding genioplasty with piezoelectric scalpel via intraoral approach, 60 patients silicone implant via external approach, and 150 patients cross-linked HA filler (Juvederm® Voluma) injection. The subjects were followed with the GAIS for up to 3 years post-procedure and patient satisfaction questionnaires at 6 and 12 months. Among the patients in the group who received HA, average postoperative soft tissue pogonium projection was 2.6 mm from the true vertical line—a line through the subnasal point perpendicular to the Frankfurt horizontal plane—compared to 5.6 mm status postsurgery. Two more injection sessions every 8 months helped maintain results over the 3-year study period. Thirteen of the 150 subjects developed less than 2 mm nodules that resolved with massage and/or 0.2-ml hyaluronidase. Based on these outcomes, the investigators concluded that patients should be stratified to either surgical or soft tissue filler augmentation according to age, size of defect (less than or greater than 4 mm), soft tissue thickness, and degree of alveolar bone atrophy. Injectable HA substances may be especially beneficial for those with less than 4 mm deficiency from the true vertical line, mild reduction in soft tissue chin thickness, and little to mild alveolar bone loss. Participants in this Italian study were all Caucasian and majority female, so the results may not be generalizable across ethnicities and gender where ideals of beauty and proportion differ (4) [58].

Other publications focus on the use of HA fillers for chin augmentation in the context of full facial reshaping. A European postmarketing study reported the perceptions of Juvederm Voluma® for restoration of facial volume at the malar cheeks and chin in patients who had previously received Restylane® injections. Twenty-seven of the 84 cases received Juvederm® Voluma to the chin, at an average volume of 0.66 ml per treatment. Nearly all patients (98%) and providers (98%) noticed improvement with 69.1% of injectors and 61% of patients preferring the results seen with Juvederm® Voluma to those with Restylane® ($p < 0.001$) [59]. Hoffmann and

the Juvederm® Voluma Study Investigators Group conducted another prospective, pan-European, postmarketing evaluation including treatment to the chin in 9% of patients. Injections were effective as measured by the Global Aesthetic Improvement Scale and Facial Volume Loss Scale, well tolerated, and simple, with over 90% of patients likely to recommend the treatment or seek it again. Additionally, physicians found the product easy to inject (95.6%) and mold (96%) and would recommend it to colleagues (98%) (4) [60].

Facial remodeling, including chin augmentation, is also popular among those of Asian descent. Bae et al. authored a retrospective review of 320 young, Asian women treated with Juvederm® Voluma, according to what they term the "diamond volumizing technique." Injections at the four points of an imaginary diamond (glabella, malar eminences, chin) help achieve a more anteriorly projected and narrow facial contour. According to this protocol, patients were anesthetized using sensory nerve blocks and received a total of 4–6 ml of Juvederm® Voluma with 0.5–1 ml at the chin from periosteal to subcutaneous layer via a 21 gauge cannula. Nearly 95% of physicians and patients notes very much or much improvement on the GAIS at 4 weeks. Adverse effects were minimal (4) [61].

Calcium Hydroxylapatite

Reconstitution of the prejowl sulcus and jawline with calcium hydroxylapatite is considered off-label in the USA but has received the Conformité Européenne (CE) certification mark in Europe. A consensus document by French experts published in the Journal of Cosmetic Dermatology provides a discussion of guidelines for jaw augmentation according to stages of the Merz Aesthetics Scale. CaHA should be injected in the deep dermis or along the dermal-hypodermal junction in a combination of linear retrograde, fanning, and/or depot techniques originating from six points to address the [1] lower jawline at the mandibular angle and prejowl sulcus; [2] upper jawline at the posterior cheek and cheek bone, as well as [3] the mid-cheek groove. More specifically, for the lower jawline, they recommend linear retrograde or fanning injections originating at the mandibular angle and prejowl sulcus at the level of the dermal-hypodermal junction or deep dermis. Periosteal injections extending from an insertion point at the inferolateral mandible and threading either submandibularly or laterally builds the jaw angle. A depression called the prejowl sulcus appears along the medial jawline anterior to the jowl as the face ages and can be filled in a similar fashion. The degree of sagging dictates the number of insertion points and requisite injection volumes. For patients who are a Merz Stage 1, inject along the lower jawline points totaling 1–2 ml; for Stage 2, inject at the lower and upper jawline totaling 3–6 ml. Those with stage 3 or 4 changes are typically better surgical candidates, but injection of over 4.5 ml CaHA can be helpful as an adjunct or if they cannot or do not want to undergo surgery. The authors noted that pretreating with botulinum neurotoxin 1 week prior minimizes muscle contractions and enhances neocollagenesis and fibroblast ingrowth. Injection at the chin to increase anterior projection can further bolster the jawline and counteract age-related bone absorption (5) [62].

Jansen and Graivier described long-term efficacy and safety data from 609 subjects treated with CaHA at multiple facial areas. Four percent of the procedures involved the chin and jawline (i.e., central dimple, prejowl sulcus defect). For these sites, patients were marked in the upright position and then injected in a retrograde technique in the subdermal-subcutaneous plane using a 27 gauge, 1.25 inch needle. The product was molded around the inferior border of the mandible and chin immediately post-procedure and during follow-up appointments over the subsequent 10–14 days. Importantly, only aggregate results for all facial injections were reported, and they were not stratified by anatomic location. At 6 months, 155 patients completed satisfaction questionnaires with a mean satisfaction score of 3.94 out of 5. Eighty-nine percent would repeat the treatment if necessary. By 12–24 months, ongoing satisfaction had declined to 69% (112 patients completed surveys), with 74%

responding they would repeat injections in the future (4) [63].

The ACELIFT is another proposed algorithm for minimally invasive cervicofacial rejuvenation that utilizes CaHA or HA along the jawline as one component in a multimodal treatment plan. In the case series, ten healthy women aged 50–62 years underwent laser lipolysis of the neck with a 1440 nm nd-YAG laser and helium-neon aiming beam (PrecisionTx™ laser system; Cynosure Inc., Westford MA) followed by fractional carbon dioxide laser resurfacing of the face and neck as well as 6–8 syringes of calcium hydroxylapatite at the midface, jawline, and chin; 40–80 units of botulinum toxin A; and topical regimen. Additional CaHA or HA was laced along the geniomandibular creases, marionette lines, and prejowl sulcus as necessary. All patients improved at least 1-point on the GAIS and Cervicomental Angle Scales at 9 months. Considering these findings, the investigators posited that although facelift is still the treatment of choice for patients with severe cervicofacial aging, the ACELIFT protocol may be an effective and safe alternative among appropriate candidates (4) [64].

Poly-L-lactic Acid

Lorenc published a review of the existing literature and clinical experience using PLLA for facial and extrafacial rejuvenation and volumization. He recommended treating areas overlying bony prominences, including the mandible and prejowl sulcus, with a 5–10 ml sterile water dilution deposited as 0.2–0.3-ml aliquots using a 28 gauge, 5/8 inch needle or cannula. As with other locations, massage should occur for 5 min, five times per day for 5 days, although there are no studies specifically investigating the benefit of this practice in lower facial regions (5) [65]. Vleggaar authored another paper on the European experience using PLLA for addressing mid- and lower-face volume deficits, and one of the three representative cases presented emphasized jawline injections with techniques similar to that outlined by Lorenc (4) [66].

Nose

None of the currently available soft tissue fillers is FDA approved for correction of nasal contour deformities. However, since the 1980s, multiple reports have documented successful nonsurgical rhinoplasty with bovine or human collagen, medical grade silicone, autologous fat or fibroblasts, HA products such as Restylane® and Juvederm® Ultra, and CaHA, with the latter two being the most common and safest (4) [67–79]. While a comprehensive review of all case studies and reports is beyond the scope of this chapter, we appraise some of the largest or most impactful below. There are also two ongoing trials that may be influential: one multicenter, single arm study of Voluma® to enhance the Asian nose [80] and one randomized, controlled study of Perlane® in the nasal dorsum and root [81].

Hyaluronic Acid

HA has been injected on the nose for multiple indications. In 2006, Han et al. described injectable HA at the nasal dorsum among 11 patients. The clinicians combine Restylane® with autologous human fibroblasts in the hopes that this cellular scaffold would stimulate collagen production even after Restylane® resorption. Results persisted at 1 year for over half, but six patients saw a 10–40% resorption in the first 6 months and then stabilized thereafter. Of note, the substantial preparatory time needed to harvest and culture in vitro fibroblasts limits the use of this technique (4) [69].

Subsequent studies have focused on the use of HA only [76]. A retrospective review of 280 cases of nonoperative rhinoplasty with EME HA, which is not available in the USA, evaluated the improvement in nasal tip ptosis among Chinese women, 15 of whom had undergone surgery in the past. Filler was layered in multiple planes (supraperiosteal, suprachondrial, intramuscular, and subcutaneous) at the nasolabial angle, nasal columella, nasal tip, nasal dorsum, nasal root/medial brow junction, and lateral sidewall via a combination of sharp needles and blunt cannulas.

At 1 month, 94.1% of third-party evaluators, 93.2% of treated patients, and 90.5% of plastic surgeons rated the results as excellent or satisfactory on a 4-point scale (excellent, satisfactory, moderate, dissatisfactory). There were no complications over 9 months (4) [82].

Another approach to correcting a dropped nasal tip involves combining HA with botulinum toxin. In a Master Class article, Redaelli reported his experience with 95 patients. Forty-five percent of subjects received preliminary botulinum toxin A to the depressor septi nasi muscles (1.5 units per side at the columella) for muscle hyperactivity, then 100% received 0.6–1.5 ml of Juvederm® Ultra at the procerus to increase the nasofrontal angle; at the tip to increase projection; and as needed, at the nasal spine to widen the nasolabial angle. Photographs taken at baseline, immediately post-injection, and every 3 months showed improvement for at least 6 months (8.8 out of 10 on a composite scale of patient and physician rating) and possibly out to 1–2 years, although the number of patients who followed up was small (eight patients at 2 years with mean 6.6 out of 10 improvement). Six patients required reinjection at 2 months. Complications were mild to moderate with one patient experiencing prolonged erythema that spontaneously resolved by month 1 (4) [83].

Vascular compromise with tissue necrosis and retinopathy are the most feared complications of injectable rhinoplasty. Direct occlusion, arterial compression, dermal and epidermal congestion, or embolization are all proposed mechanisms. A national survey by the Korean Retina Society identified 44 cases of ophthalmic artery occlusion status post filler injections at the glabella, nasolabial folds, and nasal dorsum, in descending order of incidence. Compared to those receiving HA (n = 13), patients injected with autologous fat had a significantly higher rate of severe, diffuse occlusions (86% versus 39%, respectively; p = 0.007); cerebrovascular lesions on MRI (46% versus 8%, p = 0.03); and visual deficits (p = 0.01) with more persistent vision loss at 6 months (100% versus 43%, p = 0.02)(IIIb/B) [84]. Hence, autologous fat is now infrequently used in these regions, and nasal injections are often deep on the perichondrium below the vasculature, although the tissue in this region is often thin such that vessels can lie directly over bone or cartilage.

Calcium Hydroxylapatite

The first prospective study of postsurgical or posttrauma CaHA among 13 patients to correct minor nasal sidewall depressions, deeper supratip breaks, alar asymmetries, and/or dorsal irregularities was published in 2007. Three blinded observers evaluated pre- and post-injection photographs and rated 88% of participants (15 of the 17 treated regions) as improved. Eight of 13 (62%) graded their outcomes as excellent and 2 as good. There was one case of transient dorsal erythema. The authors argued that these findings were similar to those seen with HA filler or autologous fat (4) [85].

A larger, 4-year retrospective analysis of 385 racially/ethnically diverse subjects treated in a single private practice also chronicled efficacy and safety data of CaHA. The procedures included 235 injections onto the radix area, 229 into the tip, 229 into the dorsum, 92 into the sidewall, and 17 into alar creases. Twenty-five percent received treatment to a combination of sites with an average filler volume of 0.3–0.5 ml, depending on the defect(s) size and number. Of the 295 patients for whom there were good follow-up data, the majority had some degree of resorption and required touch-ups within the first year: 44% (136) within 2 months, mainly due to undercorrection; 28% (82) between 2 and 6 months; and 18% (54) between 6 and 12 months. Adverse events were stratified by history of prior operative rhinoplasty. Approximately 80% had never had surgery, and their incidence of complications was substantially lower. Prolonged erythema and swelling for more than 2 weeks were the most common in both groups. Others included telangiectasias, sensitive tips, bruises/hematoma, cellulitis, and skin irregularities. One case of skin necrosis occurred in each group, but only the patient with a history of rhinoplasty had visible scarring (4) [75].

In contrast, some experts argue against the use of CaHA for nasal recontouring, since it is irreversible and the thin nasal skin may be susceptible to more nodularity (V/C) [86]. A head-to-head comparison of 46 patients injected with either CAHA (26 cases) or HA (20 cases) at 88 anatomic sites on the nose over a 3-year period found no significant difference in patient satisfaction between the two products. Nonetheless, all five mild to moderate complications occurred after CaHA: one case of filler migration, two of hematoma, one of nodules persisting for 2 months, and one of nasal tip erythema. There were also two severe reactions status post CaHA, including fascial cellulitis and dislocation of a polyethylene rhinoplasty Medpor implant with consequent nasal tip abscess and skin necrosis. The investigators concluded that HA should be the exclusive agent injected in the nose, given these results (4) [87].

Other Filler Agents

There are reports of other products used for minimally invasive rhinoplasty, but these are injected infrequently or have largely been abandoned altogether. In 1986, Webster et al. published the first series of 347 subjects who had received liquid silicone touch-up after rhinoplasty using small volumes of 0.03–0.08 ml per session in an attempt to limit the risk of inflammatory reactions (4) [68]. There is also a retrospective chart review of 153 patients treated with Artecoll (4) [88], and in 2014, another study compared the results of 378 patients treated with either Restylane®, Artecoll®, or silicone. All achieved substantial improvement post-procedurally, yet these effects dissipated at 1 year in the Restylane® group compared to the others. Those injected with silicone had a higher rate and more severe adverse events (4) [89].

Neck and Chest

Soft tissue fillers can be injected off-label at the neck and décolletage, but none have FDA approval for these indications.

Photonumeric Scales

The Allergan Transverse Neck Lines Scale is another validated, patented rubric based on the presence and depth of the single most severe horizontal wrinkle at the anterior third of the neck. It requires assessing visually effaceable and non-effaceable lines, but does not take into account vertical banding, which can be addressed often with neuromodulators. An expert panel used the scale to rate images from 297 participants over 2 sessions and found that 1-point differences reflect meaningful clinical differences in transverse lines. It is posited that these changes may be more related to decreasing collagen and elastin rather than platysmal muscle contraction so are more amenable to correction with fillers (1a) [90].

Hyaluronic Acid

Belotero® is effective for the treatment of facial fine lines [47] and has been used clinically at the neck, but there is little literature to support this practice.

Calcium Hydroxylapatite

A case study of a 55-year-old Taiwanese woman exemplifies the use of dilute CaHA for horizontal neck lines. She received 1.3 ml Radiesse® mixed with 1.4 ml of 2% lidocaine (1:1 dilution), deposited at the dermal-subdermal junction via serial puncture technique along each transverse wrinkle. Post-procedural bruising and edema resolved in the first week, and the patient had been observed for 16 weeks at the time of publication with sustained improvement and no complications. Chao and colleagues argued that in their experience over 20 cases, this technique was highly effective perhaps due to the neocollagenesis and decreased skin laxity that comes from CaHA, though there was no accompanying histopathologic examination. Importantly, 2 of their 20 cases developed beading along the injection sites from too superficial

placement, which resolved with saline irrigation and massage (4) [91].

Poly-L-lactic Acid

Some experts consider the neck and chest unsuitable for treatment with PLLA, as there is a paucity of adnexa and subcutaneous fat relative to the face so the risk of adverse effects (i.e., nodules) increases [66, 92]. Nevertheless, several case reports demonstrate efficacy using increased reconstitution dilutions ranging from 7 to 24 ml (4) [65].

A retrospective series of 36 patients investigated injection of PLLA at the neck (33 patients) or neck plus chest (3 patients) for flaccidity, atrophy, and wrinkling. The product was diluted with 10 ml sterile water 48–72 h in advance and then 0.1 ml of 2% lidocaine added to each 0.9 ml of suspension. 0.5 ml depots were injected every 1 cm along horizontal rhytides and massaged for 2 min. Subjects were instructed to massage for 5 min, three times daily for 7 days. This protocol required a mean 1.8 treatment sessions per patient with only one necessary among those with mild changes (n = 15) and one to four among those with more severe, visible deficits (mean 2.38 sessions). Injected volumes ranged from 4 to 7 ml per session. At baseline, 15 subjects had palpable but not visible neck deficits reported on questionnaire; another 21 had visible skin changes. Overall, 91.6% (33 out of 36) were pleased with the results, which persisted at 18 months, and would undergo treatment again. 8.3% would not—two because of unsatisfactory results and one because of ecchymoses. Three independent dermatologists also evaluated photographs taken at baseline and 60 days to determine changes over time. In the subset of patients with visible deficits, 81–100% demonstrated improvement ($p < 0.001$). Nearly 100% had some degree of ecchymoses or hematomas that resolved within 2 weeks. One patient developed nodules at the anterior cervical region but admitted to not massaging as instructed, so the bumps were injected with sterile water and vigorously massaged three times daily for 10 days. By the 60th day of the final evaluation, 80% had resolved, a case that highlights the possible importance of massage in thin décolletage skin (4) [93].

Combination Therapy

A consensus report drafted by 15 expert aesthetic dermatologists for a special issue of Dermatologic Surgery outlined combination therapies for the neck to address fat accumulation, skin laxity, structural ptosis, platysmal banding, and necklace lines. They recommended a multitier approach depending on the severity of changes with botulinum toxin A as first-line followed by microfocused ultrasound with visualization (MFU-V) and then microaliquots of low-viscosity HA or CaHA fillers at a 1:1 or 1:2 dilution with saline or lidocaine. The additions of fractionated carbon dioxide lasers or radiofrequency were other considerations. Skin tightening procedures should be performed prior to injectable filler therapy, but botulinum and fillers or MFU-V could be performed at the same appointment (5) [94]. To support these recommendations, a retrospective chart review of 101 patients treated with MFU-V plus incobotulinum toxin A (18%) and Belotero® or Radiesse® (81%) suggested that the combining procedure was as safe as each individually (4) [95].

Conclusion

The growing popularity of soft tissue augmentation has led to many novel applications. And while well-designed clinical trials exist for FDA-approved indications such as the injection of HA, CaHA, or PLLA at the nasolabial folds and of HA at the lips, there is a paucity of rigorously designed studies to support their use in other regions. Medical practitioners must carefully review existing and future literature as it becomes available, as this field is rapidly changing with the introduction of newly approved filler agents and new treatment indications almost annually since the early 2000s.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
Multiple, unique proprietary validated grading scales exist for the nasolabial folds, lips, perioral regions, jawline, chin, and transverse neck rhytides. Some were developed in the context of an FDA pivotal trial, and others have yet to be attached to clinical studies	B
Hyaluronic acid fillers can be used to treat moderate to severe facial wrinkles and folds lasting up to 1 year. Juvederm® Vollure XC is unique because correction may persist for up to 18 months	A
Hyaluronic acid fillers (Restylane®, Juvederm®, Belotero®) provide longer lasting correction of facials wrinkles, such as the nasolabial folds, than bovine collagen (Zyplast®)	A
Hyaluronic acid fillers have a similar or lower risk of adverse events compared to bovine collagen (Zyplast®). There is little risk of hypersensitivity reaction	A
Hyaluronic acid fillers (Juvederm®) with lidocaine are better tolerated than those without local anesthetic	A
Calcium hydroxylapatite filler (Radiesse®) can be used to treat moderate to severe facial wrinkles	A
Calcium hydroxylapatite filler (Radiesse®) provides longer lasting correction at the nasolabial folds than nonanimal stabilized hyaluronic acid filler (Restylane®) and human collagen filler	A
Calcium hydroxylapatite filler (Radiesse®) appears to be safe and does not interfere with interpretation of radiographic studies but does have an increased incidence of nodule formation when injected in the lips	B
Poly-L-lactic acid filler (Sculptra® Aesthetic) can be used to treat moderate to severe facial wrinkles	A
Subcutaneous papules and nodules are the most common adverse events post cosmetic injection of poly-L-lactic acid (Sculptra® Aesthetic)	A
Two hyaluronic acid fillers (Restylane®, Juvederm® Volbella) are FDA approved for augmentation of the lips and perioral region	A
Other hyaluronic acid fillers (Juvederm® Ultra) can also be used off-label in the perioral region	A
Correction of deeper, perioral rhytides with cohesive polydensified matrix filler (Belotero®) is less durable and more painful than with other hyaluronic acid filler (Juvederm®)	A
Nonsurgical, filler chin augmentation may be appropriate for patients with mild deficits. Severe micrognathia, soft tissue atrophy, or alveolar bony loss may be better corrected surgically	B
Postmarketing data suggest that patients and providers prefer Juvederm® Voluma over Restylane® for nonsurgical chin augmentation	B
Experts frequently recommend calcium hydroxylapatite (Radiesse®) for jaw augmentation and mandibular restoration	C
Bovine and human collagen, medical grade silicone, autologous fat or fibroblasts, polymethylmethacrylate (Artecoll®), hyaluronic acid (Restylane® and Juvederm® Ultra), and calcium hydroxylapatite (Radiesse®) fillers have all been used for nonsurgical rhinoplasty, with the latter two being the safest and most common. There are no currently FDA-approved agents available	B
Risk of vascular compromise, tissue necrosis, and retinopathy is more common after injection of autologous fat, compared to hyaluronic acid, at the glabella, nasolabial folds, and nasal dorsum (in descending order of incidence)	B
Calcium hydroxylapatite (Radiesse®) and poly-L-lactic acid (Scupltra® Aesthetic) are the most commonly reported fillers used for rejuvenation of the neck and décolletage	B
Multimodal therapies may be helpful for neck rejuvenation, and botulinum toxin A may be first line followed by hyaluronic acid or calcium hydroxylapatite (Radiesse®) fillers plus other procedures	C

Self-Assessment Questions

1. Hyaluronic acid fillers are FDA approved for treatment of which of the following indications?
   (a) Moderate to severe facial wrinkles such as the nasolabial folds
   (b) Lip augmentation
   (c) Correction of perioral rhytides
   (d) Chin and jawline augmentation
   (e) Nonsurgical rhinoplasty
   (f) Transverse neck lines
   (g) a, b, and c
2. Calcium hydroxylapatite fillers are FDA approved for treatment of which of the following indications?
   (a) Moderate to severe facial wrinkles such as the nasolabial folds
   (b) Lip augmentation
   (c) HIV-associated lipoatrophy
   (d) Chin and jawline augmentation
   (e) Nonsurgical rhinoplasty
   (f) Transverse neck lines
   (g) a and c
3. Data from clinical trials suggests hyaluronic acid fillers at the nasolabial folds last for how long?
   (a) 3 months
   (b) 6 months
   (c) 12 months
   (d) 18 months
   (e) 24 months
   (f) c and d
4. (True or false) Autologous fat is the filler of choice for injection at the glabella and nasal dorsum.
5. (True or false) Multimodal therapy with neuromodulators, hyaluronic acid or calcium hydroxylapatite fillers, microfocused ultrasound with visualization, ablative lasers, and radiofrequency is the best approach to neck rejuvenation.

Correct Answers

1. g: a, b, and c. There are dermal fillers FDA approved and currently available in the USA for the treatment of moderate to severe wrinkles (i.e., nasolabial folds) as well as lip augmentation and perioral rhytides. The other uses listed above are considered off-label. Products approved for the correction of moderate to severe wrinkles: Restylane® and Restylane® Lyft, Refyne, Defyne; Juvederm® Ultra and Ultra Plus; Juvederm® Vollure XC; Belotero® Balance; Sculptra Aesthetic®; Radiesse®; and Bellafill® (formerly Artecoll®/Artefill®). Products for lip augmentation: Restylane®, Restylane® Silk, and Juvederm® Volbella XC. Silk and Volbella are also approved for correction of perioral rhytides
2. g: a and c. Calcium hydroxylapatite is FDA approved, under the brand name Radiesse®, for treatment of moderate to severe facial wrinkles as well as HIV-related lipoatrophy. In 2015, it also received approval to correct dorsal hand volume loss.
3. f: Most HA fillers have been shown to last up to 1 year at the nasolabial folds. However, Juvederm® Vollure XC is unique with data suggesting up to 18 months duration.
4. False. These are high-risk areas, and complication rates (i.e., vascular occlusion and necrosis) are higher with injection of autologous fat compared to hyaluronic acid fillers.
5. True

Soft Tissue Augmentation (Temporary Injectable Fillers) on the Trunk and Extremities (Hands, Feet, Trunk)

Alyx Rosen, Shino Bay Aguilera, Drew Taylor, and Eduardo Weiss

Abstract

In 2015, over 2.4 million patients had treatments with soft tissue fillers, with the largest population between 40 and 54 years of age and ranging in age from teenagers to nonagenarians (ASPS, Plastic Surgery Statistics Report 2015, 2015) (4). This data is also representative of the patient population seeking treatment with temporary fillers of the trunk and extremities where the average age is around 60 years, with females significantly outweighing males. All skin types are represented in this demographic, but skin types II–IV are far more common than V–VI.

is around 60 years, with females significantly outweighing males. All skin types are represented in this demographic, but skin types II–IV are far more common than V–VI.

Soft tissue augmentation is utilized to help counteract the visible signs of aging that result from both intrinsic and extrinsic factors. Intrinsic factors refer to natural thinning of the dermis, bone resorption and osteoporosis, fat atrophy, and loss of elasticity, while extrinsic factors include photodamage, chronic friction, extreme temperatures, and repeated exposure to harsh chemicals especially on the hands. In photoexposed areas, long-term ultraviolet damage amplifies the natural intrinsic factors of aging.

The indications for temporary fillers inherently vary depending on the treatment location. As aesthetic procedures on the face continue to rise in popularity, there is a growing need for appropriate aesthetic interventions of non-facial areas. The application of dermal fillers solely to the face limits the possibilities that dermal fillers offer. On the hands, temporary fillers improve the appearance of pronounced muscles and tendons, prominent bones, large intermetacarpal spaces, and visible reticular veins. They can also improve the overall skin texture and turgor. Similarly, subdermal injection of temporary fillers on the dorsal feet can conceivably treat many of the same features of aging that affect the dorsal hands and improve the overall aesthetics. Chest and décolletage procedures have become increasingly popular as patients with rejuvenated and youthful facial appearances appreciate a drastic inconsistency between the treated facial and untreated non-facial skin. Temporary fillers on the chest are becoming popular treatments to address factors such as skin laxity and atrophy, fine lines, and deeper rhytides. While more traditional surgical approaches and novel, minimally invasive, heat- or ultrasound-based technologies are in much higher demand for treatment of upper arm ptosis, temporary fillers in this area have infrequently been used to reduce skin laxity and rhytides. Aesthetic complaints of the buttocks and thighs are often complex and multiple; however, those best managed with temporary fillers are lipoatrophy or volume loss and platypygia (sad buttock). There can also be a secondary minimal reduction in striae and cellulite appearance. Fillers are now utilized for augmentation while simultaneously improving the skin laxity of the buttocks. Finally, isolated cases have been reported for the use of temporary fillers to revolumize the medial ankles, improve postoperative soft tissue loss after surgery, ameliorate acne scars, or relieve metatarsalgia from high heels. Results from these procedures are based solely on anecdotal cases, and therefore significantly more data is needed to determine their overall benefit.

Calcium hydroxyapatite (CaHA; Radiesse®) was Food and Drug Administration (FDA) approved in 2015 for soft tissue augmentation of the dorsal hands [2] (1b). It was approved previously in 2010 in Canada for the same indication. While no other temporary fillers, including hyaluronic acid (HA) fillers or poly-L-lactic acid (PLLA, New-Fill®/Sculptra®, Dermik Laboratories, Berwyn, PA, USA), are FDA approved for use on the trunk or extremities, they clearly demonstrate benefit in these treatment zones and can improve the signs of aging. Most published literature supports the use of temporary fillers on the dorsal hands and chest with only a few studies, case reports, and expert opinions discussing the success of temporary fillers on the upper arms, buttocks, thighs, dorsal feet, abdomen, and other scar-like deformities. The bulk of this chapter will focus on the former.

Effectiveness

The longevity of temporary fillers on the trunk and extremities is similar to their well-established duration on the face. HA fillers last for approximately 4–6 months with few patients having sustained improvement beyond 8 months. PLLA and CaHA both have the benefit of long-term collagen stimulation. PLLA promotes neocollagenesis by fibroblasts and correction can last up to 2 years [3, 4] (2c; 5). One study demonstrated that PLLA increased dermal thickness by 4–6 mm on the cheeks and nasolabial regions, which may be extrapolated to injections off the face [5] (1b). CaHA microspheres provide aesthetic improvement by both volume enhancement and collagen biostimulation leading to improvement in skin elasticity and firmness. Evidence suggests that

CaHA can have effect from 12 or even up to 24 months [6] (1b). The longevity of PLLA and CaHA along with the collagen-stimulating effects are often advantageous over HA fillers.

Hands: Radiesse® (Merz; CaHA) received FDA approval for correction of hand volume loss in 2015 based on the results of three separate clinical studies funded by Merz [2]. The first clinical trial of Radiesse® for hand augmentation was conducted in Germany in 2008 [7] (1b). Busso et al. evaluated 101 patients with hand volume loss in a multicenter randomized trial. Patients were randomized to treatment with CaHA or delayed treatment (control group) with CaHA to the dorsal hands. After anesthetization with a lidocaine bleb, each hand was injected with CaHA in a bolus in the areolar plane. Total mean volume of CaHA injected was 3.1 ml for both hands. Only one Radiesse® treatment was performed through 12 months. Efficacy was assessed using the Busso Hand Volume Severity Scale and the Global Aesthetic Improvement Scale (GAIS) (Fig. 40.1), which was modified to include additional categories of "Much Worse" and "Very Much Worse." Blinded evaluators using study photographs reported that 66% and 56% of hands showed at least a 1-point improvement on the Busso Hand Volume Severity Scale at 3 and 6 months, respectively. Additionally, 89% and 75% of hands at 3 and 6 months, respectively, were rated as being at least improved on the revised GAIS. Of all patients treated with CaHA, 51% were still improved at 12 months after a single treatment.

In 2012, a study in Canada demonstrated the clinical utility of the Merz Hand Grading Scale (MHGS) (Fig. 40.2). The MHGS is a photonumeric scale that was initially validated for making photographic and later (in 2015) in-person assessments [8, 9] (5; 1b). Thirty patients were enrolled with 20 patients randomized to the CaHA treatment group and 10 patients randomized to an untreated control group. CaHA (1.5 ml; *note modified syringe volume) was mixed with 0.26 ml of 2% lidocaine and injected using small boluses (0.2–0.5 ml) into the dorsal hands bound laterally between the first and fifth metacarpals, proximally by the dorsal wrist crease, and distally by the metacarpophalangeal joints using a 27-gauge needle. The total number of injection points varied, and a maximum of 3.0 ml of CaHA could be injected per hand per treatment session. After injection, the hands were massaged until the desired cosmetic effect was achieved. At 1-month follow-up, all 40 hands in the treatment group had ≥1-point improvement on the MHGS compared to none in the control group, which highly correlated with a rating of "improved" or better on the GAIS. The authors concluded that a ≥1-point improvement on the MHGS was both clinically meaningful and aesthetically pleasing.

The final study performed in the US provided the primary effectiveness and safety experience that ultimately led to FDA approval [2]. In this prospective, randomized, controlled study of 114 patients, 85 were randomized to immediate treatment with CaHA and 29 were randomized to delayed treatment at 3 months. Injections were performed in the same way as the Canadian study described above except that patients were eligible for retreatment at 6 months after initial injection at

Fig. 40.1 5-Point graded global aesthetic improvement scale

Rating	*Description*
Very much improved	Optimal cosmetic result for the implant in this patient
Much improved	Marked improvement in appearance from the initial condition, but not completely optimal for this patient. A touch-up would slightly improve the result
Improved	Obvious improvement in appearance from the initial condition, but a touch-up or retreatment is indicated
No change	The appearance is essentially the same as the original condition
Worse	The appearance is worse than the original condition

Fig. 40.2 Merz Hand grading scale [9]

the discretion of the investigator with 69% of patients receiving retreatment. Live assessments were performed by blinded nonphysicians using the validated MHGS with 75.3% of treated patients demonstrating a ≥1-point improvement from baseline in both hands compared to 3.4% in the control group. At 12 months, 71.7% of patients who received a single injection of CaHA had a ≥1-point improvement on the MHGS. The findings of these three clinical studies supported the effectiveness of CaHA in rejuvenation of the dorsal hands.

Subsequently, several other authors reported similar outcomes of patient satisfaction and duration of effect. CaHA remains the only FDA-approved soft tissue filler for rejuvenation of the dorsal hands. Although differences in dilutions, total volume injected, and total treatment sessions have been reported, no comparative studies have been performed [10, 11] (4; 5).

In addition to CaHA, both PLLA and HA fillers have been utilized for soft tissue augmentation of the dorsal hands. In 2006, Redaelli injected the dorsal hands of 27 patients with PLLA. On average, patients received 4 sessions (range 3–6 sessions) with 1 month between the first 3 injections and up to 3 months between the third and subsequent treatments. PLLA was reconstituted 12 h prior to injection. The author developed a standardized protocol for treatment with 2 ml of a 5-ml dilution (0.5 ml of 3% Carbocain and the rest distilled water) per hand at initial treatment and a 1.5–2 ml of a 6–8-ml dilution (0.5 ml of 3% Carbocain and the rest distilled water) on subsequent treatment sessions. Patients were injected using a 25–27-gauge needle into the subcutaneous tissue overlying tendons in a linear bolus technique. Volumes of 0.05–0.1 ml of PLLA were delivered per injection [12] (4). Patients were evaluated using a Definitive Graduated Score (DGS) from 1 to 10 using photographic results combined with physician and patient satisfaction scores. The time point of evaluation postinjection was typically 3 months post the last treatment, and results ranged from 4 to 9 with an average of 6.55. When they evaluated the scores of all case histories of patients treated, it was a 7.8. The authors did report improvement in the appearance of tortuous veins that were sustained at 15 months postinjection. Redaelli and Forte in 2009 went on to report

the cosmetic results of 568 patients treated with PLLA in their experience. One hundred and one patients received treatment to the dorsal hands using the same 6–8-ml dilution as above. Overall, the DGS for the hands was 6.3, the lowest of all areas treated. The authors attributed the low scores to possibly using too dilute solutions and the number of sessions needed to treat the dorsal hands [13] (4). Other experts have similarly reported on the successful use of PLLA for rejuvenation of the dorsal hands [11, 14] (4).

Several HA fillers have been evaluated for use in rejuvenation of the dorsal hands. HA fillers can be either non-stabilized (native) or stabilized, meaning the native polysaccharide is made more resistant against degradation by dermal hyaluronidases through chemical cross-linking. Williams et al. looked at changes in skin physiology and clinical appearance after injection with non-stabilized versus stabilized HA fillers. Fifteen volunteers were randomly assigned to injections with either stabilized HA (Restylane Vital®, Q-Med) or non-stabilized HA (Teosyal Meso®, Teoxane) to the left and right hands. They received 0.5 ml of filler injected per hand using microdroplet placement in the mid-to-deep dermis at weeks 0, 4, and 8. Efficacy was based on a clinical hand aging score performed by a blinded dermatologist as well as biophysical parameters, including skin surface morphology, elasticity, stratum corneum hydration, and transepidermal water loss. Overall, improvement in the clinical appearance was seen with both HA fillers; however, the difference in clinical improvement at week 12 was significantly greater for the stabilized HA-treated hands. Only the stabilized HA-treated hands showed significant improvement in skin elasticity and surface roughness at week 12 compared to baseline, and there was a significantly higher hydration level and lower transepidermal water loss at week 12 for the stabilized HA-treated hands compared to the non-stabilized treated hands. Overall, efficacy trended towards baseline by week 24 [15] (1b).

Man et al. performed a blinded comparative study of the HA filler, Restylane (Medicis, Scottsdale, AZ) to collagen (Cosmoplast, Allergan Inc., Irvine, CA). Ten female patients were randomized to receive two vials of HA (1.4 cm^2) and two vials of collagen (2.0 cm^2) to different hands. Material was injected into the subcutaneous plane. Evaluation was performed based on pretreatment and 3-month posttreatment photographs assessing for vein clearance on a visual analog scale from 1 (worse than before treatment) to 5 (complete clearance of veins). Mean scores in difference for clearance were 0.95 for HA versus collagen, indicating a better clearance with the HA filler. Patient satisfaction was also evaluated and was rated higher for HA than collagen, although it did not reach statistical significance [16] (1b). Alternatively, Gubanova et al. compared HA with saline for rejuvenation of the hands. In this study, patients received 1.0 ml of HA (Restylane Vital®, Q-Med) in one hand and 1.0 ml of saline (0.9% NaCl) in the other hand. Injections were done using a multipuncture, microinjection technique into the dermal layer. Three treatments were performed 1 month apart. Efficacy was determined using the GAIS and by calculating multiple biochemical properties. When compared against saline, patient's GAIS scores from month 1 to 3 were significantly higher for HA versus saline-treated hand. Statistically significant improvements in hydration and elasticity for the HA versus the saline hand were also seen at month 3. Sixty-one percent of patients injected with HA felt the treatment effect was maintained at 12 months [17] (1b).

Chest: There are few studies looking at the benefits of temporary fillers on the chest and décolletage, and most data exists for the utilization of PLLA in this area. Mazzuco and colleagues performed a prospective study of PLLA for neck and chest rejuvenation [18] (4). Thirty-three patients had PLLA injections to the neck area, and another three patients received injections to the neck and chest. Patients with mild signs of photoaging received an average of one treatment, whereas patients with moderate to severe signs received an average of 2.38 treatments. Variations occurred in the total amount of product injected. Overall, there was improvement in flaccidity, atrophy, and rhytides with 91.6% of patients pleased with their results at evaluation 60 days after the last treatment. Independent data for patients who had both the neck and chest regions injected were not reported.

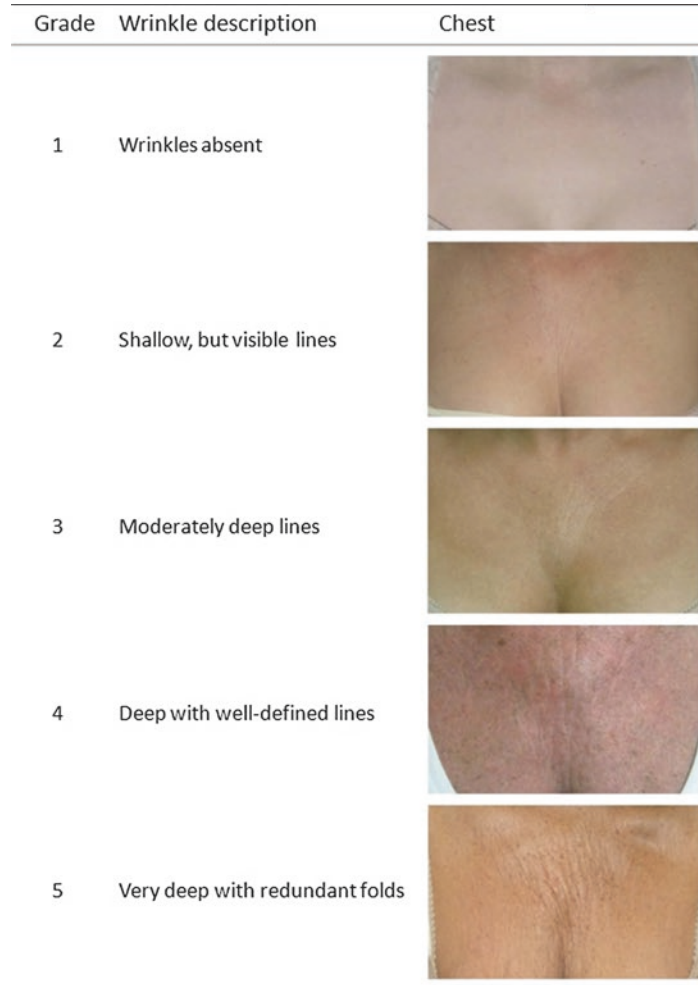

Fig. 40.3 Fabi–Bolton 5-point chest wrinkle scale (F–B scale) [20]

Bolton et al. performed a retrospective study of 28 patients using PLLA for chest rejuvenation [19] (2b). The authors simultaneously created and validated a 5-Point Chest Wrinkle Scale to address photodamage and rhytides on the chest (Fig. 40.3) [20] (1b). Patients with baseline scores of 3 or higher were candidates for the study. The authors primarily used a 16-ml dilution (PLLA; 150 mg: 14-ml saline + 2-ml lidocaine). The average number of treatments was 2.3 (range, 1–7 treatments) with a cumulative average 28.5 ml of PLLA injected (range, 3.75–104 ml). Best improvements were seen in patients who received at least three PLLA treatments with 16 ml per treatment. Eleven of the 28 patients had follow-up photography and were noted to have a 1- to 2-point improvement on the 5-Point Chest Wrinkle Scale. No difference in effectiveness was noted based on the severity of pre-treatment score.

The benefit of the HA filler, Restylane Vital® (Galderma, USA), for aesthetic improvement of the chest was evaluated by Streker et al. in an open, randomized, intra-individually controlled, split-side, single center study [21] (1b). Thirty patients were enrolled and one side of the chest was injected with the HA, using an auto-injector device. Patients received up to 4 ml per treatment session across the face, dorsal hands, and chest at weeks 0, 4, and 8. Total amount injected into the chest area was not specified. Subjects and independent blinded dermatologists used the 5-point graded GAIS [22] (1b). Significant improvement was noted for the chest at 12, 20, and 28, but not at 36 weeks, with greatest

improvement seen between 8 and 20 weeks after initial injection.

Aside from these studies, there are several reports of expert opinion or consensus recommendations regarding the treatment of the chest and décolletage with temporary fillers. In 2016, Fabi et al. published consensus recommendations for combined aesthetic interventions in the neck, décolletage, hands, and other body sites and discussed the roles of HA and CaHA in soft tissue augmentation [23] (5). For early intervention of fine lines and rhytides on the chest, Fabi et al. recommend low-viscosity HA or CaHA to stimulate neocollagenesis and improve skin hydration and elasticity. For patients requiring more aesthetic restoration for significant rhytides, low-viscosity HA or diluted CaHA is recommended in combination with microfocused ultrasound. Combined therapy will be discussed in greater detail in a later section. Chest rejuvenation with HA and PLLA has also been described in several expert opinion reports [13, 24, 25] (5; 5). PLLA injected over 2–4 treatment sessions 4 weeks apart can improve flaccidity, atrophy, and rhytides for up to 2 years. Alternatively, low-viscosity HAs Belotero® (Merz) or Restylane Silk® (Galderma) can be used successfully on the chest and last up to 8 months. Vanaman et al. are also currently investigating the safety, efficacy, and patient satisfaction of CaHA for treatment of chest rhytides. There is no consensus on which patients would benefit from treatment with an HA versus CaHA versus PLLA.

Arms: Historically, treatment of upper arm laxity and fat accumulation required a surgical approach with brachioplasty. However, there are several trials supporting the use of temporary fillers for appropriate patients desiring less invasive treatments. In a small study of 16 women with moderate brachial ptosis (corresponding to stages 1, 2a, and 2b on the Brachial Ptosis Scale) and loose upper arm skin (Fig. 40.4) [26] (4), 1 ml of

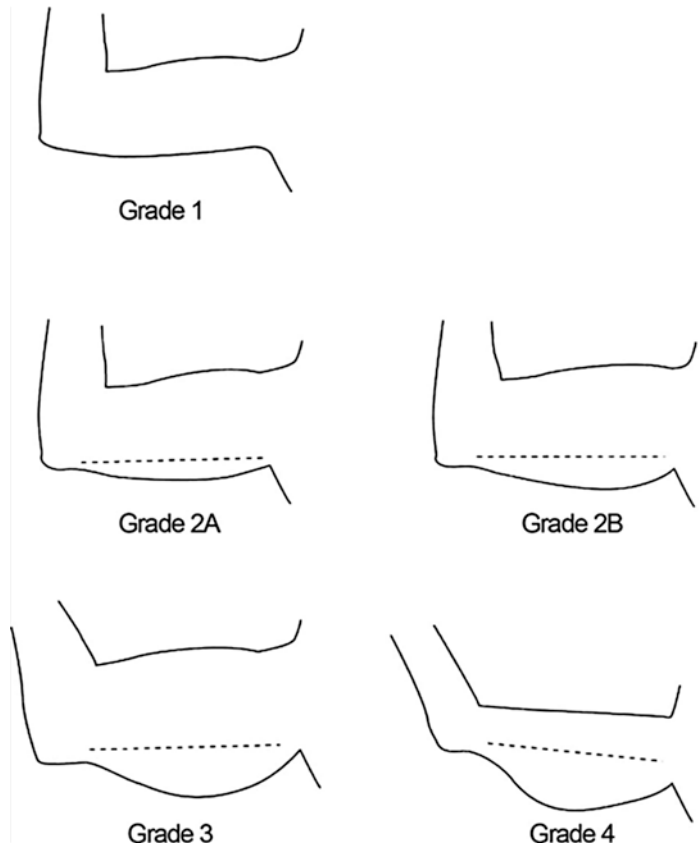

Fig. 40.4 Schematic drawing of the classification of brachial ptosis. The dotted lines denote the brachial sulcus [26]

HA (Restylane Vital®, Q-Med) was injected into the upper arm at 3 intervals 1 month apart. The authors used a capacitance device, an ultrasound Dermascan, and a suction device, Cutometer, to objectively measure stratum corneum hydration, skin thickness, and skin elasticity, respectively. Statistically significant improvement was seen in all parameters [27] (4). Two separate studies evaluated CaHA with lidocaine for rejuvenation of the upper arms. In a prospective study, 30 subjects received 1.5 ml per arm at 2 treatment sessions 1 month apart. Five months after initial injection, statistically significant improvements in skin flaccidity were observed with persistent incremental improvements with time after injection. Overall, 100% of patients were at least satisfied with the results. In this study, the authors also developed an Arm Visual Analog Score (Arm VAS) and noted no distinction of benefit based on severity. Cogorno Wasylkowsi instituted a novel body vectoring technique with CaHA for tightening of the abdomen, thighs, and brachial zone. Overall, 12 brachial zones were injected with 1.5 ml of diluted (0.6-ml 2% lidocaine without epinephrine) CaHA. Cutometer and ultrasound measurements were obtained at baseline and 5 weeks after treatment. Approximately 70% of patients had improvement in flaccidity with a mean reduction of 0.0924 mm, and 60% of patients had improved skin thickness and density of the brachial zone at 5 weeks posttreatment [28, 29] (4; 4).

Buttocks: In the buttock region, temporary fillers may be used alone or in combination with microfocused ultrasound or radiofrequency for augmentation and to improve irregularities in the surface of the skin [23]. They are best utilized in patients desiring mild to moderate correction in buttock projection and volumization who do not want silicone implants or surgical correction. Lorenc uses PLLA in this region in patients with low body mass index and insufficient fat for autologous fat transfer [30] (5). A single published report of two patients demonstrated aesthetic improvement with PLLA for the gluteal region. Although different treatment volumes and number of sessions varied for the two patients, the authors observed decreased flaccidity and improved projection in both patients [18]. Alternatively, Coleman and Pozner highlight combination therapies and sequences of treatments for correction of aesthetic concerns of the outer thigh and buttocks. Temporary fillers, including PLLA or HA fillers, can be used as second- or third-line treatments mainly for volume loss, laxity, and cellulite, in combination with other modalities (Fig. 40.5) [31] (5).

Thighs/knees/ankles/abdomen/others: Similar to the body vectoring technique used on the brachial zone, Cogorno Wasylkowsi injected 17 thigh regions and 7 hemi-abdomens with 3.0 ml and 1.5 ml of diluted (0.6-ml 2% lidocaine without epinephrine) CaHA, respectively. Cutometer and ultrasound measurements 5 weeks after treatment demonstrated a 0.0117 mm and 0.0814 mm reduction in flaccidity from baseline for the thighs and abdomen, respectively. Skin thickness of the thighs improved for 88% of patients, and a similar improvement in skin density was seen on the abdomen. Overall, 100% of subjects reported improved skin thickness in this study [29]. Redaelli and Forte demonstrated promising results for 17 patients injected with PLLA to the upper arm and medial thighs although no specifics of the treatments to these areas were provided [13]. Consensus recommendations for aesthetic improvement of the abdomen include combined treatment of CaHA to reduce skin flaccidity and increase skin density and thickness with microfocused ultrasound to tighten residual loose skin [23]. Individual reports of PLLA injected into the medial ankles, lateral abdominal depression, postoperative scar, axillary folds, pectus excavatum, and inferior breast have all been reported with improvement [13, 30, 32–34] (5; 4; 5).

Preoperative Evaluation

Although patients seeking soft tissue augmentation of the trunk and extremities encompass a wide age range, they are typically healthy and do not require any specific preoperative evaluations prior to treatment (unless considering a semipermanent filler like Bellafill® that would require a prick test prior to injection). Since

	Option 1	Option 2	Option 3

Fig. 40.5 Potential combination therapies and sequences of treatment for common conditions of the outer thigh and buttock [31]

Radiesse® for rejuvenation of the dorsal hands is the only FDA-approved temporary filler for use on the trunk and extremities, patients should be made aware that all other fillers in these areas are being used off-label. A patient's comprehensive medical history, including prior cosmetic treatments and a full list of medications, should also be obtained.

There are no specific criteria regarding temporary cessation of blood thinners for injections on the trunk and extremities. The ASDS Guidelines of Care for Injectable Fillers does recommend that patients without a medical indication for anticoagulants discontinue therapy for about 1 week before the procedure [35] (5). Patients with a medical indication for anticoagulants, however, should not discontinue their therapy prior to treatment with fillers. Additionally, patients may benefit from discontinuation of any foodstuffs, herbal supplements, and over-the-counter medications that may increase their risk of bleeding. Older patients with evidence of actinic purpura, who may or may not be on blood thinners, should be informed of the increased risk of ecchymosis, especially in areas prone to skin thinning, such as the dorsal hands or chest.

There are few absolute contraindications to injectable fillers. A major contraindication is a known allergy or hypersensitivity to the filler material or the lidocaine mixed in the syringe of the filler. Acute or delayed allergic reactions can occur with the HA products and to a lesser extent with PLLA or CaHA. CaHA is contraindicated in patients with severe allergies manifested by a history of anaphylaxis. Patients with ongoing skin infections in the area to be treated or adjacent skin should not be treated in an effort to avoid inoculation with the infecting organism. On the trunk or extremities, certain infections to consider include verruca vulgaris, herpes simplex virus, bacterial infections such as impetigo, and folliculitis. Patients with diabetes, compromised lower

extremity circulation, or any conditions that may predispose to the formation of ulcers should also be advised against temporary fillers to the feet [36] (5). Specifically, patients with bleeding disorders should avoid injections with CaHA.

Questionable contraindications or skin conditions that can be aggravated by the use of temporary fillers include connective tissue diseases, immunosuppression, and immunobullous disorders. The available data, however, is limited. Similarly, injectable fillers should be avoided in patients with active granulomatous disease as the materials can elicit an unwanted granulomatous foreign body response [4, 30].

The chest and décolletage areas demonstrate variable distribution of subcutaneous fat and decreased pilosebaceous structures in comparison with facial skin. This results in slower healing and a higher risk of scarring (secondary to a lack of stem cells in the bulge area of the hair follicle.) Also, it is important to inquire about a personal or family history of keloidal or hypertrophic scarring and educate patients on the theoretical risk with any procedure. While keloid scarring after injury occurs 18 times as often in African American patients as in Caucasian patients, the safety data from post-market studies of soft tissue fillers on the face has not shown an increased risk of keloid development [37] (5). It is unclear if this data can be extrapolated to treatment on the trunk or extremities given the proclivity of patients developing keloids on the trunk and extremities.

Best Techniques and Procedures

Prior to injection with soft tissue fillers, the areas to be treated should be cleansed with alcohol or an appropriate antiseptic. The use of topical anesthetic cream to decrease pain from needle insertion is at the discretion of the provider. When utilized, the cream is applied under occlusion on areas to be treated for 30–45 min. Nerve blocks are typically not necessary when injecting the trunk or extremities. Additionally, temporary fillers are typically diluted with lidocaine to help decrease the discomfort with injections. Lidocaine with or without epinephrine can safely be used when mixing. Although the manufacturer of PLLA recommends using sterile water for reconstitution, some practitioners safely use bacteriostatic saline, which is associated with decreased patient discomfort during injection secondary to the benzyl alcohol component. It is important to keep in mind that HA fillers vary in the degree of crosslinking, gel hardness, gel consistency, viscosity, extrusion force, HA concentration, extent of hydration, and whether they are pre-mixed with lidocaine. Global availability varies among different countries. Similarly, PLLA is supplied as a 367.5 mg or a 150 mg vial of freeze-dried powder of synthetic L-polymer of polylactic acid in the United States and Europe, respectively. The effect of injection of PLLA is dose- and not volume-dependent. CaHA can also be combined with lidocaine to mitigate the pain associated with injection. Mixing the CaHA and the lidocaine lowers the viscosity and the extrusion force found in the original Radiesse® formulation but does not compromise the properties of the CaHA [36]. CaHA with powder lidocaine (Radiesse® (+)) is now commercially available.

Hands: The area to be injected of the dorsal hand includes the space bound laterally by the fifth metacarpal, medially by the second metacarpal (although some use the first metacarpal), proximally by the dorsal wrist crease, and distally by the metacarpophalangeal joints. Regarding CaHA injections of the hand, this section will focus on the techniques used in the studies that led to FDA approval as well as alternative injection techniques that have been described in the literature.

As described above, Merz conducted three clinical studies to investigate the effectiveness and safety of CaHA (Radisse®) in treating volume loss of the hands [2]. In the US study, the 1.5-ml syringe of Radiesse® was mixed with 0.26 ml of 2% lidocaine and injected using small boluses (0.2–0.5 ml) into the dorsal hands. Following injection, the hand was massaged to evenly distribute the material. A maximum of 3 ml of CaHA could be injected per hand per treatment session. No detrimental effect on hand function was found after treatment with

Radiesse®, and there were no new safety issues identified during this 12-month study. In the German study, Busso et al. injected one vial (1.3 ml) of CaHA mixed with 0.1 ml of 2% lidocaine per hand [7]. Material was injected into the subcutaneous areolar plane as 0.5–1.4-ml boluses. The hands were massaged with the patient making a fist to evenly distribute the product.

Since the initial studies, alternative dilutions and injection techniques have been described in the literature. Most authors mix the vials of CaHA with some volume of lidocaine (ranging from 0.015 to 0.5 ml) to decrease pain with injection as well as the viscosity and extrusion force of the filler. Some experts will mix one vial of CaHA (1.5 ml) with 0.3–0.5 ml of 1% lidocaine and 1.0–1.2 ml of bacteriostatic 0.9% saline in a 1:1 dilution. Injections can be performed as small boluses of 0.2–0.5 ml of material over the entire dorsal hand or as larger boluses up to 1.5 ml. A tunneling or fanning technique with a blunt cannula can also be implemented. The thickness of the dorsal hand tissue, including epidermis, dermis, and subcutaneous tissue is 1–2 mm. Skin tenting is therefore often performed to help magnify the areolar fatty plane of injection just deep to the dermis and provide more separation between the needle or cannula and the important vascular or tendinous structures below. Regardless of injection technique, the material should be evenly spread using gentle massage after injection is complete. This is most easily performed using an emollient for ease of massage and with the patient's hand in a first position to allow for more even distribution. Injection technique for CaHA to the dorsal feet is identical to that of the hands [10, 38–40] (5, 5, 5).

Injection techniques for PLLA on the dorsal hands are based mainly on expert experience. Redaelli, in the first published case series of PLLA for rejuvenation of the dorsal hands, used an average dilution of 6 ml (range 5–8 ml) (PLLA; 150 mg). More concentrated dilutions (5 ml dilution) injected in the subcutaneous intermetacarpal tissue with a max volume of 2 ml per hand were given at the first session. Subsequently, less concentrated dilutions (max 2 ml of 6–8 ml dilutions) were used at monthly follow-up visits [12]. Lorenc recommends using a 14-ml reconstitution volume (PLLA; 367.5 mg: 5 ml of sterile water and 9 ml of 1% lidocaine) with 7 ml used per dorsal hand. Injections are performed using a 1-inch, 25-gauge needle or cannula into the loose areolar space. He recommends this high volume of reconstitution because of the close proximity of the dermis to the tendon sheaths, especially with volume loss, and also because of the reduced risk of nodule formation. Only one patient who had five sessions was noted to develop a palpable, nonvisible nodule at 15 months [30]. Sadick summarized treatment techniques from three clinical practices that used dilution volumes of 8 (6-ml sterile water + 2 ml of lidocaine) to10 ml (5-ml sterile water + 5 ml of lidocaine) [11]. Patients received an average of 1.28 vials per treatment and 2.38 treatments between 4 and 8 weeks apart. Injections were performed with a 1.5-inch, 25-gauge needle. Palm et al. described treating 130 patients with PLLA, of which 8 patients received injections in the dorsal hands [14]. Average dilution volume and number of treatments for the hands were 10.25 ml and 2.5, respectively. Only one patient developed a nodule after a single treatment with a 12-ml dilution. The 12-ml dilution will be described in detail since a single PLLA vial can only hold up to 10 ml of solution. The day prior to injection, a single vial of PLLA is reconstituted with 1 ml of 1% lidocaine and 5 ml of bacteriostatic saline or sterile water. The reconstituted product is agitated immediately prior to injection and then 1.5 ml is withdrawn into a 3-ml syringe. Next, another 1.5 ml of bacteriostatic saline is withdrawn into the syringe for a combined total volume of 3 ml. These steps are repeated until a final total of 12 ml is mixed and drawn in the 3-ml syringes [39].

Injection techniques also vary among physicians. Redaelli performed injections with patients in the Trendelenburg position to reduce vein pressure and risk of bleeding [12]. Injections can be performed using a linear threading technique or a retrograde fanning technique, usually depositing up to 0.1 ml per injection. Some experts vary the injection plane and technique depending

on the exact location on the hand. Sadick used a subdermal threading technique more proximally and a depot technique in the mid-hand. The interosseous areas were injected using a fist maneuver and into the muscle belly. Most experts perform a postinjection massage for 5–15 min, and then patients are advised to follow the rule of 5 s; massage for 5 min, five times a day for 5 days [11].

Man et al. injected 1.4 ml of HA (Restylane®, Q-Med) into a single dorsal hand. Injections were performed with the patients also in the Trendelenburg position and with their hand at rest. HA was placed subcutaneously using a threading technique adjacent to the dorsal veins. Gentle massage was performed after injection, and patients kept their hands in a neutral rest position for 2 h. Neither anesthesia nor posttreatment cooling was used [16]. In their expert review, Fabi et al. describe a similar injection technique, although they recommend mixing one vial of HA with 0.2 ml of 1% lidocaine with epinephrine [39]. Williams and Gubanova both used a microdroplet technique with a 30-gauge needle for injection of HA (Restylane Vitale®, Q-Med) on the dorsal hands. Patients received three treatment sessions 1 month apart. Williams injected a total of 0.5 ml of product per hand per session versus Gubanova who injected 1 ml per hand per treatment session. Topical anesthetic applied for 20–45 min in both studies [15, 17]. When injecting the dorsal hands, Rivkin first determines the amount of volume loss using the MHGS prior to treatment. For patients with a score of 2–3, he uses the HA filler Juvederm Voluma® XC (Allergan) and dilutes it 1:1 with 0.8 ml saline and 0.2 ml of 1% lidocaine. He injects using a 30-gauge 0.5–1-inch needle or a 27-gauge cannula. When treating patients with more severe volume loss, or MHGS score of 4, he uses undiluted Juvederm Volume® XC (Allergan) [41] (5).

Finally, one group determined a purely anatomical approach to injectable fillers of the dorsal hands. They dissected 19 fresh cadaveric hands and conducted duplex ultrasounds of 28 healthy hands to generate an anatomically designed injection technique. The technique was then validated on another eight fresh cadavers followed by magnetic resonance imaging (MRI) and dissection and compared with other common injection techniques like the ones described above. Their technique named Scrape Skin Threading Technique used a cannula to scrape the deep side of the dermis for placement of product in the fascial plane using a fanning technique with retrograde injections at two entry points. The authors of this study refrained from skin tenting as they found it lifted the desired fascial plane of injection and the dorsal veins with the skin and therefore increased the risk of vascular trauma with injection. They also performed only gentle massage to smooth out small local defects and avoided broad massaging to redistribute the product. This technique is unique and demonstrates how a thorough understanding of anatomy and incorporation of imaging techniques may help improve the approach to soft tissue augmentation of the dorsal hands or other body sites. The Scrape Skin Threading Technique can be used with any temporary filler for the dorsal hands [40].

Chest: PLLA for chest rejuvenation was most clearly delineated in a retrospective study of 28 cases [19]. The authors primarily used a 16-ml dilution (PLLA; 367.5 mg) with 14 ml of bacteriostatic water and 2 ml of 1% lidocaine with epinephrine 1:100,000, and reconstitution typically occurred overnight. Injections were performed using a 26-gauge 1.5-inch needle or cannula using a retrograde linear threading technique in the reticular dermis and subcutaneous fat layers. The central chest rhytides between the breasts were treated first, and injections followed a centrifugal pattern until all visible rhytides were treated. The boundaries of injection when treating the chest are the suprasternal notch superiorly, mid-clavicular line laterally, and the fourth rib inferiolaterally (Fig. 40.6) [25]. Most patients were treated with 16 ml of PLLA, although the authors did say that treatment volume did vary per patient depending on the severity of rhytides and volume loss. During and immediately after treatment, the chest area was vigorously massaged using a liquid soap to ensure equal dispersion of the microparticles and patients were then directed to follow the rule of 5 s. On average, patients received 2.3 treatments with a total of 28.5 ml of PLLA solution. The best

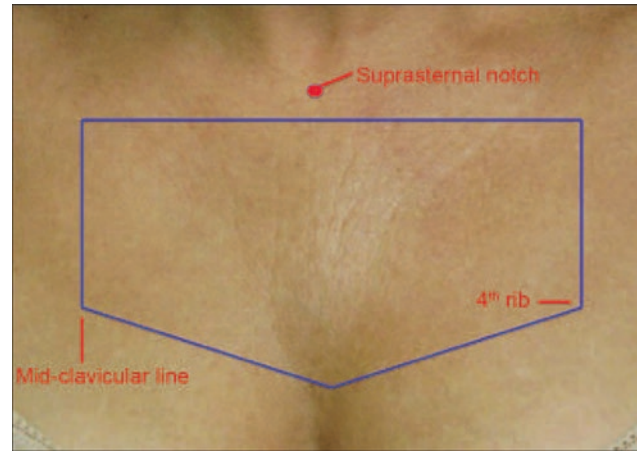

Fig. 40.6 Map of area on the chest most commonly injected with dermal fillers, with landmarks used to create boundaries [25]

improvement was noted in patients who received at least three PLLA treatments with a 16-ml dilution with 16 ml injected per treatment. Using this technique, no nodule formation was noted over the study period.

Most reviews discussing PLLA for chest rhytides also use ~16-ml dilutions with similar injection techniques. Subsequent injections are performed at monthly intervals as needed. Typically, three to four treatments are needed to establish optimal aesthetic improvement [24, 25]. The 16-ml reconstitution technique is similar to the 12-ml dilution technique described above for hand rejuvenation except that 1–2 ml of lidocaine and 6–7 ml of saline are used.

HA fillers have also been successfully used for rejuvenation of the chest. Restylane Vital® (Q-Med) is available in parts of Europe and Asia for enhancement of the neck, chest, and dorsal hands. Alternatively, Belotero Balance (Merz) or Restylane Silk (Galderma) are HA fillers available in the US that have a low viscosity and therefore spread evenly over the chest. In general, low-viscosity HA fillers that spread more easily on the chest are recommended. In a prospective study, Streker et al. used HA filler (Restylane Vital®, Q-Med) and treated half of the chest, one dorsal hand, and one side of the face. The HA material was injected using a pre-filled injector device into the mid-dermal layer using a micropuncture technique. Each injection delivered 10 μL of material. All three areas were simultaneously injected with a cumulative 4 ml at each of the three visits. No specification of volume used for the chest was delineated [21]. Belotero Balance® (Merz) mixed with 0.2–0.5 ml and Restylane Silk® (Galderma) mixed with 0.5 ml of 1% lidocaine without epinephrine can both be injected in the chest using a 30-gauge needle with either a serial micropuncture or retrograde linear threading technique. Belotero Balance® (Merz) is injected into the superficial dermis while Restylane Silk® (Galderma) is placed in the deep dermis. This provides a smoother cosmetic appearance and reduces the risk of Tyndall effect. In total, 2–3 ml of HA product are often required for treatment of chest rhytides [25].

There are no established optimal treatment methods for injection of soft tissue fillers of the upper arms, thighs, abdomen, or buttocks. This section will summarize the methods described in the literature in published studies, case reports, and expert reviews.

Arms: Independently, Amselem and Cogorno Wasylkowski evaluated CaHA to improve the skin flaccidity and aesthetic appearance of the upper arms. The enrolled subjects received treatment with CaHA 1.5 ml mixed with 0.5 ml of lidocaine solution per arm at two sessions 1 month apart. The total volume injected was 4 ml/arm. The areas to be treated were initially marked with the patient standing and arms extended away from the body with subsequent injections performed with the patient lying supine. Each arm was injected over a 150-cm^2 surface area with 50 injection points 1–2 cm

apart using a 27-gauge needle. If patients experienced bruising after the initial treatment, a 25-gauge cannula was used for the second treatment with only one or two injection points. CaHA was injected into the sub-dermis in a retrograde fanning technique. After treatment, the area of the posterior arm was gently massaged to ensure even distribution of the material [28].

Cogorno Wasylkowski similarly treated 12 separate brachial zones with CaHA. Pretreatment assessment was performed using a cutometer and an ultrascan to measure skin density, thickness, and flaccidity. Prior to injection, vector maps were designed with patients in a standing position to determine needle position during administration. For the arm, a fix point was found at the deltoid muscle, then one line was drawn 3 cm into the axillary zone, and a second line was drawn to protrude two-thirds into the arm. Several protruding lines were then drawn to cover the whole internal brachial zone. In this study, 3 ml of CaHA was diluted with 0.6 ml of 2% plain lidocaine and 1.5 ml was injected per arm in a single treatment. Injections were performed with a 27-gauge needle with 0.5 ml of CaHA injected into the deep dermis per each line of the vector map [29].

Distante et al. evaluated the aesthetic appearance of the upper arm after treatment with HA filler (Restylane Vital®, Q-Med). Patients were treated in three sessions 1 month apart. Areas to be injected were also marked with patients standing upright. A total of 1 ml of HA was injected per arm per session in small 0.03 ml aliquots spaced 1.5–2 cm apart over a 160-cm^2 surface area. Material was injected into the mid- to deep dermis using a 30-gauge needle. Follow-up evaluation was performed 3 months after the initial treatment.

Coimbra and Amorim described the use of PLLA for rejuvenation of the medial and anterior region of the arms [42] (5). One vial of PLLA was diluted with 16 ml of distilled water and 4 ml of 2% lidocaine without epinephrine with a total of 5 ml injected per arm via a "parallel stick" technique. Sessions were at intervals of 4 weeks, and the total number of sessions ranged from two to four.

PLLA, CaHA, or HA fillers can be used successfully for treatment of mild to moderate upper arm ptosis. Since each study utilized different methods for pre- and posttreatment assessment, including different arm ptosis scales, it is difficult to determine if one treatment method was superior to the others. Additional studies using consistent arm ptosis grading scales are needed to decide on ideal treatment regimen. Cogorno Waskylkoski's vector maps provide the clearest directions for injection technique and could likely be implemented independent of treatment material.

Buttocks: Mazzuco et al. describe injection of PLLA of two patients desiring nonsurgical correction for flaccidity and volume loss of the gluteal region. One patient received a total of three treatments spaced 1 month apart with two vials of PLLA injected per buttock per session. The second patient received a total of two treatments spaced 1 month apart with three vials of PLLA utilized per session. Each vial of PLLA was reconstituted to a total of 12 ml (PLLA; 367.5 mg) by mixing 10 ml of sterile water 24 h before the treatment procedure with 2 ml of plain lidocaine just before the start of the treatment. PLLA was injected with a 27-gauge 1-inch needle in a retrograde manner at a 60° angle. Aliquots of 0.1 ml were injected 1 cm apart into the superficial layer of the subcutaneous tissue. Patients massaged the area three times daily for 5 min for 1 week and were told to avoid rigorous exercise for 2 weeks [18]. Lorenc also recommends using a 12-ml dilution (PLLA; 367.5 mg) when treating the buttocks with PLLA although he reconstitutes using 5 ml of sterile water and 7 ml of lidocaine. He performs a single treatment with one vial of PLLA per buttock per session injected into the subcutaneous plane with a 25-gauge needle or cannula using a tunneling technique. Patients are re-evaluated at 6 weeks to determine the need for further augmentation [30]. One author (SBA) uses a 16-cc dilution of PLLA for cellulite on the buttocks. The areas of depression (the valleys)

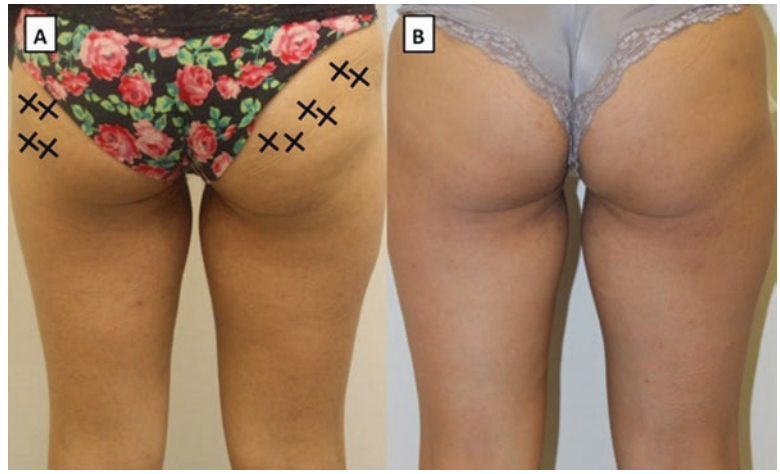

Fig. 40.7 Before (**a**) and after (**b**) one treatment of PLLA injections with 16-cc dilution in the buttocks for cellulite. X indicates point of injection

are marked with the patient standing using indirect light (Fig. 40.7) and then injected with the patient lying prone. Appropriate patient selection for soft tissue augmentation with temporary fillers of the gluteal region is essential, and patients should be educated on realistic expectations. Injections of PLLA in the buttock are typically safe because the subcutaneous tissue is thick and does not contain any main vasculature or nerves and provides an alternative to implants, permanent fillers, or fat transfer.

Abdomen/thighs: CaHA was also injected into the abdomen and thighs using the same body vectoring technique as described above [29]. For the thighs, the point of transition of skin types between the inner and outer thigh was used as an anchor from which two lines were drawn. One line followed the transition of the skin types vertically and the other extended to the middle of the fat on the inner thigh. Protruding lines were drawn from these landmarks. The vector map for the thigh was created with the intention of lifting the fat tissue from the internal side of the leg. The vector map for the abdomen was described for treatment of only one hemi-abdomen with the aim of correcting naval shape. The design can be extrapolated for bilateral injections. The anchor point was located under the ribs. A periumbilical vertical line and a second line at a 45° angle were drawn. Protruding lines were then drawn to cover the entire zone. Three ml and 1.5 ml of CaHA was injected per thigh and per hemi-abdomen in a single treatment. Injections were performed with a 27-gauge needle with 0.5 ml of CaHA injected into the deep dermis per each line of the vector map [29].

For correction of a lateral abdominal depression, one patient had improvement with two treatments 1 month apart with one-half vial of PLLA that was diluted with 8 ml of saline. PLLA was also used successfully with a 6-ml dilution (PLLA; 367.5 mg: 5 ml of sterile saline and 1 ml of 1% lidocaine) to provide volume enhancement to a postoperative scar on the upper arm after wide local excision for melanoma. The area was treated with a total of 6 ml of PLLA into the deep dermis and superficial subcutaneous fat using a 25-gauge needle [33]. One author (SBA) uses a 10-cc dilution of PLLA for skin laxity on the abdomen. The areas of depression (the valleys) are marked using indirect light similar to the markings of cellulite on the buttocks (Fig. 40.8).

Overall, these scant reports have demonstrated successful off-label use of temporary fillers for difficult-to-treat areas including the upper arms, medial thighs, and abdomen. However, additional studies are needed to determine if there is a true consistent cosmetic result. The same is true for the use of collagen-stimulating soft tissue fillers for postsurgical volume loss.

Safety

Adverse reactions to temporary soft tissue fillers can be attributed to the injection technique, the product injected, and patient comorbidities. Some of these reactions are preventable, whereas others are inevitable. Most adverse events are mild and transient.

Overall, the most common temporary adverse events experienced by patients treated with temporary fillers on the trunk and extremities are bruising, edema, and pain. These occur in >90% of all patients and require no treatment. Common duration of swelling for patients with PLLA is about 3 days postinjection due to the sterile water used to dilute the product, which is resorbed within 48–72 h [43] (5). Some patients may however experience bruising or swelling for up to 14 days posttreatment. One expert reported intolerance reactions in 1.2% of patients injected with PLLA who developed slight edema, pruritus, and erythema in the areas injected. This was not specific for sites on the trunk or extremities, but it did prompt early termination of the procedure [13].

The most notable adverse event of temporary fillers is the formation of subcutaneous nodules. While nodule formation is most commonly seen in patients injected with PLLA, it can also occur in patients treated with other fillers. Early formation of papules and nodules results from overcorrection in the injected area, uneven distribution of the product in suspension, or uneven dispersal in the injected areas [32]. In the literature, the incidence of subcutaneous nodules from PLLA varies from 1% to 6%, and even up to 44% [44] (4). They are typically palpable, asymptomatic, and nonvisible. Nodule formation from PLLA is considered a product-related adverse event that can be reduced with proper injection technique and pre- and postinjection care.

There are several well-established techniques by experts to reduce the incidence of nodule formation from PLLA in all areas of injection, particularly the trunk and extremities. The label recommendations for injectable PLLA indicate reconstitution with 3–5 ml of sterile water. Many experts have found that treatment site-specific dilutions result in decreased nodule formations. For the chest, reconstitution volumes of 16 ml or up to 24 ml are recommended. For the hands, buttocks, and medial ankles, 14 ml, 12 ml, and 12 ml have been reported, respectively. Reconstitution volumes for the abdomen and scars are clearly patient dependent and at the discretion of the physician. The label recommendations for PLLA also state that after reconstitution, the vials should sit for at least 2 h to allow for complete hydration; however, reconstitution for at least 12 and up to 72 h may also reduce nodule formation [19, 23, 24, 30]. Additionally, subcutaneous injection of PLLA, avoidance of overcorrection with excessive quantities of injected material per session, spacing of treatments at least 6–8 weeks

apart, and massaging the area posttreatment are all techniques to decrease the incidence of nodule formation. There is little objective data regarding the benefit of posttreatment massage although it is routine practice for patients injected with PLLA to help disperse the microparticles [19]. Patients are massaged during treatment, for several minutes immediately after treatment, and then with the rule of 5 s [32, 45] (4). The higher rates of nodule formation were seen in the earliest studies of PLLA with lower volumes of reconstitution and improper plane of injection. As discussed earlier, various injection techniques, including threading or multiple punctures, can be used for temporary fillers on the trunk and extremities as long as there is even distribution of the product.

The HA filler, Restylane Vital® (Q-Med), is available in Europe in a pre-filled auto-injector that delivers 10 μL of HA gel per micropuncture injection into the mid-dermal layer of the skin. With the precise amount of product placed per injection, this technology is thought to allow for more uniform results. One study performed in Europe utilized the Restylane Vital® auto-injector with no serious adverse events.

A significant proportion of nodules will resolve spontaneously with time, but treatment options for persistent lesions include excision, intralesional steroids, needle fragmentation of the nodule followed by flooding the area with saline, and massage.

Aguilera et al. recommend management of CaHA nodules with an intralesional injection of 5-fluorouracil (5-FU), dexamethasone, and triamcinolone solution [46] (4). The 1.6-ml solution is constituted using 1.0 ml of 5-FU 50 mg/ml, 0.5 ml of dexamethasone 4 mg/ml, and 0.1 ml of triamcinolone 10 mg/ml. Although this specific publication discussed management of a CaHA nodule, the authors acknowledge the solution can be utilized to treat PLLA nodules.

Granulomas are considered by some to be a separate adverse reaction that occurs with temporary fillers months or even years after injection. They are more ill-defined in comparison to the discrete early papules and nodules and are characterized by erythema and edema. The incidence ranges from 0.2% to 2% though the etiology is largely unknown [32]. Histopathologically, there is a dense granulomatous inflammation with multinucleated cells and a foreign body reaction. Steroids (intralesional, intramuscular, or oral) are the mainstay of treatment. Alternative therapies include intralesional 5-fluorouracil alone or in combination with intralesional steroids as well as oral antibiotics. The authors have found success with the tetracycline family of antibiotics in conjunction with intralesional injections of 5-FU/triamcinolone (0.9 ml 5-FU 50 mg/ml and 0.1 ml of triamcinolone 40 mg/ml) repeated at 6–8 week intervals until resolution. No studies of temporary fillers on the trunk or extremities reported granuloma formation.

Injections of fillers into the tendons of the dorsal hands can weaken tendons and cause tendon rupture. Injection into the veins can cause embolization or thrombosis. In one study, 48% of patients reported difficulty performing activities after injection to the dorsal hands. Other rare side effects reported included loss of sensation of the hand. In the pivotal CaHA study, hand function testing conducted regularly throughout the 12-month study showed no negative effect. Similarly, there was no worsening of touch sensation response at 3 months for any subject. Some authors also feel that increased bruising of the hands is associated with higher volumes of injection and therefore recommend injecting a maximum dose of 3 ml of CaHA per hand per treatment. Although necrosis has been described after CaHA injections on the face, no studies reported necrosis of the hands after injection [2, 7, 41].

Postoperative Care and Follow-Up

Patients should be directed to remove all jewelry, especially rings, prior to treatment of the dorsal hands and until all swelling has resolved to avoid compromise of circulation. Immediately after treatment with temporary fillers on the trunk or extremities, the application of ice or cold com-

presses can help minimize bruising or swelling. This is especially true for the dorsal hands. Some physicians will also prefer to wrap the hands with light compression after treatment to help minimize swelling. Other postinjection recommendations for the dorsal hands include avoiding workouts for 1–2 days and elevation of the hands above the level of the heart for 15–20 min several times the day of treatment. Patients treated with temporary fillers to the dorsal feet should also avoid wearing tight-fitting footwear for 2 weeks postinjection. Topical *Arnica* applied for several days after injection may also help reduce bruising. There is no clear data to support these techniques to reduce swelling [36, 47] (5).

Treatment with PLLA on the chest, arms, dorsal hands, and buttocks requires 2–4 treatment sessions every 6–8 weeks to obtain optimal results. Some patients require additional treatments depending on the desired aesthetic outcome. If nodule formation occurs, patients may benefit from closer follow-up. Subsequently, patients should have yearly visits for maintenance injections. There are no clear recommendations for follow-up after injection of PLLA to the medial ankles, abdomen, postoperative scars, or other off-label sites; however, patients treated in these areas should return at monthly intervals to determine response to treatment and the need for additional injections.

Follow-up visits for patients treated with CaHA or HA fillers may be scheduled from 4 to 8 weeks post initial injection to document any adverse events and provide touch-up injections as necessary. When injected into the dorsal hands, arms, thighs, and abdomen, CaHA can have 12–24 month longevity. In comparison, patients treated with HA fillers on the chest or dorsal hands typically require repeat injections every 6–8 months.

Alternative Procedures and Modifications

With the increased number of available aesthetic procedures and technologies, a multidimensional approach with complimentary treatment modalities often creates the best possible outcome. Limitations of one procedure may be easily addressed by another procedure either concomitantly or with some delay depending on the situation. There is limited data evaluating the objective benefit of complementary procedures on the trunk and extremities, and most information is based on consensus recommendations from expert physicians. Patient desire for minimally invasive procedures has drastically expanded the development of body contouring devices. When multiple modalities will be used in a single treatment site, expert consensus recommends performing skin tightening with heat or energy-based devices first, followed by injectable therapies. For areas particularly susceptible to photodamage, including the hands and chest, daily application of broad-spectrum sunscreen that protects against UVA and UVB is essential. Finally, each patient requires a detailed tailored treatment plan based on a thorough assessment of skeletal and muscular changes, the degree and location of volume loss, and the appearance of fine lines and rhytides [23].

Hands: Volume loss of the dorsal hands leads to the appearance of pronounced muscles and tendons, prominent bones, and large intermetacarpal spaces and is best treated with volume restoration. Aside from temporary fillers, autologous fat grafting has been used for rejuvenation of the dorsal hands. The invasive nature of the technique, time required for harvesting of fat from a donor site, unpredictable results, and reported complications make temporary fillers a more desirable treatment modality [48, 49] (5; 5). Fabi et al. recommend CaHA as first-line treatment followed by low-viscosity HA fillers for aesthetic restoration of the dorsal hands [23]. In addition to volume replacement with fillers, extrinsic signs of aging such as telangiectasias, erythema, solar lentigines, actinic keratosis, and ephelides of the dorsal hands can be successfully treated with the combined use of chemical peels, light-based devices, or lasers [39, 50–52] (4; 4; 5). Finally, sclerotherapy can improve the appearance of tortuous hand veins that are persistent after volume restoration [39].

Chest and décolletage: Microfocused ultrasound with visualization is the only technology FDA cleared for the improvement of rhytides in the décolletage and can significantly lift, tighten, and reduce the appearance of rhytides on the chest [53, 54] (2b; 2b) and can be used in combination with temporary fillers. As discussed earlier, the chest and décolletage have a thinner epidermis and dermis and fewer pilosebaceous units in comparison to the face. This results in slower healing and higher risk of scarring with ablative procedures. Therefore, non-ablative lasers, light-based therapies, and ultrasound technology can be used in combination with fillers. Additionally, chemical peels, sclerotherapy, and photodynamic therapy can also be part of a multi-modality treatment plan for rejuvenation of the chest.

Upper arms: Traditional brachioplasty is indicated in patients with significant adiposity and posterior arm laxity. It unfortunately has the disadvantage of being an invasive surgical approach that leaves patients with a large linear scar. Alternatively, liposuction can be used to reduce excess volume from the posterior arm. Newer energy-based devices and lasers can be used alone or in combination with temporary fillers to improve laxity, skin tightening, and irregular pigmentation of the posterior arm and elbow. Fractionated CO_2 laser for the arm has been used in one study with a 50–70% improvement in wrinkle reduction, skin tightening, and pigmentation [55] (4). Additionally, transcutaneous microfocused ultrasound, which is FDA approved for noninvasive skin tightening of the face and neck, has demonstrated success in tightening and lifting of lax skin at the elbow, arm, thigh, and knee [56] (1b).

Buttocks: As discussed earlier, the approach to aesthetic restoration of the buttocks is often complex. There are several alternative treatments for gluteal lipoatrophy or volume loss, with autologous fat transfer as the preferred procedure for patients with significant volume loss. This procedure requires an adequate supply of fat with which to transfer and is therefore performed in conjunction with liposuction. More than 200 ml of fat per side is often needed to make a substantive change [57] (4). Permanent solid silicone implants can also be used for buttock volume enhancement but require surgical creation of a pocket in the middle of the gluteal muscles for placement [58] (2b). The permanent filler polymethyl methacrylate (PMMA)-microspheres has also anecdotally been used in Brazil for the treatment of HIV-associated buttock lipodystrophy [59] (4). Typically, a single approach to volume enhancement of the buttocks with autologous fat, silicone implants, or temporary fillers is preferred.

Abdomen: Only one study demonstrated reduction in skin flaccidity on the abdomen using CaHA [29]. Therefore, improvement in the aesthetic appearance of the abdomen is best approached with treatments targeting a specific indication: skin-contour irregularities, lipohypertrophy, or dermal elastosis (e.g., after pregnancy or weight loss). Patients with significant abdominal obesity often require a combined approach with diet, exercise, and surgery. Ultrasound technology or Coolsculpting (ZELTIQ Aesthetics) can also help tighten loose abdominal skin and reduce abdominal fat.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
Indications	
Injections with soft tissue fillers for the trunk and extremities are most often indicated for patients with visible intrinsic and extrinsic signs of aging	D
Effectiveness	
Consistent use of validated grading scales for specific treatment sites will improve the objectivity of posttreatment evaluation	D
Preoperative evaluation	
Aside from Radiesse® for rejuvenation of the dorsal hands, the use of temporary fillers on the trunk and extremities is considered off-label	D
There are few absolute contraindications to injectable fillers on the trunk or extremities. These include a known allergy or hypersensitivity to the filler material or lidocaine mixed in the syringe and known skin infection in the area to be treated or adjacent skin	D
Best techniques and performance	
Advanced imaging techniques and a thorough understanding of anatomy can improve injection techniques	D
Safety	
Bruising, edema, and pain are the most common adverse events experienced by most patients treated with temporary fillers on the trunk and extremities	D
There are several well-established techniques to reduce the incidence of nodule formation when treating areas on the trunk and extremities	D
Postoperative care and follow-up	
Appropriate follow-up is dependent on the material injected, site of treatment, and occurrence of any adverse events	D
Alternative procedures and modifications	
A multidimensional approach with complimentary treatment modalities often creates the best possible aesthetic outcome for treatment of the trunk and extremities	D

Self-Assessment Questions

1. Which temporary filler is FDA approved for use on the trunk and extremities?
   (a) Radiesse
   (b) Belotero
   (c) Juvederm
   (d) Sculptra
   (e) Voluma

2. What is an absolute contraindication to filler use on the trunk and extremities?
   (a) Allergy to component in filler
   (b) History of hypertrophic scars
   (c) Connective tissue disease
   (d) Tobacco use
   (e) Anticoagulant use

3. Which PLLA dilution for trunk and extremity rejuvenation is correct?
   (a) Chest: 12 cc dilution
   (b) Arms: 6 cc dilution
   (c) Abdomen: 10 cc dilution
   (d) Buttocks: 4 cc dilution
   (e) Legs: 16 cc dilution

4. Nodule formation secondary to PLLA can be reduced with all of the following options except?
   (a) Site-specific dilution
   (b) Reconstitution for 24–72 h prior to injection
   (c) Subcutaneous injection plane
   (d) Massaging of the treatment area after injection
   (e) Addition of 5-Fluorouracil to PLLA vial prior to injection

5. The most common adverse events associated with temporary filler injection on the trunk and extremities include all of the following except?
   (a) Bruising
   (b) Pain
   (c) Pruritus
   (d) Edema
   (e) Biofilm formation

Correct Answers

1. a: The answer is a. Radiesse is the only currently available temporary filler to be FDA approved for the dorsal hand. The remaining fillers are used off-label for this area.
2. a: Answer choice a is the correct answer. Hypersensitivity to a component within the filler is an absolute contraindication and must be avoided in patients.
3. c: Answer choice c is correct. Chest is recommended to be diluted with 10 cc, arms with 10–12 cc, buttocks with 16 cc, and legs with 10–12 cc.
4. e: Answer choice e has not been shown to reduce the risk of nodule formation. The remaining options have evidence suggesting they reduce the risk of nodule formation with PLLA.
5. e: Answer choice e is incorrect. Biofilm formation can occur but is much less common than the others that occur in >90% of patients undergoing filler injections.

Treatment of Precancers with Topical Agents

Paola Chamorro and Bahar Firoz

Abstract

Actinic keratosis (AK) is one of the most common skin conditions worldwide. AK represents an intraepidermal dysplastic proliferation of keratinocytes (Berman B, Cockerell CJ. J Am Acad Dermatol 68:S10–9, 2013). It is a potential precursor to squamous cell carcinoma (SCC), with estimates of AK progression to invasive SCC ranging from 0.025% to 20%. With the incidence of non-melanoma skin cancer on the rise, treatment for AKs has been recommended to reduce the development of invasive SCC, lower healthcare expenditure, and improve patient well-being (Vale SM, Hill D, Feldman SR. Pharmacoeconomics 107:674–680, 2016). Several treatment modalities have been employed to treat AKs in an attempt to prevent progression to invasive SCC. The modalities which will be discussed and evaluated in this chapter include topical sunscreen, cryotherapy with liquid nitrogen, topical 5% (Efudex) and 0.5% (Carac) 5-fluorouracil (5-FU), topical 5% imiquimod cream (Aldara), topical diclofenac with sodium hyaluronate gel (Solaraze), ingenol mebutate (Picato), topical retinoids, and chemical peels including trichloroacetic acid and Jessner's solution applied to affected skin.

Introduction and Definition of Procedures to Be Discussed

Actinic keratosis (AK), also termed solar keratosis and senile keratosis, is one of the most common skin conditions worldwide. It is the most common diagnosis made by dermatologists for patients over 45 years of age, with a US prevalence of 11–26% and as high as 55% in patients 65 to 75 years old [3, 4]. In the United States in 2004, the prevalence of AK was estimated to be almost 40 million [5]. AK represents an intraepidermal dysplastic proliferation of keratinocytes and follows one of three paths: spontaneous remission, stable existence, or malignant transformation [1]. It is a potential precursor to squamous cell carcinoma (SCC), with estimates of AK progression to invasive SCC ranging from 0.025% to 20% [6]. The two largest studies suggest a 1-year transformation risk from less than 0.1% up to 0.6% of lesions [4, 7]. The 10-year risk of malignant transformation of AK to SCC

© Springer Nature Switzerland AG 2019
M. Alam (ed.), *Evidence-Based Procedural Dermatology*,
https://doi.org/10.1007/978-3-030-02023-1_41

has been estimated to range from 6% to 10% [8]. Metastatic risk of an SCC ranges from 0.5% to 3.3% and may account for up to 20% of deaths from skin cancer [9]. With the incidence of non-melanoma skin cancer on the rise, treatment for AKs has been recommended to reduce the development of invasive SCC, lower healthcare expenditure, and improve patient well-being [2, 5].

AKs are usually diagnosed clinically and appear as rough pink to brown macules, papules, or plaques with scale, which may be significantly hyperkeratotic. They may appear in conjunction with other signs of solar damage, specifically telangiectasias, solar lentigines, rhytides, and poikiloderma. Histologically, AKs exhibit varying degrees of intraepidermal keratinocytic atypia. Clinical and histological subtypes of AKs include the classic variant already described, hyperplastic (or hyperkeratotic), pigmented, lichenoid, atrophic, bowenoid, "cutaneous horn," and actinic cheilitis of the lips.

Much like non-melanoma skin cancer, AKs are thought to develop due to ultraviolet (UV) light exposure and resulting DNA mutations. They occur more frequently in fairer-skinned individuals but can be seen in all races. Most AKs occur in sun-exposed areas such as the head, lower lip, neck, dorsal hands, forearms, and upper chest. Increasing age, male gender, a history of AKs, and non-melanoma skin cancer are other risk factors for developing AKs. High-risk AKs are mainly associated with immunosuppression. Organ transplant recipients have a 250-fold higher risk of developing AKs and a 100-fold higher risk of developing invasive SCCs [10]. While approximately 40% of immunosuppressed patients develop invasive SCC, only 6–16% of immunocompetent individuals with AKs show this progression [10].

Several treatment modalities have been employed to treat AKs in an attempt to prevent progression to invasive SCC. The modalities which will be discussed and evaluated in this chapter include topical sunscreen, cryotherapy with liquid nitrogen, topical 5% (Efudex) and 0.5% (Carac) 5-fluorouracil (5-FU), topical imiquimod cream (Aldara), topical diclofenac with sodium hyaluronate gel (Solaraze), ingenol mebutate (Picato), topical retinoids, and chemical peels including trichloroacetic acid and Jessner's solution applied to affected skin.

Consensus Documents Regarding Procedure

Several consensus documents exist regarding AKs and the treatments employed to eliminate them [11]. The American Academy of Dermatology (AAD) published guidelines in 1995 that defined AKs as common premalignant skin tumors, which show varying degrees of epidermal atypia that may progress to SCC. They estimated that 60% of predisposed persons older than 40 years have at least one AK. Without treatment for AKs, they assert that a significant number of patients will develop one or more invasive SCCs. They list several treatment modalities and recommend consideration be given to size, location, duration, change in growth pattern, previous treatment, and certain anatomic locations such as the scalp and ear [11].

The European Dermatology Forum has also published guidelines for the management of AKs in 2006 [10]. They assert that AKs "should be classified as in-situ SCC" [10]. They mention UV exposure with or without iatrogenic exposure to psoralens and human papilloma virus as risk factors for the development of AKs. They quote a 15% prevalence rate of AKs in men and 6% in women based on a UK study. Before discussing treatment modalities, they also recommend evaluating the duration and course of lesions, lesion quantity, patient age, comorbid conditions, the patient's mental condition, anticipated patient compliance, pre-existing skin cancers, and particularly immunosuppression. They discuss that although cryotherapy is widely used, controlled studies are missing. Complete responses differ from 75% to 98%, and recurrence rates are estimated from 1.2% to 12% at 1-year follow-up. Imiquimod and 5-FU are discussed with impressive remission rates and low recurrence rates. Diclofenac in hyaluronic acid gel also shows AK remission in a few randomized controlled trials when applied for 60 or 90 days with minimal side effects.

The British Association of Dermatologists has also published guidelines for the management of AKs in 2006 [12]. In contrast to the European guidelines, they define AKs as "focal areas of abnormal keratinocyte proliferation with low risk of progression to invasive squamous cell carcinoma and higher potential for spontaneous regression." The authors discuss several factors to help determine the choice for therapy, based on efficacy, ease of use, morbidity, and cost–benefit analysis. They conclude that "there is good evidence" that 5% 5-FU cream used twice daily for 3 weeks is effective at reducing AKs on the face and back of hands by about 70% for up to 12 months. Multiple randomized controlled trials (RCTs) of imiquimod produce a similar pattern of side effects and response to 5-FU. Diclofenac gel, a relatively mild agent, reduces AK lesion count, but long-term follow-up data is lacking. Studies show topical tretinoin, when used for 1 year, has some efficacy on the face, with partial clearance of AKs. Sun block, emollient, and 2% salicylic acid ointment may reduce the AK count by a similar amount [12].

Sunscreen

Topical sunscreens are applied to the skin and ideally block both UVA and UVB ultraviolet radiation, theoretically preventing the formation of AKs. The AAD recommends application of a water resistant sunscreen with broad-spectrum coverage, and sun-protection factor (SPF) 30 or higher approximately every 2 h to sun-exposed areas [13].

A blinded, RCT undertaken in Australia during the summer between September 1991 and March 1992 evaluated the effect of sunscreen with SPF of 17 vs. vehicle cream on AKs in 431 subjects aged 40 years or older. AKs were diagnosed clinically, although a subsample had biopsies for verification and there was 81% concordance between clinical and histologic diagnosis. Subjects were asked to keep daily diaries that recorded the frequency of cream application and to avoid sun exposure and other sunscreen products during the study. Approximately, 25% of the AK lesions present at baseline had remitted in the sunscreen group after 7 months compared to 18% in the vehicle cream group. The mean number of AKs increased by 1 per subject in the vehicle cream group, whereas it decreased by 0.6 per subject in the sunscreen group (1b) [14].

In a blinded, controlled trial over 4.5 years, 1621 adults were randomized to 4 groups comparing the application of daily use of sunscreen with SPF 16 vs. application of sunscreen at subjects' usual discretionary rate. They were also randomly assigned to take either one 30 mg beta-carotene or placebo tablet each day. Beta-carotene is an antioxidant that in theory may prevent skin cancer by lowering free-radical-induced DNA damage in UV-exposed skin cells. The prevalence of AKs increased over the course of the trial for all groups; however, the increase in AK counts was 24% lower in the daily sunscreen group than that experienced in the control group, while a beta-carotene supplementation had no influence on the occurrence of AKs (1b) [15]. This RCT was conducted in conjunction with a RCT evaluating the effectiveness of daily sunscreen application and beta-carotene supplementation in preventing basal cell carcinoma (BCC) and SCC over 4.5 years, in which daily sunscreen use significantly reduced the incidence of SCC compared to no sunscreen use. Sunscreen and/or beta-carotene use had no effect on the incidence of BCC (1b) [16].

Cryotherapy

Cryotherapy is a destructive method for treating AKs that utilizes liquid nitrogen (−196 °C) to freeze and thereby destroy both normal and dysplastic cells and eliminate diseased epidermis by creating a separation of the epidermis from the dermis. Cryotherapy is a widely used and long-established treatment option that exhibits very good clinical efficacy for single lesions. In order to achieve efficacy and avoid cosmetic defects, the recommended therapy of AK lesions is a freeze time of approximately 20–30 seconds (s). As with other procedures, the potential for side effects exists, but these are, for the most part, predictable

or minimal [17]. Side effects include pain, blistering, hypopigmentation, hair loss, and scar. There are few contraindications to cryosurgery.

In a prospective, multicentered, non-blinded study, which was a subsidiary of a RCT, 90 patients with 421 clinically diagnosed AKs of 5 mm or greater on the face and scalp were treated with cryotherapy. Freeze-thaw cycles of differing lengths were employed depending on the treatment center. At 3-month follow-up, there was a 57% complete clearance rate in the intention to treat population. Complete response was 39% for freeze times less than 5 s, 69% for freeze times greater than 5 s, and 83% for freeze times greater than 20 s (2b) [18]. Cure rate for AK is technique dependent, with longer freeze times having greater clearance rate.

A RCT evaluated 71 subjects with ≥ 10 AKs on the face and scalp and compared treatment efficacy, safety, and skin quality outcomes of cryotherapy (10s freeze/thaw time, 10 lesions per session, up to 4 sessions every 3 months) and imiquimod (3 times per week for 3–4 weeks, up to 2 courses). Clinical complete response rates were 85% (260/306 lesions) for cryotherapy and 66.9% (234/350) for imiquimod. Because of bias and imprecision, the study was considered low-grade quality, and there was no statistical difference between cryotherapy and imiquimod with respect to complete clearance. The participant cosmetic outcomes and global skin quality was 82% for cryotherapy versus 100% for imiquimod. Blister formation was noted to occur at a higher rate in cryotherapy arm compared to the imiquimod arm (1b) [19].

A RCT trial with 75 patients with at least 5 AKs diagnosed clinically and confirmed histologically compared cryotherapy (20–40 s per lesion), topical 5-FU (twice daily for 4 weeks), and imiquimod (3 times weekly for 4 weeks, 1–2 cycles) with a 12-month follow-up period. Initial clinical complete clearance of lesions 4–8 weeks after therapy completion was 68% (17/25) for cryosurgery, 96% (23/24) for 5-FU, and 85% (22/26) for imiquimod. Histological clearance was only 32% for cryosurgery compared to 67% for 5-FU and 73% in the imiquimod group. The sustained clearance rate for individual lesions at 12 months was 28% for cryosurgery, 54% for 5-FU, and 73% for imiquimod. Evaluating the entire treatment field, sustained clearance at 12 months was 4% for cryosurgery, 33% for 5-FU, and 73% for imiquimod. Imiquimod resulted in superior cosmetic and sustained clearance rates, although the overall number in each group was small (1b) [20].

A strong recommendation is given for the use of cryotherapy in patients with single AK lesions or multiple discrete lesions. Low cost, availability, safety, effectiveness, and compliance make it a widely available and effective treatment modality.

Chemical Peels

Chemical peels are also an ablative modality that destroys the epidermis and variable depths of the dermis depending on the peel type. They are typically applied to the general affected area, as opposed to spot treatment, and thus are recommended for extensive facial AKs. A medium-depth chemical peel with 35–50% trichloroacetic acid (TCA) alone or a 35% TCA in combination with Jessner's solution (salicylic acid, lactic acid, and resorcinol), 70% glycolic acid, or solid CO2 may effectively treat multiple non-hypertrophic AKs [21]. Medium-depth peels cause injury at the level of the papillary dermis, and side effects may include stinging or burning pain, visible peeling (which usually lasts 5–7 days), pigmentary changes, infections, and rarely scarring. Higher rates of complications may occur in patients with a history of herpes simplex virus (HSV) infection, previous radiation exposure, immunosuppression, post-inflammatory hyperpigmentation, keloids, recent facial surgery, or taking photosensitizing medications. Patients likely to be noncompliant with posttreatment sunscreen use or who are unable to avoid sun exposure are unsuitable candidates for a chemical peel. The efficacy depends on the agent used and has been quoted as high as 75% (agent dependent) with a recurrence rate at 1 year between 25% and 35% [10].

In a nonrandomized split-face study of 15 patients, a single application of 35% TCA plus Jessner's solution was compared with 5% 5-FU applied twice daily for 3 weeks. Evaluations were conducted 1, 6, and 12 months after treatment, and both treatments reduced the number of visible AKs by 75% (3b) [22].

In another split-face comparison study, 13 patients were evaluated for response to 70% glycolic acid plus 35% TCA compared to Jessner's plus 35% TCA. AKs, fine wrinkling, and solar lentigines were evaluated prospectively with a 60-day follow-up. Improvement was clinically noted for both peels (3b) [23].

Eight patients with severe facial actinic damage were treated with Jessner's and 35% TCA on the left face and with twice daily application of 5% 5FU for 3 weeks on the right face. Clinical evaluation was performed at 1, 6, 12, and 32 months and included AK counts, random skin biopsies, and sun exposure surveys. A 78% reduction in the mean number of clinical AKs was observed at 12 months for both treatments, but the mean number of AKs increased between 12 and 32 months. They suggest 18-month follow-up in all AK patients (3b) [24]

Sixteen men with actinic damage were treated with 40% TCA peels and evaluated at 6 weeks and 6 months after treatment. Half were pretreated and post-treated with topical tretinoin. Examiners assessed clinical outcome using photographs, and patients used a self-assessment tool. The peel, both with and without tretinoin, produced improvements in actinic damage, although quantitative measures are lacking in this study (4) [25].

5-Fluorouracil

Topical 5-fluorouracil, a chemotherapeutic antimetabolite approved by the US FDA in 1970, is the most established field treatment for AK and is considered by some the traditional gold standard to which all other topical agents are compared [26]. It is a pyrimidine analog, which interferes with DNA synthesis by stopping the conversion of deoxyuradilic acid to thymidylic acid, which prevents cell proliferation preferentially in rapidly dividing cells, especially those of AKs and basal layers of the epithelium [27]. Topical 5-FU is available as a cream in 5, 1, and 0.5% concentrations and as a solution in 5% and 2% concentrations. The typical treatment regimen is either 5% cream twice daily or 0.5–1% cream once daily for 2–4 weeks. The widespread application has the advantage of treating multiple and clinically undetectable AKs. Topical 5-FU causes inflammation, erosion, and ulceration during treatment, which is necessary for therapeutic success, which develops after the first week and subsides approximately 2 weeks after treatment when re-epithelialization has occurred. These transient side effects can result in non-compliance.

A randomized double-blinded, placebo-controlled clinical trial of 932 veterans with 2 or more AKs evaluated 5% 5-FU cream and vehicle control cream applied to the face and ears twice daily for up to 4 weeks. The 5-FU group had statistically significant fewer AKs compared with the control group at 6 months (3.0 vs. 8.1) and for the overall study duration of 3 years. The 5-FU group also had higher complete AK clearance rates (38% vs. 17% at 6 months) and fewer spot treatments at 6-month intervals (1b) [28].

Three randomized controlled studies provided data evaluating 0.5% 5-FU in comparison with vehicle. Across the 3 studies, approximately 400 adult patients with at least 5 AK lesions were pooled, in which 0.5% 5-FU cream or vehicle cream was applied once daily to affected areas of the face or scalp for either 1, 2, or 4 weeks. The rate of complete clearance and mean reduction in lesion count from baseline to 4 weeks and 6 months was statistically significant and higher in the 0.5% 5-FU group than in the vehicle group (1b) [29–31].

In one intraindividual split-patient RCT of 21 patients with $\geq$ 6 AK lesions, the participant's preference of different concentrations of 5-FU cream (0.5% 5-FU applied once daily vs. 5% 5-FU applied twice daily for mean duration of 19 days) was compared. At the end of the 4-week posttreatment period, participants preferred the 0.5% concentration to the 5% concentration. No

statistically significant differences were found between the two formulations regarding minor adverse events: erythema, erosion, and pain. Complete clearance was 43% in both study groups. The mean reduction in lesion counts from baseline to end of study was higher in the 0.5% 5-FU concentration compared to 5% concentration (2b) [32].

A meta-analysis investigating the efficacy of 5-FU for AKs of the face and scalp included six studies, 146 patients with variable follow-up times ranging from 1 to 11 months. Different formulations 5, 1, and 0.5% of 5-FU were included. The meta-analytical average complete clinical response rate for 5-FU across these studies was 52.2% (SD = 18%). In one study, at 11-month follow-up, complete clearance was seen in 86.4% of the 5% 5-FU group compared to 0% in the 1% 5-FU group. Two other studies showed differing results with 5% 5-FU applied twice daily over 2 weeks, with only complete clearance of facial AKs in 6.7% of subjects at 1-month follow-up compared with 100% of subjects in another study. Two separate studies investigating 0.5% 5-FU applied for 4 weeks showed complete clearance rates at 4-week follow-up of 57.8% and 47.5% in patients with facial AKs (1a) [29, 30].

5-FU pulse therapy was evaluated in a RCT of 20 patients with a clinical diagnosis of AK on the scalp and/or face. Thirteen patients applied 5% 5-FU twice daily for 3 weeks and were compared to seven patients who applied the same cream twice daily for 1 day per week for 12 weeks. Follow-up was performed at weeks 3, 12, 24, and 52, and clinical photographs and a lesion count were performed. The groups had the same median lesion count at baseline (17.5), but in the first group, the lesion count fell and remained at 0 after week 12, whereas the second group fell to 6 at week 12, 5.5 at week 24, and 3 at week 52. Applying 5% 5-FU twice daily for 3 weeks had a statistically significant and superior efficacy than pulse therapy (1b) [33].

With regard to combination therapy, one randomized controlled investigator-blinded study of 60 patients with an average of 12 AKs compared the addition of 5-FU to cryotherapy versus cryotherapy alone. Patients underwent cryotherapy followed 3 weeks later by self-application of 0.5% 5-FU cream or placebo moisturizer cream once daily. At week 8, the reduction of AK lesions was 84% (5-FU) vs. a 69% (placebo). At week 26, however, the reduction of AK lesions was 72% (5-FU) vs. 73% (placebo). There was no significant difference between 0.5% 5-FU cream and comparator cream for either 100% or 75% clearance by the end of the study (1b) [34].

In a multicenter, randomized, double-blind, placebo-controlled, parallel group trial, 470 patients with 4–10 AK lesions on the face or bald scalp were treated with topical 0.5% 5-FU + salicylic acid 10.0% [Actikerall®] once daily or diclofenac HA or vehicle twice daily for 12 weeks. The histological clearance rate of one predefined lesion and clinical clearance rate of all treated lesions were evaluated at week 20. Respectively, the week 20 biopsy revealed AK clearance in 72% of the 5-FU/SA group, 59.1% of the diclofenac HA group and 44.8% of the vehicle group. Significantly more lesions were cleared with 5-FU/SA (74.5%) compared to diclofenac HA (54.6%) or vehicle (35.5%). Application site disorders, mainly burning and inflammation were more frequent with low-dose 5-FU/SA but were of mild to moderate intensity. Low-dose 5-FU was determined to be an effective lesion-directed treatment for AKs (1b) [35].

In a RCT, 66 patients with histologically confirmed moderate/severe hyperkeratotic AKs on the face or scalp were treated with either a 6-week course of once daily 0.5% 5-FU/10% SA or 2 cryotherapy treatments 3 weeks apart. Although the study was not powered to explore statistical differences in clinical efficacy, topical treatment with 0.5% 5-FU/SA achieved greater histological clearance (62.1% for 5-FU/SA group vs. 41.9% for cryotherapy group at day 98) and lower recurrence rate (39.4% for 5-FU/SA group vs. 84.8% for cryotherapy group) of grade II/III hyperkeratotic AKs than cryosurgery. Mean change in lesion count from baseline to day 98 was −5.2/patient for 0.5% 5-FU/SA group vs. −5.7/patient in cryotherapy groups. Drug-related severe adverse events were all skin reactions, reported in 24.2% of 5-FU/SA and 6.1% of cryotherapy patients, respectively (2b) [36].

Imiquimod

Imiquimod (IMQ) is a topical immunomodulator approved by the United States FDA in 2004 for actinic keratosis treatment. Imiquimod is a toll-like receptor-7 agonist, activating antigen-presenting cells to produce interferon, other cytokines, and chemokines. These cytokines stimulate the nonspecific innate immune response and help direct the acquired immune response. Available dosages within the United States include 5%, 3.75%, and 2.5% formulations. The manufacturer-recommended dosing regimen is application of 5% cream twice weekly for 16 weeks or 3.75% or 2.5% creams once daily for two 2-week treatment cycles separated by treatment-free intervals, whereby 250 mg of cream is applied to a 25 cm^2 area on the face or scalp. Shorter-course therapy of 5% cream with treatment-free intervals may also be effective.

A meta-analysis of nine randomized controlled trials compared the clinical efficacy of imiquimod 5% cream to placebo vehicle cream for the treatment of multiple AKs. Approximately 2300 pooled patients self-applied imiquimod 5% cream or vehicle cream 2– times weekly for 4–16 weeks. Imiquimod 5% was statistically significantly more effective than vehicle cream with complete clearance rates of 46% (imiquimod group) vs. 5.7% (vehicle) and partial (> 75%) clearance rates of 61.4% (imiquimod) vs. 11.4% (vehicle) [37, 38]. Only one study evaluated the optimal frequency and long-term effectiveness of imiquimod beyond 12–16 weeks. Approximately 82% of the patients who achieved complete clearance after imiquimod treatment were followed 16 months after treatment, in which recurrence was observed in 25% of the patients treated 3 times weekly compared to 43% who were treated twice weekly and 47% who were treated with vehicle cream (1a) [38].

Although treatment adherence to the approved imiquimod dosing regimens was good in clinical studies, the long duration of dosing may be inconvenient for patients and affect compliance. Shorter treatment duration with daily dosing imiquimod 5% cream, however, is not well tolerated. As such, the effect of varying dosing frequency of imiquimod was investigated [39]. In a phase II, multicenter, double-blind, RCT, 149 patients with ≥ 10 and ≤ 50 clinical AKs, one of which histologically confirmed, were randomly assigned to imiquimod or placebo cream applied to the forearms or hands once daily for 2, 3, 5, or 7 times per week for 8 weeks and complete clearance clinically measured. Complete clearance rates were low, however, partial clearance rates increased with increased dosing frequency. Twenty-eight subjects discontinued the study due to adverse effects. Imiquimod 5% applied more frequently than three times per week to AKs was not well tolerated (1b) [39].

To evaluate an imiquimod product that could be applied daily for AK for a short duration and to expand treatment area to face/scalp, lower concentrations were evaluated. In two randomized, placebo-controlled studies, 479 pooled patients with multiple AK lesions were randomized to placebo, imiquimod 2.5% or imiquimod 3.75% once daily for two 2-week treatment cycles separated by a 2-week treatment free interval. Both studies showed that both imiquimod 2.5% and 3.75% creams were more effective than placebo and were well tolerated in the treatment of AK. Complete and partial clearance rates were 6.3% and 22.6% for placebo, 30.6% and 48.1% for imiquimod 2.5%, and 35.6% and 59.4% for imiquimod 3.75%, respectively. Median lesion count reduction from baseline was 25% (placebo), 71.8% (imiquimod 2.5%), and 81.8% (imiquimod 3.75%.) Lesion reduction was greater with imiquimod 3.75% compared to imiquimod 2.5%, yet these results were not considered statistically significant (1b) [40].

Thirty-six patients with four or more clinically diagnosed AKs were randomly assigned to receive 5% 5-FU cream twice daily for 2–4 weeks or 5% imiquimod cream twice weekly for 16 weeks in a physician-blinded study. Evaluations were performed at baseline and every 4 weeks until 24 weeks. At week 24, the total AK count was reduced by 94% from baseline with 5-FU compared to 66% with imiquimod. Complete clearance of AKs was 84% in the 5-FU group compared to 24% in the imiquimod group. Erythema levels were initially higher in the 5-FU

group but were comparative to imiquimod by week 16. Limitations of this study include twice weekly application of imiquimod which may be a substandard regimen, small sample size, clinical diagnosis of AK made by one evaluating physician without histologic confirmation, and failure to perform an intent to treat analysis (2b) [41].

Please refer to cryotherapy section for information comparing imiquimod and cryotherapy.

Topical Diclofenac with Sodium Hyaluronate Gel

Topical Diclofenac 3% gel is a potent nonsteroidal anti-inflammatory formulated with 2.5% hyaluronic acid. There is evidence that diclofenac induces regression of AKs. Arachidonic acid (AA) metabolites have been shown to promote epithelial tumor growth by stimulating angiogenesis, mediating the conversion of procarcinogens to carcinogens, and inhibiting apoptosis [42].The production of these prostaglandins from arachidonic acid COX-2 pathway in keratinocytes increases in response to UVB radiation and may play a role in UVB-induced skin cancers (BCC and SCC) as well as AK [43]. As a selective cyclooxygenase-2 (COX-2) inhibitor, diclofenac exerts its anti-tumor effects by inhibiting the arachidonic acid cascade, subsequently decreasing the synthesis of prostaglandins. Hyaluronic acid 2.5% is a naturally occurring glycosaminoglycan with inflammation-modulating and bioadhesive properties, which serves as an excellent vehicle for topical drug delivery [44]. Common side effects include dermatitis, pruritus, and xerosis. Recommended dosing is twice per day for 90 days.

Four randomized, double-blind, placebo-controlled trials compared 3% diclofenac in 2.5% sodium hyaluronate (DHA) gel (0.25–0.5 g of 3% DHA twice daily for 60–90 days) vs. hyaluronate gel vehicle (HAV) alone (2.5% HAV twice daily for 60–90 days) in a total of 472-pooled immunocompetent patients with at least 5 AKs located on the head and extremities. Outcomes in all 4 studies evaluated the rate of complete clearance at 30 days posttreatment. Two [45, 46] studies also evaluated the rate of Participant Global Improvement Index (PGII) and Investigator Global Improvement Index (IGII) rated as "completely improved" 30 days after treatment. Analysis showed that compared to the control HAV group, the intervention DHA group showed a statistically significant higher efficacy with respect to complete clearance rates (14.6% vs. 34.9%) as well as higher rates of PGII and IGII rated as "completely improved." In the Rivers et al. study, 97 patients with AK were also treated with DHA or placebo twice daily for 60 days, in which the target lesion number score (TLNS; complete resolution of all target lesions in the treatment areas) was observed in 33% of patients in intervention group vs. 10% patients in placebo group. The cumulative lesion number score (CLNS; resolution of target and new lesions in the treatment area) was achieved by 31% of the patients in the intervention group compared to 8% of the patients in the placebo group. Common side effects included pruritus, contact dermatitis, dry skin, rash, and scaling. None of the studies had histologic verification of the AK diagnosis, and none compared DHA to other modalities used in the treatment of AKs (1a) [37, 45–47].

Two randomized controlled trials evaluated diclofenac against imiquimod. In the first trial, 3% diclofenac HA gel (twice daily for 12 weeks) was compared to 5% imiquimod (twice weekly for 16 weeks) and placebo base cream. Forty-one patients with clinical and histopathological single AK lesions were evaluated clinically every 4 weeks until 6 months for total thickness score (TTS) and PGII. Complete clearance rates for diclofenac, imiquimod, and vehicle at the end of the treatment and at 6-month follow-up were 19.1%, 20%, and 0% and 14.3%, 45%, and 0%, respectively. The average TTS value at 6 months for the diclofenac group was significantly higher than that of the imiquimod group; however, the PGII values were not significantly different. No adverse effects occurred in all groups. ($p = 0.034$, mean difference 0.85, 95% CI 0.36–1.66) (1b/II/A) [48]. The efficacy of imiquimod may be limited in this study due to underdosing as

imiquimod is usually prescribed as three times weekly use rather than twice weekly use in current clinical practice. The second trial compared 3% diclofenac HA gel (once daily for 12 weeks) with 5% imiquimod (three times weekly for 12 weeks) in 49 patients with at least 3 AK lesions. Efficacy was measured by patient and investigator global improvement scores, which were evaluated monthly for 1 year posttreatment. In this study, there were no statistically significant differences found between the two intervention groups with respect to the rate of participants with the PGII and IGII rated as "completely improved": (PGII, 28% DHA vs. 23% IMQ, $p > 0.05$, and IGII, 12% DHA vs. 22% IMQ, $p > 0.05$). There were also no statistically significant differences between the two intervention groups with respect to adverse events (1b) [49].

Ingenol Mebutate

Ingenol mebutate (IM) was approved for use in the United States, Canada, and Europe in 2012 as well as Australia and other countries thereafter [27]. Ingenol mebutate (IM) is a diterpene ester extracted from the sap of the medicinal *Euphorbia peplus* plant. It has two mechanisms of antiproliferative activity: [1] it initially disrupts mitochondrial and cell membranes resulting in rapid lesion necrosis of locally affected cells and [2] it subsequently removes residual tumor cells by selective induction of tumor-specific antibodies and pro-inflammatory cytokines via a neutrophil-mediated antibody-dependent cellular cytotoxic pathway [50–52]. Recommended therapy includes a 3-day course of 0.015% gel for the face and scalp and a 2-day course of the 0.05% gel for the trunk and extremities. The most common adverse effects of ingenol mebutate are local erythema, flaking, scaling, vesiculation, and crusting, which typically peak within the first week and resolve within 1 month without scarring. A small number of patients may experience hyperpigmentation or hypopigmentation after treatment, but the visibility is considered mild and not clinically meaningful by clinicians [50]. Ingenol mebutate and its metabolites have not been detected in blood samples for patients treated with ingenol mebutate 0.05%, suggesting no systemic absorption. The short duration of therapy and tolerable side-effect profile is associated with high rates of adherence to treatment.

In a multicenter, randomized, parallel-group, double-blinded study, 547 adult patients with an average of 4–8 AKs of the face or scalp were randomly treated with ingenol mebutate 0.015% gel or placebo vehicle gel for self-application once daily for 3 consecutive days. Additionally, 458 patients with 4–8 AKs on the trunk or extremities were randomly given ingenol mebutate 0.05% gel or placebo vehicle gel once daily for 2 consecutive days. Outcomes were complete (100%) with partial clearance (75% reduction) of all visible AK lesions and median reduction in lesion numbers on day 57. Ingenol mebutate was statistically significantly more effective for field treatment of AK when compared to vehicle gel at day 57. The rates of complete clearance (cc) and partial clearance (pc) of face/scalp group were higher in patients receiving ingenol mebutate (42.2% cc, 63.9% pc) in comparison with placebo (3.7% cc, 7.4% pc), both with $p < 0.001$. For the trunk/extremities group, clearance rates were also higher in patients receiving IM (34.1% cc, 49.1% pc) in comparison with placebo (4.7% cc, 6.9% pc), both with $p < 0.001$. The median reduction number count was also higher in ingenol mebutate treatment of both face/scalp (83% reduction) and trunk/extremities (75% reduction) groups in comparison to placebo (0% for both face/scalp and trunk/extremities). The study is limited as local skin reactions caused by ingenol mebutate reduce the blinding of the study. No other treatment modalities were used for comparison, making it difficult to interpret its efficacy compared to other established AK treatment modalities (1b) [53].

In a follow-up observational study by M. Lebwohl et al. in 2013, 100 patients with complete clearance of face or scalp lesions and 71 patients with complete clearance of trunk or extremities lesions after treatment with ingenol mebutate were observed 12 months after

treatment to evaluate the recurrence rates and safety associated with ingenol mebutate. The sustained clearance rate after 12-month follow-up was 46.1% (face or scalp) and 44.0% (trunk or extremities). Among patients with complete clearance at day 57, the percentage of reductions in AK at 12 months from the number of baseline AK prior to treatment was 87.2% (face or scalp) and 86.8% (trunk or extremities) (2b) [54].

In a multicentered, randomized, double-blind, double-dummy, vehicle-controlled, sequential-cohort dose-finding study, 222 patients with non-facial actinic keratosis were randomly assigned treatment with ingenol mebutate gel 0.05% for 2 or 3 days, ingenol mebutate gel 0.025% for 3 days, or vehicle gel for 3 days with follow-up evaluation at day 57. Primary outcome was partial clearance rate (75% reduction at day 57). Other secondary outcomes included complete clearance rate, mean reduction of AK lesions, and safety measured as local skin reactions and adverse effects. All three active treatments were significantly more effective than vehicle with regard to partial and complete clearance rates and median percentage reduction in baseline lesions. The therapeutic response was also positively correlated to dosage concentration. Partial clearance rates included 75.4% in the IM gel 0.05% for 3 days group, 61.8% in the IM gel 0.05% for 2 days group, 56% in the IM gel 0.025% for 3 days group, compared to 21.7% of the vehicle group. There were no serious treatment-related adverse effects reported, and there were no discontinuations due to an adverse effect (1b) [50].

Combination therapy of ingenol mebutate with cryotherapy has also been found to be efficacious. In a randomized double-blind vehicle-controlled study, 289 patients with 4–8 discrete AKs on the face or scalp underwent combination therapy with cryosurgery followed 3 weeks later by ingenol mebutate gel 0.015% vs. vehicle gel once daily for 3 consecutive days. Results showed that complete clearance rates were greater after cryotherapy with ingenol mebutate (60.5% at week 11; 30.5% at month 12) in comparison with vehicle (49.4% at week 11; 18.5% at month 12) (1b) [55].

Retinoids

The term retinoid includes both naturally occurring and synthetic derivatives of vitamin A. In the prevention and treatment of skin cancers, retinoids are thought to regulate the differentiation and growth of keratinocytes, interfere in the process of tumor initiation, reduce regulation of proto-oncogenes, increase expression of p53 and pro-apoptotic caspases, and sensitize keratinocytes to apoptosis [56–59]. The use of topical retinoids avoids the systemic toxicity seen with oral therapy, although there may be local adverse effects such as scaling, erythema, burning, and irritation [60]. Most of these adverse effects are seen to reach a peak during the first week and decrease over time [61].

In a randomized double-blind, placebo-controlled, parallel-group study, 79 patients with at least 5 AKs on the face, scalp, and/or upper extremities were assigned to treatment with topical isotretinoin 0.1% cream or vehicle twice daily for 6 months and were clinically assessed every 4 weeks for changes in lesion count in order to assess the efficacy and tolerability of isotretinoin. On the face, there was a statistically significant reduction in the number of actinic keratoses (mean +/− SEM) for patients treated with isotretinoin (3.9 +/− 0.6) compared with placebo (1.7 +/− 0.5) at all assessment points from 16 weeks onward ($p < 0.005$) and at the end of treatment ($p = 0.001$). There was not a significant drug effect seen for lesions on the scalp or upper extremities (1b) [62].

In a prospective RCT, 90 patients with at least 5 AKs on the face and/or scalp were treated with adapalene gel (0.1% or 0.3%) daily as field therapy or its vehicle gel for 4 weeks, followed by twice-daily treatment for 9 months. With adapalene gel 0.1% and 0.3%, the mean number of AKs was reduced by −0.5 ± 0.9 (mean ± SE) and − 2.5 ± 0.9, respectively, whereas with the vehicle gel, there was an increase of +1.5 ± 1.3 ($p < 0.05$) AKs (1b) [63].

Kligman conducted one of the largest multicentered double-blind studies on retinoids with 1265 patients with histologically confirmed AK. In

this study, published in non-peer-reviewed literature, there was a reduction of facial AKs from a mean of 11.2–8.9 (11% reduction) after 6-month use of tretinoin 0.05% cream once or twice daily ($p = 0.001$). This changed to a reduction of 47% after 15-month use ($p = 0.001$) (2b) [64].

Regarding case series on the use of topical retinoids for AKs, Bollag observed a reduction of AKs with tretinoin use. In 60 patients with actinic keratosis, 51 patients with facial lesions, and 9 patients with forearm and hand lesions, tretinoin 0.1% and 0.3% ointment was applied twice daily for 3–8 weeks. In 24 of 51 patients (47%) with keratoses on the face, lesions disappeared completely with no recurrence after 2–6 months. Although forearm and hand lesions did not disappear completely, 7 of 9 patients had a reduction of more than 50% of lesions (4) [65].

In contrast, a few studies have found that long-term use of topical retinoids do not reduce AK counts. In a RCT of 1131 patients, topical tretinoin 0.1% cream applied 1–2 times daily for a mean duration of 3.5 years was found to be ineffective in reducing the number of AKs. The study found no evidence for differences in actinic keratosis counts on the face and ears at any subsequent time point or risk of SCC in situ at 2 years (8 vs. 10%) or 5 years (18 vs. 16%) (1b/II/A) [66]. Campanelli performed a retrospective study in 61 immunocompetent patients who had applied retinaldehyde on photo-exposed body areas, and the total number of AK and skin cancers was counted. Results showed no difference in the use of 0.05% retinaldehyde for 6–142 months. As the study was not controlled, its value is limited (2b) [67].

Most of the studies are case series with small numbers of patients, often without randomization and sometimes without adequate explanation about method. Blind, randomized, and controlled clinical trials with adequate sample sizes are needed to clarify the real benefit of topical and/or oral retinoids [68]. The lack of standardization for topical retinoid treatment and lack of efficacy in larger studies makes topical retinoid treatment a poor choice when more efficacious options are available.

Organ Transplant Patients and Immunosuppression

More than 1 million patients worldwide with end-stage organ disease undergo organ transplantation [69]. Transplant recipients are at increased risk of developing skin cancer, especially squamous cell cancer (SCC) due to chronic immunosuppression. Organ transplant recipients who are on immunosuppressive medications are also up to 250 times more likely to develop AK. In patients receiving immunosuppression following renal transplantation, actinic keratoses have been reported in 38% after 5-year follow-up; however, it has been speculated that with time nearly all these patients will develop actinic keratosis [70]. Effective management of actinic keratoses could help prevent further development of invasive SCC [71].

Sunscreens can diminish the number of AKs by up to 50% in organ transplant recipients. In a prospective, single center case control study, 120 matched adult organ transplant recipients (40 heart, 40 kidney, 40 liver grafted) with AKs were enrolled. Each group had a total of 191 AKs at enrollment. Both groups received equally written and oral information on sun protection measures. Sixty subjects received treatment with a free broad-spectrum study sunscreen (SPF > 50) for daily self-application of 2 mg cm^2 to the head, neck, forearms, and hands. Within the 24-month study interval, 42 of the 120 patients developed 82 new AK (−102 sunscreen group vs. +82 control; $p < 0.01$) and 8 new invasive SCC (0 vs. 8; $p < 0.01$) and 11 BCC (2 vs. 9). In spite of equal numbers of AK at enrollment, the incidence of new AK after 24 months was significantly lower in the intent-to-treat sunscreen group as compared to the control group (89 vs. 273; $p < 0.01$, mean difference 3.07 [1.76–4.36]). The lesion count in the sunscreen group was significantly lower at 24-month visit compared to the initial visit (89 vs. 191; $p < 0.01$, mean difference 1.7 [0.68–2.72]). In the sunscreen group, an overall reduction of 53% in AK numbers as compared to initiation visit was observed after 24 months. In the control group, the AK numbers overall increased by 43%.

With an average of 5.6 applications per week throughout the 24 months, the study sunscreen was generally well tolerated (3b) [72].

A randomized controlled trial specifically addressed the use of imiquimod 5% cream 3 times weekly compared to vehicle alone for 16 weeks in 34 kidney, heart, and liver transplant patients with histologically confirmed AKs. An 8-week follow-up was performed and a punch biopsy was obtained to verify lesion resolution. Complete clearance rates for individual AKs were 62% in IMI group and 0% in vehicle group. In fact, overall lesion clearance rate for vehicle patients was −99%, showing a large increase in overall lesion count from baseline. Common adverse reactions included application site reactions followed by fatigue, headache, diarrhea, nausea, rash, and leukopenia. No patients experienced rejection of the transplanted organ (1b) [69, 73].

A randomized, placebo-controlled trial compared the safety and efficacy of topical diclofenac 3% gel (DHA) to vehicle gel in 32 solid organ transplant patients with at least 3 AK lesions in a contiguous 50cm^2 area located on the bald scalp, face, or hands. Subjects were treated with either DHA or placebo twice daily for 16 weeks, followed by final evaluation and biopsy of treatment area 4 weeks posttreatment. Complete clearance rate was 41% (9/22) in the DHA group vs. 0% (0/6) in the placebo group. Although the results show a trend toward the superiority of diclofenac, due to the very small sample size especially in the vehicle-treated group, short follow-up time, and risk of bias and imprecision, the results are not statistically significant. Side effects included mild erythema and mild to moderate swelling of treatment areas. No graft rejections were detected. In 55% of the previously cleared patients, new AKs developed in the treatment area after an average of 9.3 months. No patients developed invasive SCC within 24 months of follow-up (2b) [74].

One double-blinded, placebo-controlled study compared the efficacy of monotherapy of 0.02% tretinoin cream to a combination of 0.02% tretinoin and calcipotriol and calcipotriol and emollient in 13 adult renal transplant recipients with multiple AKs. Each patient applied the following regimens to four comparable and distinct areas of actinic keratoses on the extremities for 6 weeks: (i) calcipotriol cream 50 μg g^{-1} twice daily; (ii) 0.02% tretinoin cream twice daily; (iii) the combination of calcipotriol and tretinoin cream once daily; and (iv) cremor cetomacrogolis twice daily. The study demonstrated no significant differences in clinical, histological, and immunohistochemical parameters between the four different therapies during a 6-week treatment period (2b) [75].

Due to the high toxicity of high-dose systemic retinoid, Rook compared topical tretinoin alone with the combination of topical tretinoin and the low dose systemic retinoid, etretinate (10 mg) in renal transplant patients. Although results showed more improvement of AKs with the combination regimen, the effectiveness regarding the combination of oral and topical retinoids, versus topical retinoids, is difficult to establish in this clinical trial due to the small number of patients ($N = 11$), the high dropout rate during the study ($N = 4$), the short follow-up period, and the lack of a standard concentration for the topical retinoids in both groups (1b) [76]. Systemic retinoids have been used in the secondary prevention of AKs in renal transplant recipients. A 12-month study found that low-dose acitretin therapy (20 mg daily) is safe, well tolerated, and partially effective in chemoprophylaxis of non-melanoma skin cancer (1b) [77].

Conclusions

Several effective treatment modalities exist for the treatment of AKs. By understanding the different treatment options, physicians may tailor therapy to each patient's needs. Certain factors physicians need to consider when selecting a therapy include the number of AK lesions, the amount of background photodamage, the patient's tolerance to known side effects, and the cosmetic appearance.

An initial RCT by Thompson et al. demonstrated that the regular use of sunscreens not only prevents the development of AKs but also hastens the remission of existing ones and, by implication, possibly reduces the risk of skin cancer in the long term. Several other RCTs and case control studies confirm that sunscreen provides pro-

tection against AKs both in the general population and in high-risk patients [16, 72, 78]. One longer and larger RCT showed that daily sunscreen use reduces the incidence of SCC yet had no effect on BCC. Healthcare providers should continue to recommend sunscreen use in addition to other solar protection methods to reduce the risk of skin cancer.

Cryotherapy lacks rigorous studies investigating the efficacy for treatment of AKs. There are no RCTs comparing cryotherapy to placebo. Non-standardized freezing techniques make it difficult to interpret results. Cryotherapy is generally recommended for single AK lesions and multiple discrete lesions in immunocompetent and immunosuppressed patients. Cryotherapy is not recommended for the treatment of field cancerization. A prospective study showed a 57% complete clearance rate at 3-month follow-up, with the best clearance rates in patients treated with freeze cycles of 20 s or more [18]. A randomized trial comparing cryotherapy to 5-FU and imiquimod revealed that cryotherapy had the poorest initial clinical clearance at 6–8 weeks after treatment of multiple AKs, as well as the worst histological clearance rates and sustained clearance rates [20].

Chemical peels for AKs have the least rigorous studies to support its use. Most of the literature regarding chemical peels comprises case series or cohort studies, with small sample sizes of 16 patients or less. Only one study evaluated patients 1 year later and found a 78% reduction in mean AK count by 12 months. AK counts increased between 12 and 32 months, requiring regular follow-up in patients with AKs.

There are several RCTs and meta-analyses evaluating the efficacy of 5-FU for treatment of AKs, but dosing, follow-up, and cream strength vary between studies. In one RCT, 5-FU had the highest initial clearance (96%) of lesions 6–8 weeks after therapy completion, although a 12-month follow-up showed a sustained clearance rate for individual lesions of only 54% [20]. A meta-analysis of 6 RCTs concluded that overall complete clearance rate with varying strengths of 5-FU was 52.2%. Superior clearance rates were found when 5-FU was applied twice daily for 2–4 weeks as compared to pulse therapy, and 5% 5-FU was more effective than 0.5% [33]. Most studies only have short-term follow-up, and retreatment is recommended since lesions tend to recur by 1 year in studies with longer length of follow-up.

Imiquimod has several rigorous blinded, randomized-controlled trials investigating its efficacy for AKs. Application of 5% imiquimod shows optimal results with 3 times weekly application for 12–16 weeks. A meta-analysis reported 50% complete clearance rates for imiquimod with this regimen; however recurrence rates of at least 25% have been observed when patients were followed up to 16 months [38]. Although complete clearance rates may be lower, a regimen of imiquimod once daily for two 2-week treatment cycles separated by a 2-week treatment-free interval is often utilized [40]. Finally, imiquimod is one of the few modalities tested in organ transplant recipients and there is a complete clearance of 62% at 8-week follow-up [69].

A few RCTs have evaluated the efficacy of diclofenac, and twice-daily application for 2–3 months results in a complete clearance rate of approximately 35%. Diclofenac has been directly compared to imiquimod in two studies, but in both studies optimal dosing regimens were not evaluated. It is difficult to make comparison conclusions from these studies but both diclofenac and imiquimod appear to have efficacy [48, 49].

Ingenol mebutate has the advantage of having a short treatment course as compared to other topical therapies, potentially enhancing adherence. Recommended therapy includes a 3-day course of 0.015% gel for the face and scalp and a 2-day course of the 0.05% gel for the trunk and extremities. There are less RCTs, but complete clearance rate from one large study appears to be around 42% [53]. In one study, sustained clearance after 12-month follow-up was around 45% for the head, trunk, and extremities [54].

While previously described topical therapies for AKs have a consistent proven efficacy compared to placebo, studies for retinoids have variable results. Several small studies found reductions in AKs with topical retinoid use, but the largest study in a peer-reviewed journal of over 1000

patients found tretinoin cream to be ineffective in reducing AKs [66]. With several efficacious treatments available for AKs, retinoids should not be considered a first line therapy.

Because of the potential transition of AKs to cancerous lesions, treatment of AKs is an important component in skin cancer prevention. This is especially true for the transplant population. Several therapies are available for treatment with proven efficacy, but more head-to-head comparisons are needed to determine the best AK treatment strategies. New therapies and combinations of therapies will also likely change the way we treat AKs in the future.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
Sunscreen is an effective preventive measure against AKs	A
Cryotherapy is an effective spot treatment for clinically visible AKs, and longer freeze cycles improve efficacy	A
Chemical peels are an effective field treatment for AKs	C
5% 5-FU is an effective field treatment for clinically visible and invisible AKs when applied twice daily for 2–4 weeks; significant side effects may occur	A
0.5% 5-FU is an effective field treatment for clinically visible and invisible AKs when applied once daily to the face or scalp for either 1, 2, or 4 weeks	A
Application of 5% 5-FU twice daily for 3 weeks has superior efficacy than pulse therapy (twice daily for 1 day per week for 12 weeks) for field treatment	B
Combination 0.5% 5-FU + 10% salicylic acid is more effective in AK lesion clearance at 20 weeks compared to diclofenac HA or vehicle twice daily for 12 weeks; more cutaneous side effects occur with 5-FU/SA compared to diclofenac HA	B
Application of 0.5% 5-FU/10%SA once daily achieved greater histological clearance and lower recurrence rates of multiple hyperkeratotic AKs at day 98 compared to cryotherapy treatments 3 weeks apart	C
Imiquimod 5% is an effective field treatment for clinically visible and invisible AKs when applied 3 times weekly for 12–16 weeks	A
Significant side effects may occur and subsequently decrease tolerability and adherence when imiquimod 5% is applied more than 3 times weekly	B
Imiquimod 2.5% and 3.75% creams are both effective field treatment for clinically visible and invisible AKs of the face/scalp when applied once daily for two 2-week treatment cycles separated by a 2-week treatment-free interval and well tolerated; no statistically significant difference in lesion reduction between imiquimod strengths	B
3% diclofenac in 2.5% sodium hyaluronate gel is an effective field treatment for clinically visible and invisible AKs when applied twice daily for 12 weeks; follow-up longer than 30 days is lacking	B
Ingenol mebutate is an effective field treatment for clinically visible and invisible AKs when 0.015% gel is applied to the face/scalp once daily for 3 days or 0.05% gel is applied to the trunk/extremities once daily for 2 days	A
Combination therapy with cryotherapy followed 3 weeks later by ingenol mebutate gel 0.015% once daily for 3 consecutive days is an effective treatment for multiple AK lesions on the face/scalp up to 12 months	B
Topical tretinoin 0.05% is an effective treatment for facial AKs when applied once or twice daily for 6 months; blind, randomized, and controlled clinical trials with adequate sample sizes are lacking	B
Sunscreen is an effective preventive measure for immunocompromised organ transplant recipients	C
Imiquimod 5% cream 3 times weekly is an effective field treatment for clinically visible and invisible AKs in immunocompromised organ transplant recipients	B
Treatment with topical diclofenac 3% gel or topical retinoids in immunocompromised patients cannot be established; blind, randomized, and controlled clinical trials with adequate sample sizes are lacking	C

Self-Assessment Questions

1. In one study evaluating AKs in patients who did and did not use sunscreen, what was the percent reduction in AKs after 7 months?
   (a) 25%
   (b) 18%
   (c) 10%
   (d) 5%
   (e) 1%

2. In one study evaluating cryotherapy for complete clearance of AKs, how many seconds were necessary to achieve a complete clearance rate of 83%?
   (a) 3 s
   (b) 5 s
   (c) 10 s
   (d) 20 s

3. Twice daily application of 5-FU for 2–4 weeks shows increased AK clearance rates when compared to pulse therapy.
   (a) True
   (b) False

4. AK recurrence rates are equivalent when using imiquimod 5% cream twice weekly compared to 3 times weekly.
   (a) True
   (b) False

5. What is the recommended dosing regimen for ingenol mebutate of the face and scalp?
   (a) 0.015% gel for once daily for 2 days
   (b) 0.015% gel for once daily for 3 days
   (c) 0.015% gel once daily for 1 week
   (d) 0.05% gel once daily for 2 days
   (e) 0.05% gel once daily for 3 days

6. What is the mechanism of action for diclofenac?
   (a) Pyrimidine analog that interferes with DNA synthesis by stopping the conversion of deoxyuradilic acid to thymidylic acid
   (b) Glycosaminoglycan with inflammation-modulating and bioadhesive properties
   (c) Selective cyclooxygenase-2 (COX-2) inhibitor that inhibits the arachidonic acid cascade
   (d) Vitamin A derivative that regulates the differentiation and growth of keratinocytes, reduces the regulation of proto-oncogenes, and increases the expression of p53
   (e) Diterpene ester from the sap of the medicinal *Euphorbia peplus* plant that causes disruption of mitochondrial and cell membranes and results in a neutrophil-mediated antibody-dependent cellular cytotoxic pathway

Correct Answers

1. a: 25%
2. d: 20 s
3. a: true
4. b: false
5. b: 0. 015% gel for once daily for 3 days
6. c: selective cyclooxygenase-2 (COX-2) inhibitor that inhibits the arachidonic acid cascade

Basal Cell Carcinoma

42

Elise Ng, Joanna Dong, and Desiree Ratner

Abstract

The incidence of basal cell carcinoma (BCC) is increasing, and it is therefore important to be able to assess the comparative effectiveness of common treatments. While quality randomized controlled trials are generally lacking, there are systematic reviews comparing treatment modalities using randomized and nonrandomized data. Excision and Mohs micrographic surgery exhibit the lowest recurrence rates and are the putative first-line therapies in treating operable BCC in most patients. Randomized trials have also compared recurrence rates of excision with those of cryotherapy, radiation therapy, and nonsurgical treatment, as well as the comparative efficacy of nonsurgical treatment modalities, including photodynamic therapy and topical therapies. Selection of the appropriate treatment for any given BCC is based on evaluation of patient characteristics and co-morbidities, tumor characteristics such as histology, location, size, and primary or recurrent status, and patient preference. Cost, cosmesis, and safety must also be taken into consideration. An evidence-based summary based on Grading of Recommendations Assessment, Development and Evaluation (GRADE) is provided to assist in the decision-making process.

Epidemiology

Basal cell carcinoma (BCC) is the most common malignancy in the USA. The exact national incidence is unknown given the lack of national surveillance of nonmelanoma skin cancers (NMSCs). Further, epidemiological projections using insurance claims typically group BCC with other epithelial tumors, including squamous cell carcinoma (SCC). The most recent peer-reviewed analyses of incidence rates in 2012 estimate 2–3 million Americans with BCC annually [1–3]. While BCC has historically been thought to account for 75% of all NMSC, there is evidence of a shift toward a decreased BCC to SCC ratio

[2, 4]. This trend may be due to biases toward Medicare-based patient sampling in these epidemiology studies, given that SCC is increasingly prevalent in older age groups and BCC remains more common in younger age groups [5]. The change in incidence rates of NMSC over the last 20 years has been variably reported as one that has increased by 17–200%, depending on the population cohort [1, 2, 6, 7]. In 1994, an estimated 750,000 cases of BCC occurred in the USA, suggesting an over twofold increase in BCC incidence rates since then [8]. One systematic review reports an average rate of increase in incidence of 2% annually, with the highest rates in the USA occurring in the states closest to the equator [9]. The worldwide incidence of BCC follows the same trend. In an analysis of comparable national surveys of primarily Caucasian populations, Australia exhibited the highest BCC rates in the world, compared to lower rates found in European countries such as England, Scotland, and Croatia [9].

Chronic sun exposure, both UV-A and UV-B, is the predominant risk factor for developing BCCs. Heavy exposure in the childhood to adolescent years (ages 0–19 years) leads to latent onset of BCCs in adulthood [10]. The cumulative effect, timing, and location of exposure are complex variables contributing to this increased risk [11]. Exposure to iatrogenic UV-A, with or without psoralen use, UV-B, and ionizing radiation, especially before the age of 20, increases the risk of developing BCCs in the original treatment field [12–14]. Other independent risk factors are those that confer greater susceptibility to damage by UV or ionizing radiation: Fitzpatrick skin types I and II, light hair and eyes, genodermatoses (Gorlin syndrome, Rombo syndrome, xeroderma pigmentosum), arsenic exposure, and immunosuppressed states [15–18]. While the average age of diagnosis is 65, the risk steadily increases with age. Notably however incidence rates among young adults less than 40 years of age have increased over the last several years [5]. BCC is more common in men than women, with a ratio of approximately 1.5:1 [6].

Treatment Overview

Various surgical and nonsurgical treatment modalities exist for the treatment of localized BCC. Surgical methods consist primarily of standard excision with post-operative margin assessment, Mohs micrographic surgery (MMS), and electrodesiccation and curettage (ED&C). Nonsurgical options include radiation therapy (RT), cryosurgery, photodynamic therapy (PDT), and topical medications such as imiquimod and 5-fluorouracil (5-FU) cream. For more advanced BCC, the newly developed sonic hedgehog pathway inhibitors, vismodegib and sonidegib, offer a systemic therapeutic option.

Surgical approaches represent the most effective means of curative treatment and are the mainstay of treatment for localized BCC. Standard excision entails surgical removal of the lesion with appropriate surgical margins to the level of the subcutaneous fat. Curettage may be performed prior to excision to delineate the true borders of the tumor more accurately. Microscopic evaluation of the margins is performed post-operatively using traditional permanently fixed vertically oriented sections. Closure of the defect following standard excision utilizes methods that do not shift or alter orientation of the surrounding tissue in the event of a positive margin. Standard excision is typically performed for lesions on the trunk and extremities, where tissue conservation is not of paramount importance.

MMS entails serial excision of tissue layers with interval intraoperative margin evaluation that is performed until negative margins are achieved. Curettage is performed prior to excision by some surgeons. Tissue layers are processed using fresh-frozen tissue processing and oriented horizontally in a manner that allows for complete evaluation of the peripheral and deep margins. Serial excision of tissue layers allows for maximum tissue preservation, while the ability to confirm negative margins prior to closure enables the surgeon to undertake more complex repairs on the same operative day. Given these advantages, MMS is generally considered the

preferred technique for lesions located in cosmetically sensitive anatomic locations.

ED&C is a destructive technique in which tumor tissue is bluntly removed by scraping with a curette to the level of firm, normal dermis, followed by denaturation of the area using electrodesiccation. Three cycles of this process are typically performed. As the technique relies on destruction, one major disadvantage is the lack of histologic margin assessment [19]. ED&C is usually considered for small, low-risk lesions located in non-cosmetically sensitive areas or areas in which wound healing may be difficult. It should not be used for high-risk tumors or in areas with terminal hair growth due to the risk of tumor extension down follicular structures **(5)** [20].

Nonsurgical treatments such as RT and cryosurgery represent destructive treatment modalities. Radiation therapy is administered using varying dosage and fractionation schedules depending on the tumor characteristics and duration of treatment. Cryosurgery involves destruction of tumor tissue through exposure to extreme cold using liquid nitrogen, which is capable of freezing tissue to −50 to −60°C. A range of techniques, such as open and closed spray, can be applied, but there is no consensus regarding the optimal number of freeze-thaw cycles **(4)** [21]. Both RT and cryosurgery are generally reserved for patients who cannot tolerate surgery or for whom surgery is impractical, as both carry the drawback of poorer cosmetic outcomes compared to other treatments. RT is also used as an adjunctive modality post-operatively to reduce the risk of recurrence in high-risk patients. Importantly, RT should be avoided in patients with conditions predisposing to cutaneous malignancy and younger patients for whom long term adverse effects are a consideration [20].

Photodynamic therapy (PDT) involves the application of a photosensitizing agent, usually aminolevulinic acid (ALA) or methyl aminolevulinate (MAL), to the skin followed by exposure to visible light. This activates the photosensitizer, leading to photochemical reactions that generate reactive oxygen species and free radicals that cause cell death. Rapidly proliferating cells are selectively targeted, resulting in destruction of malignant cells. Treatment of BCC requires a red light source operating in the 630-nm range for sufficient penetration. A standardized protocol of two treatment sessions spaced 1 week apart is typically used for MAL-PDT, but treatment schedules with ALA-PDT are less well established [22].

Imiquimod 5% cream is a topical immune response modifier that is FDA-approved for the treatment of primary superficial BCCs not larger than 2 cm in diameter. The current recommended treatment regimen in the USA and Europe is application to the tumor and a 1-cm margin surrounding it five times per week for 6 weeks [23]. Topical 5-FU 5% cream and solution are approved for the treatment of superficial BCC smaller than 2 cm in diameter. This medication is applied twice daily for at least 3–6 weeks to the lesional skin **(2c)** [24]. As with RT and cryosurgery, PDT and topical therapy are reserved for nonsurgical candidates.

Vismodegib and sonidegib belong to a new class of molecules known as sonic hedgehog pathway inhibitors. They block the hedgehog signaling pathway through inhibition of the smoothened receptor. Both are oral medications that are primarily used for the treatment of locally advanced BCC not amenable to surgery or metastatic BCC. Patients with nevoid BCC syndrome who have a high number or incidence of tumors are also candidates for these medications.

Few studies have examined the relative frequency of use for each treatment modality. Available information is based on data for NMSC as a group, not BCC exclusively. In two studies using claims data, standard excision was found to be utilized most frequently, accounting for 35–76% of cases, followed by ED&C, which accounted for 14–32% of cases **(2c, 2c)** [25, 26]. The use of MMS comprises approximately 10% of all cases, but has been on the rise, increasing from 3% in 1995 to 17% in 2010 **(2c)** [27]. Its use has been noted to be as high as 39% in certain areas and settings **(1b)** [28].

Effectiveness of Treatments

Effectiveness of BCC treatment is ascertained by tumor recurrence rate (RR). In early studies of older treatment methods, reported recurrence rates varied widely, in part due to differences in the duration of follow-up. As it became apparent that only 50% of BCCs recur within the first 2 years, with this figure increasing to 82% by 5 years **(2a-)** [29], studies evaluating the efficacy of BCC treatment focused on 5-year recurrence rates (RRs) as the barometer for efficacy. Unfortunately, comparisons between most studies on treatments for BCC are difficult due to differences in patient population, tumor characteristics, technique, study design, and outcome measures.

Excision

Excision is an effective method for treatment of BCC and is considered the standard of care for low-risk lesions in non-cosmetically sensitive areas. Five-year recurrence rates among recent studies range from 3.2% to 8.5% **(2a-, 1b-)** [30, 31]. These rates are lower for lesions on the neck, trunk, or extremities, but are higher for lesions on the face, particularly those greater than 6 mm in diameter, as well as recurrent lesions **(2b, 2b)** [32, 33].

The first systematic review to investigate 5-year RR for standard excision pooled 40 years of data from studies starting in 1947, and found 5-year RR ranging from 1.2% to 23.4%, with a weighted average of 10.1%, for primary BCC, and ranging from 5.0% to 20.2%, with a weighted average of 17.4% for recurrent BCC [29]. However, it should be noted that this analysis included studies from the 1950s, when surgical techniques were not as well developed and standard margins had not been established. It was not until 1987 that Wolf and Zitelli demonstrated that a minimum margin of 4 mm is required to achieve pathologic clearance in 95% of cases of small, well-defined BCC **(2b)** [34].

A subsequent systematic review of all studies between 1970 and 1997 calculated a mean 5-year RR of 5.3% [30], with rates ranging from 3.2% to 8.0% among individual studies. More recent studies have shown similarly variable results. Trials comparing surgical excision using 3-mm margins with curettage-cryosurgery and PDT found a 5-year RR of 8.5% [31] and 1-year RR of 0% **(1b)** [35], respectively. Another comparing surgical excision using 4-mm margins with topical imiquimod found a 3-year clinical cure rate of 98% (**1b**) [36]. A large, randomized trial enrolling 408 high-risk facial lesions reported a cumulative 10-year RR of 12.2% for primary BCC and 13.5% for recurrent BCC after standard excision using 3-mm margins [33].

Curettage prior to excision has been advocated as a strategy to help delineate tumor margins and increase cure rates. One retrospective study of 403 BCCs found that microscopic tumor remained at the margins after curettage in only 14% of specimens, the majority being of morpheaform subtype (**2b**) [37]. Another study of 1983 BCCs found that performing pre-operative curettage was associated with a 26% decrease in surgical failure rate (**3b**) [38].

Electrodesiccation and Curettage

Electrodesiccation and curettage (ED&C) has a long history of use for the treatment of basal cell carcinoma. Early studies in the 1960s and 1970s initially reported very high cure rates of 98–100%, but these were subsequently criticized because of selection bias and lack of adequate follow-up [19]. There is a paucity of recent studies on ED&C, and those with 5-year follow-up data have shown less consistent results. Data also suggest that the efficacy of ED&C may vary based on tumor characteristics and location. Five-year cure rates for primary BCCs have been shown to be as high as 96% (**2b, 2b**) [39, 40] for superficial and nodular subtypes even with curettage alone [39] but as low as 73% when used to treat histologically aggressive tumors (**2b**) [41] and 60–66% for recurrent BCC (**2b, 2b**) [42, 43].

Two systematic reviews have analyzed the literature on ED&C for treatment of BCC. Cure rates from a systematic review of eight studies published between 1963 and 1985 calculated a

weighted average 5-year RR of 7.7% for primary BCC, which rose to 40% for recurrent BCC [29]. Another review of four studies between 1970 and 1997 found 5-year RRs ranging from 5.7% to 18.8% [30].

Multiple studies have shown that efficacy varies with lesion size and anatomic site. In a retrospective review of 2314 primary BCCs treated between 1955 and 1982, the overall RR was found to be 13.2% for primary BCC and 18.1% for recurrent BCC. However, when these tumors were further stratified, the 5-year RR dropped to 3.3% for BCCs located in low-risk sites (neck, trunk, and extremities) regardless of lesion size. For medium-risk sites (scalp, forehead, pre- and post-auricular, and malar areas), tumors less than 10 mm had a 5-year RR of 5.3%, while those 10 mm or larger had a RR of 22.7%. For high-risk sites (nose, paranasal, nasolabial groove, ear, chin, mandibular, perioral, and periocular areas), the 5-year RR was only 4.5% for tumors smaller than 6 mm in diameter, but 17.6% for those 6 mm or larger. Based on these results, the authors concluded that ED&C was effective for BCCs measuring less than 6 mm in diameter and those located on low-risk sites [42].

Julian et al. similarly found a high recurrence rate of approximately 20% in their prospective study of 405 BCCs, of which 60% had a superficial histologic pattern and 71% were located on the head and neck **(1b)** [44]. Consistent with this, a non-randomized, clinical trial of 257 primary BCCs in medium- and high-risk facial sites calculated a worst-case scenario—5-year RR of 20.6% **(2b)** [45]. A recent retrospective study from 2016 found a favorable overall recurrence rate of 6% among 106 tumors treated by a single physician. Of the recurrent tumors, however, 83% were located in high-risk "H-zone" areas (nasolabial fold, nasal alae, orbital area, and auricular area) **(2b)** [46].

An aggressive histologic growth pattern is another factor that has been shown to correlate with a higher treatment failure rate. In a retrospective review of 302 BCCs treated with curettage alone, 85% of which were of the nodular or superficial subtype, Barlow et al. found a favorable 5-year cure rate of 96% [39]. In contrast, a population-based, retrospective study from 2013 that included only tumors with high-risk histology found a 5-year cure rate of only 73% [41].

Operator skill has also been implicated in efficacy of ED&C. One of the earliest studies to examine 5-year RRs following ED&C for treatment of primary BCC was published by Kopf et al. in 1977. This study found that tumors treated by attending physicians had a 5-year RR of 5.7% compared to 18.8% for those treated by inexperienced residents [43].

Mohs Micrographic Surgery

Mohs micrographic surgery (MMS) has been shown to provide the highest cure rates for BCC and is considered the preferred method for high-risk and/or recurrent tumors.

Two systematic reviews from 1989 demonstrated 5-year RRs of 1.0% for primary BCC and 5.6% for recurrent BCC **(2a-)** [29, 47]. Subsequent large studies have confirmed low RRs, generally ranging from 1% to 3% for primary BCC and 4–7% for recurrent BCC **(2b, 2b, 2b, 2b)** [48–51]. In a retrospective study of 720 BCCs treated in the Netherlands between 1992 and 1999, the 5-year RR was 3.2% for primary and 6.7% for recurrent BCC [51]. The largest, prospective, multicenter study on MMS for the treatment of BCC was conducted in Australia and followed 3370 patients for 5 years between 1993 and 2002. This study found 5-year RRs of 1.4% for primary and 4% for recurrent BCCs [49]. Only two randomized, clinical trials involving MMS have been performed, both comparing it to standard excision, and these reported similar results **(2b, 2b)** [52, 53].

Recurrence rates following MMS are low even when patient selection leads to samples enriched for high-risk tumors. A prospective study conducted in the UK of 228 BCCs selected for MMS based on cosmetically sensitive or high-risk location, indistinct borders, or recurrent nature found a 5-year RR of 1.7% for primary and 4.8% for recurrent BCCs [48]. The highest rates of recurrence with MMS were found in a retrospective study of 228 BCCs treated between

1983 and 1992 in Sweden, a country with very limited access to the technique that referred less than 1% of patients for MMS at the time. In this study, all tumors had aggressive histology and the vast majority of tumors were located on the face. The authors found 5-year RRs of 6.5% for primary tumors and 10% for recurrent tumors **(2b)** [54]. A follow-up study that reviewed 587 BCCs treated at the same institution between 1993 and 2003, however, found lower 5-year RRs of 2.1% for primary tumors and 5.2% for recurrent tumors, possibly attributable to improved experience and technique [50].

Risk factors for recurrence following MMS include aggressive histopathologic subtype, prior recurrence, and higher number of stages required for clearance [49, 51]. Patients with CLL have also been shown to be at an increased risk for recurrence. A case control study of 24 patients with CLL for 33 BCCs found a 22% rate of recurrence at 5 years, which was 14 times greater than that of controls **(3b)** [55].

Curettage has been suggested as a useful technique to help delineate margins prior to surgery and increase efficacy. One prospective evaluation of 599 BCCs found that curettage significantly reduces the number of Mohs surgical stages required for BCC clearance **(2b)** [56]. Similar findings were confirmed in a study of 16 BCCs in which histologic evidence of tumor at pre- and post-curettage margins was evaluated **(2b)** [57]. Another prospective, randomized study on the subject found that curettage led to larger final wound sizes and decreased the number of stages required for clearance compared to controls but that this did not change the type of repair that was performed **(1b)** [58].

Cryosurgery

Cryosurgery has primarily been studied for the treatment of low-risk tumors, such as those with well-defined borders, that measure 2 cm or less, or have nodular or superficial histology. A wide range of recurrence rates have been reported, however, and direct comparison between studies is difficult due to variations in technique, including freeze time, number of freeze cycles, margin of normal skin included in the treatment area, and use of pre-procedure curettage [21, 59]. Additionally, most studies were performed more than 15 years ago, and many have short follow-up periods or provide limited details regarding the number of patients achieving 5 years of follow-up time.

Systematic reviews from 1989 and 1999 show recurrence rates from 0% to 7.5% among studies with at least 5 years of follow-up, and mean recurrence rates from pooled analyses range from 3% to 4% [29, 30]. More recent prospective studies have found highly variable rates ranging from 4.5% to 20.6%. A 4.5% recurrence rate was found in a prospective, randomized study that examined the efficacy of one freeze-thaw cycle for the treatment of truncal superficial BCC [60]. In the same study, the authors compared the efficacy of a double freeze-thaw cycle to a single freeze-thaw cycle for 84 facial BCCs and found a 4.7% recurrence rate for the former compared to 20.6% for the latter. Mean time to recurrence was 18 months and the shortest follow-up time was 10 months **(2b)**. In another prospective study of 88 BCCs, in which follow-up time was limited to 1 year, the clinical and histologic recurrence rates were 13% and 15%, respectively **(1b)** [61].

The highest recurrence rate was reported in 1986 by Hall et al., who found that 39% of 44 tumors recurred within 2 years of treatment despite the use of two freeze cycles. It is important to note, however, that at the time of this study, it was standard practice to use treatment temperatures between −25°C and −30°C, which were later realized to be suboptimal **(1b)** [62]. New temperature standards of −50 to −60°C were not adopted until the mid-1980s when research showed that such temperatures were required for destruction of cutaneous cancers [21]. The lowest recurrence rate has been reported by a single provider, who found a 5-year cure rate of 99.0% among 552 cases in a retrospective review. While this may be attributable to operator skill and more aggressive technique, it should also be noted that details regarding outcome assessment and the proportion of patients presenting for 5-year follow-up in this study are unclear [21].

Radiation Therapy

Studies on the use of radiation therapy for the treatment of BCC have utilized various treatment schedules. The 5-year RR for radiation therapy has generally been found to exceed 5%. Two meta-analyses reported recurrence rates of 7.4–8.7% for primary BCC and 9.5% for recurrent BCC **(2b)** [29, 63]. Retrospective studies have found 5-year RRs ranging from 4% to 16% (**2b, 2b, 2b, 2b, 2b, 2b)** [64–69].

A prospective study from over 20 years ago that employed superficial x-rays found a recurrence rate of 4% at 2 years [62]. A more recent study that investigated various forms of radiation therapy, including brachytherapy, contact therapy, and conventional radiotherapy, found an overall 4-year failure rate of 7.5% **(1b)** [70].

Predictors for BCC recurrence after radiation therapy include tumor size and stage and morpheaform subtype. Tumor size greater than 10 mm has been found to correlate with increased rates of recurrence [63, 65, 68]; in one study, size greater than 20 mm was associated with a lower response rate [69]. More advanced tumors similarly tend to demonstrate a poor response to RT, with recurrence rates as high as 56% for Stage III and IV tumors [64, 65]. In a retrospective study of 175 BCCs, morpheaform histology was associated with a 5-year RR of 27% compared to 8.2% for those with nodular histology [67].

Imiquimod

The overall efficacy of imiquimod 5% cream has been well-studied for the treatment of superficial BCC. Several large, randomized, double-blind, vehicle-controlled studies have shown complete histologic clearance rates of 79–88% with an application regimen of once daily for 6 weeks, with rest periods as needed. Post-treatment excision specimens obtained 6–12 weeks after treatment were used for histologic evaluation in these studies (**1b, 1b, 1b)** [71–73]. Two prospective trials examining long-term clinical clearance rates with daily application reported 5-year and 3-year disease-free rates of 80.4% and 84%, respectively (**1b-)** [36, 74]. A meta-analysis of 23 studies on imiquimod for superficial BCC calculated a pooled estimate of 87.3% for tumor-free survival at 1 year (**2a-)** [75]. Tumor thickness greater than 0.40 mm has been associated with a higher recurrence rate **(3b)** [76], while occlusion has not been shown to enhance efficacy **(1b)** [77].

The relative efficacy of various dosing regimens has also been investigated. Complete clearance rates as high as 100% have been reported with twice-daily application, but this regimen has been associated with an unacceptably high rate of adverse effects **(1b)** [78]. Less frequent application results in lower histologic clearance rates of 80–82% for five times per week [71, 72, 78] and 52–76% for three times per week application [71, 77, 78]. Two phase 3, randomized, vehicle-controlled trials demonstrated similar histologic cure rates after five and seven times per week application, prompting a regimen of five times per week to become the FDA-approved dosage [72].

The efficacy of imiquimod 5% cream for nodular BCC has not been as well established. There is some evidence that it may be effective with daily use for 12 weeks. A large, randomized trial comparing standard excision with topical imiquimod found an 81.8% clinical clearance rate at 3 years among 99 nodular BCCs that were enrolled [36]. A smaller study using the same regimen found a 76% histologic clearance rate among 21 patients [79]. Studies utilizing less frequent dosing regimens, however, have shown inferior results for nodular BCC. One multicenter, randomized study employing an application regimen of three times per week for 6 weeks found imiquimod 5% cream to be less effective for nodular BCC compared to superficial BCC, with histologic response rates of 50% and 76%, respectively [77]. Application regimens of twice daily three times per week for 6 weeks **(1b)** [79] and once daily three times weekly for 8–12 weeks **(1b)** [80] have been associated with histologic clearance rates of 42% among 31 patients and 64% among 90 patients, respectively.

The evidence does not support the use of imiquimod for morpheaform BCC. Only one study has included tumors with infiltrative histology. Among

the 13 tumors in this study, a clearance rate of 62% was observed for three times weekly application for 8 weeks and 56% for five times weekly application for 5 weeks **(2b)** [81]. Cure rates lower than those for superficial and nodular BCCs would be predicted given the increased depth and aggressive histologic growth pattern of these tumors, as well as the likelihood of insufficient penetration of this medication.

Photodynamic Therapy

Numerous studies have investigated the efficacy of photodynamic therapy (PDT) for the treatment of primary and nodular BCC. Both aminolevulinic acid (ALA) and methyl aminolevulinate (MAL) PDT have been shown to be effective. A meta-analysis of 13 studies on ALA- or MAL-PDT for the treatment of superficial BCC estimated a tumor-free survival of 84.0% at 1 year [75]. Comparison of results between individual studies is difficult, however, owing to lack of uniformity in treatment regimens, assessment of clearance, and length of follow-up.

Two randomized controlled trials studied MAL-PDT for primary superficial BCC and demonstrated clearance rates as high as 92–97% at 3 months, but recurrence rates were 9% at 12 months and 22% at 5 years **(1b)** [35, 82]. Other prospective studies have similarly demonstrated high short-term clearance rates of 87–93%, but subsequent recurrence rates as high as 18–24% at 24 months **(2b, 2b)** [83, 84]. With longer follow-up, PDT has been associated with 3-year tumor-free survival as low as 58.0% **(1b)** [85]. MAL-PDT has also been studied for nodular BCC. A randomized controlled trial showed a 91% clearance rate at 3 months, but an estimated complete response rate of 76% at 5 years **(1b, 2b)** [86, 87]. Another reported a complete histologic response rate of only 73%, although this was higher, at 89%, for facial lesions **(2b)** [88].

In a review of 12 studies on ALA-PDT, Peng et al. calculated an average complete clearance rate of 87% for superficial BCC versus 53% for nodular BCC [89]. A subsequent prospective, randomized trial that included both superficial and nodular BCCs found an overall 1-year histologic recurrence rate of 25% [61]. A longitudinal study with 10-year follow-up that included BCCs of all subtypes found an overall complete response rate of 75%, with a higher rate of 87% seen among those receiving two treatment sessions **(2b)** [90].

Several studies have observed lower cure rates for nodular BCC compared to superficial BCC following PDT **(2b, 2b)** [83, 84, 91, 92]. Response rates as low as 33% have been observed, though this may be partially attributable to the absence of pre-procedure debulking in this study [91]. Recurrent tumors also fare poorly, with cure rates as low as 40–63% **(4)** [90, 93]. Other factors associated with treatment failure and recurrence include ulceration, tumor thickness, and location on the limbs [91]. Recurrence following PDT generally occurs within the first 3 years after treatment [82, 87, 90]. A higher number of treatment cycles [75], fractionated delivery of PDT **(1b)** [94, 95], and the practice of deep curettage **(4)** [96] may improve treatment response.

5-Fluorouracil

There are few studies on the use of 5-fluorouracil 5% cream for the treatment of BCC, and it has only been studied for superficial BCC. FDA approval was obtained based on an unpublished study of 113 superficial BCC lesions that demonstrated a 93% clearance rate. A subsequent study of 31 tumors on the trunk and limbs found a histologic cure rate of 90% with twice-daily application up to 12 weeks **(2b)** [97]. Of note, the mean time to clinical cure was 11 weeks, substantially longer than the FDA treatment recommendation of 3–6 weeks. The only study evaluating long-term efficacy was a comparative prospective trial of 5-fluorouracil, photodynamic therapy, and imiquimod. This found a 3-year tumor-free survival of 68.2% for 5-fluorouracil, though this study used a shorter application regimen of twice weekly for 4 weeks [85].

Hedgehog Pathway Inhibitors

The effectiveness of the hedgehog pathway inhibitors in treating BCC is supported by well-designed, large-scale clinical trials. The efficacy of vismodegib for the treatment of locally advanced BCC (laBCC) and metastatic BCC (mBCC) was first established in the pivotal ERIVANCE trial, in which patients were treated with oral vismodegib of 150 mg daily **(2b)** [98]. At 18 months of follow-up, the overall objective response rates were 47.6% for laBCC and 33.3% for mBCC; 22.2% of patients achieving complete responses was observed in the former group, but none were seen in the latter. The mean duration of response was 9.5 months for laBCC and 7.6 months for mBCC, while median progression free survival was 9.5 months for both. Disease control was obtained in 83% of laBCC and 94% of mBCC patients **(2b)** [99]. Subsequent phase 2 trials have demonstrated similar response rates ranging from 46.4% to 66.7% for laBCC and 31–37.9% for mBCC **(2b, 2b)** [100, 101].

Vismodegib has also been studied for the prevention of BCC in patients with basal cell nevus syndrome. A prospective study of 41 patients found that vismodegib significantly reduced the rate of development of new operable BCC lesions compared to placebo as well as the number of existing surgically eligible tumors **(1b, 1b)** [102, 103].

The efficacy of sonidegib was established more recently in the multicenter, randomized, double-blind phase 2 BOLT trial, in which patients with laBCC or mBCC received 200 mg or 800 mg of oral sonidegib daily **(2b)** [104]. The benefit-to-risk ratio profile was found to be more favorable in the 200-mg group, leading this to become the recommended dose. In the 12-month follow-up analysis, the overall objective response rate in the 200-mg group was 58% for laBCC and 8% for mBCC. Complete responses were seen in only 5% of patients in the laBCC group, although it has been noted that if the less stringent criteria used in the ERIVANCE trial were applied to this trial, the complete response rate would increase to 20% [105]. The median duration of response was 20.2 months for laBCC and 13.1 months for mBCC, while the median progression-free survival was 21.1 and 11.1 months, respectively. Disease control was obtained in 78% of laBCC and 92% of mBCC patients **(2b)** [106].

The role of hedgehog pathway inhibitors in the neoadjuvant setting has not yet been established. Clinical trials investigating the utility of these medications to shrink tumor size prior to surgery are ongoing. There are also active clinical trials studying the tolerability of alternative dosing regimens in patients with multiple BCCs [107, 108].

Comparative Effectiveness of Common Treatments

Overall, quality randomized control trials (RCTs) comparing treatment modalities in BCC with adequate follow-up of at least 3 years and stringent analytical methods are lacking. Nonetheless, systematic reviews comparing major treatment modalities using available randomized and non-randomized trial data demonstrate that standard surgical excision and MMS exhibit the lowest recurrence rates and are the putative first-line therapies in treating operable BCC in patients without contraindications to the procedure (**2a, 1a-**; Table 42.1) [30, 109]. A number of randomized controlled trials have compared recurrence rates, the primary outcome measure for BCC, of standard surgical excision with that of nonsurgical methods.

The superiority of standard surgical excision compared to cryosurgery, RT, and imiquimod has been well demonstrated in multiple studies. A single-center study randomized 88 patients with 100 superficial or nodular BCCs of the head and neck to surgical excision ($n = 49$) or cryotherapy with pre-procedure curettage ($n = 51$). With median follow-up of 4.29 years, the calculated 5-year probability of recurrence was 8.2% in excision-treated patients and 17.6% in cryosurgery-treated patients, though the observed differences were not statistically significant ($p = 0.10$) [31]. A follow-up study involving 96 of

Table 42.1 Systematic reviews and randomized control trials comparing different modalities for the treatment of basal cell carcinoma

Study type and level of evidence	Treatment comparisons	Conclusion	Reference	Year	Location	Single vs. multicenter	Limitations
Systematic review 2a	Surgical excision, MMS, cryosurgery, ED&C, RT	5-year recurrence rates with cryosurgery and ED&C are higher compared to surgical excision and MMS	Thissen et al. [30]	1999	N/A	N/A	Only one included study on RT and no studies on PDT
Systematic review 1a	Surgical excision, MMS, CS, RT, PDT, 5-FU, imiquimod	Surgery and RT are the most efficacious; Surgical excision and MMS have the lowest recurrence rates	Bath-Hextall et al. [109]	2007	N/A	N/A	Most included trials have 3-year recurrence follow-up
RCT 1b	Surgical excision and cryosurgery (cryotherapy + curettage)	Surgical excision has putatively lower, but not statistically significant, recurrence rates than cryosurgery	Kuijpers et al. [31]	2007	Netherlands	Single	Variable follow-up between 1 and 5 years
RCT 1b	Surgical excision and RT	Surgical excision has significantly higher success rates and cosmetic outcomes than RT	Avril et al.	1997	France	Single	2-mm surgical margin criteria
RCT 1b	Surgical excision and imiquimod 5% cream	Imiquimod is inferior to surgery	Bath-Hextall et al.	2014	UK	Multi	N/A
RCT 1b	Surgical excision and ALA-PDT	ALA-PDT had significantly higher failure rates than surgical excision and should not be used as standard treatment of nodular BCC	Mosterd et al. [114]	2008	Netherlands	Single	Variable follow-up between 1 and 5 years
Non-randomized controlled trial 2b	Surgical excision and ALA-PDT	ALA-PDT non-inferior to surgical excision and has better cosmetic outcomes	Cosgarea et al. [115]	2013	Romania	Single	Non-randomized
RCT 1b	Surgical excision and ALA-PDT	Surgical excision superior to ALA-PDT; Thin tumors ($\leq$ 0.7 mm) significantly less likely to recur after PDT than thick tumors (>0.7 mm)	Roozeboom et al. [116]	2013	Netherlands	Single	N/A

Table 42.1 (continued)

Study type and level of evidence	Treatment comparisons	Conclusion	Reference	Year	Location	Single vs. multicenter	Limitations
RCT 1b	MMS and surgical excision	MMS has lower but not statistically significant recurrence rates than surgical excision	Smeets et al. [53]	2004	Netherlands	Multi	Short follow-up (18 months) for some tumors
RCT 1b	MMS and surgical excision	MMS superior to surgical excision for recurrent BCC	Mosterd et al. [52]	2008	Netherlands	Multi	N/A
RCT 1b	MMS and surgical excision	MMS leads to significantly smaller surgical defect than surgical excision	Muller et al. [111]	2009	Scotland	Single	N/A
RCT 1b	Imiquimod cream, fluorouracil cream, MAL-PDT	Imiquimod is the preferred treatment with the least recurrence rate	Arits et al. [117]	2013	Netherlands	Multi	Short follow-up (12 months)
RCT 1b	Imiquimod cream, fluorouracil cream, MAL-PDT	Imiquimod and fluorouracil are preferred nonsurgical treatments over MAL-PDT	Roozeboom et al. [85]	2016	Netherlands	Multi	Follow-up to 3 years
RCT 1b	ALA-PDT and cryosurgery	PDT non-inferior to cryosurgery	Wang et al. [61]	2001	Sweden	Single	Short follow-up (12 months)

these patients compared cosmetic outcomes of the two treatments after 1 year. Evaluations by independent clinicians and the patients favored surgical excision (**1b)** [110].

Similarly, surgical excision demonstrated superiority over RT in a randomized controlled trial of 347 patients with mean follow-up at 41 months. The 4-year recurrence rate was 0.7% in the surgery group and 7.5% in the RT group ($p = 0.001$), with significantly higher rates of patient and clinician satisfaction with cosmetic outcome in the surgery group ($p < 0.01$) [70]. In comparing surgical excision with 4-mm margins and topical imiquimod 5% cream, a large multicenter randomized investigation of 501 subjects with superficial or nodular BCC demonstrated higher recurrence rates in the imiquimod-treated group (16% vs. 2%, $p < 0.0001$) without a difference in cosmetic outcomes [36].

MMS has only been comparatively investigated with respect to standard surgical excision in controlled studies due to the putative inferiority of nonsurgical methods in treating BCCs of aggressive subtype or in cosmetically sensitive areas. In the first of such trials, 374 patients with 408 primary BCCs of the H-zone of the face or with aggressive histological subtype (morpheaform, micronodular, trabecular, infiltrative, or BCC with squamous differentiation) and 191 patients with 204 recurrent BCCs were randomized to receive MMS or surgical excision with a 3-mm margin for both methods. MMS groups exhibited a lower recurrence rate than surgical excision for primary tumors at 30-month follow-up, 2% vs. 3% ($p = 0.724$), and for recurrent tumors at 18-month follow-up, 0% vs. 3% ($p = 0.119$), although these results were not statistically significant. In this study, overall defect size did not differ signifi-

cantly between the two methods, but in tumors that necessitated more than one standard excision or Mohs stage, MMS had a greatly reduced mean defect size for both primary (4.86 vs. 8.66 cm^2, $p < 0.001$) and recurrent tumors (7.95 vs. 14.52 cm^2, $p = 0.026$) [53]. For these same patients, MMS maintained superior recurrence rates to those of surgical excision after extended 5-year follow-up for primary BCCs (2.5% vs. 4.1%, $p = 0.397$) and recurrent BCCs (2.4% vs. 12.1%, $p = 0.015$), reaching statistical significance in the latter group of participants. This is the first directly comparative prospective randomized controlled study to show significant superiority of MMS over surgical excision in the treatment of recurrent BCCs [52].

While MMS is considered a tissue-sparing surgical technique, few studies have directly compared it to surgical excision along this outcome parameter. Whereas Smeets et al. enforced 3-mm margins for both surgical excision and MMS groups and found no difference in defect size with either technique except under certain tumor conditions, a separate trial comparing MMS with 2-mm margins and surgical excision with 4-mm margins concluded that MMS significantly decreased surgical defect size regardless of tumor conditions. In this study, after randomizing 30 participants with nodular BCC to MMS, the median surgical defect area in the MMS group was 116.6 mm^2 compared to 187.7 mm^2 in the surgical excision group ($p < 0.001$) **(1b)** [111]. Given that the recommended margins for surgical excision for 95% clearance are 4 mm and that most dermatologic surgeons will use margins narrower than 3 mm in MMS, this study may be more representative of tissue-sparing outcome differences, although only nodular BCC was included [34].

Overall, both MMS and surgical excision appear to be equally effective for primary BCCs, and treatment choice in these cases can be differentiated based on patient preference, cost, and physician comfort. MMS is more effective for recurrent BCC. Cosmetic outcome with MMS may be more favorable for tissue sparing based on choice of narrow margins. Imiquimod 5% cream has been investigated as a neoadjuvant or adjuvant therapy to MMS, with variable success in reducing post-MMS surgical defect size **(1b, 1b-)** [112, 113].

While surgical excision and MMS have shown the most consistent efficacy for operable tumors, PDT is an attractive option for inoperable tumors. In a randomized controlled comparison to PDT, 171 patients with nodular BCC received either surgical excision with 3-mm margins or ALA-PDT. Median follow-up was 2.33 years and the predicted 3-year analysis of recurrence was 2.3% and 30.3% ($p < 0.001$), respectively **(2b)** [114]. However, tumor thickness, which was not accounted for in this study, may be an important prognostic indicator of efficacy of PDT in treating BCCs.

A recent study concluding non-inferiority of ALA-PDT for BCC allowed patient selection of treatment, but restricted the PDT group from nodular BCC of greater than 3-mm elevation above skin level. Over a mean follow-up period of 25 months, recurrence rate was 4.16% in the PDT group and 4.34% in the surgery group ($p = 0.64$), with superior cosmetic outcomes in the PDT group at 12 months **(2b-)** [115]. PDT may indeed be effective given appropriate patient selection for tumor thickness. A randomized controlled trial showed a projected 5-year recurrence rate of 35% in superficial BCC tumors greater than 0.7-mm deep compared to 5.6% of tumors less than or equal to 0.7-mm deep ($p = 0.018$) **(1b)** [116].

In recent efficacy comparisons of multiple nonsurgical treatment modalities, imiquimod has demonstrated the greatest superiority. In a randomized controlled trial, 601 patients with superficial BCC were randomized to receive MAL-PDT, imiquimod 5% cream, or fluorouracil 5% cream. Recurrence rates at 12-month follow-up were 27.2%, 16.6%, and 19.9%, respectively. The difference between 5-fluorouracil and the other treatments was not statistically significant, whereas imiquimod had a significantly lower recurrence rate compared to MAL-PDT ($p = 0.021$). Based on these findings, the authors concluded that imiquimod is the treatment of choice of these three treatment modalities, given its lower rate of recurrence and superiority to MAL-PDT.

Cosmetic differences at follow-up were not significant (**1b)** [117]. On an extended 3-year follow-up of these patients, recurrence rates were 42% for MAL-PDT, 30.3% for imiquimod, and 31.8% for fluorouracil, with imiquimod maintaining significant superiority over MAL-PDT (p = 0.001), and fluorouracil non-inferior to either [85]. Although 5-year recurrence rates are lacking for this comparison, these authors suggest that imiquimod and fluorouracil are preferable to MAL-PDT for the nonsurgical treatment of superficial low-risk primary BCCs. Interestingly, post hoc subgroup analysis of these findings found MAL-PDT to be 35.2% more effective than imiquimod in treating superficial BCC of the lower extremities ($p = 0.003$). However, given that these were exploratory findings, conclusions should be made with caution **(1b)** [118].

Cryosurgery has not been extensively compared to nonsurgical therapies in BCC. A phase 3 trial comparing ALA-PDT and cryotherapy (two cycles) in 88 patients with superficial and nodular BCC demonstrated that 25% of PDT-treated lesions and 15% of cryotherapy-treated lesions recurred. This difference was not significant, and PDT was considered non-inferior to cryosurgery [61].

Preoperative Evaluation and Patient Selection

Important preoperative considerations include tumor characteristics such as histology, location, size, stage, and primary or recurrent status. Patient characteristics and co-morbidities must also be considered. Assessment of these factors allows stratification of cases into high-risk and low-risk categories. High-risk tumors are those with risk factors for recurrence, such as aggressive histology, poorly defined borders, recurrent status, location on the face, perineural invasion, and underlying immunosuppression. Procedure selection is based largely upon the presence or absence of such features, in conjunction with patient preference [20].

In general, surgical treatment is considered the standard of care given its superior cure rates. For low-risk tumors, such as well-defined primary lesions with superficial or nodular histology located on the trunk and extremities, standard excision can be considered. However, ED&C should be avoided for lesions located on terminal hair-bearing skin [20]. For high-risk tumors, such as poorly-defined primary or recurrent tumors with aggressive histologic growth patterns located in cosmetically sensitive locations, Mohs surgery can be considered. Standard excision can also be utilized, but wider surgical margins should be employed and it is prudent to delay repairs pending margin evaluation.

For patients who are nonsurgical candidates or who refuse surgery, radiation therapy can be considered, although it is less effective for larger tumors and those with morpheaform histology. Radiation therapy is also used post-operatively for BCCs with perineural invasion. However, RT should be avoided in younger patients, for whom long-term consequences such as later radiation-induced malignancies are a concern, as well as patients who are predisposed to developing ionizing radiation-induced malignancies, such as those with basal cell nevus syndrome and xeroderma pigmentosum [119].

Topical therapies such as imiquimod 5% cream, 5-fluorouracil 5% cream, cryotherapy, and photodynamic therapy are reserved for nonsurgical candidates who cannot undergo RT due to inferior cure rates. Imiquimod and 5-FU are only indicated for tumors with superficial histology. Cryotherapy and PDT can be used to treat superficial or nodular BCCs, though lower cure rates should be expected for the nodular subtype. Topical therapies and PDT offer the advantage of field therapy in select patients.

The hedgehog pathway inhibitors vismodegib and sonidegib are primarily used for locally advanced tumors recurrent after surgery or not amenable to surgical treatment or radiation, as well as for metastatic lesions. Patients with a high tumor burden from basal cell nevus syndrome can also be considered for these medications to decrease the rate of new tumor development as well as the need for surgery. Sonidegib is primarily metabolized by CYP3A and should be avoided in patients taking medications that strongly inhibit or induce that pathway.

For pregnant patients, 5-FU is absolutely contraindicated (pregnancy category X). Vismodegib is category D and topical imiquimod and aminolevulinic acid are both category C. Lidocaine with epinephrine is category B.

Impact of Patient Preference

When selecting the most appropriate therapy, patient and provider preference should be weighed in conjunction with tumor and patient characteristics. Aside from efficacy, factors that may be of concern to patients include cosmetic outcome, convenience, tolerability, and cost. Cosmetic outcome is a particularly strong driver of patient preference and may be just as important in the eyes of the patient as likelihood of recurrence [120, 121]. One discrete choice experiment ascertaining patient preference for imiquimod versus surgery revealed that cosmetic outcome and adverse effects were valued more highly than clearance rate or cost [122].

The treatment modalities that have been associated with the worst cosmetic outcomes are radiation therapy **(1b)** [70, 123] and cryotherapy [31, 61, 110]. Topical therapies, though less effective, are generally associated with the most favorable cosmetic outcomes [61, 115], with imiquimod, 5-FU, and PDT yielding similar cosmetic results [117]. PDT, in particular, has been shown to have superior cosmetic outcomes compared to surgery **(1a-)** [35, 87, 124] and cryotherapy [61, 82]. Moreover, cosmetic results have been observed to improve with time following PDT [35, 84, 86]. While surgical approaches invariably cause scarring, MMS may allow for shorter scars than standard excision. The tissue-sparing nature of MMS was corroborated in a randomized trial, showing that standard excision resulted in a median defect size 1.6 times larger than those of defects following MMS [111].

In terms of convenience and feasibility, treatment options vary in duration and setting. Patients who desire a shorter treatment course and quicker healing time may prefer surgery, ED&C, cryotherapy, or PDT, which may require as few as one to two office visits. Both 5-FU and imiquimod require long, drawn-out treatment courses over weeks, with which patients may not be compliant; however, one advantage is that they can be performed at home. Radiation therapy requires multiple office visits, which may not be practical for patients with difficulties traveling to a physician's office.

In terms of cost, RT and MMS have been found to be most expensive, followed by standard excision and destructive therapies such as ED&C and cryotherapy **(4)** [26, 125–127]. Placement of the non-invasive therapies among the cost spectrum is less clear. Imiquimod is more costly than 5-FU [97, 125, 128], and PDT may exceed the cost of both [128].

Typical Treatment Plan

A 40-year-old woman with no history of skin cancer presents for treatment of a biopsy-proven nodular basal cell carcinoma on her temple. She works as a television news anchor and is extremely concerned about the potential for scarring. Although she has never developed hypertrophic scars in the past, she notes that she has friends who developed unacceptable scarring after skin cancer surgery. She would therefore like to discuss alternative treatment options she read about on the internet, specifically the "creams." Her medical history is unremarkable, and she does not take any medications. Due to her work obligations, she will only be able to take off a maximum of 2–3 weeks for treatment of her BCC.

ED&C, cryotherapy, and radiation therapy would be inappropriate treatment options for this patient given her age, the high-risk location of the lesion, and the importance of cosmetic outcome in this case. She is clearly interested in a non-invasive treatment option. Topical 5-fluorouracil would be inappropriate as it has only been studied for BCC with superficial histology. While imiquimod is similarly approved only for superficial tumors and its role in nodular BCC remains to be determined, there has been one study showing potential efficacy for nodular BCC. Even so, it has lower cure rates than surgery and this option would not be practical for the patient, as a full

course of treatment requires 6 weeks. The option of photodynamic therapy could be discussed, but the patient should be made aware of the high recurrence rates and low cure rates for nodular BCC. Given these considerations, the most appropriate treatment option for this patient would be Mohs micrographic surgery, which would likely provide her with a smaller scar than standard excision.

The treatment course for Mohs micrographic surgery requires an office visit lasting several hours, depending on the number of excision stages required. Repair would likely be performed the same day. She would not want to return to work until the time of suture removal, which would typically be 1–2 weeks after surgery. However, she would likely be able to use make-up and concealer within 3 weeks of the procedure. The probability of complications from surgery would be extremely low in a young, healthy patient such as this one. If she were to develop undesirable scarring, treatment options such as dermabrasion, intralesional corticosteroid injections, and laser surgery could be considered.

Future treatment options may employ the use of laser technology. To date, there have only been small pilot studies suggesting potential efficacy with laser surgery or laser-assisted drug delivery for the treatment of BCC. Their use is considered experimental and larger, controlled studies will be required before these results can be confirmed and these modalities adopted in practice. Lasers that have been investigated for direct treatment of BCC include the pulsed dye laser **(4, 4)** [129, 130], neodymium:yttrium aluminum (Nd:YAG) **(4)** [131], and carbon dioxide **(4)** [132] lasers, which have shown some efficacy in case reports and small case series. Lasers have also been used in conjunction with conventional therapies. A randomized trial of erbium:yttrium aluminum garnet (Er:YAG)-primed MAL-PDT versus traditional MAL-PDT demonstrated significantly lower recurrence rates in the Er:YAG laser group **(2b)** [133]. In a small study that used an ablative carbon dioxide laser to enhance topical 5-fluorouracil applied for 7 days under occlusion, a histologic clearance rate of 71% (10 of 14) was achieved for superficial BCCs **(2b)** [134]. Overall treatment success after 9 months of follow-up was 67% **(2b)** [135]. As with other destructive treatment modalities, lack of definitive histologic evaluation will be a disadvantage; use of reflectance confocal microscopy to evaluate for residual tumor post-treatment has been proposed as a means to mitigate this [132].

Safety

The risks associated with a procedure are an important consideration when weighing therapeutic options. The potential treatment modalities for BCC are each associated with a unique set of adverse events (AEs) (Table 42.2).

Surgical treatment has been established as a safe procedure with a low incidence of serious AEs. In a multicenter prospective cohort study of 20,821 Mohs micrographic surgery procedures, the incidence of AEs was 0.72%, with 0.02% being serious AEs, and no deaths were reported. The most common AEs were infections, followed by dehiscence and partial or full necrosis and bleeding and hematoma. Patients on anticoagulation therapy were at greater risk of bleeding and wound-healing complications. No cases of stroke, myocardial infarction, pulmonary embolus, or death were observed in this study **(2b)** [136], although they have been reported at the case report level, usually in the setting of cessation of antithrombotic therapy [137]. Notably, in a retrospective study of 115 patients aged 90 years and older undergoing 146 MMS procedures, only one complication was identified in the form of chest pain that resolved without hospitalization **(2b)** [138].

In a randomized controlled trial comparing MMS and surgical excision, stratification of safety outcomes by tumor type revealed no difference in postoperative complications between these procedures in treating primary BCCs, but a significantly higher rate of AEs was observed after treating recurrent BCCs with surgical excision (19%) compared to MMS (8%, $p = 0.021$). AEs included wound infections, graft necrosis, and postoperative bleeding for both procedures [53].

Table 42.2 Adverse effects (AEs) associated with treatment modalities for basal cell carcinoma

Treatment modality	Most common AEs	Uncommon or serious AEs
Surgery (excision, Mohs micrographic surgery)	Infection, dehiscence, bleeding, hematoma, hypertrophic scarring	Partial or full necrosis, stroke/myocardial infarction/death (reported with cessation of anticoagulant medications)
Electrodesiccation and curettage	Hypopigmentation, hypertrophic scarring	Infection
Radiation therapy	Acute: localized pruritus, moist desquamation Chronic: dyspigmentation, telangiectasia, atrophy, alopecia, xerosis	Skin necrosis, delayed-onset secondary malignancy Site-specific: lacrimal duct stenosis, ectropion, cataract formation
Cryotherapy	Erythema, edema, pain, blistering, hypopigmentation	Anatomic distortion, necrosis
Imiquimod	Erythema, edema, itching, pain, erosion, crusting, scaling, ulceration, headache	Flu-like symptoms (myalgia, malaise, fatigue, fever)
Photodynamic therapy	Pain, burning, stinging, itching, erythema, edema, erosions, crusting	Infection
5-Fluorouracil	Erythema, erosion	Infection
Hedgehog pathway inhibitors (vismodegib, sonidegib)	Muscle spasms, alopecia, dysgeusia, nausea, fatigue, weight loss, diarrhea	Creatinine kinase elevation, rhabdomyolysis, amenorrhea

The primary AEs associated with ED&C are postoperative hypopigmentation and hypertrophic scarring, although these tend to improve with time [43]. In a retrospective study, curettage alone without electrodesiccation may yield more favorable cosmetic outcomes; hypertrophic scarring was only noted in 0.3% of patients and hypopigmentation was judged to be less significant than traditionally seen with ED&C despite similar efficacy rates [39].

Radiation therapy is associated with acute and chronic AEs. Acute side effects include radiation dermatitis-like symptoms, such as localized pruritus and moist desquamation. Long-term effects include dyspigmentation and telangiectasia, which are seen in more than 65% of patients [70]. Chronic skin atrophy, alopecia, and xerosis also occur commonly. These consequences may lead to an unsatisfactory cosmetic result, which has been shown to deteriorate with time following radiation therapy [63, 64, 70]. In one study that assessed long-term cosmetic outcomes, 60% of physicians and 30% of patients rated radiotherapy scars as poor to fair at 4 years after treatment [123]. Uncommon but serious complications include skin necrosis, which occurs in up to 5% of patients [70], and delayed development of secondary malignancy within the radiation treatment field, a dreaded long-term sequela. Site-specific AEs include lacrimal duct stenosis and cataract formation when radiation is used for eyelid tumors [64, 70]. Fractionation of therapy may decrease the risk of untoward cosmetic effects [69].

One study comparing surgical excision and RT observed greater rates of AEs in the RT-treated group on long-term follow-up. At 4 years posttreatment, surgery-treated patients had remaining physical deformities (25%) and functional contractures (5%), while RT-treated patients had dyspigmentation and telangiectasia (65%) and radiodystrophy (41%). Three patients (n = 173) experienced ophthalmic complications, one each of cataract, ectropion, and lacrimal duct stenosis [70].

The incidence of AEs associated with cryotherapy has not been evaluated in a systematic manner. Well-known common adverse reactions include erythema, edema, pain, and blistering. Delayed events include hypopigmentation, which occurs frequently, and hypertrophic scars, which occur less commonly. Both can lead to an inferior cosmetic result. With the more aggressive treatment regimens utilized in older studies, infec-

tions, pyogenic granuloma, and anatomic distortion from damage to underlying cartilage also rarely occurred **(4)** [59, 139]. One randomized trial found slightly decreased rates of secondary wound infection using cryotherapy (5.9%) compared to surgical excision (8.2%) [31]. Cryosurgery, compared to PDT, has longer healing time and had higher rates of necrosis (7.3% vs. 0%) at 4 weeks posttreatment [61].

The safety of imiquimod has been studied in preclinical and clinical trials. Animal and in vitro studies have shown that imiquimod does not affect fertility and is not teratogenic or tumorigenic [140]. The most common AEs associated with topical imiquimod use are local application site reactions, in the form of erythema, edema, itching, pain, erosion, crusting, scaling, and ulceration. These occur frequently, but range in severity and are dose-dependent. In two randomized, double-blind, controlled studies, 29–43% experienced local skin reactions among those applying the cream five and seven times per week, respectively [72]. In prospective dose-finding studies, application site reactions were present in nearly all patients in the twice-daily application group [71, 78]. Headache occurs in 6–7% of patients [72]. Less common reactions include systemic flu-like symptoms such as myalgia, malaise, fatigue, and fever, which occur in less than 3% of patients [72].

PDT is generally well tolerated and its most common AEs include signs and symptoms associated with photosensitivity reactions, such as pain, burning, stinging, and itching. Post-treatment erythema, edema, erosions, and crusting may also be observed. The incidence of AEs can exceed 70%, but they are usually mild to moderate in severity, local in nature, and transient. Serious AEs are not typically seen [83, 84].

The most common AEs associated with 5-FU are erythema and erosion. When used for the treatment of BCC, levels of erythema are generally moderate in severity, in contrast to the robust erythema seen with the use of 5-FU for actinic keratoses. The majority of patients (>80%) do not experience pain or have scarring; when present, both are usually mild [97].

A large randomized controlled trial of 601 participants compared MAL-PDT, imiquimod, and fluorouracil in treatment of BCCs. The authors reported moderate to severe AEs during the second week of treatment at the following rates: pain (14% vs. 5% vs. 7%, respectively), burning sensation (26% vs. 9% vs. 12%), redness (41% vs. 52% vs. 51%), swelling (4% vs. 21% vs. 7%), erosion (8% vs. 16% vs. 17%), crusts (11% vs. 23% vs. 11%), vesicles and bullae (8% vs. 14% vs. 10%), scaling (5% vs. 3% vs. 6%), pruritus (12% vs. 28% vs. 21%), and tingling (4% vs. 4% vs. 4%). Overall, patients treated with either imiquimod or 5-fluorouracil reported a higher incidence of moderate to severe local swelling, erosions, crust formation, and itching than those treated with MAL-PDT. Influenza-like symptoms and a case of wound infection occurred in 4.8% of the imiquimod-treated group. Two patients (1%) of the 5-fluorouracil-treated group also developed wound infections [117].

AEs occur commonly in patients taking vismodegib and sonidegib and typically occur within the first 6 months [99]. Mild to moderate adverse effects are seen in nearly all patients taking the medications and severe events can occur in up to 52% of patients. These effects may be intolerable, as they led to study discontinuation in 17.3% and 27.8% of patients in the pivotal vismodegib and sonidegib trials, respectively [99, 106].

Vismodegib and sonidegib share similar adverse effects, which are thought to be mechanism-related. The most common adverse effects are muscle spasms, alopecia, dysgeusia, fatigue, nausea, weight loss, and diarrhea. Of these, muscle spasms, alopecia, and dysgeusia occur most frequently, with rates in large phase 2 clinical trials ranging from 49% to 84%, 43–69%, and 38–84%, respectively **(2b)** [99, 100, 141]. Serious AEs found in the sonidegib clinical trial include elevated creatinine kinase and rhabdomyolysis, which occurred in more than 2% of subjects. Amenorrhea in premenopausal patients has also rarely been reported [104, 106]. However, no medication-related deaths have been noted [99, 100, 102, 104, 106, 142].

Postoperative Care and Follow-Up

Clinical monitoring of a patient after treatment is required for two main reasons. The first is to monitor for recurrence at the primary tumor site. The second is to perform surveillance for the development of new skin cancers.

No established guidelines exist to guide appropriate monitoring frequency and duration following basal cell carcinoma treatment. In general, monitoring for recurrence is most crucial in the first 3–5 years, although recurrences beyond 5 years are not rare. In a pooled analysis of studies looking at the treatment of BCC with various modalities, Rowe et al. found that only 50% of recurrences appeared within the first 2 years after treatment; 55% appeared within the first 3 years; and 18% did not appear until 5–10 years later [29]. A large review of tumors published 2 years later similarly found the greatest risk of recurrence to be within the first 4 years [143]. In line with these findings, a retrospective study evaluating the efficacy of MMS found that 75% of recurrences appeared within 3 years of surgery [51]. However, a recent prospective study with 10-year follow-up found that recurrence beyond 5 years is not infrequent and may occur in up to 40% of primary BCCs treated with surgery [33]. Repeat recurrences tend to appear sooner, which has been attributed to the more biologically aggressive nature of recurrent BCCs compared to primary tumors **(2b)** [33, 144]. Based on these findings, a follow-up period of 5 years for primary BCC and 7–10 years for recurrent BCC has been proposed [33].

For patients with a history of BCC, the risk of subsequent NMSC is increased **(2a-, 2a, 2b, 1b)** [145–148]. The risk varies depending on whether the index BCC is a first BCC or not, i.e., whether there is a history of multiple BCCs. A meta-analysis from 2000 calculated a 3-year cumulative risk of 44% for developing a second BCC after initial BCC diagnosis. The risk of developing an SCC following an index BCC was much lower, at 6% [146]. However, this analysis included studies that included patients with a history of more than one BCC and were not exclusive to newly diagnosed patients. A recent prospective cohort study found that the risk of subsequent BCC after the first lifetime BCC is lower than it is after a non-first BCC—12.8% vs. 33.9% at 1 year, 20.0% vs. 51.8% at 2 years, and 26.7% vs. 61.3% at 3 years [148]. This implies that a substantial proportion of patients with a first BCC may never develop another BCC and may not require as frequent and aggressive screening post-treatment as those with a history of multiple BCCs.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
Mohs micrographic surgery is the treatment of choice for recurrent BCC	A
Mohs micrographic surgery is superior to standard excision and ED&C for recurrent BCC	A
ED&C can achieve cure rates as high as excision for small, low-risk BCC	B
ED&C is associated with higher risk of recurrence for lesions located on facial sites than on non-facial sites	B
ED&C should not be used for recurrent or infiltrative tumors	B
ED&C should not be used for tumors located on terminal hair-bearing skin	D
Cryosurgery has cure rates that range widely from 1% to 20%	C
Radiation therapy should not be used for patients younger than 60–65 years old	D
Radiation therapy should not be used in patients with conditions predisposing to malignancy	D

Findings	GRADE score: quality of evidence
Imiquimod 5% cream is effective for the treatment of superficial BCC	A
Imiquimod 5% cream may be effective for nodular BCC with more frequent and prolonged use	B
Imiquimod 5% cream has poor efficacy for tumors with infiltrative histology	C
Both MAL- and ALA-PDT are effective for superficial BCC	A
Efficacy of PDT for nodular and infiltrative tumors is not well established	B
5-FU may be effective for superficial BCC on the trunk and limbs with prolonged use	C
Topical therapies are generally associated with superior cosmetic outcomes compared to surgery, radiation, and cryosurgery	A
Vismodegib and sonidegib can be effective for locally advanced and metastatic BCC	A
Vismodegib can significantly reduce tumor burden in patients with basal cell nevus syndrome	A
Vismodegib and sonidegib are associated with a high incidence of adverse effects	A
Vismodegib and sonidegib are not well-tolerated and frequently discontinued by patients	A

Self-Assessment Questions

1. Which one of these statements regarding the use of imiquimod 5% cream for the treatment of BCC is FALSE?
   (a) Randomized controlled trials have found similar histologic clearance rates with five times per week and seven times per week application for superficial BCC.
   (b) Application of imiquimod 5% cream has been shown to have 5-year clearance rates of approximately 80% for superficial BCC.
   (c) Imiquimod 5% cream has not been studied for nodular BCC.
   (d) Limited evidence shows that imiquimod 5% cream has poor efficacy for BCCs with infiltrative histology.
   (e) Application of imiquimod 5% cream for three times a week rather than five times a week has been shown to be associated with a lower histologic clearance rate.

2. What is the approximate 5-year recurrence rate following Mohs micrographic surgery for primary and recurrent BCC?
   (a) primary: 3–5%; recurrent: 8–10%
   (b) primary: 1–3%; recurrent: 4–7%
   (c) primary: 1–3%: recurrent: 1–3%
   (d) primary: 3–5%; recurrent: 4–7%
   (e) primary: 3–5%; recurrent: 3–5%

3. Which of the following statements is FALSE regarding the treatment of recurrent BCC?
   (a) Excision has similar recurrence rates compared to Mohs micrographic surgery for lesions on the trunk.
   (b) Cure rates have been found to be as low as 40% following treatment with PDT.
   (c) Cure rates have been found to be lower than 70% following treatment with ED&C.
   (d) Topical imiquimod and 5-FU are not recommended for and have not been studied for recurrent BCC.
   (e) Recurrence rates have been found to be as high as 13.5% for lesions on the face following treatment with excision.

4. Which of the following is NOT one of the most common adverse effects of the hedgehog pathway inhibitors vismodegib and sonidegib?
   (a) Dysgeusia
   (b) Muscle spasms
   (c) Alopecia
   (d) Xerosis
   (e) Fatigue

5. Which of the following statements most accurately describes the safety and cosmetic outcome associated with treatment modalities for BCC?
   (a) Imiquimod, PDT, 5-FU, and cryotherapy are all associated with superior cosmetic outcomes that may improve with time.
   (b) Radiation therapy is generally associated with a poor cosmetic outcome, but this tends to improve with time.
   (c) Radiation therapy should be avoided in older patients due to the risk of delayed radiation-induced malignancy.
   (d) Vismodegib and sonidegib can result in complete responses for locally advanced BCC, but are not well-tolerated, and tumors tend to recur following cessation of treatment.
   (e) Studies have shown that patients usually value efficacy over cosmetic outcome and adverse effects.

Correct Answers

1. c: Imiquimod 5% cream has been studied for nodular BCC, but its efficacy is not as well established. There is some evidence that it may be effective with daily use for 12 weeks (as opposed to five times weekly use for 5 weeks as recommended for superficial BCC). With this more frequent and longer treatment regimen, clearance rates of 76% and 82% have been found for nodular BCC in two studies.
2. b: Retrospective and prospective studies have found that 5-year recurrence rates following Mohs micrographic surgery range from 1% to 3% for primary tumors and 4–7% for recurrent tumors.
3. a: Recurrence rates for recurrent tumors following standard excision have been found to range from 5% to 20% in various studies. In one randomized trial of facial lesions, recurrent BCCs had a recurrence rate of 13.5%. These rates are higher than is observed with Mohs micrographic surgery, which has recurrence rates of 4–7% for recurrent tumors.
4. d: The most common adverse effects reported in the vismodegib and sonidegib trials included muscle spasms, dysgeusia, alopecia, nausea, fatigue, and weight loss. Xerosis was not observed as a common adverse effect.
5. d: Imiquimod, PDT, and 5-FU are associated with superior cosmetic outcomes that improve with time, but cryotherapy has been associated with poorer cosmetic outcomes. Radiation therapy has generally been associated with poor cosmetic outcomes and this tends to worsen, rather than improve, with time. It should be avoided in younger patients (those less than 60–65 years of age) due to the risk of delayed development of malignancy. Studies have shown that patients may value cosmetic outcome and adverse effects as highly as, if not more so than, treatment efficacy. Statement d is true: The hedgehog pathway inhibitors have been associated with complete responses for locally advanced BCC, but are generally not well-tolerated, leading to high rates of medication discontinuation. In addition, tumors tend to recur following cessation of treatment. The low tolerability of these medications, combined with the tendency for tumors to recur and potentially develop resistance, poses current challenges to the use of hedgehog pathway inhibitors.

Cutaneous Squamous Cell Carcinoma

43

Nina R. Blank, Kishwer Nehal, and Erica Lee

Abstract

Cutaneous squamous cell carcinoma (cSCC) may be treated surgically, with destructive modalities, or through the use of topical agents. The risk of cSCC metastasis has been shown to increase with tumor size and depth, ear location, and immunosuppression. For cSCC lesions with higher-risk features, excision with postoperative margin assessment and Mohs micrographic surgery (MMS) are considered most effective, with MMS best utilized in locations with minimal excess tissue and/or near vital anatomic structures. While cryosurgery and electrodesiccation and curettage may be used for low-risk cSCC, current evidence supports the use of photodynamic therapy and topical agents for low-risk cSCC in situ only.

Epidemiology

Nonmelanoma skin cancer (NMSC) is the most common cancer in the United States, with over 5.4 million people affected and 3.3 million treated in 2012 [1]. The second most common skin cancer after basal cell carcinoma (BCC), cutaneous squamous cell carcinoma (cSCC), has historically been estimated to represent 20% of all NMSC [2]. Recent reports, however, have pointed to an increasing ratio of cSCC to BCC, possibly secondary to a disproportionate cSCC incidence rise in older age groups [1, 3, 4]. A study estimating NMSC frequency in the US population in 2012 reported equal incidence rates for BCC and cSCC in the Medicare population [1].

Both age and sex affect cSCC incidence, with older age portending greater risk [5–7] and male sex yielding an incidence rate between 2.5 and 2.8 times that of women [8]. Ultraviolet B radiation (290–320 nm) is the most common risk factor for the development of cSCC, through

activation of the *ras* pathway and p53 tumor suppressor gene mutations [9]. Thus, those with greatest cumulative exposure to UV radiation (i.e., fair-skinned individuals with outdoor occupational or behavioral exposure and those residing near the equator) are considered to be at greatest risk for cSCC [10–12]. Additional risk factors for cSCC include immunosuppression and ionizing radiation (Table 43.1).

The presence of actinic keratoses (AK) and other NMSC is strongly associated with future cSCC development [10, 13]. AK is considered by many to be a precursor lesion to cSCC. Estimated progression rates of AK to cSCC have ranged between 0.0% and 0.53% per lesion-year, although the reliability of these estimates has been called into question [13]. Despite this uncertainty, AK is often treated for its malignant potential and secondarily for cosmesis with therapies including topical 5-fluorouracil and imiquimod, photodynamic therapy (PDT), and cryotherapy [14].

CSCC variants include verrucous carcinoma, an uncommon entity presenting as an exophytic, verrucous lesion, and keratoacanthoma, which develops rapidly into a crater-like nodule with a central keratotic core. CSCC in situ (cSCCIS) presents with several subtypes, the most common of which are Bowen's disease, or cSCCIS on sun-exposed areas, and Erythroplasia of Queyrat, cSCCIS arising on the glans penis of uncircumcised men.

Treatment Overview

Dermatologic procedures for cSCC and cSCCIS are surgical treatments, including excision with postoperative margin assessment (POMA) and Mohs micrographic surgery (MMS); the destructive modalities electrodesiccation and curettage (ED&C), cryotherapy, and photodynamic therapy (PDT); and the topical agents imiquimod (5%) and 5-fluorouracil (5-FU, 5%). While radiation therapy may have a role in the adjuvant setting or as primary SCC treatment for nonsurgical candidates, details of this modality are beyond the scope of this chapter and will not be discussed in depth.

The intent of any SCC treatment is complete eradication of malignant squamous cells. Appropriate use depends upon invasion status (in situ vs. invasive SCC) and upon clinical and histologic tumor characteristics, more specifically, whether the tumor is considered low or high risk for recurrence. The National Comprehensive Cancer Network Clinical Practice Guidelines in Oncology (NCCN Guidelines®) delineate "low-risk" anatomic areas to be the trunk and extremities (excluding the pretibia, hands, feet, nail units, and ankles), provided the tumor is < 2 cm in diameter, and the cheeks, forehead, scalp, neck, and pretibia for < 1 cm tumors **(2b)** [15] (Table 43.2).

Nonsurgical modalities were estimated to represent 40.3% of skin cancer treatments performed on Medicare beneficiaries in 2008 [16]. These therapies do not allow histopathologic tumor margin evaluation and are thus generally limited to AK, cSCCIS, and low-risk cSCC in anatomic locations described earlier. ED&C is most commonly performed and involves alternating cycles of tumor tissue curettage down to the dermis with subsequent denaturation through electrodesiccation. This modality is preferred for nonterminal hair-bearing areas due to the risk of infundibular tumor extension inaccessible to ED&C **(5)** [15]. Wounds typically take 4–6 weeks to heal, and the clinical outcome is a white stellate scar that may

[a]Must include the peripheral rim of erythema

[b]If clinical evaluation of incisional biopsy suggests that microstaging is inadequate, consider narrow margin excisional biopsy

[c]A modified Breslow measurement should exclude parakeratosis or scale crust and should be made from the base of ulcer if present

[d]Location independent of size may constitute high risk

[e]Area H constitutes high risk based on the location, independent of size. Narrow margins due to anatomic and functional constraints are associated with increased recurrence rates with standard histologic processing. Complete margin assessment such as with MMS is recommended for optimal tumor clearance and maximal tissue conservation. For tumors <6 mm in size, without other high-risk features, other treatment modalities may be considered if at least 4 mm clinically tumor-free margins can be obtained without significant anatomic or functional distortions

Area H = "mask areas" of the face (central face, eyelids, eyebrows, periorbital, nose, lips [cutaneous and vermilion], chin, mandible, preauricular and postauricular skin/sulci, temple, ear), genitalia, hands, and feet

Area M = cheeks, forehead, scalp, neck, and pretibia

Area L = trunk and extremities (excluding the pretibia, hands, feet, nail units, and ankles)

be atrophic or hypertrophic [17–19]. Cryotherapy destroys tumor cells through cycles of liquid nitrogen freezing and thawing. Cell temperature reduction to subzero yields localized tissue destruction and vascular stasis. The treated area typically heals by second intention over 1–3 weeks with erythema, vesiculation, edema, exudation or eschar, and sloughing. Lesions may also permanently hypopigment secondary to melanocyte destruction [17, 18, 20, 21]. PDT requires application of a photosensitizing agent that accumulates preferentially within tumor cells. The most common agents are the topical porphyrin precursor 5-aminolevulinic acid (ALA) and its methyl ester form, methyl aminolevulinate (MAL). Only ALA is available for cutaneous application in the United States. Light-source irradiation of the area then activates the compound, with clinical response involving erythema, edema, and crusting over the week following treatment. These symptoms are expected to resolve within 1–3 weeks, leaving the skin without a scar [17, 18]. Imiquimod acts as a toll-like receptor agonist, inducing a type-2 helper T-cell cytokine cascade that yields cytotoxic T-cell tumor cell

destruction. Fluorouracil is a pyrimidine antimetabolite that directly targets tumor cells by inhibiting DNA synthesis [22]. Both therapies require daily or near-daily application for several weeks and create local erythema throughout the treatment course. The inflammatory response to imiquimod and 5-FU may also involve edema, weeping, crusting or scabbing, and pruritus. Clinical resolution may leave residual blanching erythema or post-inflammatory hypo- or hyperpigmentation [22, 23].

Surgical excision and MMS were estimated to comprise 35.6% and 24.1% of skin cancer treatments in 2008, respectively [16]. Standard surgical excision with POMA may be performed for low- or high-risk tumors in anatomic locations with a 4–6 mm clinical margin. The inability of standard, bread-loaf tissue processing to examine full excision margins justifies wider resection of high-risk lesions to avoid subclinical tumor transection, per NCCN Guidelines **(2b)** [15]. MMS uses en face, frozen histopathologic sections to assess the entire peripheral and deep margin and is thus the desired treatment for high-risk tumors. MMS allows for tissue preservation in aesthetically sensitive and high-risk sites such as the nose, eye, and ear. MMS' higher cost and longer time requirement have led to recommendations of its "appropriate use" to higher-risk anatomic sites such as the head and neck, pretibial surface, and nail unit; aggressive histological subtypes; ill-defined clinical tumors; and recurrent lesions [24].

Effectiveness of Treatments

Despite the high prevalence of cSCC, there are no randomized controlled trials (RCTs) that assess treatment effectiveness for invasive diseases and very few assessing therapy for in situ lesions. The following is a review of mostly observational studies reporting on outcomes such as local recurrence, regional and distant metastasis, and disease-specific death. Local recurrence and metastasis rates have been shown to increase with duration of patient follow-up irrespective of treatment modality **(4)** [25]; this should be considered when comparing studies with differing follow-ups.

Electrodessication and Curettage (ED&C)

ED&C effectiveness data is limited to retrospective studies examining unspecified cSCC recurrence after variable posttreatment follow-up periods. The earliest systematic review of these studies, by Rowe et al. in 1990, reported weighted 5-year ED&C recurrence of 3.7% in tumors described to be less than 1 cm in size **(4)** [25].

The newest systematic review, by Lansbury et al. in 2013, estimated a pooled recurrence rate of 1.7% for 8 studies with variable follow-up **(4)** [26]. Lesions treated with ED&C were small: 5 series with recorded diameters reported lesions < 2 cm in 91%, 94%, 100%, 60%, and 60% of cSCC **(4)** [27–31]. All studies encompassed various anatomic sites excluding Shiffman et al., who reported 3 recurrences (21.4%) leading to 2 metastases (14.3%) among 14 pinna cSCC within 1 year. Recurrent lesions were 2.5 cm, 3 cm, and 3 cm in size. Of the 11 cSCC without recurrence, 1 lesion was > 2 cm **(4)** [30].

Studies have not compared different ED&C techniques. Tromovitch described superior results following two ED&C sequences compared to single-cycle methods **(5)** [32]. Reschly et al. reported on 2 separate retrospective studies: the first treated 106 patients with 2 ED&C rounds and the second, 14 patients with 3 cycles. Both studies reported no recurrences after at least 2 years of follow-up **(4)** [29].

As a fundamentally lower-risk entity, cSCCIS is often studied separately from its invasive counterpart. Although a large 1988 study recorded 18.8% recurrence among 345 cSCCIS 1–5 years after ED&C **(4)** [33], other cSCCIS studies provide substantially lower recurrence rates, at 9.6% after an average of 2.25 years **(4)** [34] and 1.9% after 4 years **(4)** [28].

Cryotherapy

Both prospective and retrospective descriptive studies have examined cryotherapy effectiveness.

Rowe et al. failed to identify studies reaching 5 years of follow-up and thus recorded a short-term recurrence rate of 3.2% after an unspecified time range, with lesions primarily 1 cm or less in size **(4)** [25].

Lansbury et al. compiled 8 studies, also with variable follow-up, to report a pooled recurrence rate of 0.8%. Studies reportedly included low-risk lesions less than 2 cm in diameter **(4)** [26]. The largest study to provide 5-year follow-up data retrospectively reported no recurrences in 134 cSCC in all anatomic locations. Lesions were reported by authors to be <2 cm and amenable to cryosurgery **(4)** [35]. The prospective study with the greatest population also yielded no recurrence after a mean 4.2-year follow-up among 53 face and scalp cSCC, average 8 mm **(4)** [36]. One retrospective study analyzed anatomic sites separately in a cohort of 563 cSCC, 97% of which were < 2 cm. Authors reported a pooled 97.3% cure rate, although the definition of cure was not clearly stated. Locations with "cure rates" less than 97% were the nose (89.8%), eyelids (75%), trunk (93.7%), and scalp (90%) **(4)** [37].

Trials have not analyzed relative effectiveness of various cryosurgery techniques, and no consensus exists for pre-cryosurgery curettage, the number of freeze-thaw cycles, the amount of surrounding tissue requiring freezing, or appropriate thaw time [17, 38]. More prolonged freeze, however, may associate with deeper penetration and higher tissue destruction volume **(5)** [37, 38].

More aggressive cryosurgical treatments have been hypothesized to increase effectiveness in studies of cSCCIS **(5)** [39]. Total freezing times of 30 s and 40 s have yielded recurrence rates at 6.0% or less between 6 months and 5 years **(4)** [40, 41], while a study using a single 20-s freeze reported 21% recurrence at just 1 year **(4)** [42].

Photodynamic Therapy (PDT)

PDT is a newer therapeutic modality with effectiveness data limited to small, prospective studies with variable follow-up.

Initial treatment failure is reported more often following PDT than after ED&C or cryosurgery. Lansbury et al. compiled 14 studies reporting tumor response after PDT, yielding a pooled incomplete excision rate of 28.0%. Of five studies confirming clearance histologically, three revealed clinical examination to be insufficient in evaluating tumor response. Histologic tumor remnants were found in 2 of 10 **(4)** [43], 2 of 2 **(4)** [44], and 6 of 32 **(4)** [45] tumors presumed to have responded completely. Calzavara-Pinton et al. assessed tumor response clinically and found that microinvasive (Clark level II) and invasive (Clark level > III) lesions differed significantly in insufficient clearance, at 8 of 40 (20%) and 17 of 31 (54.8%), respectively ($p < 0.01$) **(4)** [46].

Lansbury et al. reported pooled recurrence rate at 26.4% from 8 studies examining recurrence after apparent initial complete response, none with follow-up reaching 5 years **(4)** [26]. The largest study evaluated outcomes in poor surgical candidates determined based on their general health or if tumors were large or multiple or in surgically difficult areas. Two-year recurrence rates in microinvasive and invasive lesions were 28.1% and 42.9%, respectively, values not analyzed for statistical significance **(4)** [46]. For cSCCIS, a 2003 retrospective study reported 10.5% recurrence for 129 lesions at median 44 weeks **(4)** [47]. Among patients with large lesions and multiple lesions, a 34-month recurrence was 22% **(4)** [48].

Several permutations exist of topical photosensitizer time and type (i.e., ALA vs. MAL) and of light source type, dose, and time; however, no regimens have been studied rigorously for effectiveness in cSCC.

Topical Therapies

Effectiveness data of imiquimod and 5-FU in invasive cSCC is extremely limited. A 2009 systematic review of both treatments found a single study including data for cSCC [22]. In this study, 2/7 (29%) invasive cSCC treated 5 days per week for 12 weeks failed to yield histological clearance **(4)** [49].

Topical therapies are more commonly studied in cSCCIS due to the superficial nature of both the treatment and the tumor. One RCT did compare imiquimod (n = 15) with placebo (n = 16) and found histologic incomplete clearance in 27% of patients 12 weeks after daily imiquimod application for 16 weeks (compared with 0% clearance in the placebo group, $p < 0.001$) **(1a)** [50]. A lower incomplete clearance rate was found in a prospective study among 1/15 (7%) patients applying imiquimod daily for average 12 weeks, mostly to lesions > 1 cm on the legs, examined histologically 6 weeks after treatment **(4)** [51]. The largest long-term imiquimod study was retrospective and included 56 patients treated daily for 9 weeks, with 25% clinical recurrence at 19 months **(4)** [52].

An open-label prospective study of 26 cSCCIS lesions treated twice daily with 5-FU for 8 weeks yielded 15% clinical recurrence after an average follow-up of 4.6 years, with all recurrent tumors in high-risk areas (finger, ear, cheek, penis) **(4)** [53]. Higher 1-year clinical recurrence rates—at 44% and 52%—were found in prospective studies using less rigorous treatment regimens (once daily for 1 week and then twice daily for 3 weeks) **(1b)** [54, 55]. While more intense inflammatory reactions secondary to imiquimod usage have been associated with higher tumor clearance rates, no such correlation has been established with 5-FU **(2a)** [22].

Surgical Excision with Postoperative Margin Assessment (POMA)

A majority of studies evaluating standard surgical excision effectiveness are retrospective. Measures of effectiveness include initial tumor clearance and long-term recurrence.

A 1992 prospective study used MMS to assess tumor clearance in real time using successively larger excision margins. Authors illustrated that wider margins were indicated for higher-risk tumors with greater predilection for subclinical extension. While 95% of tumors required 4 mm margins to clear well-differentiated lesions and lesions <2 cm, less-differentiated lesions and lesions >2 cm required 6 mm margins to reach the same clearance threshold. For 95% clearance of scalp, ear, eyelid, nose, and lip tumors, the 4-mm- and 6-mm-margin patterns emerged for lesions <1 cm and >1 cm **(4)** [56]. Excision margin variations have not been studied head-to-head to compare outcomes. NCCN Guidelines further stipulate that normal-skin margins begin at the periphery of any erythematous tumor rim, which manifests tumor extension **(4)** [15].

Incomplete clearance rates in clinical practice have also been pooled retrospectively. Lansbury et al. assessed 2 prospective and 9 retrospective studies to estimate a failed excision rate of 8.8%, despite variations in surgical margins and in definitions of what constitutes an incomplete excision **(4)** [26]. In the largest prospective study of 469 primary tumors, excision with 2–5 mm margins did not clear tumors in 6.4% of cases **(4)** [57], and lower clearance was seen in auricular lesions compared to other anatomic locations (20.5% vs. 4.8%, $p < 0.001$). Excision of 37 recurrent lesions also had a higher incomplete excision rate of 24.3% compared to the primary tumor rate of 6.3% ($p < 0.001$) **(4)** [57]. The highest incomplete excision rate (25%) was reported in 68 periocular, well-differentiated, and moderately differentiated cSCC tumors excised with 5 mm margins **(4)** [58].

Two systematic reviews determined long-term recurrence rates after standard excision. Rowe et al. reported a weighted 5-year rate of 8.1% in 1990 **(4)** [25]. Lansbury et al. reported pooled recurrence at 5.4% in 2013 and also calculated pooled regional lymph node metastatic rate and disease-specific death rate at 4.4% and 4.1%, respectively **(4)** [26]. A single study with 5-year follow-up retrospectively analyzed 93 cSCC, average size 13.6 mm, and reported no local recurrences but 8 (8.6%) lymph node metastases and subsequent deaths **(4)** [59]. Highest recurrence (13%) and regional metastasis (9%) rates were reported in a study of 54 cSCC on the pinna followed for at least 1 year **(4)** [60].

Among cSCCIS lesions, surgical interventions have shown lowest uniform long-term recurrence. Standard excision led to 2.8% recurrence after mean 31.5 months among 109 cSCCIS in

2008 **(4)** [61] and 4.6% after 1–5-year follow-up of 65 lesions in 1988 **(4)** [33].

Mohs Micrographic Surgery (MMS)

In 1992, Rowe et al. reported weighted 5-year recurrence after MMS at 3.1%. This rate was lowest of the treatments analyzed despite, according to authors, that MMS studies contained "many larger lesions" **(4)** [25]. Lansbury et al. reported similar local recurrence at 3.0% after pooled analysis of 10 prospective and retrospective studies with varied follow-up. Authors also pooled 6 studies to report regional recurrence at 4.2% and 4 studies to yield disease-specific death at 1.1% **(4)** [26].

The largest prospective study followed 615 primary high- and low-risk cSCC over median 43 months and reported recurrence and regional metastasis at 3% and 4%, respectively **(4)** [62]. Auricular tumors yielded significantly greater metastasis risk compared with other sites (9.9% vs. 3.4%, $p = 0.004$) **(2b)** [62]. The largest series with 5-year follow-up prospectively reported recurrence and metastasis rates of 2.6% and 0.0% among 229 high- and low-risk primary tumors, 96.4% on the head and neck **(4)** [63]. A 2010 study of a high-risk cSCC population also had low recurrence and metastasis rates, at 1.3% and 2.2%, respectively **(4)** [64]. For cSCCIS specifically, a 2008 study of 83 lesions yielded 2.4% recurrence after mean follow-up of 26.3 months **(4)** [61].

Comparative Effectiveness of Common Treatments

Caution must be exercised in comparing cSCC treatment outcomes, as individual case series may not be compared given substantial differences between recruited study populations and duration of follow-up.

ED&C and cryosurgery have illustrated the lowest recurrence rates among discrete, single-center studies and pooled analyses; however, these modalities have largely been employed in studies of low-risk lesions. Because these techniques have not been studied in higher-risk cohorts, their relative effectiveness in this population cannot be assessed. PDT has yielded poorest results for both effective tumor clearance and long-term cure among low- and higher-risk invasive cSCC.

MMS has demonstrated high effectiveness in individual observational studies, including those composed of higher-risk lesions. Although no RCTs have compared MMS with standard excision with POMA, pooled analyses from systematic reviews outlined in this chapter have illustrated lower recurrence rates after MMS than after standard excision. However, in a large, prospective cohort study published in 2013, Chren et al. failed to report statistically significant differences in 5-year recurrence between primary cSCC treated with standard excision and MMS. Treatment groups differed substantially when analyzed among all NMSC—tumors treated with MMS were smaller and more likely to lie within high-risk sites. While risk factor-adjusted analyses still failed to detect differences in recurrence, cSCC were not analyzed independently in this analysis **(2b)** [65]. MMS has proven superior to excision in tissue preservation. Van der Eerden et al. showed that among 1504 NMSC, MMS allowed significantly smaller resection defects, after adjustment for anatomic site and primary vs. recurrent disease, compared with standard excision ($3.4cm^2$ vs. $6.3cm^2$). Equivalent effectiveness was maintained at 24-month MMS follow-up and 16-month excision follow-up **(2b)** [66]. This advantage leads to the use of MMS over surgical excision in aesthetically sensitive areas and/or those with a paucity of excess tissue.

Superior effectiveness of MMS has emerged among a number of specific clinical and histologic cSCC subsets, although studies are primarily from the 1990s and earlier. Rowe et al. illustrated MMS' effectiveness in recurrent tumors, with 10% pooled 5-year recurrence vs. 23.3% after standard excision **(4)** [25]. Rowe et al. further demonstrated MMS' high cure rate over non-Mohs modalities in preventing local recurrence at 5 years for tumors located on the

ear (5.3% vs. 18.7%) and on the lip (2.3% vs. 10.5%). Although authors described lower post-MMS recurrence rates vs. non-Mohs modalities for poorly differentiated lesions, those larger than 2 cm in diameter, and those illustrating perineural invasion on biopsy, they did not provide follow-up times for these groups **(4)** [25].

PDT's poor effectiveness in invasive cSCC has limited its evaluation in rigorous studies to low-risk cSCCIS. Within this population, PDT has shown minimal and equivalent 1-year recurrence in RCTs when comparing both ALA- and MAL-PDT with cryotherapy and with 5-FU **(1a)** [23]. CSCCIS patients for whom surgical interventions are infeasible, therefore, may choose PDT over other nonsurgical modalities given the superior cosmesis it affords. Furthermore, broad areas of the skin with multiple cSCCIS lesions may be treated with PDT in a single or repeated session, increasing treatment viability in patients with suspected field cancerization [48].

Procedures for cSCC may be performed in combination such as curettage followed by PDT; however, there are no studies comparing multimodality regimens. Because surgical therapy allows for histologic margin assessment, it is often performed following failures from ED&C, cryosurgery, and PDT to ensure complete tumor extirpation. NCCN Guidelines stipulate that surgery follows any ED&C procedure in which initial curettage yields tumor down to subcutaneous tissue. This event warrants surgical excision due to greater tumor depth of invasion and given that ED&C's effectiveness derives from the physician's ability to distinguish between firm dermis and soft tumor tissue **(5)** [15]. NCCN Guidelines also advocate specifically for the use of MMS in the event that standard surgical excision with POMA fails to clear tumor margins **(5)** [15].

Preoperative Evaluation and Patient Selection

Prognostication in cSCC begins with clinical inspection and palpation of both the involved area and the regional lymph nodes and should be followed with biopsy. Imaging studies play a role in cSCC staging when deep structural involvement—including bone, deep soft tissue, and perineural invasion—or nodal metastasis is suspected. Regional nodal involvement at presentation has been shown to significantly increase mortality risk with a reported hazard ratio of 7.64 ($p < 0.0001$) **(2b)** [67] and commonly coincides with perineural invasion and invasion into subcutaneous tissues **(1b)** [68].

Following assurance that a suspicious lesion is localized to the skin, the practitioner should evaluate patient and tumor features for the classification of the cSCC as either low or high risk and for appropriate tumor staging. NCCN Guidelines for high-risk tumors and AJCC tumor staging are illustrated in Tables 43.2, 43.3**,** and 43.4. Of note, the presence of any risk factor in the NCCN Guidelines is sufficient to place a tumor under the umbrella of "high risk." Because NMSC's ubiquity has rendered it impossible to track in a cancer registry, NCCN has based its prognostic

Table 43.3 AJCC definition of primary tumor (T)

T category		T criteria
TX		Primary tumor cannot be identified
Tis		Carcinoma in situ
T1		Tumor smaller than 2 cm in greatest dimension
T2		Tumor 2 cm or larger but smaller than 4 cm in greatest dimension
T3		Tumor 4 cm or larger in maximum dimension or minor bone erosion or perineural invasion or deep invasion[a]
T4		Tumor with gross cortical bone/marrow, skull base invasion, and/or skull base foramen invasion
	T4a	Tumor with gross cortical bone/marrow invasion
	T4b	Tumor with skull base invasion and/or skull base foramen involvement

AJCC Cancer Staging Manual by Springer [69]. Reproduced with permission of Springer in the format Book via Copyright Clearance Center

[a]Deep invasion is defined as invasion beyond the subcutaneous fat or > 6 mm (as measured from the granular layer of adjacent normal epidermis to the base of the tumor); perineural invasion for T3 classification is defined as tumor cells within the nerve sheath of a nerve lying deeper than the dermis or measuring 0.1 mm or larger in caliber or presenting with clinical or radiographic involvement of named nerves without skull base invasion or transgression

Table 43.4 AJCC prognostic stage groups

When T is…	And N is…	And M is…	Then the stage group is…
Tis	N0	M0	0
T1	N0	M0	I
T2	N0	M0	II
T3	N0	M0	III
T1	N1	M0	III
T2	N1	M0	III
T3	N1	M0	III
T1	N2	M0	IV
T2	N2	M0	IV

cSCC factors on data categorized under NCCN Category 2A, described as lower level but with uniform consensus **(2b)** [15]. AJCC tumor staging for head and neck cSCC uses tumor risk factors shown, through multivariate analysis, to be independently prognostic for poor outcomes. While authors do not assign practice recommendations to different stages, the ability to accurately stage cSCC on the head and neck allows for further risk stratification. Tumors categorized as T1 and T2 without lymph node involvement are staged I and II, respectively. T3 tumors and tumors of any T category (except in situ) with any single regional lymph node involvement are stage III or higher, depending upon lymph node size and presence of extranodal extension **(2b)** [69].

Of special consideration are immunocompromised patients, proven to incur higher risk for cSCC recurrence irrespective of treatment modality. Brantsch et al. reported immunosuppression to associate with more local recurrence and metastasis at average 43 months after MMS, with hazard ratios 3.44 (p = 0.0487) and 4.65 (p = 0.002), respectively **(2b)** [62]. Chren et al. illustrated greater 5-year recurrence in NMSC treated by MMS, ED&C, or standard excision in HIV-infected vs. non-HIV-infected patients (20.8% vs. 2.8%, $p < 0.01$), with MMS comprising a minority of selected therapies in this population **(2b)** [65]. Immunosuppression is thus considered a high-risk criterion regardless of tumor type and location.

A comprehensive understanding of tumor risk allows the dermatologist to engage interdisciplinary collaboration when warranted. Patients with advanced tumors or those requiring lymph node sampling or removal may be referred to head and neck surgery or surgical oncology. High-risk patients who are not surgical candidates may be appropriately managed by radiation oncology. Finally, for those individuals expected to require extensive reconstruction or adjuvant treatment, collaboration with plastic surgery and medical oncology may be necessary.

Impact of Patient Preference

Risk stratification narrows treatment and provider options to those most medically appropriate; however, final therapy selection is a shared decision-making process between the physician and patient. Public demand for accountability and transparency in healthcare has grown over the past several years. Identification of patient concerns and expectations at the consultation opens the door to effective communication and better ensures patient trust and satisfaction throughout the treatment process [70]. Each modality's effectiveness, time requirement, post-procedure recovery, and expected aesthetic and functional outcome should be discussed in the context of the patients' treatment goals.

Patients with low-risk lesions choose between standard excision with POMA, ED&C, cryotherapy, and, in the case of low-risk cSCCIS, PDT and topical agents. Treatment duration and recovery period are considerations that may lead patients to choose one modality over another: ED&C and cryosurgery allow for short procedural times with minimal post-procedure physical limitations. Surgical excision with sutures does not require long wait times but does necessitate activity restrictions. PDT requires the most in-office time due to incubation of the photosensitizing agent, and its recovery period involves short-term avoidance of excessive indoor/outdoor light and diligent sun protection during the

healing process. Topical agents demand several weeks of at-home care and thus require a motivated patient willing to continue medication application despite the expected associated discomfort (erythema, crusting). Treatment discomfort and pain also factor into a patient's treatment decision. Studies generally illustrate more pain secondary to cryosurgery than to ED&C or PDT. In a study of cSCCIS patients, cryosurgery patients were 10.4 times more likely to report any pain than those treated with ED&C ($p < 0.001$) **(2b)** [71]. While PDT may elicit pain specifically during the light treatment, a RCT of 40 cSCCIS patients illustrated less pain following PDT compared with cryotherapy (RR 0.58, 95%CI 0.38 to 0.87, $p = 0.01$) **(1b)** [72], and a systematic review found no statistically significant difference in pain with either MAL- or ALA-PDT compared to 5-FU **(1a)** [23].

Post-procedural cosmetic and functional outcomes have been shown to vary between noninvasive treatments and may thus affect treatment selection. ED&C wounds typically have longer healing times than excisional wounds [19] and tend to leave a white scar that may permanently atrophy or hypertrophy [19]. As cryotherapy areas thaw, pain, swelling, and eschar may persist for several weeks. Like ED&C, both cryosurgery and topical treatments can leave a permanently hypopigmented scar with atrophy or hypertrophy. Although PDT causes erythema, edema, and occasional blistering or crusting, side effects are short-lived and disappear within 1–3 weeks without visible scarring. PDT has demonstrated superiority over cryosurgery and over 5-FU in long-term cosmetic outcome in RCTs **(1b)** [54, 72].

Patients with high-risk lesions are primarily treated with MMS and standard surgical excision with POMA. Dermatologic surgeons perform these under local anesthesia and in the outpatient setting, minimizing the risk of adverse events. The decision to pursue a particular approach is influenced by the time required of the patient as well as the potential aesthetic result. Cosmetic outcome was shown to be very important to patients—though secondary to cancer removal—in a prospective qualitative study of patient experiences after facial skin cancer surgery [73]. MMS requires a time commitment from the patient as the margins are assessed in real time and reconstruction performed the same day. Its ability to minimize removal of healthy tissue, however, can yield superior cosmesis. Margin status is delayed with surgical excision and POMA, and should pathology reveal the tumor to be incompletely removed, the required re-excision has potential to leave a larger scar. Asgari et al. illustrated that while there was no difference in immediate posttreatment satisfaction between MMS and surgical excision with POMA, MMS yielded greater long-term satisfaction 1 year after treatment **(2b)** [74].

Typical Treatment Plan

A 71-year-old, immunocompetent man presented with a 0.8 cm keratotic papule with poorly defined borders on the left mid-cheek, without evidence of regional adenopathy. Biopsy determined the tumor to be a moderately differentiated cSCC, 1 mm in depth, and without perineural or lymphovascular involvement. Although the small lesion lacked pathologic high-risk criteria and lay outside the high-risk "mask" area of the face, its ill-defined borders placed it within the NCCN Guidelines "high-risk" category for recurrence [15]. Its location on the cheek rendered it appropriate for the use of MMS, per published criteria [24]. The patient, a surgical candidate, was thus given the options of surgical excision with POMA and MMS.

The patient and dermatologist determined together that MMS would be the optimal therapy. The patient understood that both surgical modalities carried similar and low risks of recurrence and that MMS could require a full day in the office compared with standard excision's shorter procedure time. The patient expressed, however, that he was more comfortable knowing margin status prior to wound closure. The potential for a larger surgical defect given his tumor's risk for

subclinical extension further concerned the patient for cosmetic reasons, prompting him to elect for MMS given its capacity for tissue sparing.

The patient returned to the office for MMS a week later. He underwent the first MMS stage under local anesthesia, was provided a temporary bandage, and waited in the patient waiting area until his frozen pathology results returned. Given a positive margin in one quadrant of the excised specimen, a second stage was taken from the positive area and was subsequently negative. The Mohs surgeon proceeded to close the wound primarily. The patient was given a pressure dressing and post-procedure instructions.

At the suture removal visit, the patient reported that although his sleep was made difficult due to the location of his wound, his pain was well controlled with acetaminophen. He was instructed to continue skin exams with his dermatologist and return in a few months for follow-up of the scar. On his return, he reported that the residual redness from the scar resolved after a few weeks and that he was able to resume his usual exercise routine shortly after suture removal.

Safety

Although there is a paucity of data confirming frequency of adverse events (AE) among treatments commonly used for cSCC and cSCCIS, these therapies are generally regarded as both safe and well tolerated.

ED&C

AE secondary to ED&C include electrical burns and infection, although few studies have evaluated frequency of these outcomes. In a prospective study, 2 of 44 (4.5%) cSCCIS patients treated with ED&C developed infection sufficient to require oral antibiotics **(4)** [71]. Interference of the electrodesiccation device with implantable cardioverter-defibrillators (ICDs) has also been reported. One study calculated an AE rate in 0.8 ICD patients/100 years of surgical practice following electrosurgery for any condition. Negative outcomes due to electrosurgical interference included syncope, altered mental status, and palpitations. In this study, no significant morbidities or mortalities were reported **(4)** [75].

Cryotherapy

Cryotherapy has also generally proven safe in treatment of NMSC, with AE limited to those of wound healing, including ulceration and infection. In a prospective study, 4 of 36 (11.1%) cSCCIS patients treated with cryosurgery developed infection that required oral antibiotics **(4)** [71]. Another prospective study described post-procedural ulceration in 5 of 20 (25%) cSCCIS lesions treated with cryotherapy, leading to cellulitis requiring systemic antibiotics in 2 patients (10%). Authors reported that 16 of 20 lesions were on the legs but failed to specify anatomic sites of lesions that ulcerated **(4)** [72]. Holt described a series of 395 NMSC patients treated with cryosurgery and reported a number of AE. Three patients (0.8%) developed frank hemorrhage controlled with absorbable hemostatic sutures. The author also noted that 2 of 30 (6.7%) cases on cartilaginous sites developed scar notching due to partial necrosis of underlying cartilage **(4)** [40].

PDT

PDT is well tolerated with an excellent safety profile. Expected side effects secondary to PDT include pain, erythema, burning, irritation, and itching [54]; however, more serious events such as ulceration, infection, or bleeding have rarely been reported. A prospective evaluation of 55 patients with cSCCIS and SCC did not report any local or systemic AE (0%) outside of expected intra-procedure complaints **(4)** [46]. Wolfe and colleagues reported 4 cases of cellulitis in > 700

patients treated with PDT for AK **(4)** [76]. All patients exposed to light sources such as that required for PDT should wear protective glasses to prevent retinal damage, and patients exposed to sunlight during the 48 h after treatment risk severe phototoxicity with ultraviolet exposure.

Topical Therapies

Imiquimod yields a predictable, localized inflammatory reaction that may involve transient itching, edema, weeping, or crusting. Exuberant inflammatory responses may cause erosion or ulceration. A systematic review of imiquimod use in NMSC estimated that 3% of subjects experienced reactions of sufficient intensity to warrant treatment discontinuation **(2a)** [22]. Systemic findings, likened to a "flu-like" illness including malaise and fatigue, are rare and likely secondary to pro-inflammatory cytokines entering systemic circulation [77]. Fluorouracil also produces erythematous local reactions, ranging from mild to severe and possibly involving pain, irritant dermatitis, pruritus, and ulceration. In one study of 5-FU in cSCCIS (applied once daily for 1 week; twice daily for weeks 2–4), severe eczematous reactions developed in 7/33 lesions (21%), and ulceration occurred in 3/33 (9.1%) lesions with resultant prominent scarring **(4)** [55]. A systematic review found that 5% of subjects across 5-FU studies in NMSC discontinued therapy **(2a)** [22].

Surgical Therapies

AE following MMS and standard excision are those inherent to any local surgical procedure. AE incidence has been reported more often for MMS than for standard excision. In a 2013 multicenter prospective cohort study of 20,821 cases, 149 AE (0.72%), including 4 serious events (0.02%) were reported. Common AE were infections (61.1%), partial or full dehiscence and necrosis (20.1%), and bleeding/hematoma (15.4%) **(4)** [78]. In another prospective study of 1358 cases treated with MMS, the overall complication was 1.64%. A majority of complications involved difficulties with hemostasis; none were sufficient even to involve the assistance of another specialist, let alone require hospitalization **(4)** [79]. A prospective study of 1000 consecutive patients treated with either MMS for NMSC (n = 968) or modified MMS ("slow Mohs," n = 32) for lentigo maligna specifically evaluated the rate of surgical site infection without prophylactic antibiotics. Authors determined the rate to be 0.7% (8/1115 tumors) **(4)** [80]. Yet another 1000-patient prospective study using clean surgical technique in MMS for NMSC found an overall rate of infection of 0.91% (11/1204 tumors), with 3 of 11 infections as complications of hematomas **(4)** [81].

Relative Safety

Few studies have compared adverse events for cSCC therapies directly. One RCT compared total adverse events in MAL-PDT, cryotherapy, and 5-FU and reported total AE numbers that did not differ significantly **(1b)** [54]. Another RCT did, however, report statistically significantly fewer adverse events in an ALA-PDT group compared with 5-FU (0/33, 0% vs. 12/33, 36.4%, $p < 0.001$) **(1b)** [55]. Ahmed et al. described cSCCIS patients treated with either ED&C or cryotherapy and reported higher post-procedure infection among cryotherapy patients (4/36, 11.1% vs. 2/44, 4.5%), with all 6 infections arising on the lower legs **(4)** [71].

Postoperative Care and Follow-Up

A diagnosis of cSCC mandates careful, structured posttreatment surveillance both for tumor recurrence and for the development of new malignancies, with greatest vigilance required throughout the first 5 years after treatment.

As illustrated through Rowe et al. and Lansbury et al.'s systematic reviews in 1992 and 2013, respectively, 70–90% of cSCC recurrences and metastases have been reported in case series

and cohort studies to develop within 2 years of initial therapy. Both reviews concluded that 95% of these outcomes occur within 5 years **(4)** [25, 26].

Several studies have illustrated the greater NMSC and melanoma risk incurred by cSCC development. Mean 3-year cumulative risk of subsequent cSCC after index cSCC has been reported at 18%, corresponding to an estimated tenfold greater risk compared with the general population **(2b)** [82]. Adding to this risk, authors found mean 3-year cumulative risk of developing BCC after initial cSCC diagnosis to be 43% based upon 1 retrospective cancer registry-based study **(4)** [82]. Finally, the risk of melanoma is substantially elevated among those with personal NMSC history, on the order of eight times more risk than the general population **(2a)** [83].

Based upon these facts, the NCCN suggests follow-up based on tumor risk profile, with full skin and lymph node examination every 3–12 months for 2 years after treatment, when the majority of recurrences occur. In the 3 years following, patients should be examined every 6–12 months. Finally, a practitioner should examine the patient annually for life, in order to responsibly assess for the development of new malignancies [15].

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
The risk of cSCC metastasis increases with tumor size, depth, location on the ear, and immunosuppression	B
Surgical excision with postoperative margin assessment and Mohs micrographic surgery (MMS) are the most effective treatments for high-risk lesions	C
MMS is effective for lesions in locations with minimal excess tissue and/or near vital anatomic structures	C
There is insufficient evidence to support cryosurgery or ED&C in high-risk cSCC	C
Photodynamic therapy and topical therapies should be limited to low-risk cSCCIS	B
Clinical follow-up is based on tumor risk with visit frequency highest in the first 5 years	C

Self-Assessment Questions

1. High-risk anatomic locations for cSCC include:
   (a) Central face
   (b) Neck
   (c) Ear
   (d) All of the above
   (e) a + c only

2. A 61-year-old, healthy male presents with a 1.3 cm keratotic plaque on the right leg diagnosed as cSCC. The lesion was treated with ED&C several years prior. Which of the following would be the *most* appropriate treatment?
   (a) ED&C
   (b) MMS
   (c) Aggressive cryotherapy
   (d) Combination treatment with photodynamic therapy and curettage
   (e) Any of the above options would be appropriate

3. A 68-year-old woman presents with a 0.5 cm, well-demarcated, scaly papule on the right shoulder. Biopsy reveals well-differentiated cSCC, 1 mm in depth, without evidence of perineural or lymphovascular invasion. Which of the following would be an appropriate treatment?
   (a) ED&C
   (b) Surgical excision with 4–6 mm margins and POMA
   (c) MMS
   (d) All of the above
   (e) a + b only

4. Which of the following statements is true?
   (a) There is no consensus on best techniques for performing cryosurgery on cSCC
   (b) MMS' ability to spare tissue renders it useful for lesions on or near vital anatomic structures (i.e., nose/ear) for preservation of function and cosmesis
   (c) Of all therapies for cSCCIS, photodynamic therapy is least likely to leave permanent scarring
   (d) All of the above
   (e) b + c only

5. According to the NCCN, patients treated for cSCC should be followed with:
   (a) Full skin and lymph node examination every 3–12 months, indefinitely
   (b) Full skin and lymph node examination every 3–12 months for 2 years, every 6–12 months for 3 years, and yearly thereafter
   (c) Examination of the treated site every 3–12 months for 2 years, every 6–12 months for 3 years, and yearly thereafter
   (d) Full skin examination yearly
   (e) CSCC patients need not be followed after definitive treatment

Correct Answers

1. e: a + c only. The central face and ear are part of the "mask area" of the face, considered high-risk for local recurrence or metastasis independent of size.
2. b: MMS. Recurrent tumors are considered "high risk" for future recurrence and metastasis regardless of anatomic location. Of all therapies listed here, MMS is most appropriate high-risk lesions.
3. e: a + b only. This clinically and histologically low-risk tumor is in an anatomic location with sufficient excess tissue for linear reconstruction; therefore, ED&C and standard surgical excision are sufficiently effective therapies. MMS would be effective in permanently eradicating this tumor, but the method's costliness and greater time requirement render it appropriate for use only for higher-risk lesions and anatomic sites.
4. d: All of the above. Each of these statements is true.
5. b: Full skin and lymph node examination every 3–12 months for 2 years, every 6–12 months for 3 years, and yearly thereafter. Ninety-five percent of cSCC lesions recur or metastasize within 5 years after treatment, with a majority of these outcomes occurring within the first 2 years. Posttreatment surveillance should thus be most frequent within the first 2 years after treatment. Furthermore, patients treated for cSCC are at higher risk for NMSC and melanoma development than the general population and should thus receive full skin and lymph node examinations during follow-up visits.

Melanoma in Situ

44

Katherine T. Steele and Christopher J. Miller

Abstract

Melanoma in situ, defined as melanoma entirely restricted to the epidermis and its accompanying epithelial adnexal structures, is increasing in incidence. Detection and treatment of MIS is important, due to the risk of occult invasion or progression to invasive melanoma. There is a lack of high-quality evidence regarding the optimal treatments for MIS. The majority of MIS in the United States are treated with surgical modalities including conventional wide local excision, staged excision, and Mohs micrographic surgery (MMS). Conventional wide local excision effectively treats most well-defined primary melanomas on the trunk and extremities, but the technique has greater than a 10% risk of positive margins and local recurrence for MIS on the head, neck, hands, feet, and pretibial leg. Staged excision with microscopic margin evaluation via formalin-fixed paraffin-embedded sections and MMS achieve local clearance rates of > 98% for in situ and invasive melanomas arising in chronically sun-damaged skin. Anatomic location and history of previous treatment identify melanomas that may benefit from staged excision or MMS to detect subclinical spread of tumor prior to reconstruction.

Epidemiology

In 2017, in the United States, 74,680 cases of melanoma in situ (MIS) were expected to be diagnosed, compared to 87,110 invasive melanomas (1b) [1]. The incidence is increasing more rapidly for MIS versus invasive melanoma (2b) [2]. By definition, MIS is entirely restricted to the epidermis and its accompanying epithelial adnexal structures. MIS is a heterogeneous diagnosis with overlapping clinical and histologic subtypes. Superficial spreading MIS, which occurs most commonly on the trunk and extremities, is characterized histologically by prominent melanocytic nests and relatively less solar elastosis. Lentigo maligna, which occurs most commonly on chronically sun-exposed skin of the head and neck and distal limbs, is characterized histologically by a proliferation of atypical melanocytes at the base of the epidermis in solar elastotic skin. Acral lentiginous MIS, which occurs on the palms, soles, and digits, is characterized histologically by a proliferation of melanocytes arranged as single cells along the basal layer of the epidermis. Oral mucosal and genital melanomas in situ are examples of other less common

subtypes. Although the clinicopathologic features differ among these subtypes, surgical excision is the mainstay therapy for all of them. Therefore, this chapter will address all subtypes as a group, simply called MIS.

Detection and treatment of MIS is important, due to the risk of occult invasion (2b) [3, 4] or progression to invasive melanoma (1b) [5, 6]. Whereas 9,730 deaths were expected to occur in patients with invasive melanoma in 2017 (1b) [1], rates of metastasis and death from MIS were rare, but not zero (1b) [3, 7]. A diagnosis of MIS increases the risk to develop subsequent invasive melanomas of any stage (1b) [8].

While acral, oral, and genital MIS have unique epidemiology, general risk factors for MIS include light skin, hair, and eye color, ultraviolet light exposure, multiple nevi, and a personal or family history of melanoma (1b) [9]. The majority of MIS occur above the waist, but lower extremity location is more common in women (21%) than men (6%) (2b) [2]. The anatomic distribution of MIS shifts with age. Trunk and extremity location is most common in people <50 years old, whereas head and neck location is more common in people >70 years old (2b) [2].

Treatment Overview

Introduction

Surgical excision with clear microscopic margins is the mainstay treatment for MIS (2a) [10]. At least 94% of melanomas in the United States are treated with a method of surgical excision (2b) [11]. Topical imiquimod is a relatively new and less common treatment option, typically reserved to treat lentigo maligna in patients who are not able to undergo surgery (2a) [12].

Methods of Surgical Excision

Methods of surgical excision are divided into three categories: conventional wide local excision, staged excision with microscopic margin evaluation via formalin-fixed paraffin-embedded sections (FFPE), and Mohs micrographic surgery (MMS) with same-day frozen section microscopic margin evaluation (2a) [13].

Conventional Wide Local Excision

Conventional wide local excision removes the clinically visible MIS with a margin of clinically normal skin. No randomized control trial has compared different surgical margins for MIS, so consensus opinion and evidence from case series guide practice. In 1992, expert consensus recommended 0.5 cm surgical margins for MIS (5) [14]. Numerous case series subsequently demonstrated the insufficiency of 0.5 cm margins for up to half of MIS (2b) [15–19]. In a case series of 1120 MIS treated with Mohs surgery, Kunishige et al. demonstrated that a minimum of a 9 mm surgical margin is necessary to clear 97% of MIS (2b) [20]. Based on existing evidence, expert consensus now recommends surgical margins ranging from 0.5 to 1.0 cm, using the wider end of the range particularly for lentigo maligna (2a) [10, 21]. Peripheral excision margins are based on clinical margins taken at the time of surgery, not the gross or histologic margins measured by the pathologists [10]. This distinction is important, because the size of the clinical and pathologic margins correlates in only 12% of the excisions (2b) [22]. While there is no consensus on the depth of the excision (2b) [23–25], extending the excision to the fascia ensures complete removal of MIS extending down adnexa.

The excised specimen is fixed in formalin, with or without orienting sutures, and a pathology lab accessions the gross characteristics and divides the specimen into vertical breadloaf sections. Based on these formalin-fixed paraffin-embedded vertical sections, which sample less than 1% of the surgical margin (2b) [26, 27], a pathologist determines the adequacy of the microscopic margins. If tumor is present at the margins, the pathologist can roughly estimate the location of the residual tumor, as long as the surgeon placed orienting sutures on the initial specimen. The average turnaround time for tissue processing and microscopic margin evaluation is

3–5 days. The surgeon reconstructs the wound immediately after excision and before the microscopic margin evaluation, which risks the need for more surgery if margins are positive. Reconstruction may be delayed until the margins have been evaluated, but this is a form of staged excision.

Staged Excision with Microscopic Margin Evaluation via Formalin-Fixed Paraffin-Embedded (FFPE) Sections

For MIS at increased risk for upstaging or positive margins from conventional wide local excision, staged excision with microscopic margin evaluation via formalin-fixed paraffin-embedded sections may be utilized. Examples of staged excision techniques include the square procedure (4) [28], the spaghetti technique (2b) [29], slow Mohs (4) [30], staged excision with radial vertical sections (2b) [31], and mapped serial excision (2b) [32]. Comprehensive descriptions of each method are beyond the scope of this chapter, and readers are referred to primary sources and excellent review articles for more information (2a) [33].

While the various staged excision techniques may differ in the methods of tissue processing and the percentage of the margin examined, they all involve a pathologist's microscopic margin evaluation via formalin-fixed paraffin embedded sections prior to reconstruction. The surgeon, usually a Mohs or dermatologic surgeon with extensive knowledge of tissue processing, outlines the clinical margin of the tumor and a surgical margin of clinically normal skin. The size of the surgical margins varies by the surgeon and clinical circumstance. The initial excision is performed (contents of the initial excision vary among the techniques), and the patient returns home with a bandage until the microscopic margins have been examined.

The tissue is fixed in formalin and delivered to a histopathology lab, where it is inked and processed for microscopic examination. Melanocytic immunohistochemical stains may or may not be used. The surgeon must communicate with the laboratory personnel to maintain orientation of the tissue relative to the patient and to ensure accurate tissue processing. A pathologist interprets the microscopic margin and communicates the results to the surgeon, usually one to several days after the excision. If the margins are positive, the patient returns for a targeted excision of the residual tumor, then returns home during another round of tissue processing and margin determination. The process continues until margins are clear and the wound is reconstructed.

Tissue processing time and coordinating schedules of the numerous people involved in the care create several logistical challenges. The surgeon and patient will not be sure when the margins are clear, so timing of additional stages and/or reconstruction is uncertain. Dermatopathology labs are frequently unaccustomed to *en face* sections, so errors can occur without careful communication between the surgeon and pathology lab. Since a dermatopathologist interprets the margins, which are often challenging, the surgeon and dermatopathologist must have excellent communication about the clinical relevance of the histopathologic findings.

Mohs Micrographic Surgery (MMS)

Between 2003 and 2009, 3.5% (6872/195,768) melanomas (both invasive and MIS) were treated with MMS, and the utilization rate for MMS increased by 60% during that period [11]. Like staged excision, MMS is used to treat MIS at increased risk for upstaging or positive margins from conventional wide local excision. MMS allows same-day microscopic examination of the entire surgical margin, and pathology is interpreted by the Mohs surgeon, rather than a separate pathologist. The visible tumor is excised with a margin of clinically normal skin. Hash marks are made on the skin surface to maintain orientation relative to the patient. The surgeon grossly sections the excision specimen into pieces that will fit on a microscopic slide. The free cut edges of all grossly sectioned specimens are inked, and a surgical map is drawn to represent the method of gross sectioning and inking. The tissue is frozen, rather than formalin-fixed,

and microscopic frozen sections are cut from 100% of the complete peripheral and deep margins.

For melanoma, the frozen tissue sections are stained with both hematoxylin and eosin and a melanocytic immunohistochemical stain, such as MART-1 or MITF. The Mohs surgeon evaluates the pathology. If tumor is detected at the margin, the Mohs surgeon indicates the precise location of residual cancer on the specimen map. Targeted excision, or a second "stage," is performed around the residual tumor. Again, the free cut edges of the specimen are inked, a map of the specimen is created, and the frozen sections of the entire peripheral and deep margin of the specimen are examined by the Mohs surgeon. The process continues until clear margins are achieved. The average turnaround time for each stage is 1–2 h. Reconstruction is done usually on the same day immediately after confirming clear margin status.

Imiquimod

Imiquimod cream, which induces an immune response to atypical melanocytes, has been used as off-label primary treatment for MIS in patients who are poor surgical candidates since the year 2000 [12]. The cream is used primarily for lentigo maligna subtype of MIS (2a) [34]. Although the Food and Drug Administration has not approved imiquimod for the treatment of melanoma, consensus guidelines include consideration of the topical imiquimod as an *adjuvant* therapy for selected patients with MIS extending to the margins after surgery [10]. However, several publications document the use of imiquimod as a primary therapy for MIS.

Treatment regimens vary widely in the frequency and duration of application and margins around the clinically visible tumor. The typical treatment regimen involves application to the tumor by the patient at a frequency of 5 days per week over a total duration of 12 weeks (2a) [35]. Treatment with > 60 total applications or with >5 applications per week is associated with a higher likelihood of histologic clearance [12]. No randomized, prospective trials have compared the efficacy of imiquimod and surgery (2b) [36]. Concerns with monotherapy treatment of MIS with imiquimod include failure to respond and removal of skin surface pigmentation, which can disguise progression of MIS to invasive melanoma.

Effectiveness of Treatments

Introduction

Local recurrence is the ultimate measure of effectiveness of treatment for melanoma. Reconstruction with positive margins is another important metric, because subsequent surgeries involve more challenging margin assessment and more complex reconstruction (2b) [37]. Most studies evaluating rates of positive margins and local recurrence after conventional WLE group MIS with invasive melanoma. While precise rates for MIS may be lacking, aggregate data for invasive and in situ melanoma likely represent both groups. Invasive melanomas with a component of MIS are known to have an increased risk for positive excision margins, and MIS is the most common cause of positive margins (2b) [38]. Additional support for the relevance of aggregated data is the fact that the frequency of subclinical spread, which is the primary cause of positive margins and local recurrence, does not differ between invasive and in situ melanoma [37].

Conventional Wide Local Excision

Published Rates of Positive Margins After Conventional Wide Local Excision of Melanoma

Reconstruction is done prior to microscopic margin assessment with conventional wide local excision; therefore, this surgical technique risks reconstruction before complete excision of the MIS. The risk for positive margins after conventional wide local excision of melanoma is 2% for melanomas of the trunk and proximal extremities, compared to 12% for tumors on the head, neck, hands, feet, and pretibial leg (2b) [39].

Table 44.1 Published rates of positive margins after conventional wide local excision of melanoma (Miller et al. [39])

Reference	Rate of positive margins	Anatomic locations
Mangold et al. [38]	6% (34/543)	Head and neck: 14% (19/135) Lower extremity: 7% (9/129) Trunk: 2% (4/164) Upper extremity: 2% (2/115)
Berdahl et al. (2b) [40][b]	23% (9/40)	Upper face[a]
Christophel et al. (2b) [41][b]	12% (48/412)	Nose: 15% (6/39) Eyelid: 17% (2/12) Cheek: 14% (15/109) Ear: 6% (5/79) Neck: 10% (5/52) Forehead: 19% (5/27) Lips: 0% (0/2) Temple: 12% (3/25) Scalp: 10% (7/67)
Hou et al. (2b) [42]	8% (22/269)	No location breakdown
Parrett et al. (2b) [43][b]	5% (4/76)	No location breakdown
Sullivan et al. (2b) [44][b]	6% (7/117)	Cheek: 14% (5/36) Forehead: 4.34%(1/23) Neck: 33%% (1/3) Other sites: 0% (0/55)
Rawlani et al. (2b) [45][b]	9% (7/79)	No location breakdown

[a]Upper face defined as the forehead, periorbital region, nose, cheeks, and midfacial region superior to the nasolabial fold

[b]All melanomas were located on the head and neck

Several studies with published rates of positive margins after excision of melanomas (both invasive and MIS are included) are listed in Table 44.1.

Published Rates of Local Recurrence After Conventional Wide Local Excision of Melanoma

Anatomic location on the head and neck is an independent risk factor for local recurrence after conventional wide local excision of melanoma (2b) [46–48]. Noncompliance with recommended excision margins is also an independent risk factor for local recurrence (2b) [47]. Of 3128 head and neck melanomas reported to be treated with conventional wide local excision, 261 (8.3%) developed local recurrence. By comparison, only 1.7% (144/8409) trunk and extremity melanomas developed local recurrences after conventional wide local excision (Table 44.2).

Staged Excision with Microscopic Margin Evaluation via Formalin-Fixed Paraffin-Embedded (FFPE) Sections

Unlike conventional wide local excision, staged excision with microscopic margin evaluation via FFPE delays reconstruction until clear microscopic margins have been confirmed. Therefore, this technique should theoretically have little to no risk of reconstruction before complete excision. The effectiveness of the technique is best demonstrated by numerous references that publish low local recurrence rates (Table 44.3).

Mohs Micrographic Surgery

Like staged excision, MMS reserves reconstruction until clear microscopic margins have been achieved. Therefore, this technique should theoretically have little to no risk of reconstruction before complete excision. The effectiveness of the technique is best demonstrated by numerous references that publish low local recurrence rates (Table 44.4)

Imiquimod

Efficacy of imiquimod is difficult to assess, due to small case series, variable frequency and duration of treatment periods, short follow-up periods, and inadequate methods for assessing recurrence. Clinical assessment is unreliable to determine treatment effectiveness, because the presence or absence of visible pigment does not necessarily correlate with histologic disease (2b) [92]. Based on 347 tumors from 45 studies,

LR Local recurrence

histologic and clinical clearance rates were 76.2% and 78.3%, respectively [12]. Considering available data, the local recurrence rate after imiquimod is approximately 25%, with reported rates ranging from as low as 4.2% to as high as 50% (Table 44.5) [92].

Comparative Effectiveness of Common Treatments

Surgery is highly effective to treat MIS. The relative effectiveness of the different surgical procedures depends on tumor selection (Table 44.6).

	Conventional WLE		Staged excision	MMS	Imiquimod
Positive margins	2%	Trunk and proximal extremities	N/A	N/A	N/A
	12%	Head, neck, hands, feet, pretibial leg, genitalia			
Local recurrence rates	2%	Trunk and proximal extremities	<2%	<2%	25%
	12%	Head, neck, hands, feet, pretibial leg, genitalia			

WLE wide local excision, *MMS* Mohs micrographic surgery

For MIS of the trunk and proximal extremities, conventional wide local excision is highly effective, with an approximately 2% rate of positive margins [39] or local recurrence [49]. Up to 17% of MIS of the trunk and proximal extremities may have subclinical extension more than 5 mm beyond the clinically visible margin, and a margin of at least 9 mm is necessary to ensure complete removal of 97% of MIS [91]. Therefore, to ensure complete removal, excision of trunk and extremity MIS should involve a clinical margin on the wider end of the 0.5–1.0 cm range recommended by consensus opinion. Staged excision and MMS are also highly effective for MIS of the trunk and proximal extremities [49, 91]; however, these techniques should be reserved for a select subset of MIS at high risk for upstaging or positive margins after conventional wide local excision. Risk factors for upstaging include extension of tumor to the base of the preoperative

biopsy, the need for multiple preoperative scouting biopsies due to ill-defined clinical margins, and older patient age (2b) [103]. Risk factors for positive margins after conventional wide local excision include: noncompliance with recommended surgical margins, histologic regression on the diagnostic biopsy, the need for multiple preoperative scouting biopsies to assess ill-defined margins, and increased patient age [39].

For MIS of the head, neck, hands, feet, pretibial leg, and genitalia, staged excision or MMS improves surgical outcomes. Conventional wide local excision for MIS in these anatomic locations has an increased risk for poor outcomes, including a 12% rate of upstaging [103], a 12% rate of positive margins [39], and a 12% rate of local recurrence [49]. Location of melanoma in these anatomic areas is one of the major risk factors for upstaging or positive margins after conventional wide local excision [39, 103]. Both staged excision and MMS allow detection of upstaging, which may be important to optimize patient counseling and utilization of sentinel lymph node biopsy prior to reconstruction, to ensure complete removal of MIS prior to reconstruction, and to decrease the risk of local recurrence to less than 2%. Ensuring complete tumor removal prior to reconstruction and decreasing the risk of local recurrence is important to minimize complexity of the surgery [37] and to restore normal appearance in the anatomic locations valued most highly by patients for their cosmetic and functional roles (2b) [104]. Staged excision and MMS are equally effective; therefore, the choice between the two procedures depends on the expertise of the treating surgeons and institutional and patient preferences.

Compared to greater than 98% local clearance rates after properly selected surgeries, imiquimod has inferior local clearance rates of 76% [12], and local recurrence rates of approximately 25%, but ranging as high as 50% [92]. Due to the markedly inferior outcomes with imiquimod, its use should be reserved strictly for patients in whom surgery is not an option. Consultation with an experienced surgeon is recommended to determine the feasibility of surgery.

Procedure Selection

Preoperative Evaluation and Patient Selection

The most important test for preoperative evaluation for MIS is the diagnostic biopsy. One potential pitfall is a biopsy that only partially samples the melanoma. Partial biopsies are common for melanocytic lesions with uncertain clinical diagnosis, large size, and location in cosmetically or functionally important areas (2b) [105, 106]. Partial biopsies increase the risk that the residual lesion will harbor more advanced melanoma (2b) [107], which can affect patient counseling about prognosis, surgical margins, and indications for sentinel lymph node biopsy [103]. If biopsy of the entire clinically visible lesion is not possible, sampling as much of the lesion as possible prior to definitive excision improves microstaging accuracy.

Another potential pitfall of preoperative biopsy is interpretation of intraepidermal melanocytic lesions with equivocal diagnostic features. Histologic features of MIS overlap with junctional dysplastic nevi and atypical intraepidermal melanocytic proliferation. Discordances in pathologic interpretation are relatively common and can impact diagnosis, staging, prognosis, and surgical management (2b) [108–110]. Interpretation of biopsies of melanocytic lesions at expert melanoma centers may improve diagnostic accuracy (2b) [108, 111].

After a biopsy confirms the diagnosis of MIS, a total body skin exam should be performed, because patients with MIS have an increased risk for additional primary melanomas and other skin cancers [8]. A lymph node examination of the draining basins should be performed, since metastasis and death from MIS can rarely occur [3, 7]. Enlarged lymph nodes suspicious for metastasis should be sampled for pathologic diagnosis. Sentinel lymph node biopsy is not indicated for MIS.

The choice of surgical technique for MIS varies according to the clinicopathologic characteristics of the MIS, the expertise and resources of

Table 44.7 Comparison of logistics of different surgical treatment options for melanoma

	Conventional WLE	Staged excision	MMS
Who excises the tumor?	Surgeon	Surgeon	Mohs surgeon
Who examines the margin under the microscope?	Dermatopathologist	Dermatopathologist	Mohs surgeon
How is tissue processed?	Formalin-fixed paraffin-embedded sections	Formalin-fixed paraffin-embedded sections	Frozen tissue sections with melanocytic immunostains
Typical delay between excision and microscopic margin evaluation	2–5 days	1–3 days	1–2 h
Percentage of surgical margin examined under the microscope	<1% [26, 27]	Up to 100%, depending on method	100%
Ability to perform same day microscopic margin assessment and reconstruction	No	No	Yes

WLE wide local excision, *MMS* Mohs micrographic surgery

the surgeon, and the preferences of the patients. Conventional wide local excision is highly effective for clinically well-defined MIS on the trunk and proximal extremities. Staged excision techniques and MMS are indicated for MIS at increased risk for subclinical spread and complications from conventional surgery, such as pathologic upstaging, positive margins, local recurrence, and reconstructive surgery prior to complete tumor removal. Clinical factors that increase the risk of complications from conventional surgery of MIS and are potential indications for staged excision or MMS include location on the head, neck, hands, feet, and pretibial leg; recurrence after previous treatment; preoperative size >1 cm; and older patient age (2b) [37, 112]. Table 44.7 summarizes key differences between conventional wide local excision, staged excision, and MMS.

Impact of Patient Preference

When deciding among treatment options, patients place highest value on achieving the highest possible cure rate and avoiding reconstruction until complete removal of the cancer has been confirmed (2b) [113]. Patients also place high value on restoring normalcy to the face and hands [104]. Ensuring complete tumor removal prior to reconstruction is especially important in cosmetically and functional important locations, because subsequent surgeries to address positive margins or local recurrence are more complex [37]. Based on these patient preferences, staged excision or MMS should be strongly considered for MIS on the head, neck, hands, feet, pretibial leg, and genitalia, due to the superior local cure rates and assurance that the reconstruction will be performed only after confirming clear microscopic margins. Conventional wide local excision is sufficient for the vast majority of primary MIS of the trunk and proximal extremities. MIS that has recurred on the trunk and proximal extremities after previous treatments may benefit from staged excision or MMS. When staged excision or MMS is indicated, the choice between the two depends on the expertise of the local surgeons and the patients' desire to confirm clear microscopic margins and reconstruct in single versus multiple visits.

Typical Treatment Plan: Case Discussion

Case 1 A 51-year-old woman presents with a new pigmented lesion on the left prescapular back. Based on the lesion's asymmetric shape,

ill-defined borders, irregular color, and large and evolving size, the lesion is biopsied with a 1–2 mm narrow excision. Histology of the biopsy demonstrates MIS, characterized by a proliferation of atypical melanocytes with confluence along the basal layer of the epidermis, nesting, pagetoid spread, and extension down hair follicles. The patient returns for a wide local excision with 0.5–1.0 cm margins. The surgeon consents the patient preoperatively and excises the MIS with a 1.0-cm margin to the muscular fascia in order to maximize the likelihood of complete removal. The wound is closed immediately with a primary closure. The specimen is sent in formalin to a pathology laboratory. Three to five days later, the surgeon receives a pathology report confirming that the MIS has been completely removed. The lesion does not require any additional treatment. The patient is counseled to return at least annually for skin examinations and to perform regular self-skin and lymph node examinations, due to her increased risk for additional primary melanomas.

Case 2 A 75-year-old man presents with a growing pigmented lesion on the tip of the nose. On clinical examination, the lesion has variegated shades of brown and light tan color. Actinic keratoses and a scar from previous surgery of a basal cell cancer are adjacent to the pigmented lesion. A shave biopsy of the darkest portion of the lesion is performed. Histology of the biopsy demonstrates lentigo maligna, characterized by a near confluence of single atypical melanocytes along the basal layer and pagetoid melanocytosis. The patient returns for MMS with MART-1 frozen section immunostains. The clinically visible tumor is outlined, and the lesion is excised with a 5 mm margin of clinically normal skin to the depth of the perichondrium. Hash marks are made on the excision specimen to maintain orientation relative to patient, and a map of the specimen is drawn. A bandage is placed over the wound, and the patient waits while the tissue is processed, and the Mohs surgeon interprets the microscopic margins. Within 1.5 h, the Mohs surgeon confirms the presence of MIS in the breadloafed vertical section of the debulking excision and detects MIS along 25% of the microscopic margin. The bandage is removed, and the surgeon excises an addition 3–5 mm of clinically normal tissue around the residual MIS. Again, hash marks are made on the excision specimen to maintain orientation relative to the patient, and a map of the specimen is drawn. A bandage is placed over the wound, and the patient waits while the tissue is processed, and the Mohs surgeon interprets the microscopic margins. Within another 1.5 h, the Mohs surgeon confirms that the margins are clear. Reconstruction with a paramedian forehead flap is performed immediately after confirming clear margins. The lesion does not require any additional treatment. The patient is counseled to return at least annually for skin examinations and to perform regular self-skin and lymph node examinations, due to his increased risk for additional primary melanomas.

Safety

The actual procedures have similar safety profiles, except for variations in type of anesthesia. MMS is typically performed with excellent safety under local anesthesia, regardless of the location of the tumor (2b) [114–116]. Conventional wide local excision and reconstruction after staged excision of MIS of the head and neck may be more likely to be performed under general anesthesia, which can increase complication rates (2b) [117].

Differences in the safety profiles of procedures for MIS depend primarily on complications from positive margins or local recurrence. Positive margins or local recurrence increase the complexity of subsequent procedures [37]. Local recurrences may have a more advanced stage than primary melanoma, potentially giving patients a worse prognosis (2b) [118]. To avoid complicated procedures and melanoma progression, surgeons should choose surgical procedures that ensure complete removal prior to reconstruction.

Postoperative Care and Follow-Up

MIS has low risk for metastasis, so postoperative surveillance focuses on physical examination of the scar for local recurrence and total body skin examinations to look for additional primary tumors. The risk for metastasis and death from MIS is not zero [3, 7]; therefore examination of draining lymph nodes of previously treated MIS is also indicated. A diagnosis of MIS increases the risk to develop subsequent invasive melanomas of any stage [8].

Patients who undergo skin cancer screening have melanomas detected at earlier stages than unscreened patients (2b) [119]. Consensus guidelines recommend at least lifetime annual screening [10], which may be adjusted more or less frequently according to the patient's risk.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: Quality of evidence
There is a lack of high-quality evidence for the treatment of MIS [120]	N/A
Conventional wide local excision is effective to treat well-defined primary melanomas on the trunk and extremities [103]	A
Conventional wide local excision of MIS on the head, neck, hands, feet, pretibial leg has >10% risk of positive margins and local recurrence [39]	B
Risk factors for subclinical spread include anatomic location on the head, neck, hands, feet, pretibial leg; persistence or recurrence after previous treatment; size >1 cm; and patient age ≥ 60 [112]	B
Staged excision with microscopic margin evaluation via formalin-fixed paraffin-embedded sections achieves 98% + local clearance rates for in situ and invasive melanomas arising in chronically sun-damaged skin on the head and neck [121]	B
MMS with frozen section MART-1 immunostains achieves 99% local clearance rates for in situ and invasive melanomas in chronically sun-damaged skin [49, 89]	B
Anatomic location and recurrence status identify melanomas that may benefit from staged excision or MMS to detect subclinical spread of tumor prior to reconstruction [37]	B
Imiquimod monotherapy of melanoma results in local recurrence rates of 25% [92]	B

Self-Assessment Questions

1. A 44-year-old healthy female presents with a new 0.9 cm dark brown macule with asymmetric shape and uneven pigmentation on the right upper back. A shave biopsy of the lesion is performed and is consistent with MIS. Which management option would be the *least* appropriate?
   (a) Conventional wide local excision
   (b) Mohs micrographic surgery
   (c) Staged excision
   (d) Imiquimod monotherapy, five times per week for 6 weeks
   (e) Slow Mohs

2. A 68-year-old male with a personal history of melanoma in situ on the right cheek presents with a 1.2 cm pigmented patch on the left dorsal hand. He reports that this lesion was previously treated with imiquimod cream but persisted. Biopsy of the lesion is consistent with MIS. Which of the following is **not** a risk factor for subclinical spread of MIS in this patient?
   (a) Age ≥ 60 years
   (b) Personal history of melanoma
   (c) Size >1 cm
   (d) Location on the dorsal hand
   (e) Persistence after prior treatment

3. Conventional wide local excision for treatment of MIS of the trunk and proximal extremities is associated with a local recurrence rate of 2%. By contrast, conventional wide local excision for treatment of MIS of the head, neck, hands, feet, pretibial leg, and genitalia is associated with a local recurrence rate of:
   (a) 9%
   (b) 12%
   (c) 17%
   (d) 24%
   (e) 33%

4. A 74-year-old male has a history of melanoma in situ on the vertex scalp diagnosed 3 years ago and treated with conventional wide local excision. He presents to your clinic for evaluation, and exam shows an 8 mm hyperpigmented macule within the surgical scar on the vertex scalp. Biopsy is performed and is consistent with a recurrent MIS. Which of the following treatments have been shown to have the highest local clearance rates (≥98%) in patients with recurrent MIS located on sun-damaged skin of the head and neck?
   (a) Conventional wide local excision
   (b) Staged excision
   (c) Imiquimod
   (d) Mohs micrographic surgery
   (e) Both B & D

5. A 53-year-old female presents with a 0.7 cm dark brown macule on the left upper arm. Biopsy is consistent with lentigo maligna. After a discussion of treatment options, you decide to proceed with conventional wide local excision for definitive treatment of this lentigo maligna. What surgical margin is necessary to achieve a 97% clearance rate?
   (a) 0.3 cm
   (b) 0.5 cm
   (c) 0.9 cm
   (d) 1.5 cm
   (e) 2.0 cm

Correct Answers

1. d: Imiquimod monotherapy, five times per week for 6 weeks. Imiquimod monotherapy of melanoma results in local recurrence rates of 25% [92], whereas properly selected surgical modalities are associated with less than 2% local recurrence rates. Given this patient's young age, good health status, and location of the tumor on the trunk, she has no contraindications to surgical treatment for this MIS. Given the markedly inferior outcomes with imiquimod, its use should be reserved strictly for patients in whom surgery is not an option.
2. b: Personal history of melanoma. Risk factors for subclinical spread include anatomic location on the head, neck, hands, feet, pretibial leg; persistence or recurrence after previous treatment; size > 1 cm; and patient age ≥60 [112]. While personal history of melanoma increases a patient's risk of developing another melanoma, this has not been shown to be a risk factor for subclinical spread of melanoma.
3. b: 12%. Conventional wide local excision is effective to treat well-defined primary melanomas on the trunk and extremities, resulting in a local recurrence rate of less than 2%. Conventional wide local excision for MIS located on the head, neck, hands, feet, pretibial leg, and genitalia has an increased risk for poor outcomes, including a 12% rate of upstaging [103], a 12% rate of positive margins [39], and a 12% rate of local recurrence [49].
4. e: Both b & d. Both staged excision with microscopic margin evaluation via formalin-fixed paraffin-embedded sections and MMS with frozen section MART-1 immunostains achieve 98% + local clearance rates for in situ and invasive melanomas arising in chronically sun-damaged skin on the head and neck [49, 89, 121]. When staged excision or MMS is indicated, the choice between the two depends on expertise of the local surgeons and the patients' desire to confirm clear microscopic margins and reconstruct in single versus multiple visits.
5. c: 0.9 cm. In a case series of 1120 MIS treated with Mohs surgery, Kunishige et al. demonstrated that a minimum of a 9 mm surgical margin is necessary to clear 97% of MIS [20]. Based on existing evidence, expert consensus now recommends surgical margins ranging from 0.5 to 1.0 cm, using the wider end of the range particularly for lentigo maligna [10, 21].

Merkel Cell Carcinoma

45

Iris K. Noh and Christopher K. Bichakjian

Abstract

Merkel cell carcinoma (MCC), also referred to as primary cutaneous neuroendocrine carcinoma, is a rare but potentially aggressive cutaneous malignancy. First described in 1972 as trabecular carcinoma, MCC is believed to arise from Merkel cells which function as mechanoreceptors in the skin (Tang and Toker, Cancer 42(5):2311–2321, 1978; Toker, Arch Dermatol 105(1):107–110, 1972).

Merkel cell carcinoma · Merkel cell polyomavirus · Immunotherapy · Radiation therapy · Sentinel lymph node biopsy

Introduction

Merkel cell carcinoma (MCC), also referred to as primary cutaneous neuroendocrine carcinoma, is a rare but potentially aggressive cutaneous malignancy. First described in 1972 as trabecular carcinoma, MCC is believed to arise from Merkel cells which function as mechanoreceptors in the skin [1, 2].

Currently, conclusive evidence regarding the optimal management of MCC is limited due to the rarity of this tumor, and lack of prospective, randomized trials and other high-level evidence. The objective of this chapter is to provide those involved in the care of patients with MCC with the best evidence-based recommendations regarding diagnosis, staging, treatment, and follow-up.

A primary reference for this chapter will be the National Comprehensive Cancer Network (NCCN) Clinical Practice Guidelines in Oncology, MCC section (5) [3]. This represents a "best practices" consensus document regarding the management of MCC from a panel of recognized national experts in dermatology, surgical oncology, otorhinolaryngology, dermatopathology, medical oncology, radiation oncology, and hematology/oncology. Although this theoretically is level 5/Grade D evidence, it represents a hybrid of recommendations that is primarily based on the highest level of medical evidence available and secondarily on expert opinion.

Epidemiology and Clinical Characteristics

MCC typically presents as a red to violaceous, firm, and non-tender nodule. In one study, a majority of lesions (56%) were presumed benign at biopsy, with epidermoid cyst as the most likely

diagnosis [4]. The differential diagnosis for MCC may include basal cell carcinoma, squamous cell carcinoma, cyst, pyogenic granuloma, lymphoma, or lipoma. Sun-exposed areas of the body are the most common locations for presentation, with the head and neck region and extremities accounting for 70–90% of all cases [4–6].

The majority of individuals diagnosed with MCC are Caucasian (96%) and at least 60 years of age, with a median age at diagnosis of 76 years. Most studies report a slight male predominance [6, 7]. The US Surveillance, Epidemiology, and End Results registry reports an annual incidence rate of 0.79 per 100,000 persons (approximately 1600 cases annually in the US) and a mortality rate of 0.43 per 100,000. This represents a greater than threefold increase in MCC incidence and mortality from 1986 to 2011, which is likely due in part to a growing aging population [8].

The association with immunosuppression is well documented and seen in approximately 8–15% of individuals diagnosed with MCC [4, 5, 9]. Common underlying causes for the immunosuppressed status may be iatrogenic (e.g., solid organ transplant recipients or individuals with autoimmune disorders) or related to comorbidities such as chronic lymphocytic leukemia or HIV infection [4, 9–13].

Pathogenesis

Recent evidence suggests two distinct tumorigenic pathways for MCC, either ultraviolet- (UV) or viral-dependent. The preferential anatomic distribution of tumors on sun-exposed body surfaces and high proportion of fair-skinned individuals diagnosed with MCC have long suggested UV exposure as an important etiologic factor [6, 14]. Recent studies have identified virus-negative MCC tumors with a high mutational burden characterized by a prominent UV-signature pattern of mutations [15, 16].

In 2008, Feng et al., identified a novel Merkel cell polyomavirus (MCPyV) and described clonal integration of viral DNA in 80% of MCC tumors [17]. MCPyV is commonly acquired as a self-limited childhood infection, and seroprevalence has been reported to range between 59 and 94% among adults in the general population [18, 19]. In MCPyV-positive tumors, MCC tumorigenesis may be promoted as the result of specific truncating mutations of viral T antigens, integration of viral DNA into the human host genome, and inhibition of tumor suppressors such as retinoblastoma (RB1). In support of a dichotomy in MCC tumorigenesis, MCPyV-positive tumors were found to have a low mutational burden and lacked a UV signature [15, 16]. While conflicting evidence exists, some studies suggest that MCPyV-negative tumors may represent a more aggressive subtype associated with a worse prognosis [20].

Diagnosis

Excisional biopsy is preferred for the most accurate diagnosis and microstaging information. Narrow margins are recommended to minimize the risk of inaccurate lymphatic mapping, if a subsequent sentinel lymph node biopsy (SLNB) is indicated [3].

MCC is histologically composed of small round blue cells and can resemble small cell lung cancer (SCLC), melanoma, or lymphoma on standard hematoxylin and eosin (H&E) staining. Additional cytokeratin (CK)-20 and thyroid transcription factor (TTF)-1 immunohistochemical stains should be performed and are best interpreted by an experienced dermatopathologist (4) [21, 22]. CK-20 is a very sensitive (90–100%) but not specific marker for MCC. Up to 33% of SCLCs and 4% of extrapulmonary small cell carcinomas can also stain positively for CK-20. Therefore, staining with TTF-1, which is consistently absent in MCC but expressed in 83–85% of SCLC, is highly recommended. Of note, negative TTF-1 staining supports but does not alone confirm the diagnosis of MCC, since TTF-1 also variably stains extrapulmonary small cell carcinomas (3–42%) [22]. Other immunohistochemical markers with high sensitivity for MCC are synaptophysin, neuron-specific enolase, chromogranin A, neurofilament protein, KIT receptor tyrosine kinase (CD117), BER-EP4, and CAM 5.2 [23]. MCC is invariably negative for S-100 and leukocyte common antigen (CD45), thus distinguishing it from small cell melanoma and lymphoma, respectively.

Staging

Staging is required to help assess prognosis, aid in the counseling of patients, and guide treatment. Because the presence or absence of lymph node metastasis is the most consistent predictor of survival, SLNB is considered standard of care for optimal staging. Numerous studies have confirmed the value of SLN status as a prognostic tool. The incidence of sentinel lymph node (SLN) positivity in patients with MCC without clinical evidence of nodal metastasis has consistently been reported in the 20–50% range regardless of primary tumor size (2b, 4) [24–27]. Immunohistochemical analysis of the SLN with CK-20 and pancytokeratins (AE1/AE3) is critical for acceptable sensitivity and specificity in identifying micrometastatic MCC (4) [28, 29]. Among clinically node-negative patients with localized MCC, 5-year survival rates are consistently better among individuals with pathologically negative nodes (76–97%), compared to those with pathologically positive nodes (42–62%) (2b) [30]. In one study of 364 patients who underwent complete resection of the primary MCC, regional recurrence was 6% in patients with clinically and pathologically negative lymph nodes compared to 21% in patients with only clinically negative lymph nodes who did not undergo pathologic lymph node staging (2b) [31].

The recently published 8th edition of the American Joint Committee on Cancer staging system for MCC is based on the analysis of a total of 9387 MCC cases from the National Cancer Database (2b) [7, 32]. The updated MCC staging system separates pathological from clinical staging to create consistency with all other AJCC staging systems. Approximately 65% of patients with MCC present with stage I or II disease, 26% with stage III, and 8% with stage IV. Stages I and II represent localized disease, in which stage I signifies a low-risk primary tumor measuring ≤2 cm in diameter and stage II a high-risk lesion >2 cm. Stage II is further subdivided to differentiate between primary tumors >2 cm (IIA) and tumors that invade fascia, muscle, cartilage, or bone (IIB).

Stage III represents regional disease; specifically, stage group IIIA includes occult nodal metastasis identified after SLNB or lymph node dissection (LND), whereas IIIB includes clinically or radiologically detected regional lymph node metastasis or in-transit metastasis. The new staging system acknowledges the improved prognostication for patients with clinically detected MCC lymph node metastases without a known primary tumor, who represent approximately 4% of all MCC cases. These individuals, now included in stage group IIIA, are consistently found to have survival rates similar to those with occult nodal metastases, rather than individuals with clinically detected nodal metastases and concurrent primary tumor (stage IIIB) [7]. The most common location of metastasis is the draining lymph node basin (27–60%), followed by distant skin (28–30%), lung (10–23%), central nervous system (18%), bone (15%), and liver (13%) [6, 33]. Stage IV signifies distant metastatic disease.

Imaging

For individuals with localized MCC without clinical evidence of metastasis based on thorough history or physical examination, there is no indication for cross-sectional imaging. SLNB is the most sensitive and specific staging test. While generally unnecessary with appropriate immunohistochemical staining of the primary tumor, appropriate imaging may be considered if a cutaneous metastasis from a primary visceral neuroendocrine carcinoma (e.g. SCLC) cannot be ruled out. Appropriate staging imaging studies are recommended for individuals diagnosed with high-risk MCC, including those presenting with clinically detectable lymph node metastases [3]. Retrospective studies and meta-analyses support use of fluorodeoxyglucose positron emission tomography-computed tomography (FDG-PET/CT), citing high specificity and sensitivity due to high metabolic activity of MCC (2a, 2b) [34, 35]. CT alone has varying sensitivity and may be inadequate for bone and bone marrow metastases [35].

There are no prospective studies to evaluate the need for or the frequency of cross-sectional imaging following treatment of MCC. The need for routine follow-up imaging will greatly depend on the stage of presentation, the risk of recurrence, and patient-specific factors such as underlying

co-morbidities. The potential benefit of early detection of metastatic disease should be weighed against the cost and risk to the patient of repeated scans, including false positive results.

Treatment

Localized Disease

Treatment of primary MCC is generally by wide excision with 1–2-cm margins to fascia with the goal to achieve clear surgical margins. However, no prospective data are available to correlate margin size with recurrence risk. Historically, wide excision was performed with at least 2–3-cm margins. Existing evidence suggests that 1-cm margins may be adequate for smaller tumors, whereas 2-cm margins, when possible, may be preferable for larger tumors (stage II). In a study by Allen et al., relatively low local recurrence rates (8%) were obtained with a mean surgical margin of 1.1 cm. In this study, margins >1 cm were not superior in preventing recurrence compared to margins <1 cm (9 vs. 10%, $p = 0.83$ respectively) [26]. In a different study in which Mohs micrographic surgery (MMS) was performed for primary MCC, a mean margin of 1.7 cm with a median of 1 cm achieved negative margins in a group of tumors with a mean diameter of 1.6 cm. A margin recurrence of 4–8% and overall local recurrence of 16% were reported in this group (4) [36]. MMS may be considered as treatment for primary MCC when a tissue-sparing technique is deemed critical, provided it does not interfere with SLNB when indicated. Following excision of MCC in cases where primary closure is not possible, definitive reconstruction should be delayed until margins are pathologically verified as negative [3].

MCC tumors are known to be radiosensitive, and radiation therapy (RT) can therefore be a useful adjunct [37]. It is currently uncertain whether, or under which circumstances, adjuvant RT to the tumor bed provides a more favorable outcome. Most published studies are not standardized in their methods, which makes interpretation of the results problematic and the ability to draw meaningful conclusions difficult. Studies on the adjuvant use of RT for MCC are invariably retrospective with missing or mixed lymph node status, generally lack criteria for selection of adjuvant RT, and often group local and regional recurrences together. Furthermore, much evidence supporting the general use of regional RT in MCC antedates the routine use of SLNB. Representative studies that showed no benefit or benefit with adjuvant RT are listed in the references section for interest (2b, 4) [6, 24, 26, 31, 36, 38–45]. Clinically valuable recommendations regarding this issue come from the NCCN Practice Guidelines in Oncology. In these guidelines it is suggested that following wide excision with clear margins of a primary tumor <1 cm in diameter, without adverse histologic parameters such as lymphovascular invasion, in an immunocompetent patient, adjuvant RT may likely be omitted. Of note, single-institution studies suggest a similar approach for tumors <2 cm (2b) [31, 39]. Following wide excision of a primary MCC under all other circumstances (e.g. larger tumors, adverse histologic parameters such as lymphovascular invasion), or when sufficiently clear surgical margins cannot be obtained, strong consideration should be given to adjuvant RT to the primary tumor bed (2b) [31, 46]. 5-cm RT field margins are recommended with a minimum of 2 cm when anatomy is constraining (4) [3, 47]. Finally, if a patient is deemed inoperable for wide excision of a primary tumor due to comorbidities or based on tumor characteristics, RT monotherapy as primary treatment for MCC may be considered (4) [48–50]. Decisions regarding RT should be made based on multidisciplinary consultation, if possible [39].

Available retrospective studies do not suggest a prolonged survival benefit for adjuvant chemotherapy, which therefore has no established role in the treatment of localized MCC.

Regional Disease

For individuals with primary MCC without clinical evidence of nodal metastasis, SLNB is recommended at time of surgery, for staging and early detection of occult nodal disease [3, 29].

The recommendation relates to primary MCC in all locations, including the head and neck, where successful lymphatic mapping and SLNB can be achieved by experienced surgeons with similar false negative rates as in non-head and neck locations (2b) [51]. Sentinel lymph node biopsy should preferably be performed before excision of the primary tumor to obtain the most accurate lymphatic mapping and lowest risk of a false negative result [3].

A positive SLN confirms the presence of nodal metastasis, which is associated with a poorer prognosis compared to an individual with a pathologically negative SLN [7]. To decrease the risk of nodal recurrence, additional treatment to the involved lymph node basin is indicated. Failure to treat occult nodal disease has been shown to result in higher recurrence rates (4) [24, 52, 53]. However, optimal treatment for occult nodal disease remains uncertain. Completion LND (CLND) has been the most commonly reported treatment in the setting of a positive SLNB and has shown low rates of recurrence in several small case series (4) [52, 54, 55]. For patients with extensive lymph node involvement and/or extracapsular extension, adjuvant RT following CLND should be considered [3]. Radiation therapy has also been reported to be effective as monotherapy for occult nodal disease and may be considered as an alternative therapy for individuals in whom CLND may be associated with unacceptable morbidity [29, 56].

Importantly, if SLNB is negative, patients can be spared the morbidity of additional surgery and/or RT to the regional nodal basin. Several retrospective studies show no recurrence or survival benefit from RT to the regional nodal basin, including the head and neck, following successful lymphatic mapping and a negative SLNB (2b) [24, 25, 57].

When a clinically suspicious lymph node is detected on physical exam or imaging study, fine needle aspirate or core biopsy with appropriate immunohistochemical analysis should be performed to confirm metastatic disease. If clinical suspicion remains following a negative result, open lymph node biopsy should be considered [3]. For clinically detected lymph node metastases, without evidence of distant disease, CLND is considered standard of care, with RT as an alternative treatment for those in whom the morbidity of surgery is deemed to be unacceptable. Adjuvant RT following CLND should be considered for those with extensive lymph node involvement and/or extracapsular extension [32]. However, the available evidence is limited to case reports, retrospective case series, or meta-analyses, and prospective studies are lacking.

While earlier studies suggested a potential benefit from adjuvant chemotherapy with or without RT for patients with high-risk regional MCC [58], subsequent evidence has not confirmed a benefit (2a) [59]. In a prospective study, patients with high-risk localized or regional MCC who received synchronous RT and adjuvant chemotherapy with carboplatin and etoposide did not experience a survival benefit compared to historical controls not treated with chemotherapy (2b) [60]. Given the lack of evidence regarding the benefit of adjuvant chemotherapy and associated morbidity (including immunosuppression, a poor prognostic indicator in MCC), the use of adjuvant chemotherapy following treatment of localized or regional disease with surgery and/or RT is generally not recommended. It should be noted that case series have shown successful palliative treatment of intransit metastases with hyperthermic isolated limb perfusion with tumor necrosis factor α, interferon γ, and/or melphalan (4) [61, 62].

Distant

Historically, the most common systemic chemotherapeutic regimens for metastatic MCC have been combination therapy with cisplatin or carboplatin plus etoposide or second- and third-line chemotherapy regimens (such as topotecan, cyclophosphamide, doxorubicin, epirubicin, or vincristine). MCC is generally very sensitive to chemotherapy, with response rates reported in case reports, retrospective series and reviews as high as 60–70% [63]. However, responses are not durable, generally resulting in tumor recurrences within 4–15 months (2b) [64]. Moreover, the associated toxicity, including chemotherapy-induced immunosuppression, may have an

additional negative impact on survival (2a) [59, 65]. Factors such as an individual's anticipated lifespan and performance status, the anticipated toxicity of the selected chemotherapy regimen, and potential survival benefit should all be considered when deciding upon chemotherapy.

Advances in immunotherapy have dramatically changed the treatment of patients with metastatic melanoma since the introduction of ipilimumab in 2011 [66]. Recent studies cautiously suggest a potentially equally significant impact of immunotherapy on the management of patients with metastatic MCC. Pembrolizumab is an anti-programmed death 1 (PD-1) antibody approved for treatment of melanoma and non-SCLC. A small single-arm phase II trial of pembrolizumab as first-line treatment for 26 patients with advanced MCC recently reported a 56% response rate (4 complete and 10 partial) and 6-month progression-free survival of 67% (2b) [67]. Drug-related grade 3 or 4 adverse events occurred in 15% of the patients.

The first US Food and Drug Administration-approved treatment for metastatic MCC was granted in March 2017 for avelumab, an anti-programmed death-ligand 1 (PD-L1) antibody. Approval was based on data from an open-label, single-arm, multi-center phase II trial of 88 patients with stage IV chemo-refractory MCC. After a median follow-up of 10.4 months, the objective response rate was 32%, including 8 complete and 22 partial responses, with ongoing responses at time of analysis. Serious treatment-related adverse events were reported in 6% of patients; there were no treatment-related deaths (2b) [68]. Of note, response rates to both pembrolizumab and avelumab were regardless of MCPyV status [67, 68].

Results of ongoing and future trials are needed to confirm these initial favorable results of immune checkpoint inhibitors for the treatment of patients with metastatic MCC. Moreover, despite promising results, immunotherapy is relatively contraindicated in solid organ transplant recipients, due to the risk of organ rejection. Ongoing research and the development of targeted therapy are needed to impact the management of MCC in this cohort of patients with a generally poor prognosis. Finally, trial development is currently in progress to determine the role of immunotherapy as an adjuvant treatment for patients with MCC.

Postoperative Care and Follow-Up

Overall recurrence rates for MCC in the literature are generally high, ranging from 40% to as high as 77% on the head and neck, although this may no longer be an accurate reflection of current practice [6, 69]. The median time to recurrence is consistently around 8 months with over 90% of recurrences occurring within 2 years of diagnosis [6, 38, 69]. Therefore, close clinical follow-up with complete total body skin exam, lymph node exam, and focused review of systems with symptom-directed imaging work-up is recommended to monitor for local, regional, and distant recurrence. While no prospective evidence exists, NCCN recommends follow-up every 3–6 months for 2 years and every 6–12 months thereafter [3]. For high-risk individuals, based on disease stage or underlying co-morbidities such as immunosuppression, routine cross-sectional imaging may be considered to monitor for recurrence. Recent studies suggest that determination of MCPyV T-antigen oncoprotein may assist in the management of patients diagnosed with MCC; when present, increasing titers may have a predictive value for recurrent disease [70].

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: Quality of evidence
Histologic diagnosis	
Excisional biopsy with narrow margins is preferred to incisional biopsy	D
Appropriate immunohistochemical stains should include CK-20 and TTF-1 to differentiate between primary cutaneous Merkel cell carcinoma (MCC) and metastatic visceral neuroendocrine carcinoma	C
Appropriately experienced dermatopathologists should perform the histopathologic interpretation	D
Staging	
Initial work-up includes thorough history and physical exam with complete skin and lymph node exam	D
Imaging (CT, MRI, PET/CT) may be indicated to rule out distant metastatic disease based on clinical suspicion or in individuals diagnosed with high-risk disease such as clinically detected nodal disease	D
PET/CT has high specificity and sensitivity for metastatic MCC	B
Pathologic lymph node status is the most consistent predictor of survival	B
Sentinel lymph node biopsy should be performed antecedent or concurrent to wide excision for clinically node-negative patients	D
Treatment	
Localized disease (clinically node negative)	
Wide excision with 1–2-cm margins to investing fascia of muscle or pericranium with clear pathologic margins should be obtained whenever possible	C
Adjuvant radiation therapy (RT) to the tumor bed should be considered for larger tumors, adverse histologic parameters, or positive margins	B
Adjuvant RT may be omitted for smaller tumors (e.g. ≤1 cm) without adverse histologic parameters, in an immunocompetent individual	B
Sentinel lymph node positive: completion lymph node dissection (CLND) and/or RT to nodal basin	C
Sentinel lymph node negative: Observation of nodal basin	B
Regional disease (clinical nodal metastasis without distant disease)	
CLND	C
Adjuvant RT following CLND should be considered for those with extensive lymph node involvement and/or extracapsular extension	D
Distant disease	
Clinical trial preferred if available	D
Consider following therapies alone or combination: immunotherapy, chemotherapy, radiation therapy, and/or surgery, as clinically indicated	C
Follow-up	
Complete skin and lymph node exam every 3–6 months for year 1–2 and every 6–12 months thereafter	D
Imaging studies as clinically indicated	D

Self-Assessment Questions

1. Given the gravity of a diagnosis of MCC, accurate initial diagnosis is critical to facilitate appropriate and timely treatment. Which of the following is FALSE?
   (a) Incisional biopsy is preferred to excisional biopsy with narrow margins.
   (b) MCC is histologically composed of small round blue cells and can resemble small cell lung cancer, melanoma, or lymphoma on standard hematoxylin and eosin (H&E) staining.
   (c) Cytokeratin-20 is a sensitive marker for MCC, but it may also stain positively in small cell lung cancer.
   (d) Thyroid transcription factor-1 is a sensitive marker for small cell lung cancer and is absent in MCC.
   (e) For the highest probability of accurate diagnosis, appropriately experienced dermatopathologists should perform the histopathologic interpretation.

2. Correct staging of MCC is important to help determine prognosis and proper treatment. Which of the following is FALSE?
   (a) The most consistent predictor of survival is lymph node status.
   (b) The incidence of sentinel lymph node positivity in patients with MCC without clinical evidence of nodal metastasis has consistently been reported in the 20–50% range regardless of primary tumor size.
   (c) For asymptomatic patients with clinically localized disease, imaging studies are indicated as part of staging work-up.
   (d) Patients with clinically detected MCC lymph node metastases without a known primary tumor have survival rates similar to those with occult nodal metastases.
   (e) There is no clear evidence that early detection and treatment of asymptomatic distant metastatic disease has a significant impact on survival.

3. MCC most commonly presents as localized disease. Which of the following statements is TRUE concerning the treatment of localized disease?
   (a) Wide excision with 2-cm margins and postoperative radiation therapy is indicated for all primary tumors.
   (b) Wide excision with 1–2-cm margins and antecedent or concurrent SLNB, with or without adjuvant radiation therapy, is indicated for most primary tumors.
   (c) SLNB can be performed either before or after wide excision with equal accuracy.
   (d) Postoperative radiation therapy has been definitively shown to be beneficial in the treatment of localized disease.
   (e) Adjuvant chemotherapy is associated with prolonged survival.

4. MCC may present as regional or distant disease. Which of the following statements is FALSE concerning the treatment of regional or distant disease?
   (a) For clinically detected lymph node disease, fine needle aspiration (FNA) or core biopsy is indicated, followed by appropriate imaging studies if positive.
   (b) When FNA or core biopsy of clinically concerning lymphadenopathy is negative, open lymph node biopsy is appropriate.
   (c) There is evidence definitively substantiating a benefit from chemotherapy in the treatment of regional or distant disease.
   (d) Avelumab, a PD-L1 antibody was FDA approved for stage IV chemo-refractory MCC.
   (e) Immunotherapies have shown up to 30% objective response rates regardless of MCPyV status.

5. All patients with MCC will require close follow-up due to the propensity for recurrence. Which of the following statements regarding follow-up for MCC is FALSE?
   (a) Follow-up schedules for MCC are determined by the fact that the median time to recurrence is 8 months with 90% of recurrences occurring in 24 months.
   (b) An appropriate follow-up schedule is every 3–6 months for the first 2 years and every 6–12 months thereafter.
   (c) At each follow-up visit, a complete skin exam and PET/CT scan should be performed.
   (d) MCPyV T-antigen oncoprotein titer may assist in the management of patients diagnosed with MCC; when present, increasing titers may have a predictive value for recurrent disease.
   (e) The NCCN practice guidelines are an excellent resource to stay current on the latest in consensus and evidence-based treatment recommendations regarding MCC.

Correct Answers

1. a: Incisional biopsy is preferred to excisional biopsy with narrow margins. This is false. Excisional biopsy is preferred for the most accurate diagnosis and microstaging information. All other statements are true.
2. c: For asymptomatic patients with clinically localized disease, imaging studies are indicated as part of staging work-up. This is false. There is no indication for cross-sectional imaging for individuals without clinical evidence of metastasis.
3. b: Wide excision with 1–2-cm margins and antecedent or concurrent SLNB, with or without adjuvant radiation therapy, is indicated for most primary tumors. This is true. A is false because SLNB, a standard of care for MCC staging, is not mentioned. Not all tumors require excision with 2-cm margin and adjuvant radiation therapy. C is false because SLNB should be performed before or concurrent to the wide excision for most accurate mapping. D is false because it is uncertain whether and under which circumstances adjuvant RT provides a more favorable outcome. E is false because available retrospective studies do not show prolonged survival benefit for adjuvant chemotherapy.
4. c: There is evidence definitively substantiating a benefit from chemotherapy in the treatment of regional or distant disease. This is false; MCC is generally very sensitive to chemotherapy; however, response rates are not durable, and treatment is associated with high toxicity. All other statements are true.
5. c: At each follow-up visit, a complete skin exam and PET/CT scan should be performed. C is false because the need for routine follow-up imaging will greatly depend on the stage of presentation, the risk of recurrence, and patient-specific factors such as underlying co-morbidities. All other statements are true.

Dermatofibrosarcoma Protuberans

46

Jennifer Hau and Shang I. Brian Jiang

Abstract

Dermatofibrosarcoma protuberans (DFSP) is a rare, slow-growing sarcoma. DSFP has low metastatic potential but may be locally aggressive, exhibiting extensive subclinical extension and a high local recurrence rate. Treatment of disease centers on complete surgical resection with emphasis on negative histologic margins and maintaining good function and cosmesis. Treatment options include Mohs micrographic surgery (MMS), modified MMS, wide local excision (WLE), and WLE with circumferential and peripheral deep-margin pathologic assessment. MMS or modified MMS may allow lower recurrence rates than conventional WLE and may be considered first-line options. WLE with circumferential and peripheral deep-margin pathologic assessment may also enable lower recurrence rate with smaller margins. Postoperative adjuvant radiotherapy may be considered in unresectable disease. Imatinib mesylate may be used for unresectable, recurrent, and/or metastatic cases. Other targeted therapies may be beneficial. Treatment approach should take individual factors into account including patient comorbidities, tumor characteristics, and treatment availability.

Keywords

Dermatofibrosarcoma protuberans · Cutaneous sarcoma · Mohs micrographic surgery · Wide local excision · Imatinib mesylate

Dermatofibrosarcoma protuberans (DFSP) is a rare cutaneous sarcoma. DFSP is typically locally aggressive, with high local recurrence but low metastatic potential.

Epidemiology

DFSP accounts for 0.1% of all malignancies with an annual incidence of approximately 4.1–4.5 cases per million person-years in the United States (2c) [1–3]. DFSP typically presents in the third to fifth decade of life but may present in infants or elderly patients as well [2]. While a slight male predominance has been reported (2c) [4, 5], other large population-based studies have found a slightly higher incidence rate in women [1, 2]. Hence, there seems to be an overall similar incidence of DFSP in men and women (2c) [2, 6]. The annual incidence of DFSP in African

Americans in the United States is almost twice as high as in Caucasians and significantly higher than other racial groups [1, 2]. A pigmented variant, the Bednar tumor, accounts for approximately 5% of DFSP cases and is more common in black patients [1]. DFSP most commonly arises on the trunk in 42% of cases. Less often, it is found on the upper extremities (23% of cases), lower extremities (18%), and head and neck (16%) [2]. Rare sites of involvement include the breast, vulva, or penis (5) [7].

Risk factors for DFSP development have not yet been defined (5) [8]. Prior traumas have been suggested, though the significance of this association remains unclear. In a study of 12 African-American patients, 4 reported prior trauma (4) [9]. Associations with surgical scars, burn scars, and prior immunizations have also been reported (4) [10]. These studies suggest that approximately 10% of patients with DFSP reported prior trauma at site of the tumor. However, other studies have failed to find an association between DFSP and trauma (4) [11]. As such, the significance of trauma on DFSP development remains unclear [8].

Kurlander et al. reviewed the National Cancer Institute's Surveillance, Epidemiology, and End Results Program (SEER) data for 3734 patients with DFSP and found a 25% increased risk of a subsequent primary malignancy. This increased risk was largely due to a 21-fold higher risk of other nonepithelial skin cancers, including a subsequent primary DFSP, and 5-fold increased risk of soft tissue malignancy. Also, women with DFSP had a higher risk of subsequent female hormone-related cancers including breast cancer, other soft tissue cancers, and melanoma (2b) [12]. DFSP onset and an accelerated growth phase have been noted during pregnancy (4) [13, 14]. This raises the possibility of a hormonal influence in tumor development and/or growth, but the association remains uncertain [14]. The increased risk of subsequent primary nonepithelial skin cancers and melanoma is specifically of note as localized tumors would likely require further treatment with cutaneous surgery.

Treatment Overview

Treatment of localized disease, primary or recurrent, is complete surgical resection with negative histologic margins, either by wide local excision (WLE), Mohs micrographic surgery (MMS), or modified Mohs surgery followed by surgical repair. DFSP is characteristically a locally infiltrative tumor that can have an irregular, tentacle-like growth pattern. The tumor may diffusely infiltrate the dermis and subcutaneous tissue, as well as deeply involve fascia or muscle. The extension of the tumor may be difficult to visually define, presenting a challenge for surgical excision and contributing to the propensity for local recurrence (4) [15]. Positive or close resection margin involvement is associated with increased risk of local recurrence [4]. Confirmation of negative margins is paramount, and it should precede reconstructions requiring extensive undermining or tissue movement if possible (5) [16].

Currently, there are no standard margins for WLE [8]. The National Comprehensive Cancer Network (NCCN) and European interdisciplinary group consensus guidelines recommend 2–4-cm margins to investing fascia or muscle or pericranium (5) [16, 17]. WLE using en face tangential sectioning to allow complete circumferential and peripheral deep-margin assessment in pathologic evaluation may lead to a lower recurrence rate (4) [18, 19].

Sometimes the recommended 2–4-cm margins can be difficult to obtain in tissue-limited areas such as the head and neck. Thus, Mohs micrographic surgery is increasing in use and may be preferable for the treatment of DFSP in younger patients or tumors involving the face or neck where tissue conservation is critical. However, there is some concern that residual or peripheral DFSP cells may resemble normal benign scattered spindle cells in dermal tissue, especially in frozen sections even with the use of rapid CD34 immunostaining (5, 4) [20, 21]. This potential difficulty in histologic interpretation prompted some surgeons to send an additional

final margin of tissue for permanent formalin-fixed, paraffin-embedded sectioning and histopathologic evaluation after tumor clearance using frozen section technique. Others prefer avoiding frozen sections altogether and adopt the modified Mohs surgery technique or "slow Mohs" in which all tissue specimens are sent for permanent sectioning at every stage (5) [22].

Regardless of approach for surgical removal, repair of the surgical defect, specifically reconstruction that involves extensive undermining or tissue movement, should be delayed until after negative histologic margins are confirmed. If concern for positive surgical margins exists, split-thickness skin grafting is recommended to allow monitoring for recurrence [16].

Due to the rarity of DFSP, there are no randomized trials comparing WLE with Mohs surgery. Individual tumor characteristics, as well as functional and cosmetic concerns, should be considered when determining surgical approach (2a) [8, 23]. SEER data from 1972 to 2012 demonstrated 3381 cases treated by excision (91.7%) and 305 (8.3%) treated by MMS (2c) [24].

DFSP is radiosensitive and radiotherapy may be used for unresectable tumors, recurrent tumors, or as adjuvant therapy for locally advanced large tumors with positive surgical margins (4) [25]. If negative surgical margins are achieved, adjuvant radiotherapy is not recommended [16]. Over 90% of DFSP tumors have a t(17;22) translocation. The resulting platelet-derived growth factor beta (PDGF-beta)/collagen Type 1A1 fusion gene mutation leads to upregulation of PDGF-beta receptor that can be targeted by the protein tyrosine kinase inhibitor imatinib [15]. Imatinib may be helpful in locally advanced, unresectable, or recurrent disease [22]. Currently, imatinib is recommended for patients with positive surgical margins after re-resection, recurrent disease in functional or cosmetically sensitive areas, or in metastatic disease [15].

A small percentage of DFSP demonstrate higher-grade fibrosarcomatous change with increased cellularity, cytologic atypia, and mitotic rate and a herringbone pattern on histologic exam. These tumors are categorized as a fibrosarcomatous variant of DFSP (DFSP-FS) and are potentially more aggressive [4]. While the prognostic significance of fibrosarcomatous change and/or high-risk features including high mitotic rate in DFSP remains unclear, tumors with these histologic features should be treated according to NCCN guidelines for soft tissue sarcoma. Treatment of these tumors may include surgical excision with appropriate margins, radiation therapy, chemotherapy, and/or observation and supportive care depending on staging (5) [26].

Effectiveness of Treatments

DFSP has the best overall prognosis of soft tissue sarcomas in the US [6]. Overall, 15-year survival is 97.2% and cause-specific 15-year survival is 99.7% [2]. However, morbidity relating to tumor extent can be significant, especially in cases of local recurrence [4].

Historically, in reports from the 1960s to 1980s, wide local excision recurrence rates ranged widely from 11% to 60%, depending on location and surgical margins [22]. Interpretation of past data has been difficult as wide local excision was not well defined and margins not standardized. An association between resection margin and prognosis was demonstrated in a study of 159 patients, 51 of which had involved resection margins and 15 of which had close involvement (<1 mm from margins). At a median 57-month follow-up, 34 recurrences were noted, 29 of which developed in patients with either positive or closely involved margins [4].

As such, recent studies of WLE of DFSP advocate for wider margins and are associated with much lower rates of local recurrence (2c) [27]. In 2006, Monnier et al. performed a retrospective review study of 66 patients from a population-based French cancer registry and found a local recurrence rate of 47% with margins less than 3 cm and 7% with margins from 3 to 5 cm [5]. In 2009, Huevel et al. examined 38 patients in The Netherlands treated with WLE

with 2–3-cm margins and found negative resection margins in 95% and a local recurrence rate of 7% at a median follow-up of 89 months (4) [28]. In a retrospective study of 24 patients with primary or recurrent tumors treated with 2.5–3.3-cm margins, Khatri et al. found a 100% local recurrence-free survival at a median 54-month follow-up (4) [29]. Cai et al. studied 260 patients treated in China and demonstrated that patients treated with margins ≥3 cm had a lower local recurrence rate of 5.7% compared with a 13.6% local recurrence rate in patients treated with 1.5–2.5-cm margins (4) [30]. In a study of 244 patients with DFSP, tumor depth was strongly associated with disease-free survival in primary tumors, underscoring the importance of excision of deep fascia. Margin status was strongly associated with disease-free survival in recurrent tumors (4) [31]. Accordingly, NCCN guidelines have since established margins for wide local excision of DFSP between 2- and 4- cm and down to investing fascia or muscle or pericranium (5) [16, 32]. Additional recent studies have further supported the use of WLE for DFSP (4,4) [33, 34]. Pooled data from the past 20 years demonstrates a local recurrence rate of 7.3% in 1443 patients treated with WLE [22]. However, head and neck lesions have higher reported recurrence rates than other sites treated with WLE, up to 50–75% [23]. Up to 80% of local recurrences occur in the first 3 years after WLE [27].

While it is now largely accepted that wider surgical margins lead to decreased local recurrence, modified surgical and histopathologic approaches with decreased margins have been proposed. In a study of 204 patients, Farma et al. reported only a 1% recurrence rate in patients with DFSP treated using a modified approach with narrower 1–2-cm margins and en face tangential sectioning at a 64-month follow-up period. Defects were not closed until negative complete histologic margins were confirmed. Approximately 20% of tumors treated required multiple excisions [19]. DuBay et al. reported a 0% recurrence rate in 44 patients treated with a multidisciplinary modified WLE approach emphasizing meticulous pathologic exam [18]. Woo et al. found that intraoperative frozen section analysis of wide local excision margins had an accuracy rate of 100% when compared with permanent sections (4) [35]. These studies demonstrate that a meticulous surgical and pathologic approach that allows complete circumferential and peripheral deep-margin assessment in pathologic evaluation enables a lower recurrence rate. In this way, this modified WLE approach shares similarities with the MMS technique [22, 23].

While wide local excision has long been the treatment of choice, MMS has emerged as another effective treatment. The asymmetric and infiltrative architecture of DFSP can make determination of optimal margins for WLE challenging. In a study of 58 patients with primary and recurrent DFSP treated with MMS, Ratner et al. found that microscopic disease was detected beyond 1 cm in 70.7% of patients (4) [36]. Serra-Guillén et al. studied 74 patients treated by MMS and found microscopic disease was detected beyond 1 cm in 46% of cases (4) [37]. These studies demonstrate that subclinical extension can be extensive and vary widely, thus DFSP tumors can benefit from treatment with the MMS technique. Given the size and extent of DFSP, some authors report performing an initial debulk of clinically visible tumor before taking a first layer with wider (0.5–1.0 cm) margin around and under the debulked lesion in order to decrease number of stages required for tumor clearance (5,4) [22, 38, 39]. MMS enables a higher rate of margin clearance at time of excision. Furthermore, MMS may afford smaller defects and subsequently require less complex repairs.

In 1997, Ratner et al. reported an overall recurrence rate of 2% (specifically 0% for primary tumors and 4.8% for recurrent tumors) in a study of 58 patients treated at three institutions from 1981 to 1994 [36]. Loghdey et al. found a recurrence rate of 1.5% in a study of 76 patients treated at one center in the United Kingdom from 1996 to 2013 (4) [40]. In recent years, several other studies have demonstrated similarly low rate of tumor recurrence for patients with DFSP treated with MMS, ranging from 0 to 8.3% [15]. A systematic review of 19 nonrandomized noncomparative trials by Foroozan et al. demonstrated a mean raw recurrence rate of 1.03%

(95% CI, 0.37–2.22%) after MMS with follow-up times of 26–127 months. The mean time to recurrence in these patients was 68 months, later than that seen with WLE. Furthermore, complete excision was achieved with median maximum lateral margins of 1–2 cm [23].

Of four nonrandomized comparative trials reviewed by Foroozan et al., two were performed using fresh frozen tissue sections for MMS, one utilized formalin-fixed tissue sections for modified "slow Mohs," and one study did not clearly specify. Foroozan et al. also examined 19 nonrandomized noncomparative studies. Seven of these studies used fresh frozen tissue sections, six used formalin-fixed tissue sections, and six studies did not clearly specify. Recurrences were reported in six studies using frozen section technique, one with formalin-fixed section and three studies that did not clearly specify. CD34 immunostaining was reported in eight of these studies, predominantly for suspicious cases. However, reports of CD34 immunostaining were unavailable in the majority of studies. Overall, data is lacking to determine whether conventional frozen-section MMS, modified "slow Mohs" using formalin-fixed tissue, and immunostaining enable better outcomes [23].

Interestingly, a study of 3686 patients with DFSP from SEER data revealed that treatment type (wide local excision or MMS) did not influence overall survival [24].

Comparative Effectiveness of Common Treatments

At present, studies comparing WLE and MMS for treatment of DFSP are limited, owing largely to the relative rarity of the condition. In a retrospective review of 48 patients, local recurrence rates were statistically similar even though positive margins were higher in patients treated with wide excision than with Mohs (3.6% for WLE vs. 0% for MMS) (2b) [16, 41]. It should be noted that four of six patients with positive excision margins were subsequently treated with MMS in this study introducing a potential bias (5) [41, 42].

In a nonrandomized comparative trial, Paradisi et al. reported a significantly lower local recurrence rate with modified "slow MMS" versus WLE (1.3 vs. 20.7%). The local recurrence rate difference was even greater in patients with DFSP involving the head and neck, at 1.9% with "slow MMS" versus 51.8% with WLE (2b) [43]. A systematic review performed by Foroozan et al. also demonstrated a lower recurrence of DFSP after MMS (1.11%, 95% CI, 0.02–6.03%) versus WLE (6.32%, 95% CI, 3.19–11.02%) [23]. As a result, many authors argue that MMS is indicated in the treatment of these locally aggressive tumors and is superior to excision for DFSP treatment (5) [24, 43, 44].

In recent years, there have been noteworthy reports of WLE enabling similarly low recurrence rates. These reports highlight a modified WLE approach with meticulous histopathologic exam via en face tangential sectioning. Farma et al. found a 1% recurrence rate with narrow 1–2-cm margins at 64-month follow-up, and DuBay et al. reported a 0% recurrence rate after WLE using a similar technique [18, 19]. The low recurrence rate in these reports emphasizes the value of complete circumferential and peripheral deep-margin analysis [16, 18, 19, 23]. The success seen with this modified WLE approach, as with MMS, centers on a meticulous pathologic examination that includes full margin evaluation.

Aside from the importance of complete margin control and minimizing recurrence rates, superior treatment of DFSP also centers on minimizing the morbidity associated with significant extent of disease and surgical excision that is often required. In a retrospective study of 79 DFSP cases treated from 1990 to 2005, Paradisi et al. found that lesions treated with "slow MMS" were slightly larger clinically (56% of MMS cases were >2 cm versus 44% for WLE), but the postoperative defects were greater in cases treated by WLE (60% of defects from WLE were >10 cm versus 40% for MMS). Though the findings were not statistically significant, the differences suggest that WLE defects were larger as a result of the technique rather than tumor size, in keeping with the tissue-conserving property of the MMS technique [43]. In another study of 62

patients, DFSP tumors treated by MMS were smaller compared with those treated with WLE (5.3 cm^2 versus 14.8 cm^2, respectively). Consequently, the resulting defect was smaller for the lesions treated with MMS compared with WLE (21.7 cm^2 and 63.4 cm^2, respectively) [18].

DuBay et al. found that there was no significant difference in repair with skin grafts or tissue advancement flaps between patients treated with WLE and MMS [18]. In contrast, Meguerditchian et al. noted that in 48 cases of DFSP treated by WLE or MMS, the defect size was similar (10 cm when treated with WLE versus 9.4 cm for MMS), but primary closure was performed more often in cases treated with WLE [41]. The significance of this finding, however, has come into question, as decision for closure is largely determined by surgeon preference [42].

Serra-Guillen et al. performed a prospective study of 74 tumors treated with modified "slow MMS" using paraffin-embedded tissue in which they calculated the minimum margin that would have been needed to achieve complete clearance by conventional surgery and the percentage of healthy tissue preserved by MMS versus wide local excision with 2- and 3-cm margins. They found the mean minimum margin for clearance was 1.34 cm. The tissue conservation afforded by MMS was significant, with 49.4% and 67.9% of healthy tissue preserved when treated with MMS compared with wide local excision with 2- and 3-cm margins, respectively. The authors reported a local recurrence rate of 3% with no lymph node or distant metastasis at a median follow-up time of 59.3 months. A smaller surgical defect typically allows for reconstruction that is less complex and therefore may correlate with fewer postoperative complications and smaller scars. Given the significant percentage of tissue spared with modified MMS, nearly 70% when compared with WLE with 3-cm margins, the authors concluded that MMS likely enables enhanced functional and cosmetic results with less surgical complexity, fewer postoperative complications, and greater potential for monitoring for recurrence [37]. As a result, MMS has the potential to significantly reduce morbidity associated with the locally aggressive nature of DFSP [42].

The majority of local recurrence after WLE, up to 80% of cases, occur in the first 3 years after treatment [27]. The mean time to recurrence in patients treated with MMS was 68 months on average [23].

Decision to treat with MMS or WLE is typically mutually exclusive. However, in some cases a positive margin in WLE has been subsequently treated with MMS [41, 42] or a positive MMS margin has been cleared histologically with WLE [18]. There was no statistically significant difference in recurrence for these cases (4) [45]. Furthermore, a multidisciplinary approach to treatment has also been described in which MMS was performed to establish peripheral margin clearance using paraffin-embedded tissue sections analyzed by a dermatologic surgeon and a dermatopathologist. Deep margin clearance was then obtained in a second stage by wide local excision with a surgical oncologist in a controlled operating room with histologic confirmation by the dermatopathologist. A plastic and reconstructive surgeon then closed the resulting defect [15].

While a systematic review and several nonrandomized trials have demonstrated that MMS recurrence rates are lower and that the MMS procedure enables margin control with smaller resulting defects, it should be emphasized that data at this point is limited [23, 45]. Furthermore, recent reports demonstrate that a standardized WLE technique with meticulous, complete pathologic examination of margins may also enable similarly low recurrence rates [18, 19]. As such, the decision to treat with MMS or WLE should currently be made based on a case-by-case basis taking individual patient and tumor characteristics into account as well as availability and cost.

Preoperative Evaluation and Patient Selection

DFSP should be included in the differential for patients with a slow-growing, indurated plaque or nodule. Incisional biopsy is recommended to enable definitive histologic diagnosis. Immunohistochemical stains aid in histologic

examination; staining for CD34 is mostly positive and Factor XIIIa negative. Other tests, including nestin, apolipoprotein D, cathepsin K, and fluorescence in situ hybridization (FISH) or polymerase chain reaction (PCR) analysis for t(17;22)(q22;q13), can be useful for diagnosis. NCCN guidelines recommend appropriate confirmatory immunostaining in all cases of suspected DFSP [32]. If clinical suspicion is high and initial biopsy does not confirm diagnosis, rebiopsy is recommended. Multiple biopsies may be required as misdiagnosis is common [16, 32]. A thorough history, review of systems, and physical examination including complete skin exam and palpation of area around tumor and regional lymph nodes should be performed [22].

Imaging is not required in every case and is not routinely performed [22]. However, imaging with magnetic resonance imaging (MRI) may contribute to evaluation of extent of local disease and may be helpful for preoperative planning especially in deeply infiltrative cases (5) [46]. MRI has higher sensitivity and specificity for detecting infiltration depth when compared with palpation (67% sensitivity and 100% specificity vs. 58% sensitivity and 90% specificity, respectively). It should be noted that determination of infiltrative depth via MRI was less precise for tumors located on the head, neck, and upper thorax. MRI was also useful in evaluating recurrent tumors but was not recommended for determining lateral extent of tumors or for detecting persistent tumor in cases of incompletely excised tumors (4) [47].

Lymphatic spread is rare; thus, physical exam of regional lymph node basin is sufficient, and there is not currently a role for sentinel lymph node biopsy. Distant metastasis is also rare, at approximately 1% [22], and is more likely in patients with positive surgical margins and multiple local recurrences (4) [4, 48]. The most common distant metastasis is hematogenous spread to the lung. In cases of extensive local disease or concerning history or physical exam findings, a plain chest radiograph and other imaging may be performed to evaluate for lung metastasis [22].

There have been contradictory reports regarding prognosis in patients with fibrosarcomatous variant of DFSP (DFSP-FS) compared with DFSP. In some reports, no association between DFSP-FS and worse prognosis was found (4) [25, 49]. However, in several other reports, DFSP-FS has been associated with more aggressive behavior and increased metastatic potential (4) [4, 30, 33, 50]. In 2014, a systematic review by Liang et al. demonstrated a higher risk of local recurrence, metastasis, and death in DFSP-FS when compared with DFSP. The study found local recurrence of 29.8% for DFSP-FS versus 13.7% for DFSP, metastasis in 14.4% of patients with DFSP-FS versus 1.1% with DFSP, and death from disease in 14.7% with DFSP-FS versus 0.8% with DFSP (3a) [51]. Therefore, NCCN consensus recommends treating DFSP-FS variant as a soft tissue sarcoma rather than according to guidelines for DFSP [16, 26, 32].

In their analysis of 3686 patients with DFSP from SEER data, Criscito et al. found that older age at diagnosis, male sex, and large tumor size were negative predictors of overall survival. Patients who were male or black were more likely to have large tumors. However, when controlled for tumor size and socioeconomic status, race itself was not associated with worse overall survival. Patients of older age, black race, and those with larger tumors or tumors affecting the head and neck were more likely to receive surgery and radiation compared with surgery alone [24]. Head and neck tumors may also be associated with poor prognosis (4,4,4) [52–54]. Tumors in these locations are also associated with higher rate of recurrence. One contributing factor may be the thinner subcutaneous layer in this location, so that the muscular plane lies closer to the cutaneous surface [47].

In addition to the size and extent of the tumor based on preoperative evaluation, tumor location may also play a role in treatment modality selection. Some authors recommend WLE for trunk and limb lesions, given the relative ease of excision adequate in these locations. The WLE procedure is typically shorter, and most resulting defects may be closed primarily. Head and neck tumors, which have had much higher reported recurrence rates when treated with WLE, may be better treated with MMS. In these sites, it is

difficult to obtain the 2–4-cm margins recommended for disease control, and there are greater functional and cosmetic concerns. The ability to achieve clear margins with smaller defect size afforded by MMS and the lower reported recurrence rates support growing recommendations for treatment of DFSP tumors on the head and neck with MMS [43].

Impact of Patient Preference

Based on data presented above, MMS is associated with low local recurrence rate and potentially smaller resulting defects when compared with WLE. WLE with meticulous pathologic exam of circumferential and peripheral deep-margin assessment seems to also enable low local recurrence rates with smaller surgical defect than conventional WLE. Thus, MMS and potentially WLE with circumferential and peripheral deep-margin assessment may be preferred by patients given the lower associated recurrence rates and by patients wishing to limit size of defect. A smaller surgical defect is also preferable as it likely decreases complexity of repair and subsequent extent of scarring (5) [37, 55].

In addition to modified WLE with circumferential and peripheral deep-margin assessment, MMS, and modified MMS, conventional WLE remains an appropriate treatment, especially as MMS may not be appropriate or available in all cases [37, 55]. MMS has limitations. Some report that MMS is costlier than WLE [40]. There are additional fees associated with WLE, however, including facility fees, cost of general anesthesia, and potential re-excision costs, which should be considered (4) [42, 56]. Furthermore, access to MMS is not widely available, as it requires intensive training and specialized staff [43]. In contrast, access to surgeons able to perform WLE is far greater [45]. Often, treatment with MMS for DFSP implies a staged procedure lasting multiple hours over several days. The average number of stages reported by Paradisi et al. was 1.8, with cases ranging from 1 to 5 stages [43]. Similarly, Serra- Guillen et al. found a mean number of stages of 1.66, with 54% of cases requiring a single stage, 31% two stages, 12% three stages, 1.4% four stages, and 1.4% six stages [37]. For MMS performed with frozen-section technique, processing of large tissue sections can be time and labor intensive. Even in cases where tumor removal and repair may be performed within the same day, the time the patient is in the office may be prolonged [40]. For MMS with permanent sections or "slow Mohs," the procedure may be extended over several days and require multiple office visits, which may cause considerable burden on patients. As MMS is typically performed under local anesthesia, safe dosing limitations and patient discomfort may be limiting factors for larger tumors or deep tumors, even when tumescent anesthesia is employed (4) [43, 57]. Additionally, MMS may not be sufficient for tumor-free margins, as in cases of cortical bone involvement [40].

Given these limitations, a comprehensive, thoughtful treatment plan should be developed on an individual basis with careful consideration of patient and tumor characteristics, cost, and accessibility. Patient counseling and education including risks, benefits, and expectations is integral to determining which treatment modality is preferable [57]. Multispecialty treatment should be considered, especially for deeply infiltrative tumors and large recurrent tumors or for those that may significantly affect cosmesis or vital structures [15, 40].

As noted previously, SEER data from 1972 to 2012 demonstrated 91.7% were treated by WLE and 8.3% treated by MMS. This study also found that patients who were white, female, and/or had higher median household income were more likely to receive MMS versus WLE. This may be related to aesthetic concerns in female patients, who typically presented with smaller tumors. Higher socioeconomic status is associated with increased use of specialized services, including MMS, and there are fewer Mohs surgery practices in lower income, rural areas [24].

Typical Treatment Plan

An otherwise healthy 45-year-old man presented to a dermatology clinic in an urban setting with a 2-year history of a slowly growing, asymptomatic, flesh-colored, indurated, irregular 4 × 3-cm plaque on the upper back. The tumor was largely mobile upon palpation, and no lymphadenopathy was palpated in draining lymph beds. The patient did not have a personal or family history of skin cancer. An incisional skin biopsy was performed and demonstrated dense spindle cells arranged in a storiform pattern extending throughout the dermis and forming a honeycomb pattern at the periphery. Immunohistochemical stains were performed, and the tumor cells stained positively for CD34 and negative for factor XIIIa, thus leading to a diagnosis of DFSP.

For this localized DFSP lesion, surgical excision is the first-line treatment. A thorough discussion regarding surgical options including Mohs surgery and WLE was had with the patient. Decision was made to treat with WLE. As the lesion was located on the trunk, WLE with 3-cm margins was effectively performed. Lesions on the trunk are able to support the wide margins recommended for WLE with less functional or cosmetic impact compared with those located on the head, neck, or distal extremities. For a lesion of this size, WLE performed under general anesthesia would help to minimize patient discomfort. This otherwise healthy patient was able to tolerate general anesthesia without adverse effects. The decision was also made to treat the patient with modified WLE in which frozen histopathologic analysis of en face tangential tissue sections was performed intraoperatively to confirm circumferential and peripheral deep-margin clearance. Although this meticulous pathologic approach is a bit more time and labor intensive, it affords a lower recurrence rate than conventional WLE. This multidisciplinary approach was possible in the urban setting in which the patient lived. After confirmation of clear margins, repair was performed with split-thickness skin grafting.

At follow-up 1 month postoperatively, the graft was intact and well-healing. The patient was instructed on routine self-exam for tumor recurrence. He continued to follow-up every 6–12 months for 3 years, at which time surgical site was evaluated for recurrence, full skin exam was performed to evaluate for subsequent primary cutaneous malignancy, and a detailed history and physical was performed. After 3 years, annual lifelong follow-up was recommended.

If there are novel, less commonly used, or soon to be available treatments for this condition that may also be effective, describe these and their effectiveness (250–500 words).

For treatments that already exist but are less commonly used, describe these treatments, explain why are these less frequently selected, and compare their overall effectiveness to that of more commonly used treatments. For treatments yet to be available, describe how they may work, and what their expected effectiveness is likely to be.

As previously mentioned, DFSP is radiosensitive. There are few and conflicting reports of radiotherapy as primary treatment for DFSP (4) [58–60], and treatment with radiation alone is not recommended (5) [22, 61]. Radiotherapy is recommended for unresectable tumors and considered as adjuvant therapy for locally advanced large tumors and recurrent tumors with positive surgical margins in which further resection is not possible [25]. As adjunctive therapy, radiation decreases the recurrence rate significantly (2b, 2b, 4) [62–64].

Imatinib mesylate, a tyrosine kinase inhibitor, has emerged as an effective treatment for advanced DFSP. Several studies have demonstrated a decrease in tumor burden in some cases of metastatic disease and decreased tumor size in locally advanced cases (4, 5, 5, 4) [20, 65–68]. A multicenter prospective phase II clinical trial was terminated early to poor accrual but demonstrated clinical response in 37.5% of patients with locally advanced or metastatic disease (4) [69]. Current NCCN guidelines recommend imatinib for patients with unresectable, recurrent, and/or metastatic disease [16, 32]. NCCN

guidelines recommend cytogenetic analysis prior to initiating therapy as some tumors lack t(17;22) mutations. However, data regarding the relationship between presence of mutation and lack of response is conflicting (4) [20, 68, 70, 71].

As tumors are often large, preoperative imatinib to decrease tumor size prior to surgery would significantly decrease morbidity from disease. However, the role of neoadjuvant imatinib in patients with locally advanced disease still remains unclear. In a French study of 25 patients with primary or recurrent DFSP, patients received imatinib for 2 months prior to WLE. Only 36% of patients responded, and long-term follow-up data is needed (4) [72]. A multicenter phase II trial in Germany evaluated 16 patients with locally advanced or recurrent disease who received imatinib prior to surgery. The median treatment duration was 3.1 months, and 7.1% of patients had complete response, 50% had partial response, 35.7% had stable disease, and 7.1% had progressive disease. Median tumor shrinkage was 31.5%. One patient developed resistance to imatinib and later died of distant metastasis, but no other patient had resistance, recurrence, or metastasis [71]. It is unclear whether neoadjuvant therapy enables smaller surgical margins. More evidence is needed to determine the efficacy of imatinib prior to surgery, including long-term follow-up data as well as further investigation into optimal dosing and duration of treatment (5) [22, 73].

Few case reports have suggested that DFSP may respond to other tyrosine kinase inhibitors that target the PDGF receptor, such as sorafenib and sunitinib (5,4) [74, 75]. These treatments may be useful in cases resistant to imatinib. In a study of 30 patients treated with sunitinib after imatinib failure, 6.7% had complete response, 33.3% had partial response, 40% had stable disease, and 6% had progressive disease [75].

Safety

A multicenter study of 20,821 tumors has demonstrated that MMS is a safe procedure with very low rate of adverse events (0.72%). These complications included bleeding and hematoma (15.4% of complications), surgical-site infection (61.1%), and full or partial necrosis and dehiscence (20.1%). Serious adverse events requiring hospitalizations are rare (0.02%), and rate of permanent disability and mortality undetectable (0%). It should be noted that only 0.6% of the 20,821 tumors treated in this study were rare nonmelanoma skin cancers other than basal cell carcinoma and squamous cell carcinoma (1b) [76]. DFSP lesions can be larger and more deeply infiltrative than other more common skin cancers treated with MMS and could therefore be associated with higher rates of adverse events.

MMS for DFSP treatment may be challenging, especially for large tumors. Adequate analgesia may not be attainable for large tumors. Even with tumescent anesthesia, safe dose amounts can be a limiting factor [43, 57]. Of 14 aborted MMS cases referred for reconstruction at a single private suburban plastic surgery practice from 2005 to 2008, 50% were halted due to intolerable pain. These defects had an average surface area of 34 cm^2. DFSP accounted for 33% of aborted cases, and the average surface area of these defects was 42 cm^2. Furthermore, high individual anxiety levels and lower pain thresholds can also play a role, and patients who may not tolerate a procedure under local sedation would benefit from sedation or general anesthesia (4) [77].

For soft tissue tumor resections, wound complications also include dehiscence, cellulitis, abscess, seromas, hematomas, and necrosis (4) [78]. Reports of complications specifically associated with WLE for DFSP are limited. Kim et al. evaluated 90 cases of DFSP treated with WLE. Mean lateral margin was 2.94 cm, and 64.4% of excisions included removal of deep fascia. Skin grafts were performed in 38.9%, primary repair in 27.8%, local flap in 23.3%, and free flap in 10%. There were no major complications. Minor complications were partial graft loss, local flap congestion, and wound dehiscence [34]. Cai et al. reported on 236 patients with DFSP who received wide excision. Again, there were no serious adverse effects. Soft tissue reconstructive procedures, principally split-thickness skin graft and/or pedicle flap, were performed in 92 patients. Complications were only seen in these patients

who received soft tissue reconstructive procedures and consisted of necrosis of skin graft in 22 cases, wound infection in 6 cases, and dehiscence and infection in 2 cases [30]. For 206 patients treated with narrow-margin (1–2-cm) WLE and en face sectioning for pathologic exam, 69% were repaired with primary closure, 25% with skin graft, and 4% with tissue flaps. Postoperative complications were observed in 11% of patients and included wound dehiscence (4%), infection (3%), failed skin graft (1%), and hematoma (1%) [19]. These studies demonstrate that WLE may be associated with minor wound complications, and no serious adverse effects were reported.

Comparative safety data is scant. In a nonrandomized study comparing MMS with WLE treatment for DFSP, Meguerditchian and colleagues reported no significant difference in the postoperative wound healing and infection rates between the two treatments [41].

For patients receiving adjuvant radiation therapy, moderate fibrosis or telangiectasia may result in the radiation field (3a) [63, 79]. In 53 patients treated with either preoperative or postoperative radiation therapy adjuvant to surgical resection between 1972 and 2010 at a single institution, complications were observed in 6 patients (11%) at a median time of 9.5 months. Four were classified as severe, including skin graft failure, and two had associated soft tissue necrosis. Three patients required subsequent surgical intervention [25]. However, in 2015, a systematic review of 12 studies including a total of 167 patients with DFSP receiving adjuvant radiation treatment demonstrated no other significant complications, and gradual advances have enabled an improved toxicity profile of radiotherapy over time [79].

Postoperative Care and Follow-Up

As DFSP has historically been associated with a high local recurrence rate, follow-up and clinical evaluation of the primary site should occur every 6–12 months and routine self-examination encouraged. At follow-up visits, a guided history and physical should be performed. Routine imaging or other testing is not recommended. Metastasis is rare, but if the history and physical above compel further work-up, additional imaging studies should be performed [16]. The majority of local recurrences after WLE occur within 3 years. However, in 25–30% of patients, local recurrence appears after 5 years (4) [4, 5, 80, 81]. According to a systematic review of the efficacy of MMS for the treatment of DFSP, average time to local recurrence was 68 months. Thus, an extended follow-up period well beyond 5 years is encouraged, and lifelong surveillance should be considered [1, 23, 38, 80, 81]. Many recommend patient follow-up every 6 months for at least 3 years and then annually thereafter [52, 61]. As patients with DFSP have an increased risk of subsequent primary malignancy, patients may also benefit from lifelong dermatologic surveillance for another primary DFSP, other nonepithelial skin cancers, and melanoma in addition to monitoring for local recurrence [12].

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
DFSP most commonly affects both men and women in the third to fifth decade of life	B
Older age at diagnosis, male sex, and large tumor size are negative predictors of overall survival	B
Perform confirmatory immunostaining in cases of suspected DFSP	D
Extensive work-up including imaging is not routinely indicated, unless concerning history and physical findings or histologic features are present	D
For localized disease, treatment options include MMS, modified Mohs, WLE with circumferential and peripheral deep-margin pathologic assessment, and WLE	B
Perform WLE with 2–4-cm margins to investing fascia or muscle or pericranium	B
WLE with circumferential and peripheral deep-margin pathologic assessment may enable lower recurrence rate with smaller margins	C
MMS or modified Mohs can be used as first-line treatment of DFSP, especially for areas more prone to recurrence	B
MMS or modified Mohs enables a lower recurrence rate than conventional wide local excision	B
No significant difference in the postoperative wound healing and infection rates between WLE and MMS was found	C
Tumor depth of primary tumors and margin status of recurrent tumors are predictors of disease-free survival	C
Delay reconstruction with extensive undermining or tissue movement for reconstruction until negative margins confirmed	D
Postoperative radiotherapy may be used as adjuvant therapy for unresectable disease	B
Adjuvant radiotherapy is not recommended if negative surgical margins are achieved	B
Imatinib may be used for unresectable, recurrent, and/or metastatic cases	B
There is a 21-fold higher risk of other nonepithelial skin cancers, including subsequent primary DFSP	B
Follow-up and clinical evaluation of the primary site should occur every 6 to 12 months	D
Majority of local recurrences after WLE occur within 3 years	B
Average recurrence after Mohs was 68 months [23]	B
Follow-up should continue for many years or consider lifelong follow-up	D

Self-Assessment Questions

1. What factor is associated with disease-free survival?
   (a) Patient age
   (b) Recurrent tumor
   (c) Tumor depth
   (d) Tumor size
   (e) Male sex

2. What factor is associated with decreased overall survival?
   (a) Treatment with MMS
   (b) Treatment with WLE
   (c) Black race
   (d) Male sex
   (e) Tumor location

3. After wide local excision, most local recurrences occur:
   (a) Within 10 years
   (b) Within 6 months
   (c) Within days
   (d) Within 3 years
   (e) Within 20 years

4. More aggressive tumor behavior is associated with:
   (a) Pigmented DFSP
   (b) Fibrosarcomatous change
   (c) Myxoid DFSP
   (d) Atrophic DFSP
   (e) Bednar tumor

5. Appropriate margins for WLE of DFSP would be:
   (a) 5 mm
   (b) 1 cm
   (c) 3 cm
   (d) 5 cm
   (e) WLE is not an appropriate treatment

Correct Answers

1. c: Tumor depth. Strong predictors of disease-free survival are tumor depth and margin status. However, tumor size, patient age, and gender were not significantly associated with disease-free survival [31].
2. d: Male sex. Older age at diagnosis, male sex, and larger tumor size may be negative predictors of overall survival. Male patients with DFSP had almost twice a risk of depth compared with female patients. Treatment modality (WLE and MMS) and anatomic site were not found to affect overall survival [24].
3. d: Within 3 years. After WLE, up to 80% of tumor recurrences occur within 3 years. However, 25–30% may develop after 5 years. Therefore, close monitoring is recommended for at least 3 years, and lifelong annual monitoring should be considered [4, 5, 80, 81].
4. b: Fibrosarcomatous change. Pigmented DFSP and Bednar tumor are the same entity. Histologic variants of DFSP include myxoid, atrophic, pigmented (Bednar tumor), and fibrosarcomatous [52]. A systematic review by Liang and colleagues reported a higher risk of local recurrence, metastasis, and death in DFSP-FS compared with DFSP [51].
5. c: 3 cm. WLE is a recommended first-line treatment of DFSP. NCCN guidelines recommend 2–4-cm margins to investing fascia or muscle or pericranium. Histologic confirmation of negative margins is important. Narrower margins (1–2 cm) may also enable lower recurrence rates if meticulous circumferential and peripheral deep-margin pathologic assessment via en face tangential sectioning is employed [16, 32].

Surgical Scars

Abstract

The realm of scar therapeutics is constantly changing. Several factors need to be considered when developing a comprehensive treatment plan for scar rehabilitation, including those related to the patient and the nature of the scar. Scar characteristics can be divided by color, scar type and thickness, and body location. Many agents including topical, intralesional, light and laser-based treatment modalities can be used to revitalize and restore damaged skin. The most commonly used lasers are the pulsed-dye laser (PDL) and either fractional ablative or fractional nonablative devices. Ideally, a combination approach using topical and intralesional medications along with PDL and a fractional laser should be considered in all patients wishing to undergo treatment of their scars.

Scars are formed as a reaction to dermal injury and are characterized by local fibroblast proliferation and production of new collagen. They are the final result of many common dermatologic and surgical procedures and are the final product of wound healing. Scars can affect patients of all ages and ethnicities. Wound healing is a complex process resulting in a scar. During the wound healing process, angiogenesis occurs that is apparent clinically as erythema, telangiectasia, and edema (1a) [1]. Collagen production and other extracellular matrix substances lead to the formation of a scar, which can lead to both functional and emotional difficulties and quality of life impairment. Surgical scars take approximately 1 year to fully mature. They continue to improve in appearance after 1 year (1a) [2]. The cosmetic appearance is problematic to patients who have surgical scars on their face or other visible areas. Scars are unpredictable and vary from person to person; they can present in different forms including keloidal, hypertrophic, or atrophic. They also vary based on body location and color. It is important to consider the tension, texture, and erythema of a surgical scar. There are numerous approaches when treating a scar. All the therapies aim to improve the appearance of a scar, as they are difficult to erase completely.

Current available treatment options for scars include a combination of topical and intralesional medications, surgical interventions, laser and light devices, and microneedling. Ultimately,

depending on characteristics of the scar, some combination should be used to yield the best outcome. During the twentieth and early twenty-first century, the treatment of scars changed—the goal was no longer tissue replacement but rather tissue rehabilitation. Various modalities were used to improve the appearance of scars including topical, intralesional, and light and laser-based treatment modalities, all of which attempted to revitalize and restore damaged skin (1a) [3]. Topical medications include silicone gels and sprays, which decrease inflammation and thereby contribute to less scarring. While topical agents are convenient and non-invasive, few have shown the ability to significantly improve cosmetic and functional aspects of scars (1b) [4]. Intralesional medications that have shown efficacy include triamcinolone, 5-fluorouracil, mitomycin, bleomycin, interferon, and retinoic acid, which all target fibroblast growth and collagen production. The downside of intralesional agents is that they require serial injections over the course of weeks to months and take time to show an effect (2b) [5]. More aggressive therapies such as dermabrasion, radiation, and chemical peels have also shown to be effective. Dermabrasion is relatively quick and inexpensive; however, it requires local anesthesia and wound care for 7–10 days after treatment and can cause post-inflammatory hyperpigmentation (4) [6]. Prior to beginning therapy for scar rehabilitation, it is essential to gather information from the patient regarding time and mechanism of injury, comorbid conditions, current symptoms or functional limitations, psychological factors, and current or prior treatment and procedures (1b) [7]. It is also important to keep in mind other factors such as Fitzpatrick skin type, age, pain tolerance, symptom relief, and downtime when developing a treatment plan.

Surgical Intervention

If a surgical scar has significant tension or webbing, surgical revision is often warranted. [2] Fusiform excision is the most basic technique for surgical revision. It involves re-excision of the entire linear surgical scar with narrow margins. It can improve the appearance of the scar; however, it results in a longer incision line compared to the original scar. This technique is recommended for shorter scars.

A Z-plasty can be used if a fusiform excision is not possible. It breaks a linear scar down into a series of irregular lines, making the scar less apparent [2].

Lasers

In the late 1990s the advent of laser approaches changed the treatment of scars. These devices enabled treatment to bring about excellent results with minimal downtime with an overall low risk (3a) [8]. Lasers can improve various characteristics of scars including erythema, hyperpigmentation, atrophy, hypertrophy, and may decrease tension to increase functionality. These improvements lead to reduction in symptoms, improving functionality and cosmetic appearance (2a) [9]. They play a role in minimizing post-surgical scars as well as reducing the appearance of established scars. The most commonly used lasers are the pulsed-dye laser (PDL) and either fractional ablative or fractional non-ablative devices. These lasers improve vascularity, pigmentation, and scar thickness.

Vascular Lasers

Angiogenesis is an essential step in the development of scars, and lasers that target this proliferation of vessels are effective at improving many scar characteristics. The principle of selective photothermolysis described by Anderson and Parrish in 1983 supports the use of vascular lasers to treat surgical scars given that the target is hemoglobin (1b) [10]. By selecting the appropriate wavelength, pulse duration, and energy for a specific target, select thermal destruction of the target vessel occurs without damaging the surrounding tissue.

The pulsed-dye laser (PDL) is the gold standard for treatment of surgical scars, and there is a great deal of data which support its use and effectiveness (Ib) [11]. It is the most commonly

used laser to target vascular structures within a scar. Its effectiveness is attributed to its vascular specificity. It targets oxyhemoglobin within small blood vessels in the scar as well as telangiectasia in the surrounding skin, leading to decreased erythema and improved cosmetic appearance [2]. The PDL has been shown to stimulate collagen production and improve scar texture when used at sub-purpuric fluences. It can also provide long-term improvement in scar erythema, pliability, thickness, and pruritus [1]. It is recommended to treat the erythema of a scar prior to performing other procedures that might increase surrounding erythema and alter the optic absorption of vascular laser wavelengths. The potassium titanyl phosphate (KTP) laser is also vascular specific with a wavelength of 532 nm. A recent study done by Keaney et al. compared the PDL and KTP for the treatment of erythematous surgical scars [6]. Twenty patients with skin phototypes I to IV with matched bilateral erythematous surgical scars or a single linear erythematous scar > 5 cm less than 24 months old were included in the study. Scars were divided into equal halves with each half randomized to receive three successive treatments at 6-week intervals with either a 532 KTP laser (Excel V; Cutera) or a 595 nm PDL (Cynergy; Cynosure). Laser parameters were fixed for both devices; 532 nm laser settings were 4.6 J/cm^2, 3 ms, and a 7-mm spot while the 595 nm PDL settings were 4.5 J/cm^2, 2 ms, and a 7-mm spot size. Blinded physician assessment was done at baseline and 12 weeks after the third laser treatment using the Vancouver scar scale (VSS) including vascularity, pigmentation, pliability, and height were evaluated. The average scar age was 6.9 months and all scars were in nonfacial locations. Although improvement in scars was seen with both lasers, the KTP was found to be slightly more effective at reducing scar erythema, which was attributed to enhanced oxyhemoglobin absorption. The KTP treatments were found to be more painful and resulted in more erythema and edema when compared to the PDL. The KTP also has the potential for enhanced melanin absorption compared to the PDL, which can increase the risk for epidermal injury and pigment alteration.

There is debate as to how soon after a scar is formed laser treatment should be commenced. Several studies support the use of PDL shortly after suture removal (1b) [12]. Martinez et al. evaluated the improvement of scars, both clinically and histopathologically, resulting from dermatological surgery treated with PDL (1b) [13]. A split-scar study was performed with 30 patients, who were all Fitzpatrick skin types III or IV, where half of the scar was treated with a 595 nm PDL (Vbeam laser, Candela, Wayland, MA) settings of 7–8 J/cm^2, 1.5 ms pulse duration, and a 7 mm spot size for a total of three treatments. The other half of the scar was untreated and served as the control. Skin biopsies were obtained before and after laser treatment. Both the clinical evaluators of the scars and the pathologist examining the tissue were blinded. The histologic examination showed a presence of new collagen in seven out of ten PDL patients compared to three of ten in the placebo group, making it statistically significant. There was significant improvement on the Vancouver scar scale (VSS) in the treated half compared to the untreated half, including less erythema and improved texture. There was no difference in the inflammatory infiltrate. In summary, PDL has been proven to reduce scarring induration, swelling, erythema, and dysesthesia with minimal adverse events when treating surgical scars [1].

Fractional Lasers

Fractional lasers are the gold standard when treating the textural and structural abnormalities of scars. Both ablative and non-ablative fractional lasers have become the mainstay of scar treatment. Fractional lasers can be ablative (wavelengths of 2790–10,600 nm) or non-ablative (wavelengths 1320–1927 nm). Laser scar revision is based on the principle of controlled thermal injury to induce healing and remodeling in a specific area. The concept of fractional photothermolysis originated years ago but was formalized within the last decade and has revolutionized the management of scars. These lasers rely on bulk heating, which leads to significant thermal

injury (2b) [14]. They produce arrays of nonselective, microscopic thermal damage zones (MTZs) throughout the epidermis and dermis, to a specific fraction of the total area treated (2a) [15]. The MTZs lead to tissue contraction and induce tissue remodeling and production of new collagen, thereby improving the scar. Histological studies show tissue remodeling for up to 6 months after treatment leading to long-lasting results (2a) [16]. Laubach et al. described the histological changes induced by fractional photothermolysis in 2006 (1b) [17]. They showed the thermally damaged epidermal keratinocytes were replaced within 24 h and complete healing occurred after 7 days.

Fractional devices allow for islands of sparing in a treatment area that allow for rapid repair and stimulate collagen remodeling. Ablative fractional resurfacing (AFR) and non-ablative fractional resurfacing (NAFR) have similar mechanisms of action; however, AFR devices destroy the epidermis and dermis, while NAFR keeps the epidermis intact and forms MTZs in the dermis only. Because of this difference, AFR devices are more effective but also have more downtime and an increased risk of scarring when compared to NAFR devices (2a) [18]. Ablative devices produce a pattern of ablation and coagulation extending from the stratum corneum into the dermis with varying density and depth, separated by normal, undamaged skin. AFR devices penetrate the reticular dermis, allowing for more skin tightening when compared to traditional ablative devices [1]. Tightening is achieved by contraction of the collagen fibers in response to the denaturing laser-generated heat. As fluence increases, so does residual thermal damage, thereby causing more tightening. Fractional ablative devices include the 10,600 nm focused CO_2, the 2940 nm Er:YAG, and the 2790 nm erbium, chromium-doped yttrium scandium-gallium-garnet (Er, Cr-YSGG). Er:YAG has a higher affinity for absorption by water so its columns have a narrower rim of thermal coagulation when compared to CO_2. Fractional ablative devices have shown to improve scars by decreasing the vascularity, pigmentation, and scar thickness. AFR devices are preferred over fully ablative devices given improved safety profile and increased healing time.

Ozog and Moy demonstrated improved appearance and texture of Mohs surgical scars when treated with AFR at the time of surgery (1b) [19]. Their goal was scar prevention, rather than treatment. In addition, it was also more efficient given the laser treatment was done at the same time as surgical closure, avoiding the inconvenience of a repeat visit and anesthetic of an additional procedure. There is very little literature discussing the role of AFR at the time of surgery. It is hypothesized that compounding the laser thermal injury with surgical injury may lead to more scarring; however, preliminary studies show improvement in scar texture and color when done at the same time. A pilot porcine study by Baca et al. showed no difference in scar formation when treating surgical incisions with AFR [14]. This was based on histologic and photographic analysis. Future studies with larger sample sizes should be done to better elucidate if a true difference exists.

AFR has recently been used to help facilitate percutaneous drug delivery in the treatment of both hypertrophic and atrophic surgical scars. Microscopic ablative channels allow for drug delivery and even distribution within the tissue. Waibel et al. showed enhanced improvement in hypertrophic scars with laser-assisted drug delivery of topical corticosteroids (1a) [20]. Although the ablative channels remain open for several days, optimal absorption occurs when the medication is applied immediately following the laser procedure. It is recommended to use a Kenalog (triamcinolone acetonide) concentration of 20–40 mg/mL, depending on the thickness of a scar, applied topically until there is uniform coverage of the treated area. [2] Rkein et al. showed improvement of atrophic surgical scars treated with AFR followed by topical application of poly-L-lactic acid (each bottle diluted with 6 mL of sterile saline and 2 mL of 1% lidocaine) (2b) [21].

NAFR devices are helpful for atrophic scars; there is no bleeding because it creates a cylindrical zone of coagulation rather than a “hole.” By keeping the epidermis intact, NAFR has a lower risk of infection, pigment alteration, and further

scarring when compared to AFR. NAFR devices are the treatment of choice for flat, atrophic scars. They are also safer for darker skin types because they produce a number of narrow deeper wounds which maximize improvement in texture [2]. A significant advantage of NAFR compared to AFR is less downtime combined with an improved side-effect profile. As discussed previously, scars with erythema should be treated with a vascular laser prior to the use of fractional resurfacing. However, many clinicians have noted successful scar revision when combining PDL treatments followed by NAFR on the same visit. Several treatments are required, typically 4–6 weeks apart, and it is essential to lower the settings of each device to avoid complications [2]. Combination therapy can be considered as soon as 2 weeks after suture removal. In addition to PDL followed by NAFR, Intralesional Kenalog (ILK) and intralesional 5-FU can be performed after NAFR to avoid ulceration from bulk heating secondary to an increase in the aqueous target of NAFR (4) [22].

There is limited data comparing the final cosmetic scar of traditional fully ablative resurfacing versus ablative fractional resurfacing. Tidwell et al. looked at the difference in a split-scar study in 20 patients using the fully ablative Er:Yag compared to the fractional ablative Er:Yag (1b) [23]. The scars were treated at monthly intervals for 3 months and then followed up at 1 month and 2 months after the last treatment. Entities such as scar erythema, height, texture, and overall cosmetic appearance were examined, in addition to patient satisfaction and quality improvement. Both patients and physicians saw statistically significant improvement with the fractional ablative Er:Yag compared to the fully ablative device. One subject found improvement in scar thickness with the ablative Er:Yag. The downside of this study was the short follow-up of 5 months. Many argue that the final outcome of a scar cannot be assessed until after 12 months (3a) [24]. It is thought that ablative lasers in hypertrophic scars elicit a change in the expression of heat shock proteins, matrix metalloproteinases, tissue inhibitors of metalloproteinases, and transforming growth factor-beta that cause collagen remodeling (2a) [25]. In summary, AFR should be reserved for thicker scars and NAFR should be used for atrophic scars.

Non-ablative, Non-fractional Lasers

The role of fractional ablative, fractional non-ablative, and pulsed-dye lasers have been established in the literature. However, the role of the microsecond pulsed non-ablative 1064 nm neodymium yttrium-aluminum-garnet (Nd:YAG) laser is poorly defined. The Nd:YAG is a non-ablative, non-fractional laser that has less potential risk when compared to ablative lasers. Non-ablative lasers have a lower risk of infection, scarring, pigment alteration, and persistent erythema (2a) [26]. Tenzel et al. performed a split-face, prospective study that evaluated the use of 1064 Nd:YAG in the treatment of direct browplasty scars (1c) [27]. Scars that were less than 3 years old were treated at 2-week intervals for a total of six treatments. Laser parameters were pulse duration of 300 ms, energy of 14 J/cm^2, spot size of 5 mm, and pulse rate of 7–10 Hz for a total of 500 pulses per treatment (Xeo, Cutera, Brisbane, CA). Scar erythema, pigmentation, and height were evaluated in nine male subjects. Treatments were tolerated well with minor side effects of redness and swelling. All subjects reported improvement in the treated scars, even subjects whose scars were over 2 years old, while no subjects noted improvement on the control side. These data suggest that there may be benefit to delaying laser treatment after surgery until the inflammatory phase has subsided, however further studies are warranted.

Ezra et al. evaluated the microsecond 1064 nm Nd:YAG laser's ability to improve surgical scars after Mohs micrographic surgery (MMS) (2b) [28]. Ten patients underwent treatment for their surgical scars after MMS with treatment settings of 0.3 ms pulse duration, energy of 13–16 J/cm^2, 5 mm spot size, and repetition rate of 4–10 Hz (Laser Genesis, Cutera, Brisbane, CA). Most patients received their first laser treatment 5–8 weeks after surgery. Four patients had complete resolution of an ectropion or eclabium that

formed secondary to scar contracture as a result of MMS. For the 10 patients in this study, the Nd:YAG was found to help both the cosmetic and functional problems caused by surgical scars. The mechanism of action for scar improvement occurs by laser heating of the dermis, without damaging the epidermis, due to selective absorption of energy by oxyhemoglobin in the dermal capillaries [15]. The microsecond pulse duration allows for partial thermal relaxation of dermal capillaries, which causes gradual heating of the dermis and prevents collagen denaturation. The laser is thought to stimulate extracellular matrix and new collagen formation leading to scar improvement. The fibroblasts that produce new collagen are downregulated by the Nd:YAG laser, leading to less collagen production which decreases the appearance of a hypertrophic scar (1b) [29]. Decreased vascularity and heat shock protein stimulation are some of the alterations in dermal collagen architecture that can be seen after treatments with the 1064 nm Nd:YAG laser. The improvement in contractures is thought to occur by redistribution of collagen. In addition, since the epidermis is protected, the risk of infection and need for post-treatment care is eliminated, which can be beneficial in certain situations. It is recommended that laser treatments begin 6 weeks after surgery and subsequently at 4–8-week intervals. Although an endpoint is not defined for this device, it is important to be guided by patients' sensation of heat, which typically occurs between 43 °C and 46 °C.

Intralesional Medications

Intralesional Kenalog (ILK) (triamcinolone acetonide) and 5-fluorouracil (5-FU) can be used as first-line therapy for hypertrophic or keloidal scars, after erythema has been addressed. [2] Monthly ILK injections can be done until there is flattening of the scar. Several treatments are typically required using small aliquots of 20–40 mg/mL. The volume injected should not exceed 0.1 mL per 1 cm of scar. Skin blanching should occur when the appropriate amount is injected. If steroid is injected too frequently, at high concentrations or into the subcutaneous fat, epidermal atrophy can occur. An advantage of intralesional 5-FU is that it can be used in thickened scars without the risk of atrophy. Davison et al. showed the combination of 75% 5-FU and 25% triamcinolone (40 mg/mL) was superior to ILK alone when 0.1 mL was injected into 1 cm of scar (2a) [30]. It is important for the clinician to keep in mind that 5-FU is pregnancy category X.

There are a variety of soft tissue fillers that can be injected into atrophic surgical scars to provide additional volume. This can be done in conjunction with other therapies to achieve an enhanced effect. Goldman et al. showed that fillers are not affected by non-ablative laser/light and superficial ablative treatments (1a) [31]. Dermal fillers consisting of hyaluronic acid or calcium hydroxylapatite can be beneficial to fill and blend post-surgical depressed scars after reconstruction of skin cancer defects (2b) [32]. Hyaluronic acid fillers with a lower G prime can be injected superficially into the dermis with a lower risk of Tyndall effect.

Massaki et al. showed repigmentation of hypopigmented, atrophic surgical scars using a 1,550 nm NAFR combined with topical bimatoprost and tretinoin (2a) [33]. Fourteen subjects were treated with an average of 4–5 sessions at 4–8-week intervals, with 12 subjects having >50% improvement.

Microneedling

Microneedling, also called percutaneous collagen induction, is an alternative therapy that can be used to improve the appearance of surgical scars. It was initially used for skin rejuvenation, and it is now being used for a wide variety of indications. It is a minimally invasive procedure involving superficial and controlled puncturing of the skin by rolling with fine needles (3a) [34]. It is done in the office, using topical anesthetic, and the endpoint is uniform pinpoint bleeding. The microinjuries cause a wound healing cascade with release of various growth factors including platelet derived growth factor (PGF), transforming growth factor alpha and beta (TGF-α and

TGF-β), connective tissue growth factor, and fibroblast growth factor (FGF). This process helps break down old hardened scar tissue and allows it to revascularize. Neovascularization and neocollagenesis are initiated by migration and growth of fibroblasts. After 5 days of injury, a fibronectin matrix forms that determines the deposition of collagen. Histological examination of skin treated with four microneedling sessions 4 weeks apart shows up to 400% increase in collagen and elastin 6 months after the last treatment. Additionally, collagen bundles have a normal lattice pattern rather than the parallel pattern seen in scar tissue (2b) [35]. Results after each treatment are not seen immediately, because new collagen continues to be produced for 3–6 months after each treatment. It is recommended that 4–6 sessions are done for a significant improvement when treating all types of surgical scars [35].

Microneedling can be combined with other techniques to yield better results. There are various commercially available devices that have small microneedles (0.5–3 mm long and 0.1–0.25 mm in diameter) that break collagen bundles in the superficial layer of the dermis that contribute to scars. This leads to induction of more collagen beneath the epidermis (2a) [36]. The microneedles create small wounds in the epidermis, which enhances the delivery of drugs across the skin barrier since it bypasses the stratum corneum and delivers the drug directly in the vascularized dermis. However, laser-assisted drug delivery seems to be more effective. An advantage of microneedling over laser is a lower risk of post-inflammatory hyperpigmentation (PIH). Other techniques that damage the epidermis have a high risk of PIH, but microneedling is an exception. Microneedling has recently gained popularity given it is simple, inexpensive, safe and effective technique.

Summary

The realm of scar therapeutics is constantly changing. Many factors need to be considered when developing a comprehensive treatment plan, including those related to the patient and the nature of the scar. Scar characteristics can be divided by color, scar type, and body location. Many agents including topical, intralesional, light, and laser-based treatment modalities can be used to revitalize and restore damaged skin. The most commonly used lasers are the pulsed-dye laser (PDL) and either fractional ablative or fractional non-ablative devices. Ideally, a combination approach using topical and intralesional medications along with laser and light devices should be considered in patients of all ages wishing to undergo treatment of their scars.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE).

Findings	GRADE score: quality of evidence
Scar rehabilitation with lasers can be safely started as soon as suture removal	A
A combination approach should be used when treating scars. The erythematous component of the scar should be treated first with a vascular laser	A
After the erythema of a scar has been addressed, fractional ablative devices can improve texture. NAFR devices have a safer side-effective profile and can have similar outcomes to AFR; however, more treatments may be required	B
Microneedling is a newer technique that is safe, effective, and minimally invasive. It can improve scar texture and color and assist with transdermal drug delivery	B

Self-Assessment Questions: Surgical Scars

1. During the wound healing process, angiogenesis occurs and presents clinically as:
   (a) Edema
   (b) Erythema
   (c) Telangiectasia
   (d) All of the above

2. Several intralesional medications have shown to improve scars including triamcinolone, bleomycin, 5-fluorouracil, mitomycin, and retinoic acid. What is their mechanism of action for improving scars?
   (a) Increased angiogenesis
   (b) Decreased fibroblast growth and collagen formation
   (c) Increased epidermal turnover
   (d) Dermal injury
   (e) Neutrophil production and activation

3. When using vascular lasers (PDL, KTP) to treat surgical scars, what is the laser target?
   (a) Hemoglobin
   (b) Melanin
   (c) Water
   (d) Collagen
   (e) Keratinocytes

4. Which of the following is false regarding fractional non-ablative lasers?
   (a) They produce microscopic thermal damage zones (MTZs) throughout the epidermis and dermis
   (b) Their wavelengths are between 1320 and 1927 nm
   (c) They allow for controlled thermal injury to induce healing and remodeling in a specific area
   (d) Are helpful when treating atrophic scars
   (e) Can be used safely in all skin types

5. Microneedling causes an increase in which of the following:
   (a) Platelet derived growth factor (PGF)
   (b) Transforming growth factor alpha and beta (TGF-α and TGF-β)
   (c) Connective tissue growth factor
   (d) Fibroblast growth factor (FGF)
   (e) All of the above

Correct Answers

1. d: All of the above. Explanation: During the wound healing process, angiogenesis occurs that presents clinically as erythema, telangiectasia, and edema.
2. b: Decreased fibroblast growth and collagen formation. Intralesional medications that have shown efficacy include triamcinolone, 5-fluorouracil, mitomycin, bleomycin, interferon, and retinoic acid, which all target fibroblast growth and collagen production.
3. a: Hemoglobin. The principle of selective photothermolysis described by Anderson and Parrish in 1983 supports the use of vascular lasers when treating surgical scars given their target of hemoglobin. By selecting the appropriate wavelength, pulse duration, and energy for a specific target, select thermal destruction of the target vessel occurs without damaging the surrounding tissue.
4. a: They produce microscopic thermal damage zones (MTZs) throughout the epidermis and dermis. Ablative fractional devices destroy the epidermis and dermis, while non-ablative fractional devices keep the epidermis intact and forms MTZs in the dermis only.
5. e: All of the above. The microinjuries caused by microneedling create a wound healing cascade with release of various growth factors including platelet derived growth factor (PGF), transforming growth factor alpha and beta (TGF-α and TGF-β), connective tissue growth factor, and fibroblast growth factor (FGF). This process helps break down old hardened scar tissue and allows it to revascularize.

Post-acne Scarring

48

Greg J. Goodman

Abstract

Acne is a very common inflammatory disease with superimposed opportunistic infection, which, if left untreated, will often lead to lifelong scarring. The resultant scarring is graded for the purposes of classification and communication, but the scarring is a very individual issue with even minor scarring a great issue for patients.

The treatment of scarring is usually incomplete with surface and volumetric treatments being the mainstay. Hence, grading revolves around these issues. The milder grades 1 and 2 scarring usually require multiple surface treatments with energy-based (fractionated and non-fractionated) and other surface treatments. For more severe grades where volume is a greater issue, fractionated devices appear to be the best form of energy- and nonenergy-based devices, but often, volume restoration (fillers and surgical techniques) or volume depletion (intralesional steroids and cytotoxics) is also required. The choice of the variety of fractional delivery is made on the basis of the scar and patient characteristics. Rarely, botulinum toxin may also be needed especially in hypertrophic scarring.

In all grades, it would appear that combining treatments either concurrently or sequentially is superior to employing a single modality. Combining fractionation and non-fractional therapies may be particularly efficacious (e.g. low-strength peels and needling or fractionated lasers). Otherwise combination therapy may involve fractional devices to be used to allow deeper ingress of agents by transdermal delivery (e.g. steroids, cytotoxics, bimatoprost).

Epidemiology

Acne is so common in adolescence that it would be considered a normal stage in human development were it not for its devastating effect on the aesthetic appearance and the psychological distress it wreaks upon its sufferers (2c) [1]. Its prevalence has been estimated at 95–100% in 16– to 17-year-old boys and 83–85% in 16– to 17-year-old girls (1c) [2], (1c) [3], (1c) [4], (1c) [5]. Acne shows its polymorphous nature during its evolution as it begins with non-inflammatory comedones, evolving to the

mildly inflammatory papular pustular acne before proceeding to the more inflammatory nodulocystic lesions. Each stage appears to be separated by some 2–3 years (2c) [6], (2c) [7]. It becomes more common and severe reaching its peak between ages 14 and 17 in females and 16 and 19 in males.

Acne may also present at an atypical age. Neonatal and infantile acne usually occurs in males in their first 12 months of life and lasts for 3–4 years on average (2c) [8],(2c) [9]. Often, a family history of acne is present in these patients. Early age development of comedonal acne, in females at least, appears predictive of later, more severe disease (2c) [10].

Acne will mostly resolve by the age of 23–25 years of age, but at 40 years of age, 1% of males and 5% of females exhibit acne lesions (2c) [11]. There is also a definite group of older females who develop acne for the first time or redevelop acne in their mid to late 20s (2c) [12].

There are very few prevalence studies looking at acne scarring in the population; however, the literature suggests that it is generally correlated to the severity of acne, its site and its duration. If left untreated for a period of 3 years or longer, acne has a high incidence of residual scarring (in up to 95% of patients) (2c) [13],(2c) [14]. In a study of 2133 volunteers aged 18–70 from the general population, nearly 1% of people had acne scars, although only one in seven of them was considered to have 'disfiguring scars' (2c) [11]. Severe scarring caused by acne is associated with substantial physical and psychological distress, particularly in adolescents.

The severity of inflammation in acne has been linked to an antibody titre to *Propionibacterium acnes* [15, 16]. Those unfortunate patients with severe inflammatory acne appear to have elevated indices of lymphocyte transformation to *P. acnes* antigens (1b) [17], abnormal neutrophil chemotaxis and phagocytosis (1b) [18] and excess activation of macrophages. There is considerable evidence against *P. acnes* causing actual dermal infection, as they tend to perish rapidly in human tissue. It also seems to be unimportant whether the organisms are alive or dead in terms of their ability to incite an inflammatory response (5) [19]. Thus, the role of *P. acnes* is to incite the breach in the follicular wall and to be part of the chemotactic and pro-inflammatory cascade that follows.

The Evolution of Inflammatory Lesion to Scar Formation

The end result of follicular rupture is a perifollicular abscess. Small abscesses incorporating the horny core will point and be discharged through the skin. This will be repaired without scarring in about 7–10 days. The epidermis is always attempting repair, and cells grow from the epidermis and appendageal structures to encapsulate the inflammatory reaction. If this is complete, there is resolution of the lesion without incident. Sometimes, however, this encapsulation is incomplete and further rupture occurs, and the end result may be the appearance of multichannelled fistulous tracts (5) [20].

Other types of outcomes depend on the extent and the depth of the inflammation. If the dermal inflammation is severe, total necrosis of the follicle may ensue and sloughing will produce a focal scar [12].

If the inflammation is severe and especially if the rupture occurs deeply in the follicle, the inflammation will extend well beyond the environment of the hair follicle into the subcutis, along vascular channels and around sweat glands. This wreaks havoc in these deep tissuesinducing deep scarring and destruction of subcutaneous fat [12].

When inflammation is very deep, transepidermal discharge is often not available as a method of resolving the abscess. As healing occurs and attempts at encapsulation of this deep inflammation ensue, this may form into papules, nodules or cysts. Cysts are, in effect, giant closed comedones.

Why one patient is able to heal without scarring whilst another with apparently similar severity goes on to scar has always been vexing. One study examined this by utilising patients known to be acne scar-prone and compared them to those who did not tend to scar. The study found that there were noticeable differences in their inflammatory profiles whilst healing (3a) [21]. In particular, they found that the cellular infiltrate was large and active (CD4+ T cells, macrophages and

Langerhans cells). There was a rather non-specific response with few T memory cells, significant early angiogenesis and vascular adhesion molecule expression in lesions of patients not prone to scarring. This response is typical of a healthy, robust, type 4 hypersensitivity response with effective and rapid clearing of the offending antigen. The relative poverty of a highly specific immune response is felt to suggest that the population of patients who do not readily scar are not highly sensitised to antigens responsible for acne. A relatively large number of the CD4+ T cells could not be classified as memory/effector cells or naïve T cells, suggestive of effective removal of the causal antigens and satisfactory resolution of the inflammatory response by mechanisms straddling both the innate and adaptive immune systems [20]. In contrast, patients prone to scarring tended to show fewer Langerhans cells, lower HLA-DR expression and fewer CD4+ T cells (although with a higher proportion of T memory cells): all in all, a relatively more specific but ineffectual early response. Macrophages, blood vessels and adhesion molecules were high. Angiogenesis remains high in resolving lesions with a further stage of inflammation comprising macrophages, skin-honing memory cells and increased HLA-DR expression. They suggest that based on the poorly resolving inflammation, scarring would be a more likely outcome and suggest a role for anti-inflammatory medications.

If prolonged angiogenesis is seen in those who go on to scar, then how may this relate to the atrophic scarring seen most commonly in the post-acne scenario? One scenario could be as follows. For blood vessels to flourish and invade into an injured area, there is a required increase in metalloproteinases to cut a path for this vascular advance. Metalloproteinases are important as enzymes able to remodel the extracellular matrix (3a) [22],(2b) [23]. Three main types of metalloproteinases in the dermis appear to be particularly important:

2. MMP 1—Type 1 collagenase
3. MMP 2—Type 4 collagenase (72 kDa gelatinase)
4. MMP 3—Stromelysin-1 (Transin)

It seems that *P. acnes* triggers inflammatory cytokine responses in acne by the activation of toll-like receptors (TLR2) (2a) [24], transmembrane proteins that are able, through activation of nuclear factor (NF)-kappa B (NFkB) and downstream cytokine production, to eventually lead to activation of AP-1-regulated metalloproteinase genes. Four inhibitors of the excessive activity of these enzymes have been described: so-called tissue inhibitors of metalloproteinases (TIMP). If collagenases and other metalloproteinases are overactive or active for a longer time than required to support prolonged angiogenesis, the dissolution of dermal support may occur. It may be that the interplay of metalloproteinases and their inhibitors may be involved in the eventual scarring whether atrophic or hypertrophic, as both appear to be a breakdown of the normal balance of collagen production.

Preoperative Evaluation and Patient Selection

Objectively, we can generally divide patients according to the severity of their scarring process.

There are mitigating patient factors that will sway therapy choices; these should be assessed along with scar severity and burden of disease at the initial consultation (Table 48.1).

Treatment Overview of Single Therapy Techniques

In the following analysis, most of the techniques will highlight either studies that are not comparison studies, are opinion or consensus, or not strong enough studies to be considered for later analysis under the example comparison studies. However, they still have pertinent points to make and are worth taking on board, even if the evidence for these views may be relatively weak. There is also a bias against older techniques or those that have no obvious corporate champion; some of these such as chemical peeling, dermabrasion, punch techniques and subcision will be discussed despite their mostly anecdotal studies.

Table 48.1 Key points to be gleaned from the patient's history and examination before proceeding to plan the patient's therapy

Parameter	What needs to be considered
Activity of associated acne or skin disease	Treat this before beginning treatment for scarring
Fitzpatrick skin type	In types III and V, one should be concerned about post-inflammatory hyperpigmentation with resurfacing procedures. In type VI (black skin), there is usually only a short-term problem with pigment. For darker-skinned patients, procedures with better safety margins are usually chosen
Sex	When considering the possibilities for treatment, keep in mind that most men do not regularly wear make-up and women do not have beards to hide demarcation lines
Age	Be concerned about treating the very young and the very old (possibilities for concomitant illness and motivation)
Psychological and physical health	Make sure it is appropriate to proceed with suggested course of action. Ensure that the patient has adequate understanding of the limitations of the selected treatment
Social constraints	Ensure that adequate care is available in the postoperative period and that the patient is able to attend follow-up appointments A patient's willingness to accept varying amounts of downtime associated with individual procedures may influence choice of therapy Payment needs to be discussed, especially if there is to be a long process or if expensive equipment is to be used
Burden of disease	The treatment required will vary according to how great a disease load is present Severe scarring may require a number of procedures and even hospitalisation, whereas this is less likely with milder disease. Even with milder disease, skin condition is not guaranteed to reach patient expectations, and the individual may still need multiple (if less morbid) procedures
Type of scarring	Certain types of scarring (e.g. ice-pick, gross atrophy and erythematous macular marks) may require their own specific treatments
Site of scarring	Treatment of certain scarring sites (neck, chest and back) has a higher risk of pigmentation and hypertrophic scarring

Objectively, we can generally divide patients according to the severity of their scarring process. Within each of the grades of scarring, it is useful to construct an approach where we look for reconstructive options similar to those currently in vogue for assessing the ageing patient or cosmetic enhancement as well as other reconstructive situations. This concentrates on surface-, volume- and movement-related changes, although movement-related changes are not usually a problem in the more minor grades of scarring. The paradigm is similar off the face and in any age range with some caveats. Surface issues are best dealt with by fractionated rather than full-field treatment as healing is not as simple with off face treatments and movement issues are not usually in play. Age only makes a difference with respect to loss of tone amplifying the appearance and the decreased healing capabilities of older skin.

In essence, surface treatment revolves around the skin's texture, altering the colour of the scar and inducing or reducing collagen in the underlying tissue. Volume requires augmentation or filling to correct volume deficits or sometimes decreasing volume in terms of hypertrophic scarring.

Grade 1 Scarring

Abnormally coloured, macular disease: erythematous, hyperpigmented or hypopigmented flat marks visible to patient or observer at any distance

Vascular Lasers

This form of scarring is often actually a phase in wound healing, and erythematous scars are likely to resolve if the inflammation is removed and the mark allowed to heal.

It may occur anywhere where recent activity has occurred and will usually last longer on the body than the face where healing is slower. Intervention is required if this process is not occurring in a timely fashion or where the patient is impatient for recovery. Resolving hypertrophic scars exhibit more prolonged erythema. This is most often seen in younger patients and may occur in facial or off face scarring. More than one treatment is required in most cases of erythematous acne scars.

A number of treatments, at one to two month intervals, are required with a relatively short pulse duration in the millisecond range (5) [25] using either intense pulsed light (IPL) or pulsed dye lasers (2b) [26].

In 1995, it was reported that the flashlamp-pumped pulsed dye tunable laser was useful in the treatment of keloid sternotomy scars, with improvement in scar height, skin texture, erythema and pruritus (1b) [27] with confirmation in other studies (1b) [28] (1b) [29]. The flashlamp-pumped pulsed dye laser has also been used for erythematous scars (2a) [30] and has been compared with the long-pulsed 1064-nm neodymium–yttrium–aluminium garnet (Nd:YAG) laser on acne scars in a split-face study. Unfortunately, scar colour was not specifically addressed in the article as a parameter, although looking at the clinical photographic examples, it appeared that colour was an important part of the improvement seen in these patients (1b) [31].

Other scar types judged according to the ECCA scar classification system (1b) [32] appeared to have modest scar improvement scores. It is probably better to consider vascular lasers in a patient where the predominant scar type is erythematous, although it is worthwhile knowing that it may have a positive effect on other atrophic and hypertrophic scar types if they are also present (3a) [33].

Comments and Recommendations

(a) Vascular lasers are useful for erythematous scars (B).
(b) Multiple treatments are necessary (A).
(c) Vascular lasers may be useful in other scar types (C).

Fractionated Lasers and Devices, Pigment Lasers and Intense Pulsed Light (IPL)

Fractionated lasers may sometimes be used for hypopigmented marks and scars on or off the face with significant improvements of 51–75% in hypopigmentation in six of seven patients cited in a pilot study by Glaich et al. (4) [34]. Fractionated 1550-nm laser may have particular efficacy in treating these scars (5) [38].

A mid-infrared-wavelength, thulium (1927 nm) laser is a superficial, non-ablative, fractional device that has been anecdotally noted to be effective for the treatment of post-inflammatory hyperpigmentation and melasma that commonly highlight hypopigmented scarring.

Intense pulsed light has its advocates for treatment of post-acne scarring both alone (5) [35] and in combination with other therapies (4) [36] for atrophic and hypertrophic disease; however, at this time, conclusive evidence for its efficacy is insufficient for its recommendation here (1a) [37]. These may be useful for erythematous scars, especially non-ablative 1550-nm fractional devices, although specific references are lacking at this time.

Another new mid-infrared-wavelength, thulium (1927-nm) laser is a superficial, non-ablative, fractional device that has been anecdotally noted to be effective for the treatment of post-inflammatory hyperpigmentation and melasma (1b) [39] that commonly highlight hypopigmented scarring. In this circumstance, it would be used to treat the hyperpigmented areas, decreasing the contrast between these areas and the hypopigmented scars.

Comments and Recommendations

(a) Fractionated lasers (especially 1550-nm lasers) are useful for hypopigmented scars (B).
(b) Fractionated thulium lasers may be useful for hyperpigmented scars (C).
(c) Intense pulsed light may be useful in several scar types (C).

Repigmentation Procedural Techniques

Hypopigmented scars may be additionally helped by repigmentation procedures. These may be added to resurfacing procedures such as topical latanoprost or bimatoprost (4) [40], (1b) [41]. ReCell automated cell transfer system may also add to a successful outcome for certain types of hypopigmented scars and may have a place in 'off face' hypopigmented scarring.

Hypopigmented scarring has been reasonably refractory to treatment. There have been scattered reports of repigmentation after manual dermabrasion (4) [42] and needling (5) [43]. Some pigment transfer procedures have been attempted. A number of techniques used to treat vitiligo may also be useful in treating certain types of superficial hypopigmented scarring. Cultured and immediate noncultured epidermal suspensions may also be somewhat useful (2c) [44]. ReCell (C3, Perth, WA, Australia) is an automated commercial kit for trypsin dermal–epidermal separation that has become available, allowing immediate autologous noncultured epidermal suspension. This may improve the ease of the technique considerably over current methods (4) [45], (4) [46].

Comments and Recommendations

(a) Bimatoprost and latanoprost may be useful for hypopigmented scars (C).
(b) Pigment transfer procedures such as automated trypsin-digested epidermal cells may be useful adjuncts to the treatment of scarring (C).

Grade 2 Scarring

Grade 2 scarring is a mild, atrophic or hypertrophic disease that may not be obvious at a social distance (e.g. talking to someone conversationally in normal lighting) and is easily covered with make-up.

Manual Skin Needling or Rolling

Manual skin needling comes in many forms from a rolling apparatus with embedded pins to motorised pen-shaped instruments that vibrate needles in and out of the skin through stamping fixed pin designs. They all injure the skin engendering a wound repair cascade that, over a number of sessions, usually five to six, will improve the quality of grade 2–3 atrophic skin scars (2a) [47] (1a) [48]. This is a very useful procedure in terms of low downtime for the patient with a low incidence of complications (1c) [49]. A small but well-performed study examined the efficacy of skin needling as a treatment with clinical end points and microrelief silicon impression (1b) [49] and found it to be useful.

Comments and Recommendations

(a) Manual skin needling appears to be a useful treatment for atrophic scars (A)
(b) Multiple treatments are necessary (A)
(c) Vascular lasers may be useful in other scar types (C)

Non-ablative Non-fractional Resurfacing

This category of treatment usually describes the use of lasers and radiofrequency (RF) to bulk heat the dermis whilst simultaneously cooling or otherwise protecting the dermis (4) [50]. This set of procedures has largely given way to fractional devices due to a number of factors. These treatments have really been the forerunners to a similar technology given in a safer and more efficacious manner by fractionation (1b) [51].

It has been of some use in milder forms of atrophic acne scarring but is limited because of safety concerns when higher energies are used due to transference of energy to and wounding of the skin surface. It is not limited to the face, but if epidermal injury is sustained, it will take longer to heal and may result in complications.

These lasers use conducted heat from the chromophore to produce a diffuse dermal injury, heating to >50 °C and inducing collagen remodelling. Repeated treatments are required, and longevity of the results remains largely unknown.

This technology seems safe [49], (2c) [52] with patient satisfaction and perception of efficiency appearing reasonable, although post-inflammatory hyperpigmentation may result, especially if blistering occurs.

Comments and Recommendations

(a) Non-ablative resurfacing may be useful for atrophic scarring (C).
(b) Multiple treatments are necessary (A).
(c) Efficacy and safety may not be equivalent to fractional laser delivery (A).

Microdermabrasion

Usually microdermabrasion is only useful for the mildest forms of scarring, often in the context of comedonal disease. It is often used in early pubertal acne or in grade 2 mildly atrophic disease.

It has been suggested that microdermabrasion using aluminium oxide crystals or sodium chloride is useful in the treatment of facial scarring (4) [53], (2c) [54]. Small crystals of aluminium oxide or other agents are expelled from one nozzle towards the skin, abrading it with a series of small lacerations, with the used crystals aspirated back from the skin surface and discarded (2c) [55]. Multiple treatments are required, and results usually only see mild improvement. However, this is a safe treatment on or off the face with limited downtime which is well tolerated and comparatively inexpensive.

Its efficacy for the treatment of scarring remains uncertain (5) [56]. It may owe its efficacy to changes in skin barrier function with its consequent transepidermal water loss (1b) [57]. A number of articles attest to its efficacy, and improvement is likely to be mild, making it useful in this grade of scarring (5) [58].

Comments and Recommendations

(a) Microdermabrasion is possibly useful in milder forms of atrophic post-acne scarring (B).
(b) Multiple treatments are necessary (A).

Volume Treatments

Volume treatments may be used for grade 2 scarring, usually lower prime agents amongst the hyaluronic fillers or an approach that ignores the individual scars but concentrating instead on the areas of scars flooding this to improve the underlying skin structure (1b) [59] (5) [60].

There are permanent fillers for the treatment of post-acne atrophic scars (2a) [61] although not everybody is comfortable with this approach.

One can also use dermal fillers if the individual scars are deep enough, and flooding the dermis with superficial dermal fillers is also a possibility. Although superficial dermal fillers are unproven in scarring, they have a rejuvenating effect on skin elasticity and dermal thickness (4) [62].

Comments and Recommendations

(a) Fillers probably have a limited role in the treatment of these milder forms of atrophic acne scarring (C)

Grade 3 Scarring

Moderately abnormally contoured disease, atrophic or hypertrophic scarring obvious at conversational distance incorporating rolling and superficial boxcar-type scarring

Ablative Non-fractional Laser Skin Resurfacing

Although not conclusively shown to be effective in a Cochrane report that was later withdrawn(1a) [63, 64], ablative full-face laser skin resurfacing has for nearly two decades been considered the criterion standard for the treatment of post-acne and other types of scarring but may be giving way to fractional devices (5) [65], (5) [66].

Comments and Recommendations

(a) Ablative non-fractional resurfacing was considered in the past the best form of therapy in post-acne scarring (A).
(b) Morbidity is significant (A).
(c) Fractionated delivery may have replaced this technology in terms of efficacy and safety (B).

Dermabrasion

Dermabrasion was the first major advance in the treatment of atrophic and traumatic scarring. It is probably at its best in treating grade 3 rolling scarring and will tighten the skin somewhat in an older patient with scarring (4) [67].

Comments and Recommendations

(a) Similar comments to ablative non-fractional resurfacing

Chemical Peeling

For patients with more-severe scarring, deeper peels are usually employed if peeling agents are employed. A number of case series have been presented on the use of medium and deep chemical peeling in the treatment of atrophic scarring (4) [68]. As with any resurfacing procedure, a proportion of patients will develop post-inflammatory hyperpigmentation, but even in darker skinned patients, as in this study, they have been useful.

Comments and Recommendations

(a) As for full-field treatments generally, medium and deep peels have been largely superseded by fractionated devices or methods that limit their morbidity such as combining lower strengths with other procedures or focal delivery such as CROSS (B).

Dermal Fillers

Considering how commonplace it is to use dermal fillers, there are few references as to the use of fillers in indented scars (4) [69], (4) [70], but these are either case reports or case series. Fillers that are not often used or not used at all have been the subject of studies, but more studies need to be undertaken with hyaluronic acid as this is very widely used. A permanent filler, polymethylmethacrylate, has been investigated in a large controlled study of 147 patients with a short 6-month follow-up period. Using a validated scar scale, they achieved success in 64% of treated patients versus 33% of control subjects. Only reversible adverse reactions were seen, but one must stress the short-term study time frame (1b) [71].

Comments and Recommendations

(a) Fillers are useful in atrophic scarring (C).
(b) Morbidity is mild (A).
(c) They are useful in combination with other modalities (B).

Botulinum Toxin

Botulinum toxin may be combined with fillers, although the fillers are usually administered at a later session, once the effect of the botulinum is established. The use of dermal fillers and botulinum appears to be synergistic in many cases (4) [72]. However, more exciting is the effect that botulinum toxin may have on hypertrophic varieties of post-acne scarring and keloids. In a randomised study of 24 female patients (1b) [73],

botulinum toxin injections (5 IU/cc keloid) at three 8-weekly sessions were compared to three 4-weekly intralesional steroids (10 mg/cc), and results showed that objective parameters such as hardness, elevation, redness and subjective complaints such as itching, pain and tenderness all decreased significantly ($p < 0.01$). The volume reduction was 82.7% for the intralesional steroid group and 79.2% for the botulinum toxin group. There was a significant decrease in the height of lesions and redness score compared with baseline ($P < 0.01$) with no significant difference between both groups. All patients mentioned a significant reduction of their subjective complaints ($P < 0.01$) which was more significant in group B. Skin atrophy and telangiectasia were evident in three patients of group A. Patient satisfaction was high in both groups. Very satisfied was 50% in the steroid group versus 75% in the botulinum toxin group. Only one patient in the intralesional steroid group was unsatisfied, all others being satisfied or very satisfied.

It may be because botulinum toxin becomes a drug to consider prophylactically in at-risk patients or resolving acne lesions that are likely to become hyperplastic (4) [74].

Comments and Recommendations

(a) Botulinum toxin may have a role in prevention and treatment of hypertrophic scarring (B)
(b) Morbidity is not significant (A)
(c) This may be combined with other modalities (B)

Subcision

Subcision works by breaking up the attachments of atrophic acne scars, releasing the surface from the deeper structures, with successive treatments producing further improvement (4) [75], (4) [76]. Intradermal insertion is suitable for small superficial scars, whereas deeper dermal undermining is performed for more severely bound down scars.

Some comparative and combination studies have been performed, and multiple papers have discussed variation in the initial subcision technique. One study of 20 patients compared one to three sessions of 100% trichloroacetic acid (TCA; CROSS) to scars on the left side of the face with subcision to scars on the right side (1b) [77]. The study showed more improvement in rolling scars and less adverse reactions (pigmentation) on the subcision side ($p < 0.001$), although one wonders whether the number of TCA sessions was sufficient in this study and maybe TCA is at its best for ice-pick scars (1b) [78].

In another study (within individual, split face and single blinded, $N = 10$, 20 sides) looking at comparing subcision against another modality (porcine collagen), subcision appeared marginally superior to the filler at 3 months ($p < 0.03$) according to patients, whilst there was no significant difference in objective measure at any other time points by patients. Nine patients completed the study, and follow-up was for 6 months post-treatment. Blinded observers and patients rated improvement on a five-point scale, and both techniques performed well with patient global satisfaction rates being 3.9 for subcision and 3.5 at 6 months versus lower rates by blinded observers (2.95 for subcision and 3.05 for porcine collagen).

There is an interesting combination study looking at 50 patients receiving topical treatment, subcision, 15% trichloroacetic acid (TCA) and needling in an alternating sequence (2b) [79]. Specifically, retinoic acid 0.05% was used to prime the patient for 2 weeks prior to a single subcision session using a 24# (gauge) needle. One day later, needling with a Dermaroller was performed and retinoic acid immediately used for 30 min after the procedure. Two weeks later, 15% TCA was used until speckled frosting occurred. The sequence of fortnightly needling and TCA peeling was continued up to six cycles.

A qualitative scale was used to assess improvement (1b) [80] which categorises patients into four grades of severity of scarring (grade 4 being the most severe and grade 1 the least). This grading system has been used in this manuscript.

Out of 16 patients with grade 4 scars, ten (62.5%) patients improved to grade 2 scars and

six (37.5%) patients improved to grade 3 scars. Out of 22 patients with grade 3 scars, five (22.7%) patients were left with no scars, two (9.1%) patients improved to grade 1 scars and 15 (68.2%) patients improved to grade 2 scars. All 11 (100%) patients with grade 2 scars were left with no scars. There was a high level of patient satisfaction.

Comments and Recommendations

(a) Subcision is a useful treatment in atrophic post-acne scarring (A).
(b) Morbidity is mild (A).
(c) It is readily combined with other therapies (B).

Intralesional Corticosteroids or Fluorouracil, Combined with Silicon Sheeting

High-strength intralesional corticosteroids are commonly used in the treatment of hypertrophic and keloidal scars. Over the last decade or more, reports have appeared of intralesional cytotoxics, including fluorouracil (5 FU) (5) [81], bleomycin (4) [82] and mitomycin (4) [83], as treatments for hypertrophic and keloid scars.

A meta-analysis was performed in 2016 (1a) [84], comparing intralesional steroids as the control group (TAC) and the combination of intralesional 5-fluorouracil and steroids (TAC) as the experimental group.

A pooled analysis of patient self-assessed effectiveness showed that the experimental group achieved better results than the control group (OR = 2.92, 95% CI = 1.63–5.22, P = 0.0003). Similarly, a pooled observer assessment produced similar conclusions (OR = 4.03, 95% CI = 1.40–11.61, P = 0.010). Scar height after treatment showed that the experimental group performed better than the control group (MD = −0.14, 95% CI = −0.23–0.05, P = 0.002). The erythema score of the experimental group after treatment was superior (MD = −0.20, 95% CI = −0.34–0.06, P = 0.004). So it would appear that TAC combined with 5-FU is superior in the treatment and prevention of hypertrophic scars and keloids, with greater improvement in scar height and patient satisfaction.

Comments and Recommendations

(a) Intralesional steroids are considered a front-line agent in the treatment of hypertrophic scarring (A).
(b) Adverse reactions of atrophy and telangiectases are possible sequelae of intralesional steroids (A).
(c) Intralesional cytotoxics combined with steroids especially 5-fluorouracil may be superior to steroids (A).

Grade 4 Scarring

This grade describes severely abnormally contoured disease, usually non-distensible, and includes severe atrophic or hypertrophic scarring obvious at conversational distance and not able to be flattened by manual stretching of the skin.

Trichloroacetic Acid (CROSS Technique)

A variation of chemical peeling involving the use of 60–100% trichloroacetic acid [77], termed the CROSS technique, has raised interest in the treatment of smaller ice-pick- and poral-type scars, which have always proved a challenge.

Comments and Recommendations

(a) Focal trichloroacetic acid (CROSS) is a very useful technique for ice-pick scarring (A).
(b) Adverse reactions of erythema and post-inflammatory hyperpigmentation are possible sequelae of CROSS (A).

Punch Techniques (Excision, Grafting or Elevation)

Punch excision removes a pitted scar using a straight-walled disposable or hair transplant

punch that is slightly larger than the scar. Sutures are then placed to oppose the wound, as per a normal excision (4) [85]. Punch replacement grafting, which has been used for several decades in dermatology (5) [86], is probably best used to treat sharp-walled or deep ice-pick scars with dystrophic or white bases. Resurfacing may be performed 4–8 weeks later to flatten the grafts and further blur the margins.

Punch elevation is a variation of other punch techniques, except that the scar is not discarded. The tissue cylinder is incised down to the level of the subcutaneous fat, and the scar is allowed to float up until it reaches the same level as the surrounding skin.

One study examining the combination of fractionated CO_2 laser in two sessions with punch elevations versus just the laser alone found greater improvement when punch elevations were used ($p = 0.02$) 4 months after surgery (1b) [87]. Both sides showed excellent improvement subjectively (61.9% noted good to excellent improvement), and objectively, all scar types improved, and there was no difference in their degree of improvement.

Comments and Recommendations

(a) Punch techniques including punch grafting, punch excision and closure and punch elevation are valid techniques for deep boxcar scars (C).
(b) These techniques may be synergistic with resurfacing procedures (B).

Fat Transfer

For severely atrophic disease in which there is destruction of the deeper tissues, fat remains the optimal replacement agent. Fat is easy to work with, cheap, and readily available. It will not be rejected or result in an allergic reaction; and is without risk of communicable disease. It is making a resurgence especially with the advent of plasma-rich protein, stromal vascular fraction and stem cell technologies (2a) [88] (1b) [89].

An interesting comparison trial looked at fat transfer versus fractional CO_2 laser (1b) [90] with 20 patients divided into two equal groups and their outcomes assessed with digital photographs taken by a committee of three physicians, by a single-blinded physician and by reports of patient satisfaction.

In the fractional CO_2 laser treatment group, less than 20% of patients were graded as having excellent scar improvement, 0 as having excellent and marked scar improvement, almost 70% as having moderate scar improvement and less than 10% as having mild scar improvement. In the fat-grafting group, the scar and overall improvement were graded as 30% excellent, 30% marked, 20% moderate and 20% mild. The authors concluded that fat transfer gave superior results in the treatment of post-acne scarring versus fractional CO_2 laser.

Comments and Recommendations

(a) Fat transfer is a valid method for severe atrophy associated with acne scarring (B).
(b) Longevity and reproducibility of issues have led to interest in the addition of platelet-rich plasma and stem cells (B).

Comparative Effectiveness of Common Treatments

We will compare some of the treatments most commonly used in post-acne scarring, utilising but varying the framework from a recent Cochrane review on evidence-based acne scarring interventions (1a) [48].

1. Non-fractional non-ablative laser versus
   (a) Placebo or no treatment
   (b) Other non-fractional non-ablative laser
   (c) Fractional laser
2. Fractional laser versus
   (a) Placebo
   (b) Radiofrequency
   (c) Needling

3. Chemical peeling versus
   (a) Placebo or no treatment
   (b) Combined chemical peeling plus any active intervention
   (c) Needling
   (d) Fractional resurfacing
4. Needling versus
   (a) Placebo or no treatment
5. Non-fractional non-ablative laser versus
   (a) Placebo or no treatment

   The majority of lasers for this purpose have been the mid-infrared lasers at wavelengths of 1320 nm, 1450 nm and 1540 nm, although many wavelengths have been used. Most of the infrared studies appropriately cooled to protect the epidermis whilst targeting dermal water. Non-ablative lasers appear to have a role in the treatment of minor atrophic scarring.
   (b) Other non-fractional non-ablative laser

   Comparative studies of laser systems have been performed. In one study conducted in 2004, (1b) [91] a series of 20 patients with mild to moderate atrophic facial acne scars randomly received three successive monthly treatments with a long-pulsed 1320-nm Nd:YAG laser on one facial half and a long-pulsed 1450-nm diode laser on the contralateral facial half.

   Digital photography, microtopography measurements and cutaneous biopsies taken before and at a number of time points after the final treatment along with clinical assessment scores served as objective measurements.

   Subjective patient satisfaction surveys were obtained at the end of the study.

   Mild to moderate clinical improvement was observed after the series of three treatments in the majority of patients studied. Side effects of the treatments were mild.

   It was suggested by the authors that each system was useful, and subjective and objective parameters were aligned in the noted improvement and may indicate utility in those seeking low morbidity treatment.

Some studies have looked at treating different conditions with the same technology.

In a study from 2001 (1b) [92], a split-face, within-patient design, a 532-nm long-pulsed laser was compared to a placebo where 11 patients had either one cheek (scars) or half their upper lip (wrinkles) randomised to receive an average of three treatments with the other cheek or upper lip kept untreated. Assessment was by the blinded observer and subjective assessment. Efficacy assessment was of an average of 53.6% improvement versus just over 51% for wrinkles. The blinded observer was asked to suggest which side was treated. Adverse events were mild and transient.

In another study conducted in 2004, (1b) [50] the role of 1320 Nd:YAG in non-ablative skin rejuvenation in Asians was explored for wrinkle reduction and atrophic acne scarring. Twenty-seven female patients were included, 7 for acne scarring and 20 for wrinkle reduction. A 1320-nm Nd:YAG laser was used to treat both the cheeks and forehead for patients with wrinkles and only both cheeks for those with atrophic acne scarring. All patients received treatment in the postauricular areas. A 10-mm spot size and three passes were used in six patient treatments over 6 months.

Subjective assessment was made using a structured questionnaire before the first treatment and after their last treatment session.

Objective assessment was by the use of clinical photographs for independent observers, a cutometer to assess viscoelasticity, and biopsies were taken in the postauricular site for assessment of pathology.

Subjective assessment showed an overall satisfaction rate of 4.9 (range 0–9.8) for wrinkle reduction and 4 (range 0–10) for acne scarring. Objective assessment by independent observers rated the

degree of improvement as mild or no change in most cases. The independent pathologist who assessed increase in collagen production detected no change in 8 patients, mild improvement in 9, moderate improvement in 10 and epidermal thickening in 13. Cutometer assessment of viscoelasticity indicated improvement in most patients in both groups.

Adverse reactions of blistering ($N = 5$) occurred in all in the central facial areas, and post-inflammatory hyperpigmentation occurred infrequently and responded to treatment ($N = 3$).

The authors concluded it was an effective treatment for both conditions although on their data it seemed a very mild effect with a significant adverse event profile.

(c) Fractional laser

A randomised comparative study between Q-switched 1064-nm and fractional CO_2 laser included 64 participants with atrophic acne scars who received four sessions of either fractional CO_2 laser or Q-switched 1064-nm Nd:YAG laser (non-fractional non-ablative) at 4-week intervals (1b) [93].

Results showed that in the fractional CO_2 group, participant-reported scar improvement at 6 months post-treatment in 12 out of 32 subjects was more than 50% compared to that of 3 out of 32 in the non-fractional non-ablative group. According to subjective satisfaction ($p = 0.01$) and physicians' assessment ($p < 0.001$), fractional CO_2 laser was significantly more effective than a Q-switched 1064-nm Nd:YAG laser. All patients completed the study, and side effects were stated to be mild and transient in both groups.

Comments and Recommendations

1. The effect of non-ablative resurfacing on atrophic acne scars is mild improvement (A).
2. The different visible and infrared wavelengths used are likely to produce similar effects (A).
3. The adverse reaction profile is manageable but is not ideal (B).
4. The fractional lasers may be more efficacious than non-ablative non-fractional lasers (B).

It would appear that this type of technology was reported more frequently 10–15 years ago and new studies are not frequent, maybe suggesting this has given way to newer technologies such as fractional delivery.

2. Fractional laser versus
   (a) Placebo

A within patient trial (1b) [94] with 13 participants in which similar sized areas on each side of the face was randomised to receive 3 × monthly treatments of fractional CO_2 laser and the area on the contralateral site received no treatment (placebo).

Objectively, patients were assessed by three blinded physicians on a ten-point scale showing significantly improved skin texture and scar atrophy in all 12 participants with atrophic acne scars, from a baseline mean of 6.15 to a post-treatment mean of 3.89 for skin texture and 5.72 for scar atrophy to 3.56 at 6 months ($P < 0.0001$). One patient was excluded from this data.

Subjectively, participant satisfaction was recorded. All 13 participants reported a median satisfaction score of 4.5 at 6 months based on a numerical scale from 0 (unsatisfied) to 10 (maximal satisfaction). No untreated side data was reported.

Adverse reactions appeared frequent (such as pain) on the treated side but mild and transient.

In another trial, (1b) [95] 30 Chinese patients with atrophic acne scars on both cheeks received a split-face treatment. One side underwent four sessions with fractional 1550-nm Er:Glass laser at 20-day intervals and the other with a control cream application three times daily. Clinical response and side effects were evaluated by a dermatologist 3 weeks after each treatment and again 12 weeks after the last laser treatment. In addition, self-evaluation of satisfaction by the patients was done at the end of treatment.

Mean scores for the acne scars decreased 5.65 ± 4.34 after treatment for the treated side and 1.23 ± 3.41 for the control side. The improve-

ment in acne scars after the fractional 1550-nm Er:Glass laser treatment was more significant than the control side ($p = 0.0001$). The side effects were mild and transient.

Similar findings of efficacy over baseline using different parameters of Erbium:Glass 1550-nm lasers as their controls rather than non-treatment were found in other studies (1b) [96] 1(b) [97] with both these studies commenting on hyperpigmentation as an adverse reaction.

Comments and Recommendations

1. Fractional laser resurfacing is efficacious as against placebo or nontreatment (A).
2. The adverse reaction profile is manageable with most being mild or transient (B).
3. Hyperpigmentation amongst these adverse reactions appears the most troublesome in those of darker skin (B).

Fractionated lasers seem effective and useful for atrophic post-acne scarring.

2. Fractional laser versus
   (b) Radiofrequency

A parallel-group trial design (1b) [98] randomly divided 40 participants into two equal groups (each $N = 20$) to receive either 1550-nm Er:Glass fractional laser (Group A) or a fractional radiofrequency device (Group B) over three sessions at 4-week intervals. Subjective assessment showed in both groups that 15/20 patients sustained average to excellent improvement in the appearance of acne scars. No statistically significant difference was reported.

All 40 participants completed the trial as planned, and no severe side effects were noted. Ten percent of patients in group A (fractional laser) ($N = 2$) had post-inflammatory hyperpigmentation versus none in group B (radiofrequency). There was shorter downtime and lesser pain in group B (radiofrequency).

In group A (fractional laser), the mean ECCA grading scale was reduced from 74.25 to 55.5, a 25.0% decrease from baseline ($P < 0.001$). In group B (radiofrequency), the mean ECCA grading scale decreased from 68.75 to 56.0 ($P < 0.01$), an 18.6% reduction. There was no statistical difference noted between the two arms of treatment.

Very similar results were seen in a within-subject comparison of fractional Erbium and fractional bipolar radiofrequency in 20 Thai patients (1b) [99] being delivered in a randomised fashion to one side of the face with the alternative technology to the other. After three treatments, 4 weeks apart, subjective analysis was similar with all patients (except one withdrawal) rating both treatments as being moderately (two out of four), very (three out of four) or most (four out of four) satisfied on a four-point scale.

Quantitatively, after treatment, subjective improvement was 2.89 (SD 0.57) for the fractional Er:Glass and 2.74 (SD 0.73) for the fractional bipolar RF devices, respectively.

Objective scar improvement showed mean improvement after treatment of 2.86 (SD 0.42) and 2.70 (SD 0.37) for the fractional Er:Glass and the fractional bipolar RF ($n = 19$) devices, respectively.

Adverse events such as pain, transitory facial erythema, facial dryness and scabbing were reported for both treatments with pain being statistically less significant with the RF device (mean difference = 1.85 (SD 1.30), $P < 0.001$), whilst the opposite was true for the scab separation with the length of scab-shedding treatment being longer with the fractional RF than with the fractional laser.

Comments and Recommendations

1. Fractional laser resurfacing is efficacious as is bipolar fractional radiofrequency (A).
2. There is little likelihood that one is superior to the other (B).
3. The adverse reaction profile is manageable with both technologies (B).
4. Hyperpigmentation may be more likely in fractional laser resurfacing than radiofrequency (B).
5. Fractional radiofrequency may take more time for scab shedding (C).
6. Both technologies seem very adequate treatment for atrophic scarring (C).

Fractionated lasers and fractional bipolar radiofrequency seem effective and useful for atrophic post-acne scarring with a satisfactory and similar adverse reaction rate.

2. Fractional laser versus
   (c) Needling

In 2015 a study of 46 participants were randomised to receive either fractionated 1340nm laser or microneedling over 3 sessions, conducted monthly (1b) [100]. Of the 46 assigned patients, 42 completed treatment, 22 in the laser group and 20 in the microneedling group. Subjectively, 65% of microneedling patients and 86.4% of the laser patients perceived an improvement after the first treatment session, and 100% of participants in both groups noted improvement after the second session. Both groups improved according to objective quantitative grading, the laser group from a mean of 15.82 to 12.41 and the microneedling group 14.9 to 10.85, both showing $p < 0.001$. Boxcar scars seemed to improve more than rolling scars, and both showed better improvement than ice-pick scars. There was no statistical difference between the two interventions in terms of efficacy, whilst adverse reactions showed a longer erythema and higher incidence of post-inflammatory pigmentation in the laser group.

Comments and Recommendations

1. Needling may be a promising treatment (B).
2. Needling may be a viable alternative to other fractional resurfacing techniques (C).
3. Hyperpigmentation may not be problematic with needling as compared to other fractional technologies in skin of colour (C).

Fractionated lasers and needling are both useful treatments, and needling probably needs to be further explored as it may provide a cheap alternative to other technologies.

3. Chemical peeling versus
   (a) Placebo or no treatment

One parallel-group study from 2000 (1b) [101] addressed this comparison in which 58 women with atrophic acne scarring were randomised into three groups: one group ($n = 23$) received serial biweekly (2-week intervals) glycolic acid peels with different concentrations in gradually increasing concentration and application times; another group ($n = 20$) received 15% glycolic acid cream daily for 24 weeks; and the remaining group ($n = 15$) received a placebo cream daily. Ice-pick and fibrotic scar patients were excluded from the study. Ten patients could not complete the study, mostly in the peel group where seven were unable to tolerate higher percentages of the peels and two were lost to follow-up. All arms showed improvement in the scars on the scale used (>60% grade change, 30–60% grade change and < 30% grade change), even the placebo arm; however, according to the authors, only patients in group A (peel patients) achieved significant decrease in their scarring. In the cream group B, eight patients were only able to use the cream daily rather than twice daily, and three developed pigmentation with the use of the cream, whilst in the placebo group, one participant was lost to follow-up, although no adverse reactions were noted in this group.

3. Chemical peeling versus
   (b) Combined chemical peeling plus any active intervention

An article published in 2014 addressed a 24-patient parallel-group trial [102] and compared a single deep chemical peel versus four sessions (6-week intervals) of chemical peeling with TCA 20% combined with skin needling.

The deep peel was a non-hydro-alcoholic solution of oil phenol in 60% concentration formula. Twenty participants (ten in each group) completed the study and were included in the consequent results. Two of 12 participants in each group did not go on to their allocated treatment after study enrolment and did not take part in the analysis.

Eight months after treatment, subjective patient-reported scar improvement was 50% in all ten patients in the deep peel group and eight of

ten patients in the light chemical peeling plus needling group using a weighted scale and then a quartile grading scale (0 = minimal improvement <25%; 1 = mild improvement 25–50%; 2 = moderate improvement 51–75%; 3 = significant improvement >75%). No statistically significant difference was noted between groups in efficacy.

Scar severity scores improved by a mean of 75.12% ($p < 0.001$) in group 1 and a mean of 69.43% ($p < 0.001$) in group 2. Compared to other scar types, within the individual groups, rolling scars in group 2 improved most significantly ($p = 0.005$).

The deep peel group was a significantly morbid procedure with all participants in the chemical peeling group showing erythema for 3–4 months and pigmentation for 6 months. Two of ten participants in this group had persistent erythema for 6 months. None of the participants in the chemical peeling plus needling group showed any adverse events 1 month after the procedure.

Another study looked at the combination of peels with other technologies (1b) [103]. Three matched groups of 13 patients were assigned to receive either six sessions of needling combined with simultaneous trichloroacetic acid 20%, six sessions of 1540-nm fractional laser or alternating sessions of the two previous treatments. One patient was lost to follow-up but was included in analysis in group 1.

Prior to treatment, scar type was established (rolling, boxcar and ice-pick), and the total severity in each patient was assessed according to the following weighted scale: three points for deep, two points for shallow and one point for superficial scars.

Both patients and a blinded dermatologist rated the scar improvement on a quartile scale (0, minimal improvement <25%; (1) mild improvement 25–50%; (2) moderate improvement 51–75%; (3) significant improvement >75%).

All groups improved well on objective analysis with a mean of 59.79% (95% CI, 47.38–72.21) ($p < 0.001$) in group 1, 61.83% (95% CI, 54.09–69.56) ($p < 0.001$) in group 2 and 78.27% (95% CI, 74.39–82.15) ($p < 0.001$) in group 3. The degree of improvement was significantly higher in group 3 when compared with both groups 1 and 2 ($p = 0.007$, $p = 0.019$).

Different scars improved differently in the different groups, possibly a key finding to the synergy shown here. Rolling-type scars showed a significantly higher improvement in group 1 ($p < 0.001$), the boxcar type showed a significantly higher improvement in group 2 ($p < 0.001$) and in group 3 the highest improvement was documented for both rolling and boxcar types ($p < 0.001$). Improvement in ice-pick scars only achieved significance in group 3 ($p = 0.05$).

The degree of improvement on the global response measures was significant, objectively in 11 patients (28.2%), moderate in 22 patients (56.4%) and mild in 5 patients (12.8%).

Subjectively, 28 of 39 patients reported improvement of their acne scars, ranging from 50% to 75%. This broadly matched their improvement in scar severity score.

Comments and Recommendations

1. Deep chemical peels are efficacious but have prolonged recovery (A).
2. Light peeling (GA) may impact milder scarring (C).
3. Lighter peels enhanced by needling may reduce atrophic scars significantly (B).
4. Synergy between procedures incorporating peeling appears promising (B).

Chemical peels especially light augmented peeling like 20% TCA and needling probably needs to be further explored as it may provide a synergistic, cheap and effective alternative to or work in with other technologies.

4. Needling versus
   (a) Placebo or no treatment

One within-individual single-centre, rater-blinded, balanced (1:1), placebo-controlled, parallel-group, randomised clinical trial was carried out initially with 20 participants (15 actually entered the study and were analysed) (1b) [104]. For each participant, one side of the face was randomised for needling. Three needling treatments were per-

formed at 2-week intervals, whilst on the other side, topical anaesthetic cream only was massaged onto the control area at three treatment visits.

Two blinded dermatologists separately rated participants' acne scars based on standard digital photographs obtained at baseline and at 3-month and 6-month follow-up visits using the Goodman and Baron quantitative global scarring grading system.

Subjective improvement in scars was reported at 41% mean improvement in acne scars on the treated side with high satisfaction ratings. No adverse events were reported during the study. Pain was minimal (1.08 of 10) and expected erythema and oedema seen in all patients. No other adverse reactions were seen.

Objectively, blinded investigators assessed improvement from photographs in the needling group with a mean scar score change of 3.4 from baseline ($P = 0.03$), whilst in the untreated control group, mean scar scores did not vary significantly from baseline at 6 months with a change of only 0.4 ($P > 0.99$), using the Goodman and Baron global scarring grading system (2b) [105].

Novel and Possible Future Acne Scarring Treatments

Two treatments may be worthy of discussion here.

First, advancements in laser technologies have led to some unusual options that may allow improvements in acne scarring to be separated from morbidity. Pico laser technology has been recently described for a number of texture issues including post-acne scarring (4) [106]. A specific study (1b) [107] has looked at post-acne scarring in a single-centre, 20 patient, prospective study. Patients received six treatments with a 755-nm picosecond laser with a spot size of 6 mm, fluence of 0.71 J/cm^2, repetition rate of 5 Hz and pulse width of 750 picoseconds using a diffractive lens array. Fitzpatrick skin types I–V were enrolled.

Subjectively, mean pain score was 2.83 of 10. Patients were satisfied to extremely satisfied with improvement in appearance and texture at their final treatment and follow-up visits. Objectively, blinded assessment scores of 17 patients were 1.5 of 3 and 1.4 of 3 at 1 and 3 months, respectively (a score of 0 indicates 0–25% improvement and a score of 3 indicates >75% improvement). A three-dimensional analysis revealed a mean 24.3% improvement in scar volume, maintained at 1 (24.0%) and 3 (27.2%) months after treatment. Histologic analysis revealed elongation and increased density of elastic fibres, with an increase in dermal collagen and mucin.

The other interesting technology is the application of substances topically utilising the micro thermal zones, needle marks or ablated holes made by temporary fractionated technology or needling breaches in the epidermis. In this chapter we have seen this applied with needling and low concentration of TCA peeling (20%) acting similarly to more aggressive peels [102] and the application of bimatoprost after fractional laser for hypopigmentation [40]. An article that may be useful for atrophic scarring utilising similar concepts of percutaneous access provided by fractionated delivery has been published (2b) [108]. Although this study is uncontrolled, it offers interesting observations. Four blinded dermatologists evaluated a total of 20 photographs taken at baseline and 3 months after fractional CO_2 laser and PLLA treatments using the Modified Manchester Scar Scale.

All four blinded observers accurately identified 76 of the 80 'before' and 'after' photographs agreeing that at the 3-month follow-up visit, 95% of the scars had improved. Four criteria were evaluated: (1) overall improvement, (2) improvement in scar atrophy, (3) improvement in scar colour/dyschromia mismatch and (4) improvement in scar contour. Each of these criteria demonstrated an average improvement of at least 33%.

Typical Treatment Plans for Acne Scarring Cases

Patients with post-acne scarring are a protean group. Let us discuss a number of case examples and follow them through their experience of available and suitable treatments.

A 23-year-old female with skin phototype 2 presented with type 2 atrophic acne scarring,

somewhat visible in tangential lighting but not readily at conversational distance. She was concerned because it was visible to her in the mirror each morning and evening when cleansing her face and applying make-up and skin care. She felt that make-up did not hide but rather accentuated the appearance of her scars. She had no real barriers to treatment and was available to have a series of treatments if required and could take leave from her job if downtime in terms of healing was needed. She had no illnesses and allergies and was on no regular medications aside from vitamins and was neither pregnant nor breastfeeding. However, she was still suffering some active acne. There were no financial or lifestyle issues that would interfere with treatment planning.

A treatment plan was created, and on the basis of best evidence and limiting morbidity, a series of five to six sessions at monthly intervals of fractionated radiofrequency was suggested. However, before this was undertaken, two suggestions were made: control of her acne was considered essential before proceeding to active scarring treatment, and long-pulsed 532-nm laser is suggested for the erythema in her marks and scars [92].

The patient would be expected to experience mild to moderate discomfort from her procedures with post-treatment erythema and swelling lasting 1–2 days and treatments delivered at 4-weekly intervals.

A 40-year-old male with skin type 3 presented with more severe atrophic (grade 3–4) ice pick, deep boxcar and plentiful rolling scaring visible at conversational distance on his temples and upper cheeks. This patient's acne was inactive and the scarring stable although he felt it was getting a little worse with ageing. Financial issues and work responsibilities could interfere with treatment.

In this patient, subcision and punch techniques were suggested initially and then an alternating series of needling along with a number of low-strength (15%) trichloroacetic acid peels. Consideration needs to be given to the position of the scarring as his temples would require care with subcision to avoid the temporal branch of the facial nerve. Although the punch techniques would require dressings, they would not prohibit the patient from working for a prolonged period and could be performed in one session. They could be combined with subcision as long as the scars treated by each technique are different. Needling and 15% TCA peels were chosen for their relative inexpensiveness and low morbidity.

The patient's first procedure would be the most major one and would involve the best part of a week's recovery incorporating the punch and subcision modalities. Thereafter, alternating light TCA peels and needling either at fortnightly intervals as described by Garg and Baveja [79] or as the patient can fit into his work schedule for six cycles.

A third patient, a 17-year-old female, with skin type III has hypertrophic post-acne scarring on the jawline, chin and chest after nodulocystic acne which has now abated. The scars were quite severe and symptomatic with pruritus and tenderness. This patient was still at school and shy but impatient for a result and with a self-confessed low pain threshold.

Treatment planning is difficult with this patient as the ideal may be intralesional fluorouracil and steroids as described by Ren et al. [84]; however, mitigating circumstances here may issue challenges. If fluorouracil is considered, pregnancy prevention is required and injection is relatively frequent and painful. Here, it was decided that intralesional botulinum toxin at 8-weekly intervals as described by Shaarawy et al. [73] would be utilised in conjunction with silicon gels and sheeting finally finishing with vascular laser when erythema remained as the main unresolved issue.

Self-Assessment Questions

1. With regard to hypopigmented macular scarring
   (a) It is untreatable
   (b) It is treatable with vascular laser
   (c) It is treated by a single treatment of fractional lasers or needling
   (d) It can be treated with fractional lasers and topical agents
   (e) It is likely to settle spontaneously

2. Fractional lasers
   (a) Are not adequate replacements for non-ablative non-fractional technologies
   (b) Are more morbid with more severe adverse reactions than fully ablative procedures such as dermabrasion and full-field ablative lasers
   (c) Are mainly useful in grossly atrophic scarring as the only required treatment but needs several sessions
   (d) Are useful for both atrophic and hypertrophic disease
   (e) Are not synergistic or able to be combined with other therapies

3. Needling
   (a) Is useful for atrophic disease
   (b) Is a form of fractional technology
   (c) Is a treatment that requires several sessions
   (d) Is a treatment of limited morbidity and may be used in higher skin phototypes
   (e) All of the above

4. Intralesional cytotoxic therapy
   (a) Is mainly used for atrophic acne scarring
   (b) Is limited to bleomycin
   (c) Maybe combined with intralesional steroids
   (d) Is completely safe no matter what dose is used
   (e) Only requires one or two treatment sessions of fluorouracil in keloid therapy

5. Regarding chemical peels
   (a) Deep peels remain a mainstay of treatment especially in those of darker skin colour
   (b) Trichloroacetic acid (TCA) is used across the full face in a popular procedure termed CROSS
   (c) May be modified to treat ice-pick scars
   (d) Must not be used in combination with other treatments
   (e) Glycolic acid peels are useful in gross atrophic disease

Correct Answers

1. d: Whilst difficult to treat, hypopigmented scarring is unlikely to respond to the passage of time, vascular lasers or a single session of fractional treatments (requires a number of treatment sessions). It may be responsive to fractional lasers and topical latanoprost or bimatoprost.
2. d: Fractional technologies are superior to non-ablative technologies and less morbid than fully ablative technologies. Gross acne scarring probably requires some sort of filling agent or subcision as well as lasers to achieve success no matter how many sessions are used. Fractional lasers may be used in both atrophic and hypertrophic disease and is the correct answer. Fractional lasers are very much able to be combined successfully with other treatments.
3. e: Needling is a form of fractional technology, although it produces a more limited wound. It requires several sessions (usually about six). It produces very low-risk adverse reactions even in darker skinned patients and is useful in atrophic disease.
4. c: Intralesional cytotoxic drugs, especially 5-fluorouracil and also mitomycin and bleomycin, have been used successfully in the treatment of keloids. Multiple sessions are required, and consideration of their potential toxicity need to be kept in mind (pregnancy and immune suppression), especially if delivered with fractional lasers or needling. Since the original article in 1999, it has been common to mix 5-fluorouracil with steroids.
5. c: Deep chemical peels have become somewhat outdated because of their morbidity, prolonged recovery times and risk of adverse reactions. They are particularly problematic in darker skin types. TCA 100% may be used but is only used as CROSS to individual ice-pick scars; hence, b is wrong and c is correct. Lower strength peels may be augmented safely using needling or similar devices and are readily able to be combined with other therapies. Glycolic acid is a superficial peel only with little utility in deeper forms of scarring.

Traumatic and Burn Scars

49

J. Thomas Landers, Kent Saunders, and Peter R. Shumaker

Abstract

The addition of a chapter on "Traumatic and Burn Scars" in the second edition of this text is an acknowledgment of the interval emergence of minimally invasive technologies and techniques in traumatic scar management (e.g., ablative fractional laser resurfacing) and perhaps even a nascent niche in "trauma dermatology." Traumatic scars are inherently heterogeneous and derived from a wide variety of etiologies such as thermal burns, friction injuries, acid burns, lacerations, and blunt force. The final presentation also includes the sequelae of any related reconstructive procedures such as full- and partial-thickness skin grafting. These scars may occur in an unlimited number of locations and may have associated underlying injuries such as tissue loss and injury to bones, tendons, and nerves. Traumatic scars can cause profound disability, deformity, and chronic pain and itch, all of which may lead to significant psychosocial issues that can negatively impact treatment.

related reconstructive procedures such as full- and partial-thickness skin grafting. These scars may occur in an unlimited number of locations and may have associated underlying injuries such as tissue loss and injury to bones, tendons, and nerves. Traumatic scars can cause profound disability, deformity, and chronic pain and itch, all of which may lead to significant psychosocial issues that can negatively impact treatment.

The global burden of traumatic scarring remains poorly characterized and likely underestimated, as data is generally limited to higher-income countries in limited subsets (e.g., burns). Furthermore, initial posttrauma management may differ widely between high- and low-income countries. For example, standard post-burn care in higher-income countries includes early excision of devitalized tissue with grafting, followed by comprehensive hospital and posthospital management that includes ongoing physical therapy and other support. However, burn care in lower-income countries may more frequently be associated with delayed treatment with prolonged periods of inflammation and limited posthospital care that predisposes to higher rates of pathological scarring [1]. It is estimated that in the developed world, approximately 100 million people acquire scars each year related to surgical procedures, burns, and other injuries. Approximately 25 million of these are derived from trauma and related surgeries [2]. A frequently cited retrospective study by Bombaro et al. reported a prevalence of 67% of hypertrophic scarring in burn patients [3]. Mirastchijski et al. reviewed the costs of burn care in both the acute (immediately after injury) and longer-term (reconstruction and rehabilitation) periods [4]. When their regional data was extrapolated globally, the cost of rehabilitative care (physical therapy, splints, prescriptions, etc.) was estimated to be approximately 240 billion Euros ($297 billion) using 2006 data. This was approximately 4.4 times the estimated cost of acute care and notably did not include perhaps even much larger societal costs such as lost productivity.

Range of Dermatologic Surgery Procedures for Traumatic Scarring

This chapter will focus on minimally invasive adjunctive procedures performed frequently by dermatologic surgeons in the outpatient setting. Commonly accepted treatments for traumatic scars such as surgical intervention (i.e., "cold steel"), pressure, silicone, and physical therapy will not be discussed in detail, although they remain foundational to current paradigms in traumatic scar management. Injectables such as triamcinolone acetonide and 5-fluorouracil are well-established treatments that have been central to hypertrophic scar management for many years, whether or not the scar is traumatic in origin. However, for the purposes of this chapter, such treatments will be considered medical therapies that may be applied in conjunction with other procedures, such as laser-assisted delivery after ablative fractional laser treatment. Overall, the body of literature supporting the efficacy of various procedures for traumatic scars is limited relative to surgical and acne scars. The reasons are multifactorial, but the difficulty in performing controlled studies in the heterogeneous environment after trauma and reinvigorated interest in applications in traumatic scarring in the community are likely contributors. Furthermore, many studies do not necessarily distinguish among the various scar types when reporting their data.

The major categories of procedures selected for discussion in this chapter include "mechanical" techniques (dermabrasion and skin needling), injectables (limited to botulinum toxin and autologous fat here), and energy-based devices (radiofrequency and a variety of lasers and light devices). The largest group, laser and light devices, primarily includes platforms that target water and hemoglobin. Those that target tissue water include full-field ("thermal dermabrasion") and fractional ablative devices, including the 10,600-nm carbon dioxide (CO_2) and 2940-nm erbium–yttrium–aluminum–garnet (Er:YAG) lasers and fractional nonablative (e.g., 1540- and 1550-nm) devices. Devices that target hemoglobin include the 595-nm

pulsed dye laser (PDL) and intense pulsed light (IPL). Other laser devices that target melanin and hemoglobin, such as the 755-nm alexandrite and 1064-nm neodymium-doped–YAG (Nd:YAG), have been reported infrequently for traumatic scar treatment but may also serve as adjuncts in the setting of traumatic scarring to remove problematic hair and traumatic tattoos.

Full-field ablative lasers, such as the 10,600-nm CO_2, and vascular lasers including the 585- and 595-nm PDL have been available for decades. Full-field ablative procedures have been described sparingly for use in traumatic scars, likely due to a limited penetration depth and the extensive associated thermal injury that has rendered the technique useful mainly for focal superficial contouring. In the view of the authors, the advent of fractionation of nonablative and ablative laser platforms around 2004 and 2007, respectively, has been primarily responsible for stimulating increased interest in minimally invasive procedures for traumatic scars [5, 6]. While the 585- and 595-nm PDL has also been available for decades and is supported by multiple studies both in and out of the burn literature, relatively modest efficacy has seemed to relegate it to a subordinate role in the setting of large traumatic scars [7, 8]. Offering tunable depths of penetration and relatively low treatment densities, fractional lasers can be applied for most clinical situations with little regard for skin type and in the absence of erythema, since ubiquitous tissue water is the target chromophore.

Injectables: Botulinum Toxin and Autologous Fat Grafting

Botulinum Toxin

Reports supportive of the use of botulinum toxin to mitigate the formation of scars after trauma began to emerge around 2002. Sherris and Gassner published a case involving revisional excision of a 20-year-old traumatic scar of the forehead, followed with immediate postoperative botulinum injection into the underlying musculature to minimize tension underlying the wound (4) [9]. They later described the concept of "chemoimmobilization" in a series detailing the postoperative injection of botulinum toxin following the repair of traumatic lacerations of the forehead and central face (4) [10]. A study from Egypt in 2006 reported similar findings with the use of botulinum toxin to prevent widening of facial scars. Forty patients had unsightly facial scars excised followed by local botulinum toxin injections. In all but four cases, flatter, narrower scars were reported (3) [11]. Following these promising reports, Gassner et al. published a blinded, placebo-controlled prospective study evaluating the effects of botulinum toxin on wound healing in forehead surgeries and lacerations in 31 patients (2) [12]. A statistically significant difference in the treatment group was noted by two blinded observers using a visual analogue scale (VAS). Ziade et al. published a similar placebo-controlled study of 30 patients treated for traumatic wounds of the face in the emergency department (2) [13]. This study demonstrated statistically significant improvement in the botulinum toxin group using a ten-point VAS but did not show a significant difference using other validated scar evaluation scales including the Patient and Observer Scar Assessment Scale (POSAS) and the Vancouver Scar Scale (VSS).

In addition to efficacy through immobilization of the underlying musculature, botulinum toxin may have direct effects on scar formation through mechanisms including inhibition of transforming growth factor (TGF)-β1 and fibroblast migration and differentiation [14, 15]. A 2009 prospective case series demonstrated statistically significant improvement in erythema, itch, and pliability in 19 existing hypertrophic scars of at least 2 years of duration treated monthly for 3 months with intralesional botulinum toxin (3) [16]. A literature review and report of personal experience published by Goodman in 2010 supported the prophylactic use of botulinum toxin (5) [17]. In his assessment, limitation of dynamic movement and skin tension in the vicinity of a recent injury may prevent the undesirable effects on the

healing wound, as well as help to improve the appearance of existing scars. However, a commentary by Freshwater in 2013 argued that the comparison between the cost of botulinum toxin and the relatively modest improvement documented in existing studies did not justify the use of botulinum toxin in this manner (5) [18]. This viewpoint was supported in a recent systematic review of the literature by Prodromidou et al. in 2015 evaluating botulinum toxin for the prevention and treatment of scars (2) [19]. The conclusion of the authors was that the current evidence does not support the use of botulinum toxin for the treatment or prevention of hypertrophic scars but that additional study is warranted. However, Zhang et al. published a meta-analysis of randomized controlled trials evaluating the efficacy of botulinum toxin type A in the prevention of hypertrophic maxillofacial and neck scars (1) [20]. The authors concluded that botulinum toxin was safe and effective in improving cosmetic outcomes for scars of mixed origin but also noted that the analysis was limited by a paucity of high-quality trials.

Autologous Fat Grafting

Although the history of autologous fat grafting (AFG) for volume correction spans over 100 years, it was not fully recognized until the 1990s that grafted fat might induce active tissue remodeling in addition to providing simple volume replacement. This remodeling process appears to be driven primarily by adipose-derived stem cells present within the graft (5) [21, 22]. In 2007, Sardesai and Moore conducted a prospective cohort study including 14 patients with facial scars of various etiologies (3) [23]. They noted statistically significant improvements in dermal elasticity, scar thickness, and perceptions of stiffness despite the subdermal placement of the graft. Klinger et al. followed 20 patients for 1 year after fat grafting and found statistically significant improvements in scar elasticity as measured by durometer, as well as improvements in appearance and patient perception of pain as measured by the POSAS (3) [24].

Burns are the most studied etiology with respect to a potential role for AFG in traumatic scar management. In 2010, Caviggioli et al. published a case series including 24 patients utilizing AFG for reconstruction of the nipple–areola complex following burns, a technique that they called "nipple resuscitation." At 2-year follow-up, patient satisfaction was good or excellent for all patients, and improvements in skin texture, softness, and elasticity of the nipple–areola complex were also noted (3) [25]. Bruno et al. conducted a split-scar clinical and immunohistochemical study including 93 burn scars that showed a relative normalization in examined specimens at 6 months, accompanied by corresponding functional and aesthetic improvements (2) [26]. A retrospective evaluation of a single session of fat grafting as an adjunct to secondary burn reconstruction of the hand by Byrne et al. demonstrated statistically significant improvements in range of motion, scar quality, and hand outcome scores in 13 patients followed for an average of 9.1 months (3) [27].

Jaspers et al. utilized a comprehensive scar evaluation protocol including the Cutometer to measure scar pliability and POSAS and DSM II ColorMeter to evaluate scar quality to study the effects of single-session AFG on adherent scars. At 3-month follow-up, statistically significant improvements in pliability and POSAS scores were noted (3) [28]. In a long-term follow-up study, these effects were sustained for 1 year after a single session of AFG (3) [29]. Fredman et al. published a small cohort study in 2016 that demonstrated improvement in refractory neuropathic pain following severe burns in six of seven patients treated with AFG. Assessments were performed using the Patient-Reported Outcomes Measurement Information System (PROMIS), an 11-item questionnaire funded by the NIH that measures pain and quantifies the effects on daily life. Additionally, improvements in pruritus and scar pliability, texture, and color were reported (3) [30]. In contradistinction, a recent, randomized, prospective, controlled, split-scar pilot study evaluated the efficacy of AFG compared to saline infiltration in mature burn scars in pediatric patients. Six to 12 months after treatment, no significant differences were noted in the treatment and control arms using the Vancouver Scar Scale (VSS) (2) [31].

Two systematic reviews of the literature addressing the role of AFG in scar rehabilitation were published in 2015 (3,2) [32, 33]. Both detailed the overall promising results seen with AFG, noting improvements in both the appearance and the quality of the treated skin. These observations have been supported by consistent changes on histopathological evaluation of the treated tissue. However, they concluded that the level of evidence supporting the efficacy of the technique is relatively low, and additional studies are warranted.

"Mechanical" Methods

Despite recent advances in energy-based treatments for the cosmetic and functional sequelae of traumatic scarring, established "mechanical" techniques are associated with varying degrees of experience and evidence. Although the volume of data is limited with regard to the treatment of traumatic scars, dermabrasion and needling (percutaneous collagen induction, PCI) will be introduced here.

Dermabrasion

Conceptually, dermabrasion is one of the most intuitive forms of procedural scar revision. This technique has been traced back as far as ancient Egypt, when sandpaper was used to revise scars [34]. The limited available literature regarding this technique for traumatic and burn scars reflects use primarily for cosmetic (i.e., textural irregularities) rather than functional sequelae, as mechanical dermabrasion is associated with significant potential for worsening scarring when performed over large areas in compromised scar tissue. In 1998 Yarborough compared 97 traumatic and surgical scars treated with dermabrasion within 4–8 weeks of injury to 64 mature, traumatic facial scars of at least 3 months duration (3) [35]. Assessments were unblinded and performed by the author. He reported that immediately after re-epithelialization in the early intervention group, the outlines of the scars were essentially unchanged but the contours were improved. Over the next 3–6 months, he reported near resolution of the scar in 89% of these patients and significant improvement in all cases. He reported only modest improvement at best in the mature scar group.

Emsen published two case series evaluating manual dermabrasion with sandpaper for the treatment of traumatic and surgical scars. The first included six patients with facial burns and nine patients with postsurgical or posttraumatic scars (4) [36]. The burn patients were treated in the very early phases of recovery, essentially to remove the damaged tissue. The non-burn traumatic scars were more mature. Photographs were evaluated by three physicians to assess the degree of improvement. The author concluded that the best results were seen in patients with superficial and partial-thickness burn injuries. In the non-burn scars, the results were mixed with a trend toward a better response in younger scars; this raised questions about how early intervention may or may not have affected the trajectory of scar development. The second was a larger series of 41 patients; 23 of these patients had scars resulting from burns or trauma. (4) [37]. Each patient was treated with a single session of manual dermabrasion and evaluated after an average of 29 months. Patient satisfaction was rated on a four-point scale (not good, good, very good, excellent). One patient graded the cosmetic outcome as good, and the rest of the traumatic and burn scars were rated as very good to excellent at the end of the study period. These series only addressed cosmetic concerns and did not assess changes in scar thickness, pliability, or other functional characteristics.

A handful of case reports and series are also present in the literature. In 2011, Surowitz and Shockley reported the effective use of a rotary dermabrader to resurface traumatic facial scars 6–24 months after injury (4) [34]. All three patients were injured in motor vehicle accidents, resulting in superficial and deep soft tissue injuries. Following removal of foreign material and surgical repair, dermabrasion was utilized primarily to address contour and textural irregularities of the resultant scars. The authors concluded, upon comparison of before and after photographs, that the dermabrasion had improved the

appearance of the scars. Kirschbaum reported an excellent cosmetic outcome in a traumatic facial scar due to a motor vehicle accident treated with manual dermabrasion performed approximately 2.5 months after injury (4) [38].

Microneedling

Skin needling is another technique that has been practiced for many decades but has evolved since the concept of microneedling was introduced in 1995. It is a minimally invasive procedure that involves superficial puncturing of the skin by a roller or other device affixed with very fine needles. Although radiofrequency and other light- and energy-based variations are available, the original technique has gained popularity due to the associated safety, simplicity, and low cost [39]. Similar to dermabrasion, there is some evidence for efficacy in the treatment of the cosmetic sequelae of traumatic scarring but little to address the functional sequelae.

A cohort study was published in 2010 evaluating PCI using the Medical Roll-CIT (Vivida, Cape Town, South Africa) in post-burn scarring (3) [40]. This study evaluated 16 patients with mature burn scars treated with one to four sessions of microneedling. Patients and two independent observers rated the scars prior to treatment and 1 year after treatment utilizing the VAS, VSS, and POSAS, with statistically significant improvement documented with each. Furthermore, histological comparison demonstrated considerable normalization of the collagen/elastin matrix, a thickened and normal-appearing epidermis, and return of rete ridges. Similar findings were published by the same group in a 2008 prospective study which included 72 burn and acne scars (3) [41]. Improvements in the histologic architecture and upon clinical evaluation with the same scar scales were reported.

A study including 25 patients with symptomatic burns scars treated with a series of microneedling treatments was published in the Korean literature in 2010. Statistically significant improvements in itch induration, pain, and restriction were noted within an average of five treatments, but the study failed to demonstrate statistically significant improvement in joint deformity or the shape of the scar (4) [42]. The age of the burn scars and the specific assessment tools utilized were not presented, which limits the conclusions that can be drawn.

Laser and Light Therapy

Vascular (Target Hemoglobin)

Erythema is a normal finding within the initial weeks of injury and initial scar formation, but prolonged erythema can be a sign of persistent inflammation and pathological scar formation. Laser and light wavelengths absorbed by hemoglobin may therefore have a potential role in traumatic scar management whenever significant erythema is observed. Since shorter wavelength devices in the visible spectrum also demonstrate significant melanin absorption, caution is warranted for darker skin types. While vascular laser treatment has long been shown to be efficacious in the management of surgical and acne scars, the available data is more limited for traumatic scars. Among vascular-specific devices, the 585/595-nm pulsed dye laser (PDL) is the most studied. Although early studies yielded encouraging results, more recent studies with longer follow-up periods have demonstrated more mixed results. Other common devices used to treat erythematous scars (whether early or pathological) include the 1064-nm neodymium–doped–yttrium–aluminum–garnet (Nd:YAG) laser, 532-nm potassium titanyl phosphate (KTP)/frequency-doubled Nd:YAG laser, and broadband intense pulsed light (IPL).

585/595-nm Pulsed Dye Laser

In 1994, Alster reported improvement in 14 patients with traumatic and surgical scars at least 2 years after injury treated with the 585-nm PDL. Scars were documented with clinical photographs evaluated by blinded observers and with rubber surface impressions at 6-month follow-up (3) [7]. She noted that the degree of clinical improvement was proportional to the number of laser treatments received, with 9 of 14 patients receiving 2 treatments 6 weeks apart and 5

patients receiving only a single treatment. No complications were observed. In 1998, Alster and Nanni evaluated 16 patients with 40 scars (including 16 burn scars) treated with the 585-nm PDL. Patients received an average of 2.75 treatment sessions at a minimum interval of 6 weeks. All patients demonstrated improvement in scar appearance based on photographic evaluation by two blinded physicians. Of note, 50% of patients reported pretreatment pruritus that decreased within one or two sessions (3) [43].

In 1997, Sheridan et al. reported no significant improvements as evaluated by the VSS in ten children with hypertrophic burn scars who received one treatment with the 585-nm PDL, despite each site having the expected clinical endpoint of mild post-treatment purpura. No significant side effects or complications were noted (3) [44]. An early treatment study (< 8 weeks after injury) by Liew et al. in 2002 demonstrated initial improvements after treatment with the 585-nm PDL in two separate sessions at 6-week intervals for five burn scar patients, but at follow-up 6 and 9 months after treatment, there was no significant difference between the treated and untreated sites (3) [45]. No side effects were seen in any patient. The authors concluded that early intervention with the PDL helped to hasten scar resolution. In 2003, Allison et al. reported a study in which 38 patients with burn scars of mixed ages received three treatments with the 585-nm PDL at monthly intervals (3) [46]. Patients were assessed at 6 and 12 months after treatment using the VSS and a pruritus scale. They found that there was no significant difference between treated and untreated sites using the VSS, regardless of the age of the scar, and that improvement was seen in both sites. There was, however, a statistically significant reduction in pruritus at 6- and 12-month follow-up. In 2005, Kono et al. reported the treatment of 15 Asian patients with 22 hypertrophic scars with the 595-nm PDL. Nine of the 15 patients had scars resulting from burns. All patients received two treatments at 4-week intervals, and evaluations were performed using photographic and clinical assessment 1 month after the last treatment. Blinded observers documented statistically significant improvements in the VSS, and additionally, there were reported improvements in symptoms such as pain, pruritus, and burning of the treated scars (3) [47]. Bailey et al. published a pilot study in 2012 comparing the effects of early PDL treatment plus standard compression therapy to compression therapy alone in patients undergoing burn scar reconstruction with skin grafts on the extremity. Two to three laser treatments were applied to one-half of the graft seam at 6-week intervals, and scars were evaluated using the VSS. Laser-treated areas demonstrated greater improvement in height, pliability, pigmentation, and vascularity than compression alone (3) [48].

Other Laser and Light Devices that Target Hemoglobin

1064-nm Nd:YAG

The 1064-nm Nd:YAG has been reported in both long- (ms) and short-pulsed (ns) modes for the treatment of hypertrophic scars. In 2010, Cho et al. reported improvements in keloids and hypertrophic scars associated with a series of treatments with the 1064-nm Q-switched (ns) Nd:YAG laser (3) [49]. Twelve patients with 21 scar sites, 3 of which resulted from trauma or burns, were treated with 5–10 sessions at 1- to 2-week intervals. Using the VSS, statistically significant improvements in pigmentation, vascularity, pliability, and height were all noted at the 3-month follow-up. Observed side effects were a mild prickling sensation during treatment and mild post-treatment erythema, both of which resolved within a few hours.

In 2012, AkaishI et al. reported the results of a study including 22 patients with hypertrophic and keloid scars treated with the long-pulsed (ms) 1064-nm Nd:YAG (3) [50]. Of the 22 patients, 5 had scars resulting from burns or other trauma. The number of treatments ranged from five to ten at 3- to 4-week intervals. Scars were evaluated using the Japan Scar Workshop score, based on a four-point scale (0–3) assessing the degree of associated erythema, hypertrophy, hardness, itching, and pain (maximum of 15 points). The authors reported a significant

decrease in total scores with no reported complications. In 2015, Koike et al. reported the results of 102 patients with hypertrophic scars and keloids treated with a long-pulsed 1064-nm Nd:YAG laser at 3- to 4-week intervals over a 1-year span (3) [51]. Of the 102 patients, just over 10% developed their scars after trauma. The average Japan Scar Workshop score dropped significantly for both hypertrophic scars and keloids over the 1-year observation period, but the authors noted that hypertrophic scars responded better than keloids to the treatment course.

532 nm

In 2003 Cassuto and Emanuelli reported the results of a study involving 23 mature scars treated with a frequency doubled long-pulse 532-nm laser. Sixteen of the 23 scars resulted from burns or trauma. At the end of the study, an average improvement of 81% was reported after two to three treatments. Nineteen out of 22 patients developed microcrusting that resolved within 1 week, but all patients reported satisfaction with the treatment (4) [52].

Intense Pulsed Light

In 2014, Sarkar et al. published a prospective study evaluating the use of intense pulsed light in 19 patients with immature, nonhypertrophic burn scars. Study areas received four treatments at 21-day intervals using a 590-nm cutoff filter. Using the VSS, statistically significant improvements in vascularity, pliability, and height were observed at 1-year follow-up. Treatments were well tolerated, and most patients complained of only mild snapping sensation with treatments (3) [53]. In 2008, Erol et al. published a prospective study including 109 patients with hypertrophic scars of varying etiologies; 43 of the 109 had scars resulting from burns and other trauma. After a minimum of six sessions at 2- to 4-week intervals, clinical improvements were noted in 92.5% of patients including appearance and reductions in height and hardness; 58.7% were rated as good or excellent on photographic evaluation. Side effects such as pain and darkening were noted but quantity was not reported (3) [54].

Ablative Lasers

Ablative lasers are comprised primarily of the 10,600-nm carbon dioxide (CO_2) and 2940-nm erbium–yttrium–aluminum–garnet (Er:YAG). Absorbed avidly by ubiquitous tissue water, these lasers vaporize tissue in a precise manner based on the properties of the delivery system and operator-determined parameters. Although ablative platforms have been available for decades, they had been used relatively sparingly for the treatment of traumatic scars until the advent of microfractional technology around 2007 [6]. The transition from relatively large superficial wounds (mm) up to hundreds of microns deep ("full field") to an array of narrow (μm) and widely spaced columns with penetration up to thousands of microns ("microfractional") has helped to revolutionize traumatic scar management. Initially limited largely to surface contouring of traumatic scars in what amounted to a controlled burn, ablative fractional lasers have advanced full-thickness scar remodeling with promising applications for treating both the cosmetic and functional sequelae of traumatic scars. With significantly higher water absorption, Er:YAG lasers are associated with less thermal "leakage" and a narrower rim of coagulation around the ablative columns than CO_2 lasers. This generally leads to a greater propensity for bleeding, but the relative impact of tissue coagulation on subsequent tissue remodeling remains not fully defined.

10,600-nm CO_2

In 1998, Bernstein et al. reported improvement in 30 patients after scar treatment with a full-field ablative CO_2 laser. All patients (two of these patients had traumatic scars) had greater than 50% improvement based on photographic evaluation by four independent observers graded on a quartile scale 4 months following a single treatment session (3) [55]. Before the development of fractional laser technology, Whang et al. reported improvements in scar texture, color, and relaxation in two patients with hypertrophic burn scars using a "pinhole" method, essentially drilling a series of individual holes in the scar tissue using a small spot size (4) [56]. Lee et al. conducted a

retrospective study including nine patients with hypertrophic scars treated with a combination of laser-cision and the pinhole method in 2014. The authors reported mild to moderate improvement in all patients on photographic assessment using a quartile scale (4) [57]. Waibel and Beer first reported the successful use of an ablative fractional CO_2 laser for the cosmetic improvement of a mature facial burn scar in 2009 (4) [58]. In 2010, Weiss et al. reported a series of 15 patients with non-acne atrophic scars (two of which were traumatic scars) that were treated with a course of three AFR treatments at 1- to 4-month intervals. At 6-month follow-up, patient and investigator scores documented improvements in texture, pigmentation, atrophy, and overall scar appearance. Furthermore, image analysis with a three-dimensional optical profiling system revealed a 38.0% mean reduction in scar volume and a 35.6% mean reduction in maximum scar depth (3) [59].

Kwan et al. addressed the use of ablative fractional CO_2 laser resurfacing (AFR) specifically for functional improvements in a patient with traumatic scar contractures associated with an improvised explosive device in 2011 (4) [60]. In 2012, Shumaker et al. reported the successful application of AFR for a range of functional sequelae associated with traumatic scarring (4) [61]. Overall evidence and a histopathological basis for the efficacy of AFR were bolstered by Ozog et al. in 2013. Ten patients with burn scars received a series of three AFR treatments. Evaluation included VSS and POSAS scores as well as biopsy specimens taken before and 2 months after the final treatment. The authors noted improvements in scar appearance accompanied by a relative normalization of scar architecture and a collagen subtype profile (type I and III) resembling that of non-wounded skin (3) [62]. Perry et al. documented objective improvements in range of motion and subjective reductions in pain, associated with a course of AFR for scar contractures of the upper extremities in a retrospective analysis from 2014 (3) [63]. Anderson et al. synthesized the results of an accumulating number of early reports and series documenting the successful use of AFR for traumatic scars in a consensus paper published in 2014. The authors noted the promising early results and safety of the technique and advocated for more widespread use guided by further research (5) [64].

Since the consensus report described above, the literature has been characterized by additional larger studies with increasing contributions from the burn community. The literature to date demonstrates notable consistent efficacy and safety. Khandelwal et al. published a retrospective study including 44 adult and pediatric patients with burn scars who received a course of AFR. Statistically significant improvements in VSS were documented without reported complications (4) [65]. El-Zawahry et al. performed a prospective split-scar study including 15 burn scars treated with a course of AFR. Three months after the third treatment session, statistically significant improvements in VSS, POSAS, and patient evaluation scores were noted. In addition, scar histopathology revealed concomitant decreases in collagen bundle thickness and density (3) [66]. Blome-Eberwein et al. published a prospective controlled study involving a series of 3 AFR treatments in mature burn scars (48 treated, 32 control). Subjective and objective measurements included VSS, POSAS, cutometer, spectrometer, ultrasound, and sensory evaluation at least 1 month after the final treatment. The authors noted statistically significant improvements in scar thickness, sensation, erythema, and pigmentation (3) [67]. In 2016, Levi et al. reported results from a retrospective study including 131 patients with symptomatic burn scars and skin grafts treated with a course of AFR. A questionnaire was administered that included patient-reported outcome measures. The overall patient satisfaction was 96.7%, with a very low rate of complications and reported reductions in neuropathic pain, tightness, and pruritus along with improvements in scar appearance and pliability (3) [68].

In 2016, Issler-Fisher et al. published results from a prospective study including 47 patients with 118 burn scars treated with at least a single session of AFR. Subjective and objective outcome measures included VSS, POSAS, ultrasound,

assessment of neuropathic pain and pruritus, and quality of life using the Burns Specific Health Scale. Patients with hypertrophic scars also received topical application of a corticosteroid suspension immediately after treatment. The authors reported improvement in thickness, texture, color, and scar symptoms, accompanied by improvements in quality of life in patients with both mature and immature scars (3) [69]. Lee et al. performed a prospective uncontrolled study including 11 patients with burn scars treated with a series of ten AFR treatments at approximately 5-week intervals. VSS assessments 6 months after the final treatment showed significant improvement from baseline. Histologic findings included changes in the upper dermis with newly formed dermal papilla that corresponded to clinical improvements in surface smoothness and tension. Post-inflammatory hyperpigmentation and itching sensation were the most common adverse effect reported, although the treatments in this study were relatively aggressive including multiple passes and a large number of treatments at relatively narrow intervals (4) [70].

Zadkowski et al. reported results from a study in which 47 pediatric patients underwent 57 AFR procedures for mature burn scars. Scar thickness was determined by ultrasound, and VSS assessments were completed independently by the surgeon and the parents of the patients at 1, 4, and 8 months following the procedure. The VSS improved in all treatment areas as evaluated by both the parents and physicians, accompanied by statistically significant improvements in scar thickness measured by ultrasound (3) [71]. In 2017, Poetschke et al. published a prospective study including ten patients treated with a single session of AFR. Each treatment followed a standard treatment paradigm involving multiple passes that included deep microfractional treatment as well as focal superficial ablation appropriate for the selected treatment area. Scar evaluation included pre-treatment and post-treatment assessment 6 months after AFR using POSAS, VSS, Dermatology Life Quality Index (DLQI), and an imaging system. The authors noted significant improvements in POSAS, VSS, and DLQI, as well as scar relief and firmness (3) [72].

2940-nm Er:YAG

In 2000, Kwon et al. published a study including 36 patients with various types of mature scars (including burn and other traumatic scars), treated with single-session resurfacing using a pulsed full-field (non-fractionated) 2940-nm Er:YAG laser. Nine of 12 hypertrophic scars, 17 of 20 depressed scars, and 2 of 4 burn scars improved by more than 50% as evaluated by 2 independent physicians and surgeon based on a quartile assessment scale 6–12 months after treatment. Postoperative erythema was observed in five patients (four with burn scars) 4 months after treatment, and one patient developed post-inflammatory hyperpigmentation 3 months after treatment (4) [73]. In 2005, Eberlein et al. published their experience treating burn scars using a full-field Er:YAG laser in the setting of a large burn center. Twenty-four patients with 96 scars received a single session of Er:YAG laser, and cosmetic improvements were noted consistently in a variety of body sites (4) [74]. Kim et al. published a study including 12 patients with 15 scars following facial lacerations with primary repair in 2012. Scars were treated with a 2940-nm fractionated Er:YAG laser over four sessions at 1-month intervals, beginning at least 4 weeks after injury. All treated scars demonstrated improvements on follow-up assessment 1 month after the final treatment using the VSS and an overall cosmetic scale (3) [75].

Nonablative Fractional Laser Resurfacing

Evidence supporting the use of nonablative fractional laser resurfacing (NAFR) for burn and other traumatic scars is limited primarily to case reports and series and a few small prospective trials. Despite this limited level of evidence, there are encouraging results that appear consistent with the results seen in other types of scarring and rejuvenation. The first report describing the concept of fractional photothermolysis was published by Manstein et al. in 2004. The authors assessed clinical effects including linear

shrinkage and a wrinkle score after facial treatments, as well as corresponding histology (3) [5]. In 2008, Waibel and Beer first described the successful use of NAFR for clinical improvements in a woman with hypertrophic burn scars of the face refractory to intralesional corticosteroids and PDL treatments (4) [76]. The report heralded the coming explosion in interest in the use of fractional photothermolysis for traumatic scars over the coming decade. Waibel et al. published a prospective uncontrolled pilot study including ten patients with burn scars who received a course of five monthly treatments with a 1550-nm nonablative fractional laser. Overall improvement was noted in 90% of subjects as documented by blinded investigators 3 months after the final treatment, with 60% rated as moderate to excellent. Ninety percent of subjects demonstrated improvements in skin texture, and 80% in dyschromia and atrophy or hypertrophy. Persistent erythema was present in one subject at the 3-month follow-up, but otherwise, no adverse events were reported (3) [77].

Vasily et al. performed a prospective clinical and histological study including 33 traumatic or postsurgical scars treated with a 1540-nm nonablative fractional laser. Treatment response was evaluated through blinded photographic assessments. The authors reported that following three to seven treatments, 73% of scars improved 50% or more. Histologic assessment of a surgical scar demonstrated rapid re-epithelialization within 72 h of treatment, and "renewal and reorganization" of collagen fibers within the dermis 2 weeks after treatment. Side effects including swelling and erythema were mild, and downtime was reported as minimal to none in all subjects (3) [78]. Haedersdal et al. conducted a prospective randomized controlled (side by side) trial including 17 patients with mature burn scars treated with a series of three monthly 1540-nm laser treatments in 2009. Blinded response evaluations were performed 4 and 12 weeks after the final treatment. At the end of the study, skin texture was significantly improved compared to controls, but no difference was noted in pigmentation. Patients evaluated scars to be moderately or significantly improved and were satisfied with the treatment. One patient developed minor scarring (2) [79]. Taudorf et al. conducted a similar prospective randomized controlled trial evaluating the efficacy of a series of three monthly 1540-nm NAFR treatments for mature burn scars in 17 patients up to 6 months after treatment. Outcomes including modified POSAS and patient-evaluated satisfaction and improvement were documented, in addition to histological assessment. Treated areas demonstrated statistically significant improvements in appearance, with corresponding remodeling noted on histology at 6 months. Of interest, at the 6-month follow-up, 11 of the 17 patients were noted to have discrete erythema, hyperpigmentation, or imprints from the laser grid pattern in the treatment area, although none were judged as inferior to baseline appearance. In the opinion of the authors, these findings were due to the use of standardized, rather than customized treatment settings (2) [80].

Other Modalities

Recent interest in the minimally invasive management of traumatic scars has resulted in newer approaches with as-yet limited associated evidence. While inclusion of every attempted modality is beyond the scope of this chapter, given their prevalence for other applications, radiofrequency treatments and low-level laser therapy (LLLT) will be discussed briefly here.

Radiofrequency

Wang et al. published a prospective study employing fractional microplasma radiofrequency technology for nonhypertrophic postburn scars in 95 Asian patients in 2017. Patients received three to five treatments at 8- to 16-week intervals. The authors reported an overall response rate of 86.3%, with statistically significant improvements in scar color, thickness, and pliability using the POSAS before and 6 months after the final treatment. Complications included prolonged post-inflammatory hyperpigmentation, acne eruption, herpes simplex eruption, and abnormal hair growth, without severe adverse events noted (3) [81]. Pinheiro et al. performed

monopolar radiofrequency treatment and histopathological evaluation in a 61-year-old woman with long-standing hypertrophic burn scars on her abdomen in an area that was to be removed by abdominoplasty. She received five sessions of monopolar radiofrequency with corresponding epidermal temperatures both above and below 40°C. Histology demonstrated favorable collagen remodeling at temperatures below 40°C but fibrosis at temperatures above 40°C (4) [82].

Low-Level Laser Therapy (LLLT)

Gaida et al. performed a prospective controlled study evaluating the use of LLLT with a 400-mW 670-nm laser twice weekly for 8 weeks in 19 patients with burn scars. Adjacent untreated scar tissue served as a control. Scar evaluation using the VSS and a VAS for pain and pruritus demonstrated improvements, if limited in some, in 17 of the 19 patients without negative effects (3) [83]. Vranova et al. published a comparative prospective controlled study evaluating the efficacy of LLLT at 670 nm alone, and LLLT plus treatment with the PDL. Forty-one children with facial scars were included in the study, and evaluation using the POSAS was performed at 4, 8, and 12 weeks. Statistically significant improvements were noted in both treatment groups at all time points, and enhancements in scar quality were noted for the combination group in all evaluations except for pigmentation and pliability (3) [84].

Early Intervention

An accumulating body of literature exists supporting early laser intervention to optimize surgical scars, but studies focusing on traumatic scars are much more limited at this time. Considering the tremendous worldwide morbidity resulting from traumatic scarring (especially burns) and the advent of very promising and minimally invasive technologies (e.g., fractional photothermolysis), early procedural intervention is mentioned briefly here despite a lack of "maturity" in the literature. In their 2010 article, LeClére and Mordon reviewed decades of experience in laser scar "prevention," the concept of minimizing scar formation in the early period after wounding with minimally invasive laser procedures (5) [85]. Indeed, at the end of the last millennium, McCraw et al. reported the successful use of the 585-nm PDL for prophylactic scar management in a combined group of patients with 171 elective and traumatic incisions. They noted that treatment within the first few weeks of injury resulted in faster resolution of scar stiffness and erythema and less frequent development of hypertrophic scarring (3) [86]. As noted above in the vascular laser section, Liew et al. [45], Allison et al. [46], and Bailey et al. [48] all noted at least some indication of improved outcomes associated with early intervention with the PDL after injury. The potential benefits of early intervention are certainly not limited to PDL. For example, Capon et al. reported significant improvement in burn and surgical scars as evaluated by a VAS after early intervention with an 810-nm diode laser (3) [87]. The potential benefits of techniques such as AFR to minimize hypertrophy and contracture formation after traumatic injury and associated reconstruction have been proposed previously, and in some centers, it is already standard practice to begin treatment with vascular and fractional lasers within weeks and months of major trauma (5,4) [64, 88]. Large, prospective, controlled studies are still needed to confirm the benefits of adjunctive laser and other procedures and to elucidate the optimal timing, settings, and combinations.

Comparative Effectiveness of Common Treatments

High-quality evidence is relatively limited for individual treatment modalities in the treatment of traumatic scars and in even shorter supply for comparative studies. Furthermore, given the relatively noninvasive nature of many of the procedures featured in this chapter and the inherently heterogeneous nature of traumatic scars, they are frequently used in combination to address distinct components of the presentation (e.g., contracture, textural irregularity, dyspigmentation,

etc.). This section will therefore include discussion of studies evaluating combined procedures for traumatic scarring in addition to available comparative studies.

The multimodal approach is exemplified by Hultman et al. who published short-term (3) [89] and long-term (3) [90] results from a prospective, before–after cohort study including 147 burn patients with hypertrophic scars treated with a combination of PDL for pruritus and erythema and CO_2 AFR for stiffness and abnormal texture. Laser treatments were initiated a minimum of 6 months after burn injury and continued every 4–6 weeks until a plateau was reached (average 2.8 sessions). Outcome measures included the VSS and the University of North Carolina "4P" Scar Scale (UNC4P), which rates pain, pruritus, paresthesias, and pliability. The authors noted rapid, significant, and durable improvements using both the VSS and UNC4P which continued during the 25-month follow-up period. In 1998, Alster et al. published a split-scar study examining the effect of full-field (non-fractionated) CO_2 laser ablation alone and in combination with 585-nm PDL for nonerythematous hypertrophic scars. Twenty scars were treated with ablation, and one half of each scar was also treated with the PDL. Global assessment and erythema spectrometry scores were improved after laser treatment in both groups, and the results were more significant in the combination group (3) [91].

Since the PDL is one of the most widely accepted energy-based interventions in the treatment of traumatic scars, it is also frequently included in combination treatments. Asilian et al. published a randomized prospective clinical trial including 69 patients with keloids and hypertrophic scars of various etiologies who were assigned to one of three treatment groups: intralesional triamcinolone acetonide (TAC) 10 mg/mL injected weekly for 8 weeks; TAC (40 mg/mL) mixed with 5-fluorouracil (5-FU, 50 mg/mL) in a 1:9 ratio injected intralesionally weekly for 8 weeks; and intralesional TAC and 5-FU plus 585-nm PDL at 1, 4, and 8 weeks. Based on patient assessments and evaluation of photographs by a blinded observer, the overall efficacy was similar between the TAC + 5-FU and TAC + 5-FU + PDL groups, but there was greater improvement and increased patient satisfaction in the group that included PDL (2) [92]. Bowes et al. published a prospective comparative study evaluating the efficacy of a 585-nm PDL compared to a 532-nm frequency-doubled Nd:YAG laser in both Q-switched (ns) and variable pulse (ms) modes for the treatment of pigmented hypertrophic scars. The scars of six patients were divided into four segments: three treatment segments and an untreated control. After an average of 3.3 treatments at 4- to 6-week intervals, scars were evaluated at 22 weeks using the VSS. Statistically significant improvement was noted after treatments with both the Q-switched 532-nm laser and the 585-nm PDL, without a significant difference between them. The sites treated with the variable pulse 532-nm laser did not differ significantly from controls. Interestingly five of six patients chose the Q-switched 532-nm laser site as the best overall (3) [93]. Lee et al. published a report including two cases of traumatic scarring of the chin successfully treated with a combination of intramuscular botulinum toxin and 595-nm PDL (4) [94]. Park et al. reported two cases of traumatic facial scars successfully treated with a course of PDL combined with 1550-nm NAFR. Following three and five sessions at intervals of 9–15 weeks, the authors reported dramatic cosmetic improvement documented in clinical photographs (4) [95].

In 2010, Cervelli et al. published a study comparing CO_2 AFR performed in both microfractional and macrofractional modes with "classic" dermabrasion in 60 skin type II and III patients with posttraumatic and pathological scars on the face. Photographs were evaluated 12–15 months after treatment using the Manchester Scar Scale. Greater improvements in skin tone, texture, and appearance were observed by both the investigators and patients in the scars treated with AFR. No major complications were observed in either group, and minor complications included transient erythema and edema. The authors concluded that AFR was a viable alternative for the treatment of moderate to severe scars (3) [96]. Ibrahim et al. published a case series in 2016 including 13 patients treated with a CO_2 laser using a

"pinpoint" technique followed by NAFR with a 1540-nm laser. Photographs were evaluated using the VSS and a five-point grading scale. Significant improvement was noted in vascularity, pigmentation, and height, but not pliability (3) [97]. Cho et al. published a case report involving the successful treatment of a burn scar with a combination of a CO_2 laser using the pinhole technique and collagen induction therapy (microneedling) (4) [98]. Another case report documented the successful treatment of a traumatic facial scar with a combination of a 1064-nm Nd:YAG and an ablative 2790-nm yttrium–scandium–gallium–garnet (YSGG) ablative laser (4) [99].

In 2011, Cervelli et al. conducted a prospective randomized comparative trial including 60 patients with traumatic scars. The patients were divided into three treatment groups and received regimen of fat grafts and platelet-rich plasma, 1540-nm NAFR, or both. At the end of the study, all three regimens were reported as effective on blinded physician assessment, but the most effective was the combination treatment followed by NAFR alone (2) [100]. Ohshiro et al. detailed an algorithmic approach to scar management based on clinical findings. Multimodal treatments including LLLT and PDL for erythema, Q-switched lasers for hyperpigmentation, NAFR for superficial scarring, and AFR for thicker scars were advocated (4) [101].

Fractional Laser and Radiofrequency-Assisted Delivery of Therapeutic Agents

Waibel et al. performed a prospective uncontrolled pilot study involving 15 patients with hypertrophic scars following surgery, burns, and other trauma that were treated with CO_2 AFR and immediate postoperative topical application of TAC suspension at a concentration of 10 or 20 mg/mL. Patients received three to five treatment sessions at 2- to 3-month intervals and were reevaluated 6 months after the final treatment. Scars were evaluated based on overall appearance, dyschromia, hypertrophy, and texture using a quartile scoring scale. Eleven of the 15 patients were noted to have over 75% improvement, and the remaining had 50–75% improvement with no adverse effects reported (3) [102]. Issa et al. published a case series in which four patients with hypertrophic scars were treated with ablative fractional radiofrequency followed by the application of topical triamcinolone acetonide suspension 20 mg/mL and acoustic pressure ultrasound to enhance drug delivery. "Complete resolution" was noted in scars of the nose and mandibular area after a single treatment; four treatments were required for a scar on the neck, and partial resolution was observed after four sessions on an extremity. Mild atrophy was noted after treatment of the neck scar (4) [103]. Rkein et al. published the results of a prospective uncontrolled pilot study including 19 patients with atrophic scars resulting from surgery, trauma, and acne treated with CO_2 AFR and immediate application of topically applied poly-L-lactic acid (PLLA; Sculptra®, Galderma Laboratories, L.P.) in 2014. Photographs were evaluated by blinded observers using the modified Manchester Scar Scale 3 months after treatment. Improvement was documented in 95% of the evaluated scars, and the authors noted there may be a synergistic effect between AFR and PLLA. However, the lack of control limited the ability to discriminate between the individual contributions of the laser and PLLA (3) [104]. Massaki et al. treated 14 patients with hypopigmented scars (two following trauma) with 1550-nm NAFR and topical bimatoprost 0.03%. Patients received a mean of 4.5 NAFR treatments at 4- to 8-week intervals, and an independent observer evaluated photographs taken 4 weeks after the final treatment using a quartile scale. Five patients had >75% improvement, while 12 of the 14 had >50% improvement. Side effects were limited to mild transitory post-treatment edema and erythema (3) [105].

Preoperative Evaluation

Traumatic scar evaluation begins like any condition—with the history and physical examination. Important amplifying information includes the mechanism and time since the injury, any

associated injuries, the presence and degree of symptoms such as pain and itch, functional limitations, previous evaluations and treatments, and any pending surgeries or other procedures. Physical examination findings will include considerations of scar location, area of involvement, color (erythema and dyspigmentation), texture and contour irregularities, pliability (stiffness) and range of motion, and the degree of disfigurement. For patients with severe traumatic scarring and existing or incipient functional limitations, physical and occupational therapists can be critical in ongoing contracture management and in properly documenting baseline deficits and treatment progress (e.g., degrees of range of motion, etc.). Additionally, surgical consultation should be considered for any patient with significant functional limitations or for refractory scars.

Periodic traumatic scar evaluation at initial presentation and at intervals is critical to determine the best initial treatment course and evaluate outcomes for both clinical treatment and research to determine the effectiveness of novel therapies. For primarily research purposes, there are a variety of tools and instruments available to assist in gathering both objective and subjective data. These fall into two main categories: (1) clinical scar assessment, facilitated with more than a dozen published and validated scar evaluation scales, and (2) instruments to objectively evaluate scars according to four key components (color, surface area, height/depth, pliability). Furthermore, specialists in physical and occupational therapy can assist with measurements delineating any functional deficits (i.e., degrees of range of motion) [106].

Scar evaluation scales vary considerably depending on their intended purpose but usually integrate to varying degrees: the visual characteristics of the scars, functional impairment, and impairment in quality of life. To date, there is not a single comprehensive scale that adequately incorporates all of these characteristics. In the treatment of traumatic scars, probably the most notable deficiency is the evaluation of function; this is likely because previous minimally invasive therapies have been rather ineffective in the context of severe functional impairment [107]. The most commonly used scales are the VSS and the POSAS. The VSS was developed in 1990 to evaluate burn scars and has provided a foundation for scar evaluation for decades [108]. It assigns numerical values to individual scar characteristics including pigmentation, vascularity, pliability, and height. The POSAS is probably the most common scar evaluation scale used currently to evaluate burn scars. Introduced by Draaijers et al. in 2004, it contains components to be completed by both the clinician and patient [109]. In addition to evaluating physical characteristics of the scar, notably it incorporates subjective information from the patient perspective.

Traditional and emerging imaging techniques can offer objective structural information to supplement physical examination findings, particularly for research purposes. Scar thickness can be determined readily and noninvasively with traditional techniques such as high-frequency ultrasound. Objective evaluations of color (a composite of both vascularization and pigmentation in the area of interest) are offered by instruments such as the Chroma Meter (Minolta, Osaka, Japan). Scar pliability can be determined by instruments such as the Cutometer (Courage and Khazaka Electronic GmbH, Cologne, Germany) [106]. Optical coherence tomography (OCT) is a light-based technology that can offer superficial structural information, such as collagen architecture and tissue vascularity, which otherwise might only be available through skin biopsy. A variety of new devices can construct three-dimensional models of the area of interest to provide information such as scar height, width, elevation, and volume at baseline and over time [110].

Little data exists to pair the relative efficacy of various treatments to patient characteristics such as gender, skin type, scar age, presence or absence of a contracture, etc. However, there are some relevant findings that can guide treatment. Since erythema is more common in younger scars and can be prolonged in pathological scars, it follows that vascular devices will be more useful in these subpopulations. Furthermore, a mature, hypopigmented scar lacks the hemoglobin chromophore. An important observation is the relative safety of fractional devices, both ablative and nonablative,

in a wide variety of skin types. Furthermore, there is mounting evidence that fractional devices offer significant efficacy in the correction of both hyperpigmentation and hypopigmentation. Fractional devices can also be used in mature as well as early scars since tissue water is the chromophore.

Impact of Patient Preference

By the time they present to the dermatologic surgeon, patients who have suffered significant traumatic injury have frequently endured multiple major procedures related to associated reconstruction. Procedure fatigue is a common issue, and the ability to offer management options with predictable efficacy and minimal morbidity in the outpatient setting is frequently well received. All of the procedures discussed above are generally well tolerated in the outpatient setting, and with the possible exception of the donor site after fat grafting, they require minimal postoperative care and downtime. All are also generally associated with a relatively minor risk of complications such as dyspigmentation, relative to the posttrauma baseline. Postoperative pain is also generally minimal and rarely rises above the level of any baseline pain issues. Safety data is limited in the setting of traumatic scars. When treated with appropriate parameters, the risk of worsening scarring also appears to be minimal; once improvements are realized, they tend to be cumulative with little tendency to return to baseline. Interestingly, judicious application of the above procedures seems to have a low tendency to induce new hypertrophic scars and keloids or to worsen existing ones.

Multiple treatment sessions at approximately 1- to 3-month intervals for cumulative improvements are needed. Dermatologic surgeons have assumed a relatively new but expanding role in the treatment of traumatic scars. At present, reimbursement has not caught up with advances in techniques, and it may be challenging in areas to find providers with expertise in traumatic scar management, and billing issues may not be straightforward. For this reason, the availability of traumatic scar treatment and/or insurance reimbursement for treatment may be uneven in the near term [111]. Despite this current reality, effective but minimally invasive treatments are now available that can lead to consistent improvements in cosmetic appearance and function for patients, and continued increases in availability are expected.

Typical Treatment Plan

As illustrated above, while multiple dermatologic surgery procedures demonstrate promise for managing traumatic scars on an individual basis, large high-quality studies to guide optimal timing, combinations, parameters, and treatment order are still generally lacking. Furthermore, there are as many presentations of traumatic scars as there are patients. For these reasons, a "typical" treatment plan must be considered with appropriate flexibility and is still based largely on the experience of the treating physician. Was the scarring the result of a linear laceration from a blade? A large body surface area burn? A dog bite? What is the skin type of the patient? For instance, vascular-specific lasers have less to offer a patient with Fitzpatrick skin types V and VI due to competing absorption from epidermal melanin. With the above in mind, let us consider a patient with a significant but relatively localized thermal burn. This example has been chosen because rehabilitation from this type of trauma has only recently been considered under the umbrella of dermatologic surgery, yet it is amenable to management in the outpatient setting. Additionally, the larger surface area and need for reconstructive procedures such as tissue substitutes and split-thickness skin grafts require considerations relatively removed from linear surgical and acne scars discussed elsewhere.

Case Example

A woman in her 20s presented approximately 4 months after suffering second- and third-degree thermal burns of the anterior neck and upper chest.

Fig. 49.1 A woman in her 20s approximately 4 months after a thermal burn of the anterior neck and upper chest reconstructed with cadaveric and autologous split-thickness skin grafts. She complained of decreased range of motion, pain, and itch. Moderate erythema and textural irregularity are noted

Treatment at the local burn center included debridement followed by cadaveric and autologous split-thickness skin grafts. Her posthospital care also included compression therapy with a customized molded plastic garment. On examination, the site was well healed, but erythematous mildly hypertrophic scars were noted (Fig. 49.1). Range of motion was limited with upward and side-by-side gaze. She had moderate textural irregularity including prominent horizontal corrugations near along the junction of the neck and chest, and she complained of moderate pain and itch.

In the experience of the authors, the timing of this presentation (approximately 6–16 weeks after injury) is fairly typical and is characterized by increasing clinical and social stability, as well as incipient scar hypertrophy and contractures. While the relative efficacy of early intervention has not yet been defined, this period appears to be a reasonable starting point for the dermatologic surgeon to consider procedural management. The treatment pathway selected will depend on multiple factors including the patient's dominant presenting complaint (e.g., restriction, itch, cosmetic appearance), age of the patient, age of the scar (including associated erythema), sensitivity, skin type, and patient preference at a particular point in time. Accumulating reports indicate that minimally invasive dermatologic procedures such as fractional lasers and vascular lasers may safely begin within a few months of injury, much earlier than the traditional standard of approximately 1 year for surgical revision. Traumatic scars are inherently heterogeneous, so naturally, a treatment plan may include various modalities concurrently or in serial sessions.

Scar Minimization

Prolonged healing time after injury has been associated with pathological scar formation. While this chapter is focused on the treatment of existing scars, procedures that expedite wound healing could minimize the ultimate impact of scars. The emergence of "tissue copying" provides an excellent example of the potential for advancements in dermatologic surgery procedures to reduce the burden of scarring. The concept is derived from the lessons of fractional photothermolysis. In tissue copying, an array of numerous narrow but full-thickness tissue columns containing remnants of all cutaneous adnexal structures can be harvested scarlessly from the donor site and be applied to the wound to attempt to push wound healing toward remodeling rather than scarring. Commercially available devices are the horizon [112]. Other procedural examples for early intervention include photobiomodulation (low-level light/laser therapy), a noninvasive procedure that shows promise in scar minimization when applied early in the wound healing process and may be applied painlessly over larger areas. Botulinum toxin injection may be considered for injection directly into the scarline or underlying musculature shortly after injury, particularly for more localized areas of trauma such as lacerations.

Procedural Considerations

Young scars are frequently erythematous, so vascular-specific devices such as the PDL have been a mainstay for decades. They may be

applied in concurrent or alternating sessions with other modalities. Nonablative fractional resurfacing is frequently considered by the authors for textural improvement and dyspigmentation, so it could be a good choice for integration here at some point. Focal areas of hypertrophy may be amenable to intralesional or laser-assisted delivery of corticosteroids and antimetabolites. The patient's primary complaint in this case was limited range of motion. Ablative fractional laser resurfacing appears to be more effective than other laser modalities for mild to moderate scar contractures and was selected as the initial treatment in this case. Since they generally heat tissue water, fractional devices can also be integrated readily for more mature scars without erythema and for patients of virtually any skin type. If lasers are unavailable, skin needling with or without laser-assisted delivery can be considered.

If vascular and fractional devices are combined in the same session, it makes sense to perform the vascular treatment first as the immediate skin changes after fractional lasers may interfere with the vascular treatment. If laser-assisted delivery is performed, it is prudent to treat the hypertrophic areas first and apply the agent within a few minutes of treatment. The interval between ablative fractional treatments should likely be a minimum of 1 month, but more commonly in the practice of the authors, it is approximately 6–12 weeks. After the "heavy lifting" is done with ablative fractional resurfacing (usually three to five treatments), NAFR may be integrated later in the treatment course. While fractional ablative resurfacing has largely supplanted fully ablative resurfacing for burn scars, it can still be useful when applied judiciously to improve focal textural or pigmentary abnormalities. Patients with tissue deficits and contour irregularities may be candidates for synthetic fillers or autologous fat grafting.

Mitigation of pain during treatment is an important consideration when employing ablative fractional resurfacing, though most traumatic scars of limited involvement can be treated in the clinic setting. Topical anesthetics applied under occlusion for an hour or more can be effective, especially when supplemented with forced cold air or cold packs. Infiltration of local anesthetic or regional blocks can also be considered in appropriate areas. Systemic medications such as opiates and/or benzodiazepines can be used in patients with sensitivity or extensive involvement. One effective combination used frequently by the authors for adults without contraindications is intramuscular ketorolac with oral diazepam or lorazepam about 30 min prior to treatment. Children or adults with extensive injuries may even require general anesthesia. Downtime after treatment is minimal, and generally, the only post-procedure care includes the application of petrolatum for 1–2 days after an ablative fractional laser treatment. The approximate interval between laser treatments is 1–3 months, with less invasive procedures such as vascular lasers, nonablative fractional lasers, and steroid injections toward the shorter end of the spectrum.

For this patient, a series of CO_2 AFR procedures was initiated, along with laser-assisted topical application of triamcinolone acetonide at a concentration of 10 mg/mL at approximately 6-week intervals. Microfractional treatments were performed beginning at a pulse energy of 40 mJ and 5% density (Lumenis UltraPulse, DeepFX™, Yokneam, Israel). Optimal treatment settings have not yet been elucidated in the literature, but in the experience of the authors, large traumatic scars should be treated at low densities with depth proportional to scar thickness and other factors such as tolerability. Focal non-fractional contouring of textural irregularities can be considered and was performed in this case (Active FX™, 125 mJ, density 5, small spot, high repetition rate with wiping) (Fig. 49.2). Large confluent areas of scar tissue should not be de-epithelialized to help avoid worsening scarring, since the relative lack of adnexal structures lowers the healing potential compared to unaffected skin. Excellent improvement in range of motion was noted within 2 weeks of her first treatment. After two treatments (approximately 4 months after her first treatment), significantly decreased erythema was observed along with much improved texture and pliability (Fig. 49.3). Furthermore, she reported substantially decreased pain and itch. Additional improvements in tex-

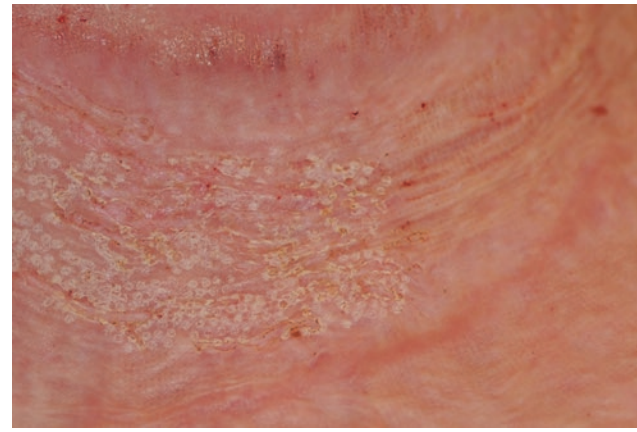

Fig. 49.2 Ablative fractional resurfacing in both microfractional and macrofractional modes was applied in this case. The entire scar sheet was first treated with microfractional resurfacing to a depth of approximately 1.5 mm at a low density. Within minutes of laser treatment, triamcinolone acetonide suspension at a concentration of 10 mg/mL was applied. Focal contouring was then performed using "full-field" laser ablation. Evidence of microfractional treatment appears as tiny dark dots in the background, while macrofractional treatment appears as white crusts

Fig. 49.3 Following two treatments, excellent improvements in erythema, texture, pliability, and range of motion were observed along with subjective improvements in pain and itch. Further improvement could likely be achieved with additional ablative fractional treatments, vascular laser treatments, and nonablative fractional laser treatments

ture and color could likely be achieved with additional ablative and nonablative fractional laser treatments and somewhat less invasive vascular and/or nonablative fractional laser treatments.

Safety

Fortunately, the entire range of procedures discussed in this chapter is associated with few reports of serious side effects or complications. In part, this is because these applications originated in experienced hands. As noted in the discussion on efficacy, there is also a paucity of safety data at present. In the future, as more experience is gained with procedures such as AFR, systematic evaluations of safety must follow. Autologous fat grafting is unique in this group since there is also a degree of associated donor site morbidity. It should also be noted that all of these devices and techniques have alternative aesthetic applications. In contrast to normal skin, scar tissue resulting from trauma and associated reconstruction is often devoid of adnexal structures and therefore underprivileged and underperforming with regard to healing. The therapeutic window for traditional rotary dermabrasion, for example, is relatively narrow in normal skin. The situation is even more perilous in the setting of large traumatic scars. Aggressive dosing and multiple concurrent procedures with cumulative injury should be approached with caution and humility.

Postoperative Care and Follow-Up

Scars are dynamic entities in a constant state of remodeling driven by various factors such as the time after injury, body location, tension, etc. Appropriate monitoring after treatment depends on the age of the scar, associated inflammation, presence of any pathological scarring (hypertrophic scars or keloids), and any associated injuries. In the first few weeks and months after injury and

reconstruction, traumatic scars proceed through a maturation process generally characterized by changes such as contraction and decreasing erythema. As noted above, mature scars that respond to treatment do not seem to have much of a tendency to revert back to the pretreatment state. However, early scars or pathological scars may need continued observation. Persistent erythema, symptoms such as pain and itch, and developing contractures are indications that additional treatment may be required. Surgical consultation may be required for symptomatic contractures to reduce tension, replace tissue deficiencies, and more favorably orient tissues. Appropriate wound care and physical therapy may also be required to achieve optimal results.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
A range of effective, safe, and minimally invasive procedures are currently available for the management of traumatic scarring, but the current quality of evidence in the supporting literature is still generally moderate at best. Additional large, prospective, controlled studies are required to confirm efficacy and elaborate appropriate treatment parameters	B
Procedures with GRADE B recommendations include *botulinum toxin* (considered both in the surrounding musculature and intralesionally), *autologous fat grafting*, *microneedling*, *pulsed dye laser*, *Nd:YAG laser*, *CO_2 ablative fractional laser resurfacing*, and *nonablative fractional laser resurfacing*.	B
Procedures with GRADE C recommendations include *dermabrasion*, *intense pulsed light*, *532-nm laser*, *full-field CO_2 and Er:YAG laser resurfacing*, and *low-level laser therapy*	C
Procedures with GRADE D recommendations include *microplasma radiofrequency*	D

Other Findings

1. **Among the procedures discussed in this chapter for traumatic scarring, ablative fractional resurfacing and autologous fat grafting stand out for their potential life-changing benefits.**
2. **Dermatologic surgery procedures can be an extremely helpful adjunct to traditional rehabilitative efforts for traumatic scar management.** For the benefit of our patients and practices, this skill set should become a part of the standard repertoire of any expert in cutaneous procedures.
3. **Early procedural intervention to mitigate scar and contracture formation is worthy of additional study and has the potential to revolutionize scar treatment paradigms.** Most investigations to date have focused (understandably, given their relatively small size and reproducible nature) on postsurgical scars, so a detailed discussion has not been included here. However, existing reports suggest there are promising potential benefits in anticipatory rather than strictly reactive scar management after trauma.
4. **Dermatologic surgery procedures such as laser hair reduction for amputees or patients with hair redistribution after trauma reconstruction, short-pulsed laser treatment for traumatic tattoos, and botulinum toxin for hyperhidrosis in amputees can be extremely helpful adjuncts in a comprehensive rehabilitative program.** A detailed discussion is beyond the scope of this chapter, but these issues frequently go hand-in-hand with traumatic scarring.

Self-Assessment Questions

1. You are designing a prospective study on the management of hypertrophic scars. What is an appropriate assessment tool that can be used to evaluate the treatment response?
   (a) Vancouver Scar Scale
   (b) Toronto Scar Scale
   (c) Patient and Family Assessment Scale
   (d) Photographs only

2. True/False: The efficacy of most traumatic scar management procedures is supported by high-quality data derived from large, prospective, randomized controlled trials.

3. You are evaluating a 23-year old-female with dark macular hyperpigmentation adjacent to a scar resulting from a bicycle accident. Which adjunctive laser procedure might be most useful to treat the pigment?
   (a) Long-pulsed (ms) 1064-nm Nd:YAG
   (b) Q-switched (ns) 1064-nm Nd:YAG
   (c) 595-nm PDL
   (d) Intense Pulsed Light

4. A male with Fitzpatrick type V skin type has a hypertrophic traumatic scar on his back. Which laser may NOT be an appropriate choice for treatment?
   (a) Long pulse (ms) 1064 Nd:YAG
   (b) Q-switched (ns) 1064-nm Nd:YAG
   (c) 595-nm PDL
   (d) 10,600-nm fractional ablative CO_2

5. Which of the following laser modalities would likely be most appropriate just prior to topical application for laser-assisted delivery of topical corticosteroids in the treatment of a hypertrophic burn scar?
   (a) 595-nm PDL
   (b) 1064-nm Nd:YAG
   (c) Dermabrasion
   (d) Fractional CO_2

Correct Answers

1. a: The Vancouver Scar Scale (VSS) was developed in 1990 as the first validated scar scale to aid in the assessment of burn scars. It evaluates the scar according to four parameters including pigmentation, vascularity, pliability, and height to generate a score that ranges from 0 to 13, with higher scores indicating increased severity.
2. False: Although a range of dermatologic surgery procedures demonstrate promising results well worthy of continued study, the heterogeneity of traumatic scars and relatively nascent interest in minimally invasive procedural management have contributed to an overall moderate quality of evidence at the present time. Several of the most commonly recognized procedures are GRADE B as indicated above.
3. b: The history suggests a traumatic tattoo from dirt and asphalt. Lasers with a narrow pulse width (nanosecond and picosecond) can be useful adjuncts to treat traumatic tattooing, as well as having some demonstrated efficacy for various scar types.
4. c: The 595-nm wavelength demonstrates significant absorption by both hemoglobin and melanin. The constitutive pigment of this patient may increase the risk of complications such as dyspigmentation and worsening scarring. The longer-wavelength 1064-nm Nd:YAG can be a safer choice in patients with darker skin types.
5. d: Pretreatment with a variety of laser platforms can increase percutaneous absorption of topically applied substances to varying degrees. However, due to the uniformity of the wounding pattern, epidermal disruption, and available depth of penetration, fractional CO_2 laser treatment is the best choice in this group.

Excess Subcutaneous Fat

50

Lindsey Yeh and Sabrina Fabi

Abstract

Excess subcutaneous fat is one of the most common cosmetic concerns in the United States. Removal of excess subcutaneous fat has become an increasingly popular procedure in an outpatient setting. A large variety of devices with varying methods of fat removal or destruction are now available. The methods of treatment range greatly and include tumescent liposuction, injections with deoxycholic acid, cryolipolysis, and treatment with laser and ultrasound devices. The technology, effectiveness, and safety of these various treatments methods are reviewed in this chapter.

Keywords

Subcutaneous fat · Tumescent liposuction
Cryolipolysis · Body contouring
Fat-reduction

Epidemiology

Over 2/3 of the adult population in the United States is overweight or obese [1]. According to the American Society for Dermatologic Surgery 2017 Consumer Survey on Cosmetic Dermatologic Procedures, the most common concern of those surveyed was excess fat, which is consistent with the data over the past few years. Eighty-five percent of the participants reported that they were bothered by excess weight and more specifically 74% had undesired fat under the chin [2]. Fifty-eight percent of the consumers were considering body sculpting [2]. Not surprisingly, there has been an increasing desire for new methods of excess fat removal and body contouring.

The accumulation of fat is influenced by genetic predisposition, lifestyle, diet, as well as aging. Even in those who are not clinically overweight, patients often desire treatment of areas with excess fat that persist despite adherence to a rigorous exercise routine and diet regimen. Others may be genetically predisposed to store fat in undesirable areas including hips, outer thighs, abdomen, waist, and inner thighs. Excess fat in selective areas, such as the submental region, can increase with age and can signify aging and be aesthetically undesirable. Lipomas can develop over time and most commonly present between the fourth and sixth decades of life with a slightly greater incidence in men than women. Lipomas are often solitary; however,

M. Alam (ed.), *Evidence-Based Procedural Dermatology*,
https://doi.org/10.1007/978-3-030-02023-1_50

multiple lipomas can be seen in lipomatosis. Other than surgical excision and liposuction for larger lesions, there are limited treatment options. Abnormal distribution of subcutaneous fat can also occur with medications such as highly active antiretroviral therapy and prolonged use of prednisone or systemic diseases such as Cushing's disease.

Which Dermatologic Procedures Address This Issue?

Given the pervasiveness and demand for treatment of fat in selective anatomical areas, there has been an advent of new non-invasive treatments. The destruction and reduction of subcutaneous fat is achieved through various mechanisms. There is the direct removal of adipose tissue through liposuction. Tumescent liposuction is a safe and effective method of treating excess subcutaneous fat; however, patients are often hesitant to undergo an invasive procedure. Minimally invasive treatments such as injections of deoxycholic acid are gaining popularity. Many non-invasive procedures are available that were designed to target specific areas of the body ranging from abdomen, flanks, arms, thighs and submental area. The non-invasive devices deliver laser energy, ultrasound, or radiofrequency to induce adipolysis, a reduction in adipocyte size, and/or neocollagenesis. There are also many devices that are FDA cleared for treatment of cellulite, but not specifically approved for treatment of excess fat. The devices approved for cellulite treatment often may have the additional benefit of some reduction in fat. None of these procedures are weight-loss alternatives and are all meant to be performed on patients that are within their ideal body weight and not those that have BMIs >30 (Table 50.1).

Invasive Body Contouring Techniques and Devices

Tumescent Liposuction

Liposuction has been a long-standing procedure for the surgical removal of unwanted subcutaneous fat through small incisions and thin cannulas. Tumescent liposuction was introduced by Jeffrey Klein, MD, in 1988 and has substantially decreased the recovery time, risk, and cost associated with liposuction. Tumescent liposuction is the gold standard for removal of adipose tissue on all parts of the body including submental fat, jowls, buffalo hump, back, arms, abdomen, suprapubic area, waist, hips, buttocks, thighs (inner, outer, and anterior), knees, calves, and ankles. The majority of patients can be treated with satisfactory results in a single session. There is a greater ability to contour areas to the satisfaction of the patient and physician. An additional advantage of tumescent liposuction is the ability to treat multiple areas in one session but still limited to a total of 5 liters of aspirate per session to avoid fluid shift. The cost of the procedure may seem prohibitive initially; however if the need for multiple treatments with non-invasive techniques is taken into account, it may be the most cost-effective treatment option with superior outcomes in just one treatment session.

Tumescent liposuction involves the use of large volumes of normal saline typically containing 500–1000 mg of lidocaine, 1 mg of epinephrine, and 12.5 mL of 8.4% sodium bicarbonate per liter of normal saline that is injected into the subcutaneous fat layer. This allows for safe administration of up to 55 mg/kg of lidocaine prior to liposuction, which is less than the standard recommended safety dose of lidocaine for analgesia in cases where liposuction will not be performed [3]. Epinephrine provides an added

Table 50.1 A summary of the number of treatments recommended, effectiveness and adverse events of available treatments for fat reduction

Device/ Technique	Mechanism of action	FDA approval	Number of publications	Number of treatments needed	Amount of reduction in abdominal circumference	Discomfort/side effects
Tumescent liposuction	Suction-assisted lipolysis	7 mg/kg of lidocaine dose limit	–	1	Variable based on patient and surgeon's preferences	Hematomas, bruising, hyper/ hypopigmentation at cannula entry site
SmartLipo	1064 nm, 1320 nm, and 1440 nm laser	Laser-assisted lipolysis	13	1	Variable based on patient and surgeon's preferences	Minor swelling, bruising, skin burns
Kybella	Injectable deoxycholic acid	Treatment of submental fat	15	2–6	Submental fat: 21.9% decrease in thickness (2 mg/cm^2 × ≤ 6 treatments)	Pain, swelling, edema, bruising, paresthesias at injection site
CoolSculpt	Cryolipolysis	Reduction of subcutaneous fat of the flank, abdomen, submental fat, and thighs	30	4–6	Abdomen: 10–28.5% or 1–4.5 cm after 1 treatment Submental fat: 20% or 2 mm after 2 treatments Thighs: 0.9 cm after 1 treatment	Numbness, tingling, bruising, transient erythema, dysesthesia
Liposonix	HIFU	Non-invasive abdominal circumference reduction	13	1	Abdomen: 2.5 cm after 1 treatment	Mild to moderate pain during procedure. Tenderness, hard lumps, ecchymosis, edema
UltraShape	Low-intensity focused ultrasound	Non-invasive abdominal circumference reduction	12	3 every 2 weeks	Abdomen: 3.58–3.95 cm after 3 treatments at 4 week intervals	Transient pain during treatment, erythema, and small blisters
Vanquish	Radiofrequency	Non-invasive abdominal circumference reduction	8	4–6 treatments weekly	Abdomen: 4.93 cm (range 1–13 cm) after 4 weekly treatments	Mild redness, swelling, temporary increased sensitivity to heat
VelaShape	Bi-polar radiofrequency, infrared light, pulsed vacuum, mechanical massage	Reduction of cellulite and temporary reduction of thigh and abdominal circumference	4	1–3 treatments every 2 weeks	Abdomen: 1.25 cm after 3 weekly treatments and 1.4 cm after 6 weekly treatments Buttocks: 0.5 cm after 6 weekly treatments Thighs: 1.2 cm after 6 weekly treatments Arm: 0.39 cm after 3 weekly treatments	Heat sensation during treatment, erythema, edema
SculpSure	1060 nm laser	Non-invasive treatment of adipose tissue in the abdomen and flank	4	1	Abdomen: 24% after one treatment	Mild to moderate tenderness, numbness, stinging

benefit of minimal blood loss through the vasoconstrictive effects of epinephrine. Sodium bicarbonate is needed to neutralize the acidic pH of lidocaine. The tumescent fluid is warmed to 27–40 °C to minimize the risk of hypothermia and slowly infiltrated (<100 mL/min) for patient comfort. Small incisions are strategically made in areas where scars can be hidden. A small cannula is inserted through the incision. Patients should be advised that there would be small scars remaining at the incision sites.

Patients do require at least 2 days of recovery and swelling in treatment areas can persist for a month. Vigorous exercise is prohibited immediately after treatment and compression garments should be worn for a minimum of 3–4 days postprocedure for optimal results. Patients are typically seen on postoperative day 1 to remove blood-tinged soaked pads from undergarments. Results continue to improve over a period of 3–6 months as the skin contracts.

Standards of care for monitoring and laboratory studies vary. Complete blood count with quantitative platelet count, prothrombin time, partial thromboplastin time, and β-human chorionic gonadotropin in women of childbearing age should be obtained. Additional studies should be ordered based on the patient's medical history, including hepatitis C panels and human immunodeficiency virus (HIV) testing. Tumescent liposuction is contraindicated in patients taking blood thinners, with a history of bleeding disorders, uncontrolled hypertension, hepatic insufficiency, immunosuppression, diabetes, pregnancy, and hernias at the site of desired liposuction. Due to the high use of epinephrine, the use of tumescent liposuction is contraindicated in those with a history of hyperthyroidism, cardiovascular disease, and pheochromocytosis.

In a review of over 4000 cases of patients undergoing tumescent liposuction by single surgeon, there were no reports of hospitalization, nerve damage, deep vein thrombosis, seromas, or permanent lymphedema. There were reports of three large hematomas that resolved over a few months with cold packs, anti-inflammatories, and pain control. One case of erysipelas was reported that rapidly resolved with antibiotics (2b) [4]. Data from a study of 15, 336 patients demonstrated a good safety profile for tumescent liposuction which has been found to be safer than traditional liposuction. There were no reports of death, hypovolemic shock, pulmonary embolism, seizures, or toxic reactions (2b) [5]. Tumescent liposuction performed in an outpatient setting under local anesthesia is safe and effective when performed by qualified physicians.

Laser-Assisted Lipolysis (LAL)

Despite the effectiveness and safety of tumescent liposuction, skin laxity or stretch marks can be a persistent issue after successful treatment with liposuction. To help address this issue, laser lipolysis was introduced. In 2006 the FDA-cleared SmartLipo (CynoSure, Inc., Westford, MA), a 1064 nm neodymium/yttrium aluminum garnet (Nd:YAG) laser system, for surgical incision, excision, vaporization, ablation, coagulation of all soft tissues and for laser-assisted lipolysis. Similar to tumescent liposuction, patients typically only require one treatment unless a significant amount of adipose tissue removal is desired or if additional contouring is needed. The length of the session may last anywhere from 45 min to 2 h for each area treated. Preoperative evaluation is identical to a patient to be treated with tumescent liposuction.

The device reduces adiposity with the added benefit of reducing blood loss, ecchymosis, and recovery times that simultaneously targets fat for destruction while tightening the skin (2b, 2b, 2b) [6–8]. Localized tumescent anesthesia is used after which laser energy is delivered through a 1 mm cannula to the subcutaneous tissue through the small incisions made in the treatment area. Ultra-short, high peak power laser pulses are delivered. Newer devices can fire multiple wavelengths to selectively target different types of tissues. The Smartlipo TriPlex (CynoSure Inc., Westford, MA) has three wavelengths (1064 nm, 1320 nm, and 1440 nm) that can be delivered individually or in various combinations. The 1064 nm and 1320 nm wavelengths are converted to heat after absorption by the adipose tissue,

which causes expansion and subsequent rupture of fat cells. The 1064 nm and 1329 nm wavelengths are also absorbed by oxyhemoglobin, which enhances coagulation of blood vessels in the fat tissue and hemostasis [6]. The 1320 nm energy also targets water and therefore has a greater effect on dermal collagen and skin tightening (5) [9]. Adipocyte membranes are lysed and fat tissue is ablated through thermolysis and later aspirated out. Simultaneously, there is coagulation of the tissue, which promotes collagen tightening and hemostasis [7, 8]. Histological examination of adipose tissue after exposure to the laser emitting cannula showed degenerated cell membranes, dispersed lipids, and heat-coagulated collagen fibers (2b) [10].

Investigators in a prospective, randomized, double-blind controlled trial comparing laser-assisted lipoplasty with suction-assisted lipoplasty treated comparable ipsilateral topographic areas of the body. There were no major clinical differences found between the two sides. Less pain was observed and higher triglycerides were detected in the LAL-treated side (1b) [11]. Badin et al. [8] reported improvement of skin flaccidity in areas that were already moderately flaccid or those with high potential for flaccidity if conventional liposuction were performed. A split abdomen study directly comparing LAL to liposuction alone showed greater reduction in surface area and skin tightening on the laser-treated side at 1 month and 3 months post-procedure. One side was treated with LAL followed by aspiration, and the contralateral side was treated with the laser cannula and fiber without delivery of laser energy followed by tumescent liposuction. In the same study, adverse events were limited to minor swelling and bruising in the treatment areas (1b) [12].

In a review of 537 laser-assisted liposuction cases, there was a low complication rate of 0.93%, which included infection and minor skin burns. Only 3.5% of the patients required a touch-up procedure. There were no reports of skin ulceration, dimpling, necrosis, permanent sensory nerve damage, persistent edema, or systemic complications (1c) [13]. LAL did not affect blood levels of hemoglobin, hematocrit, or triglycerides up to 1 month after treatment (1c) [14]. Although there has been some evidence of potential skin tightening, the procedure carries disadvantages of additional equipment cost, increased procedure time, and increased risk of thermal injury.

Deoxycholic Acid

Deoxycholic acid (Kybella, Kythera Biopharmaceuticals Inc., Westlake Village, California) was approved by the FDA in 2015 for the treatment of moderate to severe submental fat in men and women over 18 years of age. The FDA has not approved the safety and effectiveness of the treatment of subcutaneous fat outside the submental region, although there have been case reports of off-label uses for treatment of lipomas and HIV-associated lipohypertrophy [15, 16]. Deoxycholic acid is a bile acid produced in the body that emulsifies fat for absorption in the intestines. Kybella is a synthetically derived deoxycholic acid that is adipolytic when injected, disrupting adipocyte membranes and irreversible cell breakdown and adipocyte lysis, prompting mild inflammation and recruitment of macrophages for clearing of the cellular debris (1b) [17]. Histological evaluation of tissue after treatment with deoxycholic acid showed adipocyte lysis as early as the first day after treatment. After 7 days, lipid-laden macrophages and septal inflammation can be observed in the septal layer and by day 28, nearly all inflammation has resolved while fat lobule atrophy is visualized along with neovascularization and neocollagenesis (1c) [18].

Multiple phase III clinical trials in Europe, the United States, and Canada have demonstrated the effectiveness and safety of deoxycholic acid (1b, 1b) [19, 20]. European studies indicate that both 1 and 2 mg/cm^2 dosages are effective for reducing submental fat; however greater improvements were seen with the 2 mg/cm^2 dose (1a) [21]. The REFINE-1 trial, a multicenter, randomized, double-blind, placebo-controlled trial conducted in the United States and Canada, treated patients with 2 mg/cm^2, for a maximum of 10 mL (50 mg), five vials, per treatment session, at approximately 28-day intervals for up to six treatments. Improvement was graded by both the patient and

clinician with the Patient-Reported Submental Fat Rating Scales (PR-SMFRS) and the Clinician-Reported Submental Fat Rating Scales (CR-SMFRS), respectively. MRI before and after treatment demonstrated an 8 times greater reduction in submental volume in responders when compared to placebo-treated subjects. Seventy percent of the subjects treated were responders compared to 18.6% in the placebo group. Fifty-five percent responded in two treatments and 75% responded after four treatments [20]. Even with reduction of submental fat, skin laxity remained unchanged or even improved [21]. Patients who responded to treatment were followed for 1 year, and over 90% maintained a clinical improvement [21]. Long-term follow-up concluded that reductions in submental fat were sustained and maintained for up to 4 years in approximately 80% of patients [22].

Optimal patients are those with palpable fat located submentally in the preplatysmal plane. To ensure fat is not located behind the platysma, patients are asked to grimace on exam and submental fat is pinched to ensure it is still palpable. Patients with significant skin laxity and minimal to no fat are not ideal candidates for treatment with deoxycholic acid. Those that had more severe submental fullness required more deoxycholic acid, which may prove cost prohibitive, especially when considering off-label indications. A single treatment takes approximately 5 min to perform. In the trials patients were treated as early as 4 weeks from the last injection even when mild swelling was still present, but in clinical practice longer treatment intervals of 6–8 weeks are recommended to allow all swelling to subside and it can take up to 6–8 weeks for full results from a single treatment to be seen.

Adverse events related to deoxycholic acid injection are localized to the injection site and include pain, swelling/edema, hematoma/bruising, anesthesia, erythema, induration, paresthesia, and nodules. Most patients only experienced mild to moderate symptoms that resolved within 28 days of treatment, with swelling and paresthesias being the most common. Adverse events were typically most severe after the first treatment and improved with subsequent treatments. The more concerning adverse effects of marginal mandibular nerve paresis, ulceration, and dysphagia were rare and resolved without sequelae [20]. The sense of dysphagia is related to the injection volume and posttreatment swelling and edema. Marginal mandibular nerve paresis presents with an asymmetrical smile and is likely due to injection 1.0–1.5 cm above the inferior border of the mandible above which the marginal mandibular nerve runs medial to the facial artery. Superficial injections can cause skin ulcerations. To avoid ulceration, injections should be made midway into the preplatysmal fat. A single case report of alopecia in the beard area of a male after treatment with deoxycholic acid has been reported. The alopecia has persisted in the treated areas despite topical treatment with 0.03% bimatoprost (Latisse, Allergan, Irvine, CA) [23].

Non-invasive Body Contouring Techniques and Devices

Cryolipolysis

Cryolipolysis was introduced in 2007 based on observations that lipid-rich areas were more susceptible to injury from cold temperatures as observed in cold-induced panniculitis such as popsicle panniculitis in children or equestrian panniculitis seen in young women. The exposure to cold temperatures elicits a localized inflammation of the subcutaneous fat resulting in rupture of the adipose tissue cells and death of adipocytes. Inflammation is seen histologically 3 days after exposure and peaks at 14 days. After 14–30 days of treatment, phagocytosis of lipid by macrophages is seen. After the inflammatory response subsides, a lower volume of fat cells is left with no residual evidence of inflammation and no persistent damage to any tissues (1c, 1c, 1c) [24–26]. The FDA cleared a cryolipolytic device (CoolSculpting®, ZELTIQ Aesthetics, Pleasanton, CA) for reduction of subcutaneous fat in the flank, abdomen, thighs, submental area, bra fat, back fat, underneath the buttocks (also known as the banana roll), and upper arm. It was

also recently FDA cleared for the treatment of skin laxity in the submental area.

Typically, excess tissue is placed between two cooling plates through a vacuum suction with varying lengths of contact time. Optimally, the subcutaneous fat layer is cooled to 4 °C for a total of 35–75 min per applicator, depending on the applicator that is used. There is no downtime, no need for analgesics during the procedure, and patients are able to resume normal daily activities immediately. Multiple animal and clinical trials have proven the efficacy and safety of cryolipolysis through histological, caliper, visual comparisons and ultrasound findings. In a review of 19 studies, an average reduction of 14.67–28.5% fat was reported through caliper measurements, and average of 10.3–25.5% reduction was reported based on ultrasound measurements of various treatment areas (2a) [27]. Shek et al. [28] showed significant abdominal fat reduction of 4.5 cm after a single treatment. Three months after the initial treatment, a second treatment was administered and additional significant improvement was seen (0.4 cm, for a total of 4.9 cm from both procedures) when compared to baseline (4) [28].

In a multicenter, prospective, nonrandomized study of 32 patients treated with cryolipolysis in the flank and back, over 80% of the patients reported fat reduction at 4-month follow-up after just one treatment. Ultrasound of a 1/3 of the patients revealed 22.4% reduction in fat (4) [29].

Treatment of submental fat with a specialized applicator for the area was found to be safe and effective. After two cycles of treatment, ultrasound measurements showed a mean fat layer reduction of 2.0 mm (range + 2.00 mm to −5.9 mm), which correlates with a 20% reduction in the submental fat layer and was statistically significant ($P < 0.0001$). At follow-up 77% of the treated patients reported visible fat reduction (4) [30].

After one treatment of the inner thighs, there were 0.9 cm mean reduction in circumference and a 2.8 mm reduction of fat thickness at 16-week follow-up (4) [31]. In another study of 11 subjects treated with cryolipolysis in the inner thighs, there was an average 20% reduction in fat layer thickness corresponding to a 3.3 mm reduction (4) [32]. In a prospective, nonrandomized study, ultrasound images were analyzed, and a 2.6 mm fat layer reduction was calculated after just one treatment (4) [33].

A pilot study evaluating the use of cryolipolysis to reduce upper arm fat revealed a mean reduction of 15.3% in the fat layer, which corresponds to 2.03 mm, after one treatment cycle. The contralateral arm was not treated and served as a control (4) [34].

There have been multiple reports of effective fat reduction with off-label treatment of areas such as anterior brassiere rolls, lumbar rolls, hip, medial knee, and ankles, but patients need to have the appropriate distribution of fat in these areas so that the applicators can fit properly and not cause irregularities with treatment [27].

Long-term follow-up of two case studies showed enduring treatment effects even 6 or 9 years. Only one flank was treated and despite an extended period of time passing and weight fluctuations after the last treatment, the decrease in adipose tissue on the treated side persisted (3b) [35]. Enhanced clinical outcomes have been reported with 2 min of manual massage (1 min of kneading, 1 min of circular massage) immediately posttreatment. The mean fat reduction was 44% greater with massage than without when measured by ultrasound and with no increase in adverse effects (3b) [36].

Studies have not produced any significant adverse effects. No abnormal cholesterol, triglyceride, low-density lipoprotein, high-density lipoprotein, or any decline in liver function have been detected even after multiple treatments in 1 day (4) [37]. Adverse effects are limited to mild discomfort during treatment, numbness and tingling (lasted a mean of 3.6 weeks, all resolved within 7 weeks), bruising, and transient erythema (4) [26, 38]. Some patients report posttreatment pain that occurs more commonly in women and neuropathic pain that is not responsive to medication. In a retrospective review of 125 patients, 19 developed posttreatment pain, 100% of which were female. Onset of pain occurred on average at 3 days and lasted anywhere between 2 and 60 days (mean 11 days). All cases were self-

limited and the majority of patients experienced pain relief with oral gabapentin (4) [39].

Incidents of paradoxical adipose hyperplasia (PAH) have been reported. Patients develop a well-demarcated, firm subcutaneous mass in the area of treatment approximately 3–6 months after treatment that persists. Although it was initially thought to be a rare phenomenon, as cryolipolysis gains popularity, the frequency has increased and occurs in 0.021% of treatments with 55% of the cases occurring in men. Of the reported cases, PAH was more commonly developed in the chest and anterior lower abdomen. The increased susceptibility of men developing PAH has been attributed to difference in fat distribution between men and women. Men have more visceral adipose tissue that is not appropriate for cryolipolysis. Differences in the orientation of the fibrous septa in fat may also contribute to differences as well as inadequate tissue draw (4) [40].

Contraindications to cryolipolysis include conditions exacerbated by cold exposure such as cryoglobulinemia, cold urticaria, and paroxysmal cold hemoglobinuria, as well as a hernia directly in the area to be treated [26]. Caution should be taken in patients with scars over the area to be treated. Patients that have unrealistic expectations and are looking for more than 20% reduction in adipose tissue from a single session are not ideal candidates. A second treatment can be performed to achieve more fat reduction as early as 6 weeks from the initial treatment. Patients that do not have an inch to pinch, do not have enough tissue to be drawn up into the vacuum-assisted applicators, and are better candidates for the flat applicator if there is enough fat for the flat applicator can sit on and do not create any drop-offs. Patients should be encouraged to return 2–6 months after the initial treatment. A study that took ultrasound measurements of subcutaneous fat 2 and 6 months after one treatment with cryolipolysis found a 20.4% reduction in the subcutaneous fat later after 2 months and 25.5% after 6 months [38].

High-Intensity Focused Ultrasound (HIFU) (Liposonix)

High-intensity focused ultrasound (HIFU) (2 MHz, >1000 W/cm^2) utilizes the energy behind high-frequency acoustic energy to target subcutaneous adipose tissue at depths that can be controlled by wavelength and energy level. The adipose tissue is ablated through thermal effects and mechanical (cavitational) effects. When the adipose tissue is raised to temperatures above 55 °C, it induces coagulation and necrosis causing virtually instantaneous cell death. Cavitation disrupts the adipocyte membrane through negative acoustic pressure. The Liposonix system (Valeant Pharmaceuticals, Hayward, CA) is the only FDA-cleared HIFU device for non-invasive waist circumference reduction. Energy depth with this device is fixed at 1.3 cm so patients need to have at least an inch of palpable fat in the area to be treated, especially over bony landmarks to avoid cutaneous burns and a BMI of ≤30. Areas that can be treated are limited by the size of the handpiece.

A retrospective chart review of 85 patients who underwent only a single treatment of the anterior abdomen and flank areas with HIFU found a 4.6 ± 2.4 cm mean reduction in waist circumference (range −9 cm to +4 cm) at 3-month follow-up. A total energy dose of 104–148 J/cm^2 (mean 134.8 J/cm^2) was delivered (4) [41]. Solish et al. [42] randomized patients to three passes of 47 J/cm^2 (total energy dose of 141 J/cm^2), 52 J/cm^2 (156 J/cm^2), or 59 J/cm2 (177 J/cm^2). They did not find significant differences in waist circumference between groups at 12 weeks. However, the group that received the highest energy treatment achieved a greater reduction in waist circumference at 4 weeks than the lower energy groups. At 12 weeks, participants' waist circumferences were an average of 2.5 cm smaller, and no significant differences in waist circumference measurements were seen between the different treatment groups (4) [42]. Jewell

et al. [43] reported statistically significant improvement in waist circumference in groups treated with energy levels of 59 J/cm^2 (177 J/cm^2) compared to a sham group in the intent to treat population. In a per-protocol population, statistical significance was seen in both the 59 J/cm^2 (−2.52 cm; p = 0.002) and the 47 J/cm^2 group (−2.10 cm; p = 0.04) when compared to the sham group (2b) [43].

Few patients reported prolonged tenderness, hard lumps, ecchymosis, or edema [41]. There were no reports of scarring or burns (2b) [44]. Typically patients only report mild to moderate pain during the procedure, which in practice sometimes requires a narcotic analgesic for pain mitigation. The pain severity seems to increase with the level of energy delivered. The procedure typically takes 1.5–2 h to treat the full abdomen and flanks. Bruising and edema resolved within 12–16 days. Lipid profiles, markers of inflammation, coagulation of liver or renal function, hematologic assessments, or blood chemistry after treatments did not reveal any abnormalities. Sixty to seventy-seven percent of patients felt that the treatment with HIFU met or exceeded their expectations. Up to 92% of the patients would be willing to undergo additional treatments for optimal results [43]. Contraindications for using HIFU include pregnancy, implanted electrical devices, current use of anticoagulant therapy, a coagulation disorder, cancer, hernia, and sensory loss in the treatment area.

Low-Intensity Focused Ultrasound (UltraShape)

Low-intensity focused ultrasound (UltraShape, Syneron Medical, Yokneam, Israel) is a device that emits low-intensity focused ultrasound (200 ± 30 kHz, 1.75 W/cm^2). It is FDA approved for non-invasive reduction of abdominal circumference via fat cell destruction. Three treatments are administered every 4 weeks. A single treatment session can last from 60 to 120 min. Newer platforms have reduced treatment times of 40–60 min. The acoustic waves cause changes in pressure within the fat cells creating bubbles in the fluid surrounding the adipocytes, which disrupt and lyse the fat cell membranes. The liquefied fat is then released as triglycerides. The ultrasound waves are focused on adipocytes and do not affect other tissues or skin appendages. The transducer delivers ultrasound energy 1.5 cm below the epidermis. Therefore an appropriate candidate for the device should have at least 3 cm of tissue that can be pinched. All areas can be treated with a single handpiece; therefore the treatment area is not limited by pre-determined applicator sizes. The majority of the available data evaluates treatments at 4-week intervals, but a study by Ascher showed significantly reduced circumferences in areas treated after three treatments every 2 weeks (4) [45].

A prospective study conducted in Spain treated 30 subjects with the UltraShape Contour I in the abdomen, flank, and off-label areas including the inner and outer thighs, inner knees, and breasts in males (4) [46]. Each area was treated three times at 1-month intervals. Participants showed significant progressive improvement after each treatment session in all treatment areas as measured by pre- and posttreatment photographs, ultrasound, and circumference measurements. The mean reduction in fat thickness was approximately 2.27 ± 0.8 cm by ultrasound measurements, while the mean abdominal circumference reduction was 3.95 ± 1.99 cm. The greatest reductions were seen in the outer thighs and the smallest changes were seen in the inner thighs [46]. A multicenter study (with centers in the United States, the United Kingdom, and Japan) reported a mean reduction of 2 cm in abdominal circumference and 2.9 mm in fat thickness after a single treatment session (2b) [47]. The findings were not as promising in a study evaluating the same number of treatment sessions in Southeast Asians. It was postulated that the smaller frame

of the participants made the treatment less effective or clinically apparent (4) [48].

Ascher [45] evaluated the effectiveness of three treatments with UltraShape at 2-week intervals instead of waiting 4 weeks between treatments, which is the schedule that the majority of the other studies followed. After the first treatment, the abdominal circumference of participants decreased by a mean of 2.47 cm (range 0.85 cm to −7.50 cm). After the second treatment, mean reduction was 3.52 cm (range, 0.5 to −8.00 cm) and − 3.51 cm after the third treatment. Eighty-four days after the last treatment, the mean reduction in abdominal circumference was 3.58 cm (range, 1.0–10.00 cm). These results were comparable to the results when treatments were administered 4 weeks apart. There were also no increased reports of adverse events [45].

No severe adverse effects have been reported. Infrequently patients experience transient pain during the treatment, mild erythema, and small blisters. No paresthesias, hematomas, ecchymoses, or edema, which may be seen more commonly with other body contouring treatments, has been reported. Cholesterol levels were not affected by the treatment; however mild increases in triglycerides were reported; however levels remained within normal limits. Since triglycerides are processed through the liver, there could potentially be concern for steatosis, but liver ultrasounds did not demonstrate any fat deposition in the liver [46].

Radiofrequency (Vanquish, Velashape)

Focused field radiofrequency energy (Vanquish, BTL Aesthetics, Prague, CR) is the first non-invasive focused field radiofrequency treatment for the reduction of subcutaneous fat. It is FDA cleared for non-surgical circumferential reduction of the abdomen. The technology is based on an oscillating electrical current that creates heat through collision of charged molecules and ions. Fat is an insulator with the ability of inner polarization. The electrical dipoles in the adipose tissue arrange in one direction against the polarization of the electrical field. The oscillating electrical current forces the electrical dipoles to oscillate also, creating heat in the subcutaneous adipose tissue. The applicator is designed to selectively deliver a focused energy with specific impedance that targets the adipose tissue layer. This limits energy delivered to the dermis, epidermis, and muscles. The adipose tissue is heated to 45–46 °C, while epidermal temperature remains under 42 °C. The radiofrequency is delivered through an applicator positioned over the targeted area approximately1cm above the skin. The applicator is large enough to simultaneously treat the abdomen and flanks. Patients are encouraged to stay well hydrated prior to and after the treatment to aid the body in eliminating dead fat cells. Recommended therapy consists of 30-min weekly sessions over a 4-week time period. Possible side effects include mild redness, swelling for approximately 1 h, and temporary increased sensitivity to heat (4) [49].

Biopsies taken from porcine tissue after one radiofrequency treatment showed desquamation of superficial layers in the epidermis, perivascular infiltration, alteration, and significant destruction of the adipose tissue [50]. After four treatments the biopsy revealed infiltration of foamy macrophages and neutrophil granulocytes. After a recovery period, histological examination of the skin biopsies revealed focal disintegration in adipose tissue and thick fibrotic septa. The epidermis, dermis, and adnexal structures were not affected. DNA analysis identified DNA damage indicating apoptosis of adipocytes (1c) [50].

In a prospective clinical trial of 35 patients, a mean reduction of abdominal circumference 4.93 cm (range 1–13 cm decrease) was reported 4 weeks after weekly treatments for 4 weeks [49]. Five subjects showed a reduction of 1 cm or less and four subjects had over 10 cm reduction of the abdominal circumference. Patients reported transient mild to moderate erythema over the treatment areas, which resolved within 60 min. 90.5% of the subjects did not report any pain.

Overall 71% were satisfied with the results. Three of the participants did show a significant response to the treatment, most likely due to a thin fat layer [49]. It was a well-tolerated treatment with no downtime and no need for additional use of compression garments or special posttreatment care. Clinical data regarding both the long-term effectiveness of focused field radiofrequency is limited at this time.

Other devices that utilize radiofrequency technology are the VelaSmooth and VelaShape (Syneron Medical Ltd., Yokneam, Israel), both of which make use of bipolar RF, infrared light (700–2000 nm), and a vacuum for mechanical tissue manipulation. VelaShape is FDA cleared for cellulite and circumferential reduction. The VelaShape III is a new high-power version of VelaShape (Syneron Medical Ltd., Yokneam, Israel) and is FDA cleared for reduction in cellulite and for the temporary reduction of thigh and abdominal circumference. The infrared light heats the tissue at 3 mm of depth and optimizes the penetration of the radiofrequency energy by preheating the target adipose tissue and minimizing impedance of this tissue. The bi-polar radiofrequency penetrates to a deeper level at 15 mm. The vacuum and massage rollers mechanically manipulate the tissue and increase local circulation and lymphatic drainage enhancing fat metabolism. The application of the thermal energy to the dermis induces collagen contraction and neocollagenesis. The vacuum further potentiates neocollagenesis through mechanical stress imposed on dermal fibroblasts. These effects correlate with clinical reduction in skin laxity and circumference reduction. There is no direct destruction of the adipocytes through this treatment, but there may be a decrease in adipocyte size due to cell dehydration and increased metabolic use of stored energy from the heat energy that is applied.

The recommended treatment frequency for the Velashape III is typically 1–3 treatments about 2 weeks apart. Each session lasts for approximately 20 min. It has been shown to be safe and effective in reducing the circumference of the arms, abdomen, and thighs. The ideal candidate should have a BMI of 30 or less. No specific recommendations are given based on minimum or maximum requirements of subcutaneous fat; however, the hand piece is a vacuum device and requires adequate suctioning of subcutaneous tissue.

In a prospective clinical trial, 35 female patients with skin laxity and unwanted subcutaneous fat in the abdomen/flanks, buttocks, or thighs were treated with the VelaShape II weekly for 6 weeks. The average reduction in circumference at 3-month follow-up was 1.4 cm in the abdomen/flanks, 0.5 cm in the buttocks, and 1.2 cm from the thighs. Ninety-three percent of participants demonstrated some type of change to the thickness of the fat layer, and on average, a 29% reduction was seen between baseline and 1-month follow-up visits. Patients experienced erythema, edema, and a strong heating sensation associated with treatments (4) [51]. In 2009, Brightman et al. [52] treated 29 postpartum subjects with VelaShape and found a significant reduction in abdominal circumference 3 months after the last treatment as well as improved skin laxity. The abdomen and flanks were treated once weekly for 4 weeks. The same study also treated the upper arms once a week for 5 weeks. A significant reduction in arm circumference was seen after the third treatment (0.387 cm, $P = 0.0076$) and continued reduction was seen through the fifth treatment. At 1- and 3-month follow-up post-procedure, the reduction in arm circumference remained significant, but not after 6 months. The average reduction in abdominal circumference after three treatments was 1.25 cm ($P = 0.0130$). At the 3-month follow-up evaluation, average abdominal circumference lost was 1.82 cm. Subjects tolerated the treatment well and at no point were any treatments discontinued due to patient discomfort. No adverse events were reported other than mild erythema which was noted immediately after the treatment and dissipated within an hour. Some patients had small ecchymoses that resolved in 5–7 days (4) [52]. There are no follow-up studies beyond the first few months after treatment with VelaShape to assess long-term outcomes.

Laser

Laser 1060 nm (SculpSure)

A 1060 nm diode laser (SculpSure, Cynosure, Westford, Massachusetts) was the first FDA-cleared laser for the non-invasive treatment of adipose tissue in the abdomen and flank in 2015. The device uses a 1060 nm diode laser that specifically targets the adipose tissue and heats the tissue between 42 °C and 47 °C with contact cooling to minimize damage to the epidermal or dermal layers of the skin. Melanin is also not highly targeted at this wavelength and therefore thought to be safe for all skin types. The device destroys adipocytes through the elevated temperatures. Each device has a bracket that is placed over the abdomen and flank, with four applicators applied to the skin that do not require suction assistance. The placement of the applicators can be personalized for each patient. The easy placement and size of the applicators allows for potential off-label use to treat other areas of the body. Each treatment takes only 25 min. There is no downtime and patients can resume all activities immediately after the procedure.

The clinical data specifically evaluating the 1060 nm diode laser for the treatment of adipose tissue is limited. In a prospective study, 49 subjects received treatment of 1 flank with the 1060 nm laser and the contralateral flank served as a control with no treatments [53]. Photos and ultrasound measurements of fat thickness were performed at baseline and follow-up at 6 and 12 weeks posttreatment. Board-certified dermatologists correctly identified the photograph of the treated flank 90.3% of the time. Statistically significant reductions in the treatment flank compared to the control side were seen at weeks 6 and 12 and 96% of the subjects were satisfied. Ultrasound measurements revealed a 13% reduction in fat thickness of the flanks 12 weeks after treatment. The most commonly reported side effects were mild to moderate tenderness, numbness, and stinging all of which resolved within 1–3 weeks (4) [53]. Seventeen patients treated in the abdomen or flank showed a 24% reduction in fat based on ultrasound, MRI, and photographic evaluation (4) [54]. However, clinical data regarding both the long- and short-term effectiveness of 1064 nm diode laser is still limited.

The advantages of the 1064 nm diode over cryolipolysis are shorter treatment sessions, less discomfort, and an additional benefit of collagen stimulation. There is also increased flexibility with treatment areas as the treatment is not limited to a minimum required volume of excess fat required to fit into handpieces as seen with cryolipolysis. Presently there are not comparative studies to confirm that one is superior or that patients prefer one to the other.

Appropriate Pre-op Evaluation and How It May Impact Procedure Selection

Body contouring treatments are most appropriate for people within normal weight range, limited skin laxity, and small problem areas. The patient must have fat that can be pinched, good skin quality, and realistic expectations of outcomes and potential side effects. Poor candidates for the procedure include those who are obese (BMI $\leq$ 30 kg/m^2), have excessive skin laxity or poor skin quality, and significant visceral fat. It is best to evaluate the patient unclothed and assess for muscle tone and excess fat that can be held between the fingers by squeezing the fat after the patient has engaged their transverse abdominis muscle.

Patients with significant skin laxity or large volumes of excess skin will likely be poor candidates for treatments that exclusively address excess subcutaneous fat. Additional treatments to address skin laxity should be recommended as well and may even require surgical intervention and appropriate referrals to plastic surgery should be made.

Devices such as cryolipolysis are limited by the size and shape of the adaptors. If there is not

enough tissue to create a strong vacuum suction, the treatment will be ineffective and increases the risk of adverse outcomes. A flat applicator can be used in areas where there is not enough fat to pinch, but there must be enough fat to be treated by the size of the applicator. In these cases, alternatives such as deoxycholic acid for submental fat may be a better option. For treatment of large areas such as the entire abdomen, devices such as the 1064 nm diode laser, HIFU, or focused field RF may be more appropriate depending on patient expectations, pain tolerance, and ability to return to the practice multiple times, respectively. Otherwise, tumescent liposuction remains the gold standard as it provides the most flexibility and control over the volume of fat removed and with the advantage of more precise contouring.

Understandably, many patients hesitate to undergo invasive procedures such as tumescent liposuction.

However, for the patient that is a good candidate and open to tumescent, they can be reassured that it is a safe and effective procedure and is still the gold standard for treatment of unwanted subcutaneous fat.

Prior to all treatments, it is important to obtain photos that are standardized for background, lighting, and positioning for the most accurate before and after photos. Monitoring and documenting weight gain/loss throughout the treatment period is highly recommended. There will not be significant changes in weight after the non-invasive treatments; however there will be inches lost which patients should be aware of and should be documented. Circumference can be measured at consistent points above and below the umbilicus. Patients should continue their current exercise and diet plan as to not regain any weight, as the pockets of unwanted fat are likely to recur. Most importantly, setting realistic expectations of results and number of treatments that may be needed should be communicated clearly with the patient prior to initiating any treatment plan.

Conclusion

The wide range of non-invasive devices now available is variably effective, but all with relatively similar safety profiles. The overall discomfort is tolerable or eased with oral analgesics or anxiolytics and most side effects are transient and self-limiting. Most devices are only FDA cleared for the reduction of abdominal circumference.

Deoxycholic acid and cryolipolysis are comparable in the treatment of submental fat. Both methods reduce submental fat by a mean of 20% [30]. Deoxycholic acid is invasive and requires injections, while cryolipolysis is not invasive, but cannot be used universally as it requires owning the device and being able to obtain a good fit with the adaptor. The prolonged and significant edema patients experience after deoxycholic acid injections may not be acceptable to patients. Cryolipolysis can cause bruising, erythema, and numbness but is short lived.

The bipolar RF, infrared light (700–2000 nm), vacuum, and mechanical tissue manipulation device (VelaShape) and cryolipolysis deliver similar reductions in thigh circumference, 1.2 and 0.9 cm, respectively, but differ in the number of treatments required to achieve those results. The 1.2 cm reduction after treatment with VelaShape was after weekly treatments for 6 weeks, while the 0.9 cm reduction seen after only one session of CoolSculpt [31, 51]. Based on Shek et al.'s [28] findings, cryolipolysis is more effective at reducing abdominal circumference. After just one treatment with cryolipolysis, a reduction of 4.5 cm was found compared to 1.25 cm after three treatments with VelaShape [28, 52].

A modest reduction in abdominal circumference of 1.25–1.4 cm was seen with the VelaShape even after three to six weekly treatments, while a 3.58–3.95 cm reduction was seen after three treatments with UltraShape [46, 51]. HIFU (Liposonix) and cryolipolysis both achieved significant reductions in abdominal circumference after only one treatment, 2.5–4.6 cm and 1–4.5 cm, respectively [31, 41, 43]. A 24% reduc-

tion in abdominal circumference was reported after one session using the 1064 nm diode laser (SculpSure), which is similar to the results seen with CoolSculpt [31, 53].

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE).

Tumescent liposuction remains the gold standard for removal of subcutaneous adipose tissue (A). The largest volume of subcutaneous tissue can be removed in one session and allows for contouring. It continues to be a safe treatment in the hands of trained dermatologists. Laser-assisted lipolysis has the added benefit over tumescent liposuction of improving skin laxity, but with a risk for thermal burns (B). Non-invasive modalities have gained popularity due to their ease of use, minimal adverse events, and reduced downtime. The tradeoff is that multiple treatments are often required to achieve desired results and even after many treatments, reduction in subcutaneous adipose tissue may still be modest (A). Of the non-invasive treatments, cryolipolysis has the most FDA-approved uses and data to support its effectiveness. Although other treatment modalities can eventually have similar outcomes, the results are achieved only after multiple treatments compared to one or two treatments with cryolipolysis (B). Deoxycholic acid is an effective treatment for submental fat but has significant discomfort and swelling for weeks after treatment. In practice, the advantage of deoxycholic acid is that it does not require large, cumbersome, and pricey devices and does not require the patient to fit perfectly within a set applicator size. This flexibility allows for more contouring and personalized treatment. The radiofrequency and ultrasound devices are effective but still relatively new; therefore data is still limited on the permanence of the treatments. All treatments reviewed have been found to be safe and effective, without significant adverse outcome, but with any treatment, discussion and clear counseling with patients prior to any procedure will allow for the best outcomes and patient satisfaction (B).

Self-Assessment Questions

1. Cryolipolysis is contraindicated in patients with a history of:
   (a) Hypertension
   (b) Diabetes
   (c) Cryoglobulinemia

2. Which of the following statements regarding paradoxical adipose hyperplasia (PAH) is NOT true?
   (a) Occurs more frequently in male patients than female patients.
   (b) PAH is self-limiting and will resolve over time.
   (c) Most commonly develops in the chest and abdomen.

3. Which of the following statements is true regarding marginal mandibular nerve paresis seen with deoxycholic acid injections?
   (a) Presents with an asymmetrical smile.
   (b) Is likely due to injection 1.0–1.5 cm below the inferior border of the mandible.
   (c) Typically resolves without sequelae.
   (d) All of the above are true.

4. True or False? Tumescent liposuction is significantly less safe than non-invasive body contouring treatments.

5. True or False? It is necessary to monitor triglycerides and cholesterol levels and check hepatic panel prior to and after treatments that induce adipocyte lysis.

Correct Answers

1. c: Cryoglobulinemia
2. b: PAH is self-limiting and will resolve over time
3. d: All of the above are true
4. False
5. False

Skin Laxity

51

Jingyun Gao and Diana Bolotin

Abstract

Over the past decade, there has been a surge in demand for minimally invasive treatments for aging skin. Patients seek non-surgical treatments due to reduced procedure-associated risks and faster recovery time compared to traditional surgical methods. One component of aging skin is the appearance of laxity, which is due to thinning of the epidermis, loss of dermal connective tissue and atrophy and/or redistribution of subcutaneous fat, or all of the above. Innovation in energy-based devices has created multiple avenues to address the various factors leading to skin laxity. This chapter will discuss the mechanism of action, efficacy and safety of ablative and non-ablative lasers, infrared light, ultrasound, and microneedling in treatment of skin laxity.

Keywords

Ablative laser · Non-ablative laser · Infrared light device · Radiofrequency device Microfocused ultrasound · Microneedling Skin laxity

Epidemiology

Skin laxity is an acquired condition in which the skin becomes loose and redundant over time. Histologically, changes in all three layers of the skin contribute to appearance of lax skin. With aging, thinning of the epidermis and effacement of the rete ridges result in flattening of the dermal epidermal junction, which contributes to fine wrinkles and epidermal laxity. Loss of dermal connective tissue volume due to decreased production and altered organization of collagen bundles and elastic fibers leads to rhytids and dermal laxity. In addition, atrophy and redistribution of subcutaneous fat, as well as bone resorption such as that seen in cheekbones, can further accentuate the appearance of age-related skin laxity [1, 2].

Environmental and hormonal factors also contribute to the development of skin laxity. Smoking acts synergistically with ultraviolet radiation on the skin, causing superficial and deep dermal elastosis and reducing hydration of the stratum corneum, all of which contribute to appearance of lax skin [3–5]. Smoking also accelerates collagen degradation via upregulation of matrix metalloproteinases while inhibiting new collagen (types I and III) formation within the dermis [6–8]. In a cross-sectional study done in Japan, subjects' age, pack-years of smoking, and sun exposure were all independent factors in causing facial wrinkles [9]. Estrogen and progesterone have also been shown to induce keratinocyte

https://doi.org/10.1007/978-3-030-02023-1_51

proliferation and collagen synthesis and inhibit matrix metalloproteinase [10–12]. Hence, the loss of these hormones in post-menopausal skin leads to epidermal and dermal atrophy and subsequent formation of rhytids [13]. Finally, smoking and loss of estrogen together cause decreased water retention within the epidermis and dermis, giving the appearance of reduced turgor and perhaps explaining why female smokers have a higher risk of skin laxity and aged appearance than their male counterparts [14, 15].

Less commonly, medical and genetic conditions may be causal factors for focal and diffuse laxity of skin. This can be due to genetic disorders such as cutis laxa or pseudoxanthoma elasticum or acquired conditions such as granulomatous slack skin of mycosis fungoides. Evidence regarding treatment of these rare conditions is sparse and thus will not be addressed in this chapter.

Treatment Overview

Treatment options for skin laxity include surgical and non-surgical modalities. Surgical options include facelift, neck lift, brachioplasty, and abdominoplasty. Many of the surgical treatments covering a wide area (such as abdominoplasty) are performed by plastic surgery under general anesthesia. Recently, options for less invasive techniques for skin tightening have become available to the practicing dermatologist. Patients seek non-surgical options due to the overall reduced risk and faster recovery time in comparison with traditional surgical methods. In the 2013 data of the American Society for Aesthetic Plastic Surgery (ASAPS), there were 293,388 cases of non-surgical skin tightening, in comparison with 129,807 facelift and 27, 898 neck lift; and over 80% of patients who underwent these procedures were female [16]. The 2014 data showed that non-surgical tightening has become the 7th most popular procedure in the non-surgical category and 5th most popular among male patients [17]. Another 58% increase in non-surgical skin tightening procedures was noted in 2015 [18].

Given that epidermis, dermis, and the subcutis all contribute to appearance of skin laxity, tightening treatments can be organized by the depth and layer of skin each method and device targets. For example, ablative and non-ablative lasers, such as carbon dioxide (CO_2, 10,600 nm), erbium: yttrium-aluminum-garnet (Er-YAG, 2940 nm), and erbium: glass (Er-Glass, 1540 nm), target the epidermis and superficial dermis, while microneedling, filler, radiofrequency, ultrasound, and infrared devices act almost exclusively on the dermis and subcutis with minimal effects on the epidermis. This chapter will discuss each method and device in detail, including supporting evidence in the literature regarding their efficacy as treatments of skin laxity and their potential risks or side effects.

Literature Review

Lasers

Lasers and lights have been used as treatments of mild to moderate skin wrinkling for over a decade. These treatments primarily target epidermal and dermal skin laxity. They are typically classified into ablative and non-ablative categories. Both categories of lasers are available as fractionated and non-fractionated devices. In general, ablative lasers are more effective and require fewer sessions for treatment of skin wrinkling than non-ablative lasers, but they do require longer recovery time. Fractionating either laser further reduces recovery time and complication rate but may require multiple treatment sessions [3/B] [19].

Ablative Lasers

Ablative lasers, such as CO_2 (10,600 nm) and erbium:yttrium-aluminum-garnet (Er:YAG) (2940 nm) lasers, are both strongly absorbed by water within the tissue, which leads to instantaneous vaporization of the epidermis and denaturation of collagen within the superficial portion of the papillary dermis. This stimulates re-epithelialization and new collagen and elastin synthesis over time. The result is tighter skin tone, improved skin texture with reduction in fine

wrinkles and smoother skin surface. Non-fractionated ablative lasers are associated with potential hypopigmentation, hyperpigmentation, and scarring; however, overall the risks are low [20, 21]. Fractionated ablative lasers work on similar principles as described above but cause microscopic zones of thermal injury of the skin and hence reduce the risks associated with ablative lasers such as scarring while also allowing a shorter recovery time [22].

In an earlier small study by Fitzpatrick et al., nine patients (unspecified Fitzpatrick skin type) underwent one split-face treatment with non-fractionated CO_2 laser versus Er:YAG. Prior to treatment, four tattoo dots were applied to the upper eyelids and distance between them served as a marker for degree of skin tightening. On the CO_2 laser-treated side, there was an average of 43% tightening immediately and 34% tightening at the 6-month follow-up as measured by shortening of vertical distances between the tattooed dots. This is in comparison with the 42% and 36% seen on the Er:YAG laser-treated side at 1- and 6-month follow-up, respectively. Of note, scarring was not seen on the CO_2-treated side but three patients did develop scarring on the Er:YAG-treated side [4] [23]. Another retrospective study reported results for 47 patients (Fitzpatrick type I–III, except for one patient with type IV) who underwent non-fractionated CO_2 laser resurfacing of the entire face. Using pre- and post-operative photography and a facial rhytids score, the authors reported a 45% improvement at long-term follow-up with mean duration of follow-up of 2.3 years. Of note, 55% of the patients had some complications including milia, acne, hyperpigmentation, hypopigmentation, viral infection, and ectropion [4] [20].

The advent of fractionated ablative lasers allowed for retention of improvements in skin laxity seen with non-fractionated treatments while decreasing complication rates and recovery time. In a prospective, single-blinded study by Tierney et al., 25 patients (unspecified Fitzpatrick skin type) with varying degrees of eyelid laxity were treated with ablative fractional CO_2 laser. At 6-month follow-up, there was an average of 65.3% improvement in eyelid laxity based on blinded assessment by two physicians using pre- and post-operative photography and a pre-set laxity score. The authors also reported that an average of 2.44 sessions were required for significant improvement [4] [24]. This is further corroborated by the study by Bonan et al., in which 45 patients (Fitzpatrick type I–III) received 2–3 treatments of fractional CO_2 laser on periorbital skin. Before and after photographs, as well as photographs at 2 weeks, 4 weeks, 3 months, 6 months, and 12 months after the final treatment, were evaluated by three independent dermatologists. At the 12-month follow-up, all the patients were found to have improvements in eyelid skin tightening, skin laxity, skin texture, periorbital fine lines, and rhytids clearance; more specifically, 5 patients (11.1%) achieved excellent improvement, 11 patients (24.5%) marked improvement, 15 patients (33.3%) moderate improvement, and 14 subjects (31.1%) slight improvement [4] [25].

Non-ablative Lasers

Non-ablative lasers used for the treatment of skin laxity are generally in the infrared range, such as the neodymium:yttium-aluminum-garnet laser (Nd:YAG, 1064 nm, 1320 nm, and 1440 nm), erbium-doped glass fiber laser (1550 nm), and thulium-doped fiber laser (1927 nm). Similar to the ablative lasers, these infrared-range lasers target the water-containing tissues, allowing heating of the dermis to stimulate collagen production and remodeling. In contrast to the ablative laser, the epidermis is protected by various forms of cooling. Like their ablative counterpart, these lasers also come in fractionated form, allowing for fewer side effects and less downtime.

Of these lasers, the long-pulsed 1064 nm Nd:YAG has been most extensively studied. In a recent prospective blinded randomized split-faced study, 20 Korean patients (Fitzpatrick type III–IV) underwent 3 treatment sessions at 4-week intervals using long-pulsed Nd:YAG on one side of the face. Using the untreated side of the face as control, they found that the treated areas showed an average reduction of 45.1% in wrinkle grade. Furthermore, objective measurements using a Cutometer, which measures elasticity of the skin,

also showed significant improvement of the treated side. Biopsy of treated and untreated skin confirmed an increase in collagen and elastic fibers on the treated side [4] [26].

Combination treatments of different non-ablative laser modalities have also shown promise in synergizing improvements in skin tone. In a study of 150 patients (Fitzpatrick type I–V) with facial aging, 50 patients were treated with 532 nm KTP, 50 were treated with 1064 nm Nd:YAG, and 50 were treated with both. Pre- and posttreatment photographs were evaluated by an independent observer, and degree of redness, pigmentation, rhytids, skin tone/tightness, and texture were scored on a 0–10 scale. After 3–6 treatments, patients treated with the 532 nm KTP laser alone showed 35% improvement in skin tone/tightening and 27% in rhytids. Patients treated with the 1064 nm Nd:YAG laser showed 16% improvement in skin tone/tightening and 13.6% in rhytids. Patients treated with both KTP and Nd:YAG lasers showed the most significant improvement of 44.8% in skin tone/tightening and 37.6% in rhytids. Skin biopsy specimens from all treatment arms taken at 1-, 2-, 3-, and 6-month intervals demonstrated new collagen and elastin formation [2b] [27].

Another non-ablative device is the 1550 nm erbium-doped glass fiber (Er-Glass). In a study of 24 patients (Fitzpatrick type I–II) with mild to moderate periorbital and perioral rhytids, each patient underwent 3 monthly treatments with a fractionated Er-Glass laser, and pre- and posttreatment photography were evaluated by a blinded observer using a quantile grading scale. At 6 months posttreatment, mean improvement was 2.1 for the periorbital area, and 2.0 for the perioral area, which corresponded to 51–75% improvement [4] [28]. In a retrospective study of patients (Fitzpatrick I–IV) treated with 1550 nm Er-Glass system for upper and lower eyelids and using similar methodology of evaluation as above, all patients ($N = 31$) had some degree of eyelid tightening, with 25.8% of patients achieving 50–75% improvement and 19.4% achieving 75–100% improvement [4] [29].

In addition to treatment of rhytids, the 1550 nm Er-Glass laser has also been used for treatment of pigmentary disorders such as melasma. In a study of 50 patients (Fitzpatrick type I–III) with mild to moderate facial ($N = 30$) and non-facial ($N = 20$) photodamage, rhytids, and dyspigmentation, each patient underwent three successive treatments at 3–4-week intervals, and pre- and posttreatment photographs at 3-, 6-, and 9-month intervals were evaluated by a blinded assessor using the same quantile scoring system as above. Specific clinical attributes assessed included dyspigmentation, wrinkling, and surface irregularities. The authors found that maximum clinical improvement was noted at 3 months following treatment, with mean score of 2.23 for facial skin and 1.81 for non-facial skin. At the 9-month follow-up, 73% of patients treated on the face and 55% of patients treated on other areas achieved at least 51–75% improvement [4] [30]. The newer, 1927 nm thulium fiber glass laser has also been shown to be effective in reducing laxity and rhytids, in addition to being a treatment for melasma and other pigmentary abnormalities [4] [31].

Returning to the subject of epidermal versus dermal laxity, ablative and non-ablative lasers differ in their ability to improve epidermal laxity, with ablative lasers such as CO_2 and Er:YAG suitable for treatment of both epidermal and superficial dermal laxity and non-ablative lasers targeting primarily the dermal component. This limitation on the non-ablative laser can be ameliorated to some degree by combining it with a different device, such as the 532 nm KTP laser mentioned above [27]. The fractional 1550 nm Er-Glass laser has also been shown to improve epidermal textural irregularities [31]. Despite earlier reports of dyspigmentation and scarring, the overall risks are low in long-term studies [21]. Regardless, both ablative and non-ablative technologies are effective in inducing skin tightening, and the ultimate decision most likely depends on each individual patient's degree of skin laxity and preferences for recovery time and number of treatments.

Infrared Light

Like the non-ablative laser, infrared (IR) light devices target water molecules within the dermis

while protecting the epidermis with cooling. In a prospective cohort study of 13 female patients (unspecified Fitzpatrick skin type) who underwent two treatments using an infrared device in the 1100–1800 nm range, 11 of the 12 patients who completed the study were noted to have obvious improvement by an independent observer and continued to improve after the 1-month follow-up. The authors further noted that the changes were more dramatic for individuals with neck laxity due to excess pendulous skin than those with laxity due to excess submental fat [4] [32].

Because of its epidermal sparing properties, infrared devices have also been studied in patients with darker skin tone and found to be equally effective and safe. In a prospective split-face, single-blinded study of 13 Chinese women (Fitzpatrick type III–IV), the side of the face treated twice using an 1100–1800 nm IR device, 3 of 13 patients reported mild improvement and 7 reported significant improvement at 3-month follow-up. When evaluated by an independent assessor using comparison photography, 5 out of 12 patients were noted to have some degree of improvement of the treated side using the untreated side as control [3b] [33]. In another prospective study of 21 Asian patients (Fitzpatrick type IV–V) who underwent 3 treatments with the same device, 19% reported mild, 38% moderate, and 43% good improvement. Of note, there were seven episodes (of 63 total treatments) of superficial blistering. These occurred in the early phase of the study when higher fluences were used. Those patients did develop temporary post-inflammatory hyperpigmentation, which resolved by 6 months after the treatments [4] [34].

While infrared devices can also be used on non-facial sites, the improvement in laxity is usually more subtle than that of facial sites. In a study of 20 patients (Fitzpatrick I–IV) with mild to severe laxity of upper arm skin who underwent treatment using an IR device, there was very small (0.38 cm) but statistically significant decrease in measured arm circumference but minimal improvement in subjective and objective photographic assessment [4] [35]. In a larger study by Felici et al., 303 patients (unspecified Fitzpatrick skin type) underwent infrared treatments of the abdomen, legs, and buttocks; and although 60% of patients reported being satisfied or very satisfied, the degree of satisfaction was lower in patients who had had prior treatments on their face or neck [3b] [36].

In summary, IR is an effective treatment for facial laxity. Similar to the non-ablative lasers, it primarily targets dermal laxity while sparing the epidermis. With proper cooling, it can be safely used in patients with pigmented skin as shown above [33, 34]. However, while it has been shown to be effective on non-facial sites, the results were less impressive [35, 36]. Side effects such as blistering and post-inflammatory hyperpigmentation are infrequent and temporary, and most occur when higher fluence settings are used [34].

Radiofrequency

Radiofrequency (RF) devices were initially approved by the FDA for treatment of periorbital laxity. These devices work by delivering an alternating current through the skin. The current is converted into heat energy following Ohm's law (Energy = $I^2 \times Z \times t$, where I is the current, Z impedance, and t time). Like the laser and infrared devices, heating of dermal tissues leads to immediate collagen contraction followed by neocollagenesis and neoelastogenesis.

Unlike light-based modalities discussed previously, RF is not limited by scatter and absorption of energy by water molecules in the upper dermis and hence can penetrate deeper into the dermis and subcutis. This is particularly true for monopolar (with grounding pads) and unipolar (without grounding pads) RF devices. In the initial study by Fitzpatrick et al., 86 patients (Fitzpatrick type I–IV) underwent a single treatment of the periorbital area using a unipolar radiofrequency device. Following RF treatment, 83.2% of patients demonstrated at least a 1 point reduction on the Fitzpatrick Wrinkle Scale as evaluated by a blinded observer using comparison photography, and 66.4% of patients were noted to have a greater than 0.5 mm eyebrow lift posttreatment [2b] [37]. Subsequent studies using unipolar RF devices have shown similar efficacy for treatment

of skin laxity in non-periorbital regions. In a study by Alster et al., 28 of 30 patients (Fitzpatrick type I–IV) showed at least 25% improvement of nasolabial and mesolabial fold laxity after a single treatment, and 17 of 20 patients showed at least 25% improvement of neck laxity [4] [38].

This is further supported by Finzi et al. in which 25 patients (Fitzpatrick type I–V) underwent one treatment of RF using multipass vector (mpave) technique. In contrast to conventional RF protocol in which the treatment is delivered in one single pass with no overlap, the mpave technique takes into account the direction needed for facial lift and delivers progressively more passes in areas that require the most tightening. More specifically, the lower cheeks are treated in an expanding teardrop configuration centered on the pre-auricular region with the smallest teardrop receiving the most number of treatments. Similarly, more passes are utilized over either the mid-eyebrow or lateral-eyebrow forehead depending on the types of brow lift the patient is looking for. Using pre- and posttreatment photography and a quantile scoring system, 80% of patients showed at least 26% improvement 3 months after treatment [4] [39].

Similar to IR devices mentioned previously, RF devices are felt to be safe and effective in pigmented skin. In a study with 85 Japanese female (Fitzpatrick type III–IV) patients, the authors found 78.0% improvement in jowls, 69.5% in marionette lines and nasolabial folds, and 73.8% in other facial wrinkles when evaluated by an independent observer using comparison photography and pre-set 5-point scales. Complications were seen in 7 patients, including edema (3), burn (1), blister (1), and secondary hyperpigmentation (2). In all cases, the complications were transient and resolved by 3 months [4] [40].

More recently, studies have also been done using bipolar radiofrequency devices, which provide much better control of depth in comparison with the unipolar devices and theoretically reduce the amount of thermal damage and its potential complications [41]. Bipolar devices can also be coupled with microneedles to deliver energy to a precise depth within the skin without affecting the epidermis and have real-time temperature feedback to avoid overheating [42, 43]. In a prospective, open-label, multicenter trial of 100 patients (Fitzpatrick I–IV) with mild to severe facial and neck laxity, the authors found that 100% of the patients showed an improvement in rhytids, with mean improvement of 1.6 points (25.6%), and 95% of the patients demonstrated an improvement in laxity, with a mean improvement of 0.7 (24.1%) on the Fitzpatrick Wrinkle Scale after a single-pass treatment [2b] [42]. A later study by the same authors showed that optimal improvement is achieved when the skin temperature is maintained at 67 °C for 3–4 s [2b] [43]. In another study of 20 Japanese patients (Fitzpatrick type III–V) who underwent treatment for facial skin tightening using such a device, there was an average of 12.1 ml volumetric reduction of the face at 6-month posttreatment, calculated using three-dimensional volumetric photography [4] [44].

While theoretically unipolar and bipolar radiofrequency devices all have their own advantages and disadvantages, the clinical significance of these differences is yet to be determined. A randomized, split-face study showed no statistically significant difference between the devices. However, it should be noted that in the same study, neither device yielded significant improvement in skin laxity when subjects were evaluated using a comprehensive photoaging grading scale by a blinded observer [4] [45].

Both unipolar and bipolar RF devices can be used for tightening in all areas of the face, neck, and even the eyelids. There are devices currently on the market that allow for both unipolar and bipolar settings, which in theory allows for heating of the superficial and deep dermis [46]. Like the IR and microfocused ultrasound technology (discussed below), RF is also safe for pigmented skin. It should be noted that having a pacemaker and defibrillators are absolute contraindications for radiofrequency device use. Other relative contraindications include morphea, scleroderma, and other collagen vascular diseases [47, 48]. Given the unpredictable heating patterns of joint prostheses or other implants, it is also recommended to avoid using these devices directly over or within the vicinity of the prosthesis [49].

Ultrasound

Microfocused ultrasound (MFU or MFU-V for concurrent visualization) delivers energy to the dermis and subcutis by inducing molecular vibration within the tissue. This vibration is then translated into heat, which leads to thermally induced denaturation of collagen and subsequent dermal and subcutaneous remodeling. It can be calibrated to deliver different frequencies, with higher frequency affecting more superficial dermis and lower frequency penetrating into deeper subcutis. Because of its ability to precisely target different depths, MFU is able to spare the epidermis without the need for aggressive cooling. MFU also has the advantage over other devices in that it allows visualization of the dermis and subcutis during treatment. Unlike lasers and RF devices which deliver three-dimensional cones of energy to the skin, the MFU device emits energy in 25 mm lines. During treatment, the device is marched along this line (parallel to the direction of intended lift) at set spacing to deliver a uniform plane of energy. This process is repeated until the entire treatment area is treated with the parallel linear array of US pulses [50]. In the pivotal study by Alam et al., 30 of the 35 (86%) patients (unspecified Fitzpatrick skin type) who underwent treatment using intense focused ultrasound device on the face and neck showed significant brow lift 90 days after treatment, with mean brow lift of 1.7 mm [2b] [51]. In another study by Oni et al., 63.6% of patients (N = 93, most patients had Fitzpatrick type II skin) with lower facial and neck laxity showed objective improvement 90 days after the procedure [2b] [52]. These findings are later confirmed histologically in a prospective study by Suh et al., in which 22 Korean patients (Fitzpatrick type III–VI) underwent single treatment for facial laxity, and 73% and 77% of patients self-reported much improvement of jawline and nasolabial fold laxity, respectively. Skin biopsies obtained before treatment and 2 months after treatment from 11 patients demonstrated increased dermal collagen and straightening of elastic fibers [2b] [53].

In addition to the face, neck, and eyelid, MFU devices have also been studied on other anatomic locations. In two small studies, 9–15(56%) patients had aesthetic improvement in elbow skin laxity and 24 of 28 patients (86%) had improvement of knee skin laxity following treatments when evaluated by blinded assessors [4] [54, 55]. In another study of 31 patients who underwent treatment of the right buttock, 81.5% (N = 27) showed overall improvement by physician global assessment at 90 days posttreatment, and 89.5% (N = 19) at 180 days posttreatment. It is interesting to note that majority of patients in the study stated that they would not recommend treatment to family or friends on posttreatment survey; however, the author did not further comment on the reason for this [4] [56].

When comparing the efficacy of this modality on different anatomic sites, Park et al. concluded that MFU is most effective on the jawline, followed by cheek and perioral areas, in decreasing order [4] [57]. In a different study, Alster et al. showed that MFU appears to be more effective for tightening of the upper arm and knee than the thigh and that the dual-depth treatment of the upper arm, knee, and thigh was also found to be slightly better than single-plane treatment [4] [58].

Since the ultrasound devices can be calibrated to deliver energy at different frequency and depth, combinations of different settings to treat superficial and deep dermal laxity have also been studied. In a small-scale study by Pak et al., seven Korean patients (unspecified Fitzpatrick skin type) underwent treatment for periorbital laxity; a 1.5 mm probe was used for eyelid skin, and a 3.0 mm probe was used for the orbicularis oculi muscle and septum. Each patient had before and after computed tomography imaging, which demonstrated a mean of 0.5 mm increase in distance between the orbital rim and most protruding portion of the lower eyelid. Clinically, this translated to increased fullness of the infraorbital rim [4] [59]. In another retrospective analysis of 28 Korean patients (Fitzpatrick type III–VI) who underwent MFU device treatment for facial laxity, each patient had 3 sessions, 4 weeks apart, with 200–300 treatment lines per session using 4 MHz with 4.5 mm transducer followed by 8 MHz with 3 mm transducer. Evaluation by independent assessors and comparison photography showed

that 32.1% of the patients had significant improvement and 57.1% had some degree of improvement 3 months after the last treatment [4] [60]. Contrary to the Alster study above, a more recent study of MFU treatment of the neck ($N = 41$, Fitzpatrick type I–III) showed that the differences between using single depth (7 MHz, 3 mm) and double depth with two transducers (4 MHz, 4.5 mm, and 7 MHz, 3 mm) were insignificant [4] [61].

MFU devices can be used for lifting and tightening of many anatomical locations, including the face, neck, arm, knee, thigh, and buttock. It has the advantage of inducing energy at precise depth within the dermis and subcutis, while sparing the epidermis from thermal damage, and hence is safe to use in all skin types. Its noninvasive and non-ablative nature also allows the patient to resume work and social activity immediately after the treatment. However, because it does not induce any injury to the epidermis, it is also unlikely to have effect on the epidermal component of skin laxity. And like many of the other energy devices, it is associated with intraoperative discomfort and potential bruising. MFU devices have also been observed to cause temporary motor nerve paresis and dysesthesia lasting up to several weeks. Only a few cases have been reported in the literature thus far, with branches of the facial nerve being most commonly affected and deep branch of the supraorbital nerve more rarely affected [4] [62, 63].

Combination Devices/Multimodality Treatment

Given the advantages and limitations of each individual modality discussed thus far, there is great interest in the industry in combining the different modalities into one single device. There are currently several devices on the market approved by the FDA that combine RF and light-/laser-based technology, collectively called ELOS (electro-optical synergy) device. However, whether combination devices are significantly better than single devices has yet to be determined. In a study using a combination of broadband IR (700–2000 nm) and bipolar radiofrequency, 19 Chinese patients (Fitzpatrick III–V) underwent 3 treatments at 3-week interval. At the 3-month follow up, 17 of the 19 (89.5%) patients reported moderate to significant improvement in skin laxity of cheek, jowl, periorbital area, and upper neck, and 15 of 19 (78.9%) patients reported moderate to significant improvement of the nasolabial fold. However, when evaluated by blinded observers using comparison photography and numerical scoring (−1 to 3), the improvement was less remarkable, with 26.3% of patients achieving mild to moderate improvement in periorbital, nasolabial, and upper neck laxity, 36.9% in jowl, and 47.3% in cheek laxity. Zero of the 19 patients achieved the level of significant improvement [4] [64]. In two studies examining the combination device of radiofrequency and diode laser, only modest improvements were noted in facial rhytids after three treatments at 3-week intervals [4] [65, 66].

In a later study examining the use of a combination of bipolar radiofrequency, infrared, vacuum, and mechanical massage device, 19 post-partum patients (Fitzpatrick type I–V) who underwent 5 weekly treatments for the upper arms showed a statistically significant decrease of arm circumference of 0.625 cm at the 5th treatment. At 1- and 3-month posttreatment follow-ups, mean reductions of upper arm circumference were 0.71 cm and 0.597 cm, respectively. Ten patients also underwent four weekly treatments of the abdomen and flanks, and the noted reduction of abdominal circumference at the 3rd treatment was statistically significant at 1.25 cm. At 1- and 3-month follow-ups, the reduction in abdominal circumference was 1.43 and 1.82 cm, respectively [4] [67].

Microneedling

Unlike the energy-based technologies discussed thus far, microneedling is performed with micron-sized puncture devices that are designed to breach the uppermost layers of the skin without vaporization or heating of tissue. Depending on the shape, length, and width of the microneedle, it can be designed to penetrate through different layers of the epidermis and/or dermis. Microneedle puncture of the upper dermis has been shown to induce neocollagenesis via induction of physiologic wound-healing cascades, a process commonly

referred to as percutaneous collagen induction (PCI) [68].

While microneedling has been most well-studied in scar revision, literature on its use in skin tightening remains scarce. In one small study of ten patients (Fitzpatrick type III–IV) with Glogau class II–III wrinkles, all patients underwent six sessions of microneedling at 2-week intervals. At the 3-month follow up, the authors note an approximately 60% improvement in facial wrinkling and an 80–90% rate of patient satisfaction with the treatment. Biopsies obtained at baseline and at 1 and 3 months after initiation of therapy showed increased epidermal thickness and increased type I, III, and VII collagen in the dermis [4] [69].

As previously mentioned, microneedling has also been coupled with bipolar radiofrequency devices for treatment of skin laxity. It works by allowing the current to pass between the microneedles, thus allowing precise depth and energy delivery while sparing the epidermis from thermal injury. Details of the studies regarding such technologies are summarized in the RF section earlier.

Effectiveness of Treatments

In general, it is accepted that minimally invasive skin tightening treatments achieve more subtle effects on skin laxity in comparison with the traditional surgical approaches. However, there have been very few studies examining and quantifying the differences in outcomes between these approaches. One study examined the relative improvement of patients who underwent RF treatments versus patients who underwent traditional surgical lift, in which before and after images of 15 patients who had radiofrequency and 6 patients who had surgical lifts were blindly evaluated using a four-point laxity grading scale. The average improvement was 0.44 among RF-treated patients and 1.20 among the surgical group ($P < 0.001$). The improvements relative to baseline were 16% for RF treatment and 49% for the surgical facelift [4] [70].

Comparisons between noninvasive treatment modalities are also lacking in literature. It was thought that laser-based devices tend to perform slightly better than other energy devices such as radiofrequency. However, whether this translates into clinical significance is yet to be determined. In a split-face study in which patients were treated with a long-pulse Nd-YAG device on one side of the face and a radiofrequency device on the other, improvement was greater on the laser-treated side in terms of laxity and wrinkles but essentially the same in terms of texture and pigmentation [4] [71]. In another split-face study of the same design, upper face improvements, including forehead and periorbital lines, brow, and eyelid positions, were essentially the same on both sides (30.2% and 31.3% improvement for laser and RF, respectively, $P = 0.89$), while lower face improvements, including malar cheeks and jowl positioning, nasolabial fold depth, and fold extension, were greater on the laser-treated side (35.7% and 23.8% improvement for laser and RF, respectively). However, the differences were not statistically significant ($P = 0.074$). Yet, when the entire face was evaluated, improvement in facial laxity was significantly greater on the laser-treated side (47.5% and 29.8% improvement for laser and RF, respectively, $P = 0.028$) [4] [72].

Safety

Infrared, radiofrequency, and ultrasound devices are generally safe for all skin types with low risk of adverse events reported in the literature [20]. Transient erythema and edema are to be expected and often used as a treatment endpoint. The most common adverse event with these devices is overheating, which, in mild cases, causes patient discomfort. If not recognized immediately, however, it can then lead to superficial burn and full-thickness permanent scar [73, 74]. To reduce the potential risks for overheating and scarring, lower fluence settings with higher numbers of passes are preferred over more traditional high fluence settings. Some newer devices provide temperature feedback which helps mitigate the risk of overheating. In the event of overheating, treatment should be aborted immediately, and a

cooling device should be applied until all symptoms and signs of overheating resolve.

Ablative nonfractional lasers, such as the CO_2 laser, are associated with potentially more serious complications, including bleeding, crusting immediately following procedure, severe acne flare, hyper- and hypopigmentation for several weeks to months following procedure, and potential scarring. And while the introduction of fractionated lasers, use of higher fluences, and shorter pulse widths have lessened the collateral thermal damage associated with traditional ablative lasers, these resurfacing lasers still have the potential of causing scarring, discoloration, and infection. Fortunately, a recent large multicenter study has shown very low rates of adverse events reported with CO_2 resurfacing (0% for fractional and nonfractional pulsed) [2a] [60]. However, smaller studies over the years have reported complications which should be taken into consideration when planning treatments and obtaining informed consent from patients. One such study, mentioned previously, showed that 55% ($N = 47$) of the patients who underwent non-fractionated CO_2 resurfacing for rhytid and solar aging had some form of complication, most commonly milia and acne which occurred in 14 cases (30%), hyperpigmentation in 8 cases (17%), and hypopigmentation in 6 cases (13%). In the same study, one patient developed infection and another developed ectropion. Most of the complications were resolved within 1 year with the exception of one case of hypopigmentation and one case of hyperpigmentation which were resolved by 2 years [4] [20].

The side effects of microneedling and microneedling coupled with radiofrequency have not been well documented, particularly when used for the treatment of skin laxity. It is more commonly used for the treatment of acne scars, from which the safety data may be extrapolated to some extent. Reported complications include mild erythema, edema, superficial bleeding, and desquamation as well as more serious consequences such as delayed local hypersensitivity reaction and scarring [75–78]. In a case series by Soltani-Arabshahi et al., three women developed foreign body-type of granulomatous reactions following procedures. All three women had applied topical serum (two cases of vitamin C and one case of a gel product) prior to the microneedling session. These cases were thought to be delayed-type hypersensitivity granulomas due to intradermal tattooing of the topical product [4] [77]. A long-term adverse effect of radiofrequency microneedling is thought to be similar to traditional radiofrequency, and limited to pain during procedure, as well as self-limited erythema, edema, and dyspigmentation [4] [79].

Preoperative Evaluation and Patient Selection

Given all the available treatment options, patient preferences play a major role in choosing the most appropriate treatment modalities. While the current trend is for more patients to prefer the idea of noninvasive tightening procedures over traditional surgical approaches, patients should be made aware during the initial surgical consultation that surgical lifts usually provide more dramatic improvement in laxity. Patients should also be informed of the potential side effects of each individual modality that they are considering. Specifically, a discussion of the potential for scarring or pigmentary changes, the recommended number of treatment sessions, timeline between each treatment and peak effect, as well as the length of recovery time is critical before deciding on the best treatment option.

During initial evaluation, the following patient factors should be noted: (1) degree of skin laxity, (2) depth of skin laxity, (3) patient's Fitzpatrick skin type, (4) history of prior treatments including injectables, and (5) other medical conditions and comorbidities. The ideal candidates for noninvasive tightening procedures are those who are relatively young, and with mild to moderate skin laxity. Patients with severe deep wrinkling and skin laxity may not be satisfied with the more subtle improvement offered by noninvasive modalities. Patients with epidermal laxity will benefit the most from laser resurfacing procedures unlike those with deep dermal and subcutaneous laxity who may do better with surgical lifts or IR, RF, or MFU devices, depending on the degree of involvement. Radiofrequency, ultrasound, and

infrared devices are generally safe for patients with type III–V skin; however, if concerned, a test spot can be done to evaluate for potential dyspigmentation several weeks prior to scheduled procedure. Furthermore, in patients with a pacemaker and/or a defibrillator, RF devices should be avoided. Other medical conditions to consider include morphea, scleroderma, as well as a history of joint prosthesis or other implants [47, 48].

There has been much debate in the field regarding use of noninvasive skin tightening devices in patients who have had dermal filler treatment. It was postulated that the heat generated by these devices may break down the injectable filler, which may have unpredictable remodeling and/or inflammatory effects in the skin. However, surprisingly, in a pilot human study and in animal models, patients saw greater improvement when radiofrequency is used in conjunction with hyaluronic acid [80, 81]. Additionally, studies have not shown any adverse events when laser, light, or ultrasound modalities are used on human skin injected with polymethyl methacrylate (PMMA) [82]. Similar lack of adverse events was reported for calcium hydroxyapatite filler combined with RF therapy [83].

In a recent consensus recommendation by Fabi et al., a stepwise treatment approach using neuromodulators first, followed by soft-tissue filler, and then MFU were recommended. The experts further recommended spacing individual treatments by 1–2 weeks to allow resolution of local side effects from each treatment, such as swelling and bruising. This timing also allows assessment and re-assessment of patient's need after each treatment. However, for patients who desire all treatments within the same day, MFU was recommended before injections to avoid contamination of the transducer as well as unintended manipulation and displacement of filler material [84].

Typical Treatment Plan: Case scenario

Case study 1: Patient JS is a 53-year-old Asian female with Fitzpatrick type IV skin who presented to the clinic complaining of "wrinkling around her eyes and droopy eyelids." She reported that one of her friends just had a facelift but she is interested in something that is less dramatic. She works as an account manager at a local bank and prefers to be able to return to work with minimal recovery time. On examination, there were static and dynamic medium-depth rhytids involving bilateral lateral canthi as well as mild laxity of upper eyelid skin. She was not interested in injectable therapies and strongly preferred a noninvasive option for her skin laxity.

Given patient's skin type, radiofrequency, infrared laser, as well as microfocused ultrasound treatment options were discussed. After explaining the potential risks for pain, erythema, and bruising for either procedure, patient proceeded with MFU-V. Dual-depth protocol was used to target the deep dermis, subcutaneous fat, as well as orbicularis oculi muscle and septum (15 lines with 1.5 mm probe and 15 lines with 3 mm probe for each infraorbital area) as described by the study by Pak et al., [49]. The patient's pain was controlled with an intramuscular ketorolac injection and she did not require nerve blocks. After the treatment the patient had mild erythema and edema at the treated sites and was able to return to work the following day. At her 3-month follow-up, her periorbital skin appeared tighter and she was very pleased with the outcome.

The patient then returned to the clinic a few months later and complained of loose skin on her bilateral upper arms. Her daughter is getting married in about 6 months, and she would like to wear a sleeveless dress but feels self-conscious about her "saggy" upper arms. She asked whether the same procedure she had around her eyes can be done for the arms. On examination, the patient had mild to moderate skin laxity of bilateral upper arm as well as moderate amount of subcutaneous fat.

Given the degree of subcutaneous fat, noninvasive devices such as MFU, IR, or RF alone are unlikely to provide significant result for the patient. However, she would be a good candidate for sequential treatment that involves traditional liposuction or noninvasive fat removal such as cryolipolysis (not discussed in this chapter) followed by MFU or IR to tighten the dermal component of the laxity. Alternatively, this patient

may also benefit from brachioplasty. However, there is a higher risk of visible scar at the incision sites and a longer recovery time associated with an invasive procedure. After discussing all treatment options, patient opted for traditional liposuction followed by MFU. At her 6-month follow-up, she brought you a picture of her at her daughter's wedding and informs you that again she is pleased with the result.

Of note, there are very few reports in the literatures specifically addressing the timing between different modalities of treatment for skin laxity and even fewer addressing the timeline between traditional liposuction and noninvasive tightening procedures. This could be due to the fact that most studies excluded individuals who had undergone other surgical or non-surgical tightening procedures. However, in general, combinations and successive treatments were thought to be safe and even possibly synergistic [50, 85, 86].

Case 2: Patient HG is a 59-year-old Caucasian female with Fitzpatrick skin type II who presented for evaluation of loose skin around her lower cheeks and chin. She endorsed multiple blistering sunburns as a child and years of tanning bed use in her youth. She also informed you that she has tried over-the-counter retinol cream in an attempt to reduce her wrinkles and correct her skin tone but has not seen any benefit. On examination, patient had numerous tan macules with feathered borders on forehead, nose, and cheek consistent with solar lentigines; she also had prominent nasolabial fold and marionette lines. Overall, her skin appeared thin and crinkly. She brought a picture of herself from 10 years ago, which showed more prominent cheekbones and slimmer jawline.

This patient is a good example of epidermal and dermal thinning, redistribution of subcutaneous fat, and skeletal bone resorption with aging. Her history of UV exposure also contributed to the epidermal and dermal process, in addition to development of solar lentigines. After performing a thorough skin exam to ensure that this patient does not have any evidence of skin cancer, treatment options including ablative lasers such as the CO_2 laser (fractional), non-ablative lasers such as the Q-switched Nd:YAG, as well as dermal fillers, to reconstitute volume, were discussed. The potential side effects and recovery time for each procedure were discussed. The patient proceeded with fractional CO_2 laser as she is retired, was able to devote time to recovery from a more aggressive therapy, and wished to minimize the number of treatments. Patient was provided with verbal and written care instruction as well as valacyclovir for prophylaxis to be started prior to her procedure.

The patient tolerated the treatment well but called the clinic the following day asking how long she would stay red, oozy, and crusted. She apologized that she could not recall all the details of the conversation and she was having a hard time putting on her reading glasses to read the written instructions. The care instructions and expectations of healing time were again reviewed with the patient. At her 1-month follow-up, the patient's facial skin appeared tighter and more luminescent. The fine wrinkling of her skin completely abated. In addition, solar lentiginosis was markedly improved. She informed you that while the recovery process was longer than she had imagined, she is very pleased with the result.

Postoperative Care and Follow-Up

For non-ablative lasers, radiofrequency devices, and infrared and microfocused ultrasound devices, heating and denaturing of collagen is instantaneous, and the patient may experience immediate skin tightening during and after the procedure. However, neocollagenesis and elastogenesis may take weeks to months to take effect. Majority of the studies evaluated patients at 1, 3, and 6 months post-op. In some studies, effects were sustained to slightly diminished at 1 year after the procedure.

After treatment with ablative lasers, patients will invariably experience oozing and crusting post-operatively. Even the newer short-pulse CO_2 laser requires a 1–2-week recovery period following the procedure depending on the settings used. It is essential to follow up with patient during and after the recovery to ensure proper

healing. Similar to non-ablative technologies, dermal remodeling continues to occur after the initial treatment, and patients' skin laxity may continue to improve months after the procedure.

Depending on the modality used and settings implemented, improvements can be subtle, as evidenced by multiple studies showing subcentimeter improvement in arm/abdomen circumference and 1–2 mm in brow lift. Hence, pre- and posttreatment photography and measurements are crucial. Many studies used commercially available standardized photography systems that take high-resolution photographs from multiple angles with controlled lighting and exposure allowing both the patient and physician to objectively evaluate the results.

Conclusions

Given current trends and demand for minimally invasive approaches to treating skin laxity, light-based devices, radiofrequency, and ultrasound can offer modest degrees of improvement for patients with mild to moderate degree of skin laxity. With the exception of ablative nonfractional lasers, these devices have the advantage of minimal side effect profiles and recovery times in comparison with surgical procedures. However, more research is needed to determine optimal settings of these devices on different anatomic locations (particularly non-facial sites), and further comparative studies are needed to evaluate relative efficacy of various devices compared to each other. Furthermore, given the rapid technology development and increasing popularity of these treatment modalities, it is important that practitioners maintain continuous education on the mechanisms and logistics of these devices.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
Noninvasive devices are thought to be less effective than surgical lifts; however, they have the advantage of less downtime, no requirement of general anesthesia (local anesthesia may still be needed), and less risks of scars	B
RF, IR, and US can all lead to some degree of improvement in skin laxity objectively and subjectively	B
RF, IR, and US have been extensively studied in patients with Fitzpatrick IV–V skin and are thought to be safe	B
Ablative lasers, and some of the non-ablative lasers, have the advantage of targeting both epidermal and dermal components of skin laxity	B
Most studies were focused on skin laxity on the face. IR and US can also be used on other anatomical site, though usually they are less effective on non-facial site. Patient satisfactions are also lower for non-facial site, especially if patient had had treatment of the same device on the face	B

Self-Assessment Questions

1. Which of the following is an absolute contraindication for the use of a radiofrequency device?
   (a) Presence of joint prosthesis
   (b) Presence of bare-metal coronary stent
   (c) Presence of defibrillator and/or pacemaker
   (d) Presence of dental implants
   (e) Presence of dermal and subcutaneous filler material
2. Which of the following devices has been shown to cause temporary motor nerve paralysis and dysesthesia?
   (a) Ablative laser
   (b) Radiofrequency
   (c) Infrared
   (d) Microfocused ultrasound
   (e) Microneedle
3. Which of the following devices are considered safe to use on darkly pigmented skin?
   (a) Radiofrequency
   (b) Infrared
   (c) Ultrasound
   (d) A & B
   (e) All of the above
4. If patient reports pain or intense heat during an IR procedure, the operator must perform which of the following?
   (a) Move the device to a different area of treatment
   (b) Remove the device entirely from the patient
   (c) Turn off the IR device but allow the cooling device to stay on the patient with cooling on
   (d) Apply topical lidocaine to the affected area
   (e) Reassure the patient that this is normal response
5. All of the following patients may benefit the most from noninvasive skin tightening procedure alone or in combination with other treatments. Which of the following is most likely to benefit the most from noninvasive procedure alone?
   (a) 69-year-old with loose sagging chin
   (b) 70-year-old with moderate to severe jowls
   (c) 48-year-old with excess skin on abdomen after bariatric surgery
   (d) 37-year-old with mild abdominal skin laxity after three pregnancies
   (e) 72-year-old with “bat wing” arms

Correct Answers

1. c: The presence of defibrillator and/or pacemaker is an absolute contraindication to use of a radiofrequency device. The presence of joint prosthesis may lead to abnormal heat conduction and RF devices should be avoided within the vicinity of prosthesis but can still be used elsewhere on the body. The presence of filler has not been shown to cause abnormal tissue response when used in conjunction with radiofrequency devices. In fact, in animal models and a pilot human study, the patient saw greater improvement when radiofrequency is used in conjunction with hyaluronic acid.
2. d: Ultrasound devices have also been observed to cause temporary motor nerve paresis and dysesthesia lasting up to several weeks. Only few cases have been reported in literature thus far, branches of the facial nerve being the most common locations and rarely the deep branch of the supraorbital nerve.
3. e: RF, IR, and US have been extensively studied in patients with Fitzpatrick IV–V skin and are thought to be safe. In particular, the US devices can be calibrated to deliver energy to a precise depth within the skin while sparing thermal damage of the epidermis. However, if dyspigmentation is ever a concern, a test spot can be done weeks prior to the procedure.
4. c: The most common adverse event during IR procedure is overheating of the skin leading to a superficial burn. When patient complains of intense heat or pain, it is imperative that the operator turn off the energy-delivering portion of the device but still allow the handpiece to be in contact with the affected skin so that the tip may continue to cool the area.
5. d: The ideal candidates for noninvasive tightening procedures are those with mild to moderate skin laxity. The 70-year-old with moderate jowls may benefit from RF, IR, or MFU-V, but younger patients typically do better than older patients. The other patients listed most likely will require surgical procedures to achieve desired results.

Lentigines and Dyschromia

52

Hao Feng and Arielle N. B. Kauvar

Abstract

Lentigines are benign, pigmented macules that are frequently a cosmetic concern for patients. Solar lentigines are an early sign of dermatoheliosis and are common in lighter skinned individuals. Procedures used alone or in combination to treat solar lentigines include topical creams, cryotherapy, microdermabrasion, chemical peels, intense pulsed light, and lasers. Nanosecond domain lasers and intense pulsed light sources are the workhorse modalities for treatment of lentigines, and experience is growing with picosecond lasers. Other methods include cryotherapy, millisecond domain long-pulsed lasers, non-ablative fractional lasers, and lightening creams, which can be used alone or in combination. Treatment approaches are tailored for each patient based on the skin and lesion color, as well as tolerance for downtime and multiple treatment sessions. Test treatments can help the clinician find the treatment with the most efficacy and the least side effects. Most treatment modalities are extremely well tolerated without significant adverse events. Strict sun protection is required to prevent post-inflammatory pigment alteration and lesion recurrence.

Epidemiology

Lentigines are benign pigmented macules that result from an increased number and activity of epidermal melanocytes with increased melanin in keratinocytes and melanocytes [1, 2]. Solar lentigines result from both chronic sun exposure and acute sunburn [3] and are the earliest sign of dermatoheliosis. They occur on sun-exposed skin, including face, neck, hands, forearms, and upper chest [4, 5], and patients often seek treatment for aesthetic concerns. Solar lentigines are commonly seen along with seborrheic keratosis, actinic keratosis, and both melanocytic and keratinocytic skin cancer [6–8]. Other types of lentigines include lentigo simplex (ephelides or freckles) and mucosal melanotic macules. Patients with xeroderma pigmentosum who are hypersensitive to ultraviolet radiation due to

defective DNA repair mechanisms develop solar lentigines at a very young age [9]. Rarely, lentigines are seen in resolving plaques of psoriasis [10, 11]. We will focus our discussion in this chapter primarily on solar lentigines.

Solar lentigines may be seen in any skin type, but are most common in Caucasian populations due to their low levels of melanin, which protects from the effects of ultraviolet radiation. In whites, solar lentigines can be found in 20% of individuals younger than 35 years of age and more than 90% of individuals older than 60 years of age [12, 13]. Solar lentigines are seen in individuals after the age of 20 who had two or more sunburns.

Treatment Overview

Procedures used to treat lentigines include topical creams or gels that inhibit melanogenesis and non-specific destructive modalities including chemical peels, cryotherapy, microdermabrasion, lasers, and light sources. Lasers may be used to ablate tissue or for their selective targeting of melanin [20].

Topical treatments aim to disrupt melanin synthesis pathway. The most commonly used agents are hydroquinone and tretinoin [14]. Other topical agents that have been used effectively include azaleic acid, tazarotene, adapalene, and mequinol [14]. Botanical therapies for the treatment of solar lentigines produce mixed results [15]. Topical therapies are often used as a first-line treatment for patients who desire a more conservative, nonphysical treatment modality.

Cryotherapy is widely available and has been used as a safe and effective treatment option. It utilizes melanocyte's vulnerability to injury at temperatures around −4° C to −7° C [14]. A single freeze-thaw cycle is usually sufficient and effective.

A variety of chemical peels, including trichloroacetic acid, Jessner's solution, salicylic acid, glycolic acid peels, have been used individually or in combination to treat solar lentigines [14]. Patients with large areas of involvement and uneven pigmentation may benefit from peels.

Microdermabrasion removes solar lentigines through mechanical abrasion of the pigmented epidermis and superficial dermis [14]. This may be effective for a few localized and focal areas on the extremities, but would not be a desirable option for widespread lesions.

Both ablative and pigment-specific lasers and light sources have been used to treat solar lentigines. Continuous-wave CO_2 (10,600 nm), erbium yttrium aluminum garnet (Er:YAG) (2940 nm), krypton (520–530 nm), copper vapor (511 nm), potassium titanyl phosphate (532 nm), argon diode (488–630 nm), and tunable dye lasers were used in the 1970s and 1980s. They produced non-specific destruction of pigmented lesions and, with excellent technique, could be used to remove superficial pigmented lesions with acceptable outcomes. Due to diffusion of thermal damage, scarring and dyspigmentation was a significant risk.

The development of the concept of selective photothermolysis by Anderson and Parish enabled the creation of a new generation of pulsed lasers that could selectively target pigmented lesions without the risk of non-specific tissue heating and limit the risk of adverse effects [16]. Selective photothermolysis of pigmented lesions requires the use of wavelengths that are preferentially absorbed by melanin and pulse durations that confine thermal injury to the targeted chromophores (i.e., melanosomes within pigmented melanocytes or keratinocytes) [16, 17]. In theory, this requires pulse durations in the nanosecond (or less) domain to match the thermal relaxation times of these targets. In practice, however, longer microsecond and millisecond domain pulses may be used in the case of lentigines because the pigment is confined to the epidermis, and focal epidermal destruction can heal without scarring. Pigment-specific nanosecond lasers used to treat lentigines include the quality-switched (QS) ruby (694 nm), QS alexandrite (755 nm), QS neodymium-doped yttrium aluminum garnet (Nd:YAG) (532 nm and 1064 nm), and the 510-nm pulsed dye laser [14, 17]. Novel picosecond domain lasers also produce excellent results for epidermal pigment. Millisecond-pulsed ruby, alexandrite, Nd:YAG, and the 595-nm pulsed dye [18–22] lasers as well as intense pulsed light sources (IPLs) can be safely used as well for the aforementioned reasons.

IPLs use a filtered flashlamp to produce noncoherent light in the 500–1200-nm range in

conjunction with cutoff filters to adjust the spectrum of light emitted to achieve more vascular or pigment selectivity. Similar to a laser, the range of wavelengths is chosen for selective chromophore absorption and the millisecond pulse durations render it safe for use in the treatment of pigmented epidermal and vascular lesions [14, 23]. Posttreatment downtime is minimal, but multiple treatments at 2- to 4-week intervals are often needed to achieve maximal results.

When treatment of diffuse photodamage is sought, controlled ablation or heating of tissue layers with full-surface, short-pulsed CO_2 and Er:YAG lasers can safely remove the epidermis and variable portions of the dermis. Fractional photothermolysis is another approach to selective removal of epidermal or dermal tissue that relies on spatial selectivity, where thousands of microscopic foci of tissue are damaged and replaced by wound repair. Because of the fractional nature of these injuries, a greater number of treatment sessions is usually required for pigmented lesions. A more in-depth discussion of these modalities can be found in Chaps. 47 and 49.

Effectiveness of Treatments

The effectiveness of cryotherapy for treating solar lentigines has been examined in several studies. Zouboulis et al. studied six patients with large, solitary solar lentigines in a prospective case series and found full remission of all lesions with excellent cosmetic results. At 10-month follow-up, there was no evidence of recurrence or dyspigmentation at the site of treatment (4) [24]. The same group also reported a randomized, controlled, prospective trial of 20 patients with small solar lentigines and found substantial improvement in 80% and 100% of patients with minimal skin atrophy observed at follow-up in 10% and 60% of patients treated for 5 and 10 s of contact cryotherapy, respectively (1b) [25]. In a randomized, controlled, comparative study with blinded observers, the distribution of graded response rate to liquid nitrogen were 11%, 12%, 20%, 59%, and 32% for poor (0–25%), fair (26–50%), good (51–75%), excellent (76–90%), and clear (91–100%) responses, respectively (1b) [26]. Stern et al. also found good responses (at least moderate lightening and no more than slight textural change) in 61% and excellent responses (substantial decrease in pigmentation or return to normal skin color and no textural change) in 23% of patients treated with cryotherapy (1b) [27]. The rate of recurrence is not well studied although one paper reported a rate of 55% at 6 months [28].

IPLs can safely treat solar lentigines in phototype I–IV skin. Kawade et al. found 18 of 45 (40%) Asian patients with facial lesions showed more than 50% improvement, and 16% had more than 75% improvement as evaluated by photography and observation after an average of four IPL treatments at 2–3 weeks intervals. There were no complications of hyperpigmentation or scarring (2b) [29]. Sasaya et al. studied the effectiveness of IPL with a 515-nm filter on dorsal hand lentigines. They found 62% of patients had more than 50% improvement, and 23% had more than 75% improvement with no patients showing hyperpigmentation or scarring after treatments (2b) [30]. Tanaka et al. assessed treatment of solar lentigines in 40 Asian subjects using short-wavelength (500–630 nm) IPL, delivered with a targeted tip and contact cooling. Ninety percent of patients were satisfied with the results and no serious adverse events were observed (2b) [31]. Bjerring and Christiansen treated 18 patients with solar lentigines and found pigment reduction was achieved in 96% of the patients with the average clearance of 74.2% (2b) [32]. Galeckas et al. treated ten patients three times at 3–4-week intervals, and blinded investigators found improvement in 82% of dark and 62.5% of light lentigines (2b) [33].

The CO_2 and argon lasers were the first lasers used to treat lentigines. Dover et al. treated 146 lesions in 5 patients with 1 treatment session of CO_2 laser and found a gradual dose-response clearance with 81% of lesions substantially lightened or cleared at the highest tested fluence (2b) [34]. In a retrospective study, Fitzpatrick et al. treated 83 lentigines in 26 patients with a CO_2 laser and found all lentigines had 100% clearance (2b) [35]. Stern et al. conducted a randomized, controlled, prospective trial and found 25% and

62% of lentigines had excellent and good results, respectively, with the argon laser, while 23% and 61% of lentigines had excellent and good results, respectively, with the CO_2 laser (1b) [27].

Nanosecond domain, QS lasers produce excellent results for lentigines. These include the frequency-doubled QS Nd:YAG (532 nm), QS ruby (694 nm), QS alexandrite (755 nm), and QS Nd:YAG (1064 nm). In general, one to two treatment sessions are required to achieve a satisfactory response.

Tse et al. found a 67% mean percentage clearing after one treatment in six patients treated with QS ruby laser (4) [36]. Kopera et al. achieved good clearance of 196 solar lentigines on the forearms of eight female patients with one treatment session and observed no recurrence or adverse events during 6–8 weeks of follow-up (2b) [37]. The effects of QS ruby laser on solar lentigines in 91 patients with skin type II, III, and IV were studied by Sadighha et al. (2b) [38]. Complete clearance was achieved in all patients after one or two treatments. Post-inflammatory dyspigmentation occurred in 7.8% of patients with Fitzpatrick skin type II, 9.8% of patients with type III, and 16.6% of patients with type IV; all improved over a 6-month follow-up period [38]. Treatment of dorsal hand lesions in 11 patients showed a response in all subjects after 1 treatment; 24 weeks following three treatments, the numbers of subjects showing 51–75%, 26–50%, and 1–25% improvement were five, four, and one, respectively, with one patient dropping out due to pain (1b) [39].

Kilmer et al. performed a multicenter, single-impact, dose-response study of lentigines with the frequency-doubled QS Nd:YAG laser and found greater than 75% pigment removal was achieved in 60% of those lesions treated at higher-energy fluences (2b) [40]. Tse et al. found a 58% mean percentage clearing after one treatment in six patients [36]. Treatment of 12 subjects by Suh et al. produced 51–100% and 26–50% improvement in 83% and 17%, respectively (4) [41].

Kaminaka et al. conducted a prospective, randomized, split-face comparative study in eight Asian patients with facial solar lentigines using low-fluence 1064-nm QS Nd:YAG weekly for ten sessions on one cheek. They found 62.5% of patients had greater than 50% clearance after the final treatment with a recurrence rate of 13% at 6 months follow-up. 75% and 62.5% of patients were satisfied with their clinical response at the end of ten treatments and at 6 months follow-up, respectively (1a) [42].

Using the QS alexandrite laser, Kagami et al. retrospectively studied a cohort of 49 Japanese patients following 1–5 treatments with at least 3-month intervals and found 2%, 24.5%, 26.5%, 20.4%, and 8.2% of patients had 96–100%, 76–95%, 51–75%, 26–50%, and 0–25% clearance, respectively (2b) [43].

Millisecond duration long pulse alexandrite and pulsed dye lasers can be safely used to treat lentigines, because the pigment is confined to the epidermis and dermal-epidermal junction. In a prospective trial with a blinded investigator and control groups, Rosenbach et al. treated 21 lentigines in 11 patients with Fitzpatrick skin types II–IV and found 25%, 67%, and 10% of lesions had 91–100%, 76–90%, and 51–75% improvements, respectively, with one to two treatments at 4-week intervals (1b) [44]. The long pulse alexandrite laser successfully treated lentigines in two Japanese patients without pigmentary changes, scarring, or recurrence (4) [45]. Vano-Galvan et al. treated five patients with ten light-colored solar lentigines using the combination of cryotherapy plus long pulsed alexandrite laser and found all lesions showed substantial lightening with no adverse events during treatment and after 1 year of follow-up (4) [46]. Trafeli et al. found improvement in lentigines 6 weeks after treating 16 subjects. The darker lentigines achieved the best lightening with few side effects and minimal downtime (2b) [47].

The pulsed dye laser was safe and effective for the treatment for lentigines in multiple studies. Kono et al. showed 83.3% clearance rate (1b) [22]. The group did a follow-up validation study with 54 Asian patients using similar settings with the pulse dye laser and found 70% excellent, 24% good, and 4% fair responses with only 1 patient developing post-inflammatory hyperpigmentation (2b) [21]. Kauvar et al. showed that pulsed

dye laser with a modified pulse sequence and compression handpiece produced objectively moderate (26–50%) improvement in pigmented lesions in 24 phototype I–III patients with photoaged skin (4) [18]. In a study of 12 Caucasian female patients using the 595-nm pulse dye laser with a compression handpiece and no epidermal cooling, Garden et al. demonstrated clearance of 75–100% in 43%, 59%, 76%, and 79% of the lesions treated after one, two, three, and four treatments, respectively, at 4–6-week intervals (4) [19].

Non-ablative and ablative fractional lasers successfully treat photodamage-associated lentigines and dyschromia [14, 17]. The non-ablative devices heat microscopic foci of tissue, with typical microscopic thermal zones measuring 150 microns in diameter and the depth and density of beams can be varied. The resulting damaged tissue, comprised of thermally denatured columns of tissue, is eliminated trans-epidermally, and new epidermis and dermis replace the treated tissue [17, 48]. Multiple treatment sessions, typically 4–6, are needed for pigmented lesions because of the fractional nature of the treatment. Multiple wavelengths are currently available including 1927 nm, 1320 nm, 1440 nm, 1550 nm, and 1565 nm. An advantage of these treatments is that they also produce improvements in texture and vascularity, as they target tissue water, and treat everything in the path of the laser beams. Treatment with the fractional 1927-nm laser also reduces actinic dysplasia. Brauer et al. in a prospective, multicentered study investigated the safety and efficacy of a fractionated 1927-nm non-ablative thulium laser for the treatment of photoinduced pigmentation in 40 subjects. Moderate to very significant improvement in solar lentigines was observed in 68% of subjects at 1 month and in 51% of subjects at 3 months after the second treatment (2b) [49]. Treatment is safely performed in all skin types and also on non-facial skin. Healing is associated with edema, erythema, and desquamation lasting 4–7 days. Fractional ablative lasers (CO_2, Er:YAG, and YSGG) are typically used on the face only because of the higher risk of adverse events when used on adnexal-poor skin. Treatment of photodamage with fractional ablative and non-ablative lasers is addressed in depth in Chaps. 17 and 18.

Comparative Effectiveness of Common Treatments

Given the multitude of therapeutic modalities in the physician's armamentarium to treat solar lentigines, we now review the relative effectiveness of these procedures. These various therapies are not mutually exclusive, as they may be used in combination or sequentially. For example, Hexsel et al. in 2014 published their investigator-blinded, randomized clinical trial of 50 patients and found that triple combination cream consisting of fluocinolone acetonide 0.01%, hydroquinone 4%, and tretinoin 0.05% enhanced the effects of cryotherapy in the resolution of solar lentigines (1b) [50].

Chemical Peel Versus Laser

A split-lesion study comparing trichloroacetic acid (TCA) 35% peel and frequency-doubled QS 532-nm Nd:YAG laser therapy of 37 facial lentigines in 20 Asian patients with skin types III–IV showed better improvement on the laser-treated areas in 65% of patients, superior improvement on the TCA-treated areas in 14%, and similar improvement in 21%, with similar safety profiles (1b) [51].

Topical Cream Versus Laser

A prospective, open-label trial in 15 patients, Fitzpatrick skin types I–IV, with symmetrically distributed solar lentigines on the back of both hands compared one or two treatments with a QS ruby laser versus triple-combination cream (hydroquinone 5%, tretinoin 0.03%, and dexamethasone 0.03%) for 7 weeks accompanied by ultraviolet protection. The QS ruby was found to provide a statistically significant superior lightening when compared with topical therapy at the end of therapy and at 12-week follow-up. Both had acceptable side effect profiles although QS ruby laser caused more hyperpigmentation and crusting, all of which resolved by 20 weeks (1b) [52].

Cryotherapy Versus Laser

Stern et al. conducted a randomized, controlled, prospective trial comparing liquid nitrogen cryotherapy, argon laser, and low-fluence carbon dioxide laser in the treatment of solar lentigines at 99 sites in 13 patients. Cryotherapy produced significantly better results than either the continuous-wave argon or CO_2 laser treatment. There was infrequent skin atrophy for all three treatment modalities (1b) [27]. In another randomized, controlled, comparative study with blinded observers comparing liquid nitrogen, the frequency-doubled QS Nd:YAG laser, the continuous-wave HGM K1 krypton laser, and the 532-nm diode pumped laser in 27 individuals with solar lentigines on the backs and dorsal hands. The frequency-doubled QS Nd:YAG laser provided the best lightening with the fewest adverse effects (1b) [26]. Seirafi et al. enrolled 24 patients with Fitzpatrick's skin types II–IV with facial or hand lentigines and performed an evaluator-blinded randomized clinical trial comparing pulse dye laser and cryotherapy. They found pulse dye laser was more likely to produce substantial lightening of the solar lentigines than cryotherapy, especially in subjects with skin types III and IV, but there might be no difference in those with type II skin (1b) [20].

IPL Versus Lasers

In a split-face trial of 17 Asian patients, examining 2 treatments of IPL versus 1 treatment of QS alexandrite laser, there were similar rates of improvement. The laser caused post-inflammatory pigmentation in eight patients, which resolved within 6 months, and there was no hyperpigmentation following IPL treatment. The results after IPL were better than QS alexandrite laser among those with post-inflammatory hyperpigmentation after laser treatment (1b) [53].

Between Lasers

Negishi et al. conducted a prospective, randomized, parallel-group study with 196 Asian subjects comparing a single treatment with either QS ruby or QS frequency-doubled Nd:YAG laser with mild (endpoint of slight immediate whitening of the lesion) or aggressive (endpoint of very obvious immediate whitening) irradiation. They found no differences in efficacy both between the two lasers or between the mildly and aggressively irradiated groups. Aggressive treatment with QS lasers resulted in a high post-inflammatory hyperpigmentation incidence (33% and 23% vs 7% and 8%), while having no advantage in efficacy (1b) [54]. Noh et al. reported a prospective, randomized, double-blinded, split-face comparison pilot study with a QS 660-nm or QS 532-nm Nd:YAG laser in seven Asian women with facial solar lentigines. This new 660-nm wavelength ruby-like Nd:YAG laser uses a handpiece equipped with a solid dye to convert the 532-nm QS Nd:YAG laser energy to 660 nm. There were no significant differences between the two groups at 4- and 8-week follow-up [55].

In comparison trials, QS lasers are more effective than fractional ablative CO_2 lasers. Schoenewolf et al. conducted a randomized, controlled trial of an intra-individual, side-to-side comparison of 11 patients and found better clearance with the QS ruby laser compared to a fractional ablative CO_2 laser used to treat dorsal hand lentigines [39]. A prospective, single-blinded, randomized, intraindividual controlled trial study in 25 Thai patients with skin phototypes III–IV found significantly better outcomes with the 532-nm QS Nd:YAG laser compared to the fractional CO_2 laser by both colorimeter assessment and physician grading scale with no significant difference in post-inflammatory hyperpigmentation. Eighty percent of the patients treated with 532-nm QS Nd:YAG laser had excellent self-assessment results versus 8% in fractional CO_2 laser group. There was faster healing time and a lower pain score with the fractional CO_2 laser treatment (1b) [56].

Single-session treatment with thin-layer Er:YAG laser "micropeel" was compared with QS Nd:YAG laser [57] in a split-face, evaluator-blind, randomized controlled study in 15 Asian patients. The immediate effects were better with the QS Nd:YAG at 2-week follow-up, but that group had a higher incidence of hyperpigmentation at 4-week follow-up (1b) [58]. The same group performed a second split-face, evaluator-blind, randomized controlled study and

found similar improvement with QS Nd:YAG laser alone as compared to QS Nd:YAG laser plus Er:YAG micropeel combination therapy at 2 weeks. However, there was a higher incidence of post-inflammatory hyperpigmentation in the combination group (73% vs 40%), thus making the QS Nd:YAG monotherapy to be more favorable (1b) [59].

Kono et al. compared treatment of solar lentigines with a pulsed dye laser (1.5-ms pulse duration) used with a compression handpiece to reduce competing absorption by hemoglobin and a QS ruby laser in 18 Asian patients with facial lentigines with Fitzpatrick skin types III–IV. Clearance rates were 70.3% and 83.3% for QS ruby and pulsed dye lasers, respectively, with higher rates of posttreatment erythema and dyspigmentation in QS ruby group (1b) [22]. Chan et al. conducted a split-face, randomized control study in 34 Asian patients and found similar results with a millisecond domain and nanosecond domain frequency-doubled 532-nm Nd:YAG laser with respect to both clinical efficacy and adverse effects, including post-inflammatory hyperpigmentation, which resolved with bleaching agents and glycolic acid creams (1b) [60]. Ho et al. conducted a retrospective analysis of four different lasers in the management of solar lentigines in Asians. Each patient received 1–4 treatments (mean of 1.8), at 4–6 weeks intervals, depending on the clinical response. They found no statistically significant differences in efficacy with the pulsed dye laser, QS 532-nm Nd:YAG, and long-pulsed 532-nm KTP lasers. The long-pulsed alexandrite laser did not produce significant clearance of lesions. The post-inflammatory hyperpigmentation occurred in 20% of patients following long-pulsed alexandrite treatment, 10% after QS Nd:YAG laser treatment, and in none after pulsed dye and long-pulsed KTP laser treatment (2b) [61].

In summary, QS lasers, long-pulsed lasers, and IPLs are effective in treating solar lentigines with an excellent safety profile. In Asian patients, treatment with less aggressive laser parameters and longer pulse durations is associated with a lower risk of post-inflammatory hyperpigmentation.

Preoperative Evaluation and Patient Selection

A thorough medical history including medical conditions, current and previous medications, allergies, and results of prior treatments should be obtained at the initial consultation. Patients should be questioned about a history of systemic gold therapy (which is a risk factor for laser-induced chrysiasis when treating with nanosecond and picosecond lasers), herpes simplex virus in the treatment area (which can be reactivated with treatment), and a history of keloid formation, abnormal wound healing, and post-inflammatory hyperpigmentation. The patient's expectations and allowable downtime should be carefully considered and weighed when planning treatment and deciding between various modalities.

On physical exam, the clinician should evaluate the patient's skin phototype, the number, extent (scattered vs diffuse), and location of lentigines of interest. It is important that the clinician is confident of the diagnosis, especially if another provider is referring the patient. Differentiating solar lentigines from other pigmented lesions can sometimes be difficult. Lesions that are clinically suspicious for melanoma or dysplastic nevi should be appropriately evaluated prior to laser treatment. There have been reported cases of malignant melanoma being referred to as solar lentigines for cosmetic treatment [62]. These reports highlight the importance of careful evaluation of pigmented lesions before treatment. If there is any doubt, it is prudent to perform a biopsy to confirm diagnosis before treatment.

It is important to emphasize the need for using broad-spectrum sunscreens and practicing sun-protective habits in order to optimize treatment results. Pre- and posttreatment with bleaching agents could minimize posttreatment dyspigmentation and further optimize results, particularly in individuals with a tendency toward hyperpigmentation [63]. Discussing realistic expectation is also important, as the greater the contrast between background skin and lesion, the more likely the clinician is to achieve success and avoid adverse outcomes.

Impact of Patient Preference

Patient preferences may significantly impact the treatment selection. Topical therapies are considered first-line treatments for patients who desire a more conservative, nonphysical treatment modality. Cryotherapy is widely available and may be utilized in patients who are limited by their budgets. Patients with large areas of involvement and uneven pigmentation may benefit from peels, such as trichloroacetic acid. In deciding between QS laser treatments and IPL, patient's preference regarding cost-effectiveness, number of sessions, and downtime tolerance need to be carefully weighed. QS lasers will generally only require one to two treatment sessions and are thus more cost-effective than IPL, but they carry a greater risk of erythema and post-inflammatory hyperpigmentation, especially in darker-skinned individuals. IPLs are a good option when treating a large surface area, such as the chest or arms, as most systems come equipped with large rectangular spot sizes that can be used to paint in the whole cosmetic unit, but usually require more treatment sessions. Familiarity with individual device settings as well as clinical endpoints during treatment is essential as aggressive treatment with IPL in darker-skinned or sun-tanned individuals can produce adverse events including blistering, hypopigmentation, and scarring. Nonablative fractional lasers can also be considered to achieve both skin rejuvenation through collagen remodeling and simultaneous removal of pigmented lesions including solar lentigines.

Typical Treatment Plan

The treatment plan for each patient will vary depending on the patient's skin type, the number, density and color of lentigines, the tolerance for downtime, multiple treatment sessions, and the cost. Standardized photographs should be taken prior to and after each treatment session. The patient should not be suntanned at the time of treatment, especially if planning to treat with IPL or laser devices. Topical bleaching creams, chemical peels, microdermabrasion and cryotherapy should be considered first if budget considerations are primary. The following discussion centers on device-based treatment of lentigines.

If the patient has light phototype skin and scattered lesions, a QS laser is the first line of treatment. For patients with darker skin types or those prone to hyperpigmentation, treatment with a millisecond duration laser, IPL, or low-fluence QS 1064 nm should be considered as first-line treatment. Concomitant use of bleaching cream should be considered in patients at high risk for post-inflammatory hyperpigmentation. When numerous lesions are present on the background sun-damaged skin, non-ablative fractional lasers should be considered, as they will address additional concerns.

For the experienced clinician, laser test spots are not usually required for treating individuals with light phototype skin and a low risk of post-treatment pigment alteration. In an individual with a higher risk of adverse events, test treatments are desirable with one or multiple devices, and results and complications are evaluated at approximately 4 weeks. Some of the most common complications to look for include textural change, scarring, pruritus, hypo- or hyperpigmentation, and immediate pigment change. If the clinical outcome is satisfactory, full treatment of all lesions can then be pursued. If post-inflammatory hyperpigmentation develops at the test sites with lasers, consider using IPL for treatment. In patients who are prone to develop hyperpigmentation, consider using topical bleaching creams such as hydroquinone for 1–2 weeks before treatment and then adding a topical corticosteroid immediately after laser treatment for 2–3 days. Patients should be counseled on adhering to daily sunscreen use to optimize treatment outcomes and maintain results. Patients should return for a follow-up visit at 4–6 weeks, at which time re-treatment may be performed if necessary.

Novel Treatments

Lasers with picosecond domain pulses have recently been commercialized. With pulse durations 100–1000 shorter than nanosecond

lasers, these high peak power devices disrupt pigment such as melanin or tattoo ink primarily via photoacoustic effects and cavitation rather than thermal effects. The physics of laser-tissue interactions predict that picosecond pulses should produce faster clearance of tattoo ink with a lower incidence of adverse effects compared to nanosecond lasers, which is being borne out in recent literature. Early studies and anecdotal reports also suggest that picosecond lasers may be able to clear pigmented lesions more quickly with fewer side effects.

The picosecond 755-nm alexandrite and 532-nm Nd:YAG picosecond lasers have been used successfully to treat solar lentigines. Chan et al. published on their early experience with the picosecond 755-nm alexandrite laser and found a fair (25–49%) improvement in the one patient treated for lentigines (4) [64]. Treating with a picosecond 532-nm Nd:YAG laser, Guss et al. found greater than 75% clearance in more than 78% of the lesions in a retrospective chart review of 255 treated solar lentigines in 6 Fitzpatrick skin type IV individuals. Five of the 6 patients only required one treatment and in only 2 of the 255 lesions developed post-inflammatory hyperpigmentation (2b) [65]. The higher safety profile of picosecond laser in darker-skinned individuals is supported by a retrospective study by Levin et al., where the investigators found 4 of 25 (15%) darker-skinned patients treated with QS lasers for pigmented lesions developed permanent dyspigmentation, while all side effects, including post-procedural hyperpigmentation, in the 755-nm picosecond laser treatments were temporary and resolved within 3 months (4) [66].

A new 660-nm ruby-like laser, which used a handpiece equipped with a solid dye that converts the 532-nm QS Nd:YAG laser energy to 660 nm, is effective in treating facial solar lentigines [55]. Noh et al. conducted a prospective, randomized, double-blinded, split-face comparison pilot study in seven Asian women and found no significant difference in improvement was found between the 660-nm ruby-like laser and 532-nm QS Nd:YAG laser based on both subjective and objective measures. There was decreased post-inflammatory hyperpigmentation at 8 weeks after treatment with the 660-nm laser, which likely related to the lower coefficient of absorption for melanin and hemoglobin at 660 nm compared to 532 nm [55, 67]. The 660-nm ruby-like laser potentially provides another treatment option for lentigines in Asian skin based on this study.

Safety

Generally, both selective and nonselective physical modalities and topical treatments are safe in the treatment of lentigines. The most common side effects are erythema and dyspigmentation. Textural change and scarring are rare, and when they do occur, they are usually preceded by post-treatment blistering or ulceration from excessive tissue damage.

Treatments that result in prolonged erythema and edema, such as cryotherapy, continuous-wave, and ablative lasers, have an increased risk of post-inflammatory hyperpigmentation in darker phototype skin.

In general, pulsed lasers that selectively damage pigment by confining thermal damage to lesional tissue carry a very low risk of textural change and scarring in all skin phototypes, but transient hyperpigmentation has been reported to occur in up to 20–25% of darker skin, and in Asian skin with the use of QS lasers, 532 nm in particular. The risk is very low in white, non-suntanned skin. The risk is highest when treating with the 532-nm lasers due to enhanced absorption by melanin as well as hemoglobin, compared to longer wavelength devices. There is more erythema and edema after treatment, as well as purpura due to strong absorption by hemoglobin. At 532 nm and 694 nm, care must be taken to use the lowest possible fluence and avoid pulse stacking to minimize these risks [56, 57]. The risks are lower with the 755-nm alexandrite and 1064-nm Nd:YAG lasers due to lower absorption by melanin, but clearing low contrast, lightly pigmented lesions become more of a challenge.

The estimated risk of post-inflammatory hyperpigmentation in darker-skinned patients using QS lasers is approximately 25%, although studies show various results ranging from 0% to 47% [38, 53, 65, 68]. Kang et al. in a retrospective multicenter study involving 5 hospital clinic sites and 516 patients found the overall incidence of post-inflammatory hyperpigmentation was 20.3% during treatment of solar lentigines using a QS 532-nm Nd:YAG laser (2b) [69]. For patients at high risk for post-inflammatory hyperpigmentation, QS 1064-nm YAG laser can be used in conjunction with good sun protection. Gradual fading, rather than rapid clearing of lentigines, occurs with successive laser treatments.

Millisecond lasers have been used to treat dark-skinned patients in an attempt to cause less non-lesional epidermal damage and post-inflammatory hyperpigmentation. In the case of millisecond pulse duration lasers and IPLs, selective photothermolysis predicts slow heating of the lesion rather than photomechanical disruption of the melanosomes and pigment-containing cells observed with nanosecond domain lasers. At appropriately chosen fluences, post-inflammatory hyperpigmentation will be minimized. When too high a fluence is used with millisecond pulse widths, adverse effects may be even greater due to non-specific absorption of thermal damage. In a study done comparing long-pulsed and QS Nd:YAG 532 nm in Asians showed long-pulsed is safer with lower risk of post-inflammatory hyperpigmentation [60].

Postoperative Care and Follow-Up

Patients should follow up around 4–6 weeks to evaluate for efficacy and post-procedure complications. Patients should be counseled on rigorous ultraviolet protection as solar lentigines can recur and new lesions may develop. Since solar lentigines are markers of dermatoheliosis, patients should also be screened for skin cancer as dictated by the individual's circumstances.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
Solar lentigines are common, especially in sun-exposed areas and in lighter skinned individuals	A
Benign lentigines can sometimes be difficult to differentiate from benign pigmented lesions	B
A variety of topical and physical procedures effectively treat solar lentigines	A
Lasers are generally more effective than topical creams, chemical peels, and cryotherapy	B
IPL has minimal downtime but requires more treatment sessions for solar lentigines than lasers	B
IPL and fractional non-ablative lasers can be used to simultaneously improve skin tone and texture in addition to treating lentigines	B
Patients with darker skin color are more prone to complications such as dyspigmentation after physical treatments with lasers and cryotherapy	B

Self-Assessment Questions

1. A 57-year-old man with Fitzpatrick skin type II was referred by a colleague for cosmetic removal of a pigmented lesion that has been changing and growing in size over the past year. The patient said the referring colleague told him it was a lentigo, and he desires a treatment with minimal downtime. On dermoscopy, the lesion is asymmetrical and has multiple colors. What should you do next?
   (a) Treat with liquid nitrogen cryotherapy
   (b) Treat with intense pulsed light
   (c) Treat with QS ruby laser
   (d) Treat with topical hydroquinone cream
   (e) Biopsy the lesion
2. Which of the following laser is generally the safest for treating solar lentigines in darker-skinned patients?
   (a) QS 532-nm Nd:YAG laser
   (b) QS 694-nm ruby laser
   (c) QS 755-nm alexandrite laser
   (d) QS 1064-nm Nd:YAG laser
   (e) CO_2 ablative laser
3. A 45-year-old woman with Fitzpatrick skin type III desires treatment for multiple solar lentigines on her face and cannot have anything more than minimal downtime. Which treatment modality do you recommend?
   (a) QS 532-nm Nd:YAG laser
   (b) Intense pulsed light
   (c) Ablative CO_2 laser
   (d) Non-ablative 1927-nm laser
   (e) Picosecond 755-nm laser
4. Which of the following is not a treatment for solar lentigines?
   (a) QS lasers
   (b) Cryotherapy
   (c) PUVA therapy
   (d) Topical bleaching agents
   (e) Fractional non-ablative lasers
5. A 64-year-old woman with Fitzpatrick skin type III desires treatment for multiple solar lentigines on her dorsal hands and bilateral upper extremities. She wants the least number of treatments, does not mind downtime, and has a history of post-inflammatory hyperpigmentation. You have multiple light-based and laser modalities available. What is the next best step in management?
   (a) Treat all lesions with IPL
   (b) Treat all lesions with QS 694-nm ruby laser
   (c) Treat all lesions with QS 532-nm Nd:YAG laser
   (d) Treat all lesions with cryotherapy
   (e) Do test spots treatments with various modalities

Correct Answers

1. e: Biopsy the lesion. Solar lentigines can sometimes be diagnosed incorrectly. If the clinician sees evidence that suggests a different diagnosis and especially if there are worrisome signs (multiple colors, asymmetry, changing), then a biopsy is needed to confirm diagnosis before treatment.
2. d: QS 1064-nm Nd:YAG laser. QS 1064-nm Nd:YAG laser emits a longer, near-infrared ray that is capable of penetrating into the deeper regions of the skin. It tends to spare the epidermis and avoid damage there which would cause posttreatment dyspigmentation in darker patients who have higher concentration of melanin at the dermal-epidermal junction.
3. a: Intense pulsed light. Of all the treatment modalities listed, IPL has minimal to no downtime. However, patients will need multiple treatment sessions.
4. c: PUVA therapy. PUVA has been demonstrated to cause PUVA lentigines. All other options have been shown to be effective in treating solar lentigines.
5. e: Do test spots treatments with various modalities. To ensure efficacy and avoid unwanted complication such as post-inflammatory dyspigmentation, it is best to spot test with different treatment modalities to evaluate for efficacy and complications. This ensures that the best treatment can be established quickly per patient preference and full treatment for all the lesions can then be pursued.

Melasma

53

Bridget P. Kaufman and Andrew F. Alexis

Abstract

Melasma is a common acquired disorder of hyperpigmentation characterized by symmetric brown macules and patches on sun-exposed skin. The treatment of melasma often necessitates a multifaceted approach combining broad-spectrum photoprotection, topical agents, and, in refractory cases, chemical peels and laser/light therapy. Superficial chemical peels, including glycolic, salicylic, and trichloroacetic acid, are safe and cost-effective procedures that remove excess cutaneous pigment through controlled chemical injury followed by skin regeneration. Lasers and light-based devices, including fractional resurfacing and Q-switched lasers, are also effective in the treatment of refractory melasma, particularly when used in combination with topical depigmenting agents. Microneedling and picosecond lasers have more recently been added to the treatment armamentarium. This chapter provides an evidence-based approach to the treatment of melasma with laser and light-based devices, chemical peeling agents, and other dermatologic procedures. Herein, the authors review the safety and efficacy of dermatologic procedures and provide evidence-based recommendations for procedural selection and peri-procedural care in melasma.

Melasma · Hyperpigmentation
Hypermelanosis · Laser treatment · Fractional resurfacing · Chemical peel

Epidemiology

Melasma is a common acquired disorder of hyperpigmentation characterized by symmetric light to dark brown macules and patches on sun-exposed skin. This condition most commonly affects the forehead, cheeks, and chin of individuals with Fitzpatrick skin types (FST) III and IV, but can be seen in any skin type [1, 2]. Melasma may be divided into three distinct types—epidermal, dermal, and mixed—depending on the depth of melanin pigment within the skin, which can typically be determined via Wood's lamp examination [3, 4].

Melasma affects approximately five to six million individuals in the United States [5]. The prevalence varies by ethnic group and may be as high as 8–36% in skin of color, including people of Middle Eastern, Hispanic, and African descent [6–9].

It more commonly occurs in women, often between pregnancy and menopause, with a mean age of 34 [2]. Men may also develop this condition, and studies in India have reported that as many as 20.5–25.83% of melasma cases occur in males [10].

Although there are numerous etiologies implicated in the pathogenesis of melasma, the strongest contributor is exposure to sunlight [2]. Other contributory factors include pregnancy [11, 12], hormonal changes [2], use of oral contraceptives or hormone replacement therapy [13], thyroid disease [14], and family history of melasma, especially in those with darker skin types [2]. In males, the development of melasma has been attributed to subtle testicular resistance, resulting in low levels of testosterone [15].

The pathogenesis of melasma, regardless of the underlying etiology, is thought to be due to an increased number of melanocytes (melanocytosis) and increased melanin production (melanogenesis) within the skin as a result of alterations in gene expression and cellular signaling pathways [4, 16–18]. Melasma skin exhibits upregulation of genes involved in melanin biosynthesis and melanocyte markers, including TYR, MITF, SILV, and TYRP [18]. Increased vascularization due to elevated levels of vascular endothelial growth factor and downregulation of lipid metabolism genes have been implicated in its development and are important to consider when choosing an optimal therapy [17, 18].

Treatment Overview

The treatment of melasma often requires a multifaceted approach combining broad-spectrum photoprotection, sun avoidance, topical compounds, and, in refractory cases, chemical peels and laser/light therapy. Sunscreens with SPF 30+ and topical medications that target melanin production are first-line therapies. Hydroquinone and triple combination creams (TCC) containing hydroquinone, corticosteroids, and retinoids are the most commonly used topical therapies and are considered the gold standard of treatment due to their high efficacy [19–23]. For those who achieve insufficient response with topical therapy alone, additional improvements can be observed when combined with procedures such as chemical peels, light therapy, and laser treatments, which are typically considered to be second- and third-line [1, 19].

Chemical peeling is a safe and cost-effective procedure that aims to remove excess epidermal, and perhaps some dermal, pigment through controlled chemical injury followed by regeneration of the skin [20]. Typically, superficial peels are the most appropriate therapy for melasma, and medium-depth and deep peels should be used with caution or avoided altogether due to increased risk of dyschromia [21]. The peels most commonly used for melasma include glycolic acid (GA), salicylic acid (SA), and trichloroacetic acid (TCA) [1]. Other options include 1% tretinoin, Jessner's solution (salicylic acid, lactic acid, and resorcinol), and fruit peels. While published utilization data for chemical peeling agents are not available, expert opinion suggests that GA peels are the most frequently used peels for melasma worldwide.

Several lasers have also been studied in the treatment of melasma (Table 53.1). Melanin within the skin is targeted best at wavelengths of light ranging from 600 nm to 1100 nm, and, therefore, lasers that emit wavelengths within this range are often chosen for its treatment [22]. These lasers can be divided into the following categories based on their unique properties:

- Ablative non-fractionated lasers: 10,600 nm carbon dioxide (CO_2), 2940 nm erbium-doped yttrium aluminum garnet (Er:YAG) [*reported but not widely utilized in melasma due to high risk for adverse events; contraindicated in Fitzpatrick skin types IV–VI*]
- Fractional ablative lasers: 10,600 nm fractional CO_2, 2940 nm fractional Er:YAG
- Fractional non-ablative lasers: erbium (1410 nm, 1540 nm, 1550 nm), diode (1440 nm, 1927 nm), and thulium fiber (1927 nm)
- Quality-switched lasers:
  - Green light—frequency doubled quality-switched neodymium-doped yttrium aluminum garnet (FD QS-Nd:YAG or QSNYL) (532 nm)

Table 53.1 Laser and light therapies for the treatment of melasma

Author	Device	n	FST/Race	Treatment	Results	Side effects and recurrence
Ablative non-fractional lasers						
Nouri et al. [24]	950 μs pulsed CO_2 Open-label, 2 groups: 1. CO_2 laser alone 2. CO_2 + 2nd pass QSAL 755 nm	8	IV–VI	1 session **CO_2 laser** 300 mJ/cm^2 950 μs pulse **QSAL** 6 J/cm^2	Complete resolution of melasma in test spot at 6 months in combination group	Peripheral hyperpigmentation in 50% of subjects in CO_2 laser only group No recurrence at 6-month follow-up
Angsuwarangsee and Polnikorn [25]	Ultrapulse 950 ms CO_2 Prospective, split-face: 1. CO_2 laser plus QSAL 2. 750 nm QSAL alone	6	II–V	1 session **CO_2** 300–350 mJ/cm^2, 60 W, 8 mm OR collimated, 300 mJ, 5Ws, 3 mm **QSAL** 5–7 J/cm2, 5 Hz, 60 ns, 3 mm	MASI decreased in 83.3% of subjects on combined side versus 50% on QSAL side. MASI increased on QSAL side in 16.6%	Contact dermatitis and hyperpigmentation observed in combined group Severe PIH at 6-month follow-up in skin types V–VI
Manaloto and Alster [26]	Er:YAG 2940 nm	10	II–V	1 session Collimated 5.1–7.6 J/cm^2, 8 Hz, 5 mm, 3 passes	Mean MASI decreased from 19.1 at baseline to 10.6 at 6 months Melanin reflectance spectrometry score decreased from 48.8 at baseline to 43.6 at 6 months	PIH at 3–6 weeks' post-treatment with associated increase in MASI above baseline (100%)
Attwa et al. [23]	Er:YAG 2940 nm	15	II–IV	Monthly, 6 sessions 1.0 J, 5 Hz, 5 mm, 2 passes	Statistically significant decrease in MASI from 5.95 ± 3.3 before treatment to 2.47 ± 1.7 at 6-month follow-up Physician assessment demonstrated 50–100% improvement in 80% of subjects	Oozing and facial edema PIH at 2–4 weeks after last session (20%) Recurrence at 6-month follow-up in 33%
Ablative fractional lasers						
Diosti et al. [27]	Fractional Er:YAG	10	III–V	Monthly, 3 sessions 1400 mJ/P, 2 Hz, 7 × 7 tip, 3 passes	Change in MASI not statistically significant At 6-month follow-up, 70% of subjects reported subjective mild or moderate improvement in melasma Considerable reduction in melanin pigment in the basal layer in 70%	PIH (10%) Recurrence at 4-month follow-up in 40% of subjects

(continued)

Table 53.1 (continued)

Author	Device	n	FST/ Race	Treatment	Results	Side effects and recurrence
Trelles et al. [28]	Fractional CO_2 3 groups: 1. Anti-pigment cream 2. Fractional CO_2 laser 3. Fractional CO_2 laser + anti-pigment cream	30	II–IV	1 session 350 ms, 7.5 W	Subject self-assessment demonstrated 100% efficacy in all 3 groups at 1 month and 70% efficacy in combined group only at 10 months (0% efficacy in monotherapy groups)	Mild stinging, burning, erythema, crusts
Non-ablative fractional						
Naito [29]	1550 nm Er:glass	6	III–IV	Monthly, 3–4 sessions 6–8 mJ, 250 MTZs/ cm^2	At least 20% physician-graded improvement in melasma in all subjects	PIH (16.6%)
Wind et al. [30]	1550 nm Er:glass Single-blinded, split-face RCT: 1. 1550 nm Er:glass + TCC 2. TCC alone	18	II–V	4–5 sessions 15 mJ, 8 passes, 14–20% coverage	Physician global assessment, melanin index, and L-value showed a significant worsening of pigmentation at the laser-treated side Majority of patients preferred TCC at 6-month follow-up	Erythema, burning sensation, edema, and pain PIH after two or more laser sessions (31%)
Rokhsar and Fitzpatrick[31]	1550 nm Er:glass	10	III–V	Weekly or bimonthly 4–6 sessions 6–12 mJ 2000–3500 MTZ/cm^2	Physician-rated improvement of 75–100% in 6/10 subjects	PIH in FST V (10%)
Kroon et al. [32]	1550 nm Er:glass Observer-blinded RCT: 1. 1550 nm Er:glass 2. TCC	20	II–V	Bimonthly, 4 sessions 10 mJ, 2000–2500 MTZ/cm^2, 8 passes, 14–20% coverage	No objective difference in physician global assessment between groups Mean treatment satisfaction higher in laser group at 3-week follow-up	Erythema, burning sensation, facial edema, and pain No PIH or hypopigmentation Recurrence in 50% of subjects in each group at 6-month follow-up
Goldberg et al. [33]	1550 nm Er:glass	10	III–IV	Bimonthly, 4 sessions 6–10 mJ, 2000–2500 MTZ/cm^2	Good improvement (51–75% lightening) in FST III and fair improvement (26–50% lightening) in FST IV at 3 months Decreased melanocytes on light and electron microscopy	No PIH
Manela-Azulay and Borges [34]	1540 nm Er:glass	10	II–VI	Monthly, 3 sessions 8 mJ–15 mJ/MB, 15 ms, 5 mm	75–100% improvement in 29% and 50–75% in 71% of subjects who completed study	Second-degree burns (20%) and polymorphic light eruption (10%) No recurrence at 3 months

Tourlaki et al. [35]	1540 nm Er:glass	78	II–IV	Monthly, 3 sessions 15 mJ, 3600/4000 MTZs/cm^2, 15 ms, 15 mm spot, 4 passes, 50% overlap	Mean MASI significantly reduced compared to baseline at 1 month and 6 months' post-laser treatment	Transient edema and erythema No PIH Partial recurrence at 6-month follow-up
Polder and Bruce [36]	1927 nm fractionated thulium	14	II–IV	Monthly, 3–4 sessions 10–20 mJ, 6–8 passes	Statistically significant reduction in MASI at 1 month (51%), 3 months' (33%), and 6 months' (24%) post-treatment	Moderate erythema and mild edema No PIH Marginal recurrence at 6 months but improved from baseline
Brauer et al. [37]	1927 nm diode	23	I–IV, VI	Bimonthly, 4–6 sessions 5 mJ, 5–10% density, up to 8 passes	Investigator-rated marked or significant (51–100%) improvement in melasma in 40% of subjects and moderate improvement in 25–30% at 1 month and 3 months' post-treatment	Mild edema, mild-to-moderate erythema, flaking Transient perioral PIH (4.3%) No recurrence at 3 months
Quality-switched lasers						
Taylor and Anderson [38]	QSRL (694 nm)	4	II–VI	1–6 sessions 1.5–7.5 J/cm^2, 40 ns, 5 mm	No change in pigmentation or worsening of pigmentation in all patients No change in epidermal melanin on biopsy specimens at 2 months' post-treatment	Edema, erythema PIH (25%), confetti-like hypopigmentation (25%)
Tse et al. [39]	Frequency-doubled QS Nd:YAG and QSRL 2 test spots within the same lesion	3	NA	1 session	Subjects demonstrated no improvement in melasma with either laser	
Zhou et al. [40]	Low-fluence QS Nd:YAG	50	III–IV	Weekly, 9 sessions 2.5–3.4 J/cm^2, 10 Hz 6 mm spot	Mean MASI scores decreased 61.3% from baseline to end of study (10.6–4.1, $p < .001$). Mean decrease in MI was 35.8%	Burning sensation, erythema, urticaria, tiny purpura No PIH Recurrence rate of 64%
Brown et al. [41]	Low-fluence, large spot QS Nd:YAG	20	II–IV	Weekly, 8 sessions 2–4 J/cm^2 8–10 mm spot	19 out of 20 subjects demonstrated 25–100% lightening in melasma	Results maintained at 1-month follow-up Melasma flares seen at 3 months after last treatment

Table 53.1 (continued)

Author	Device	n	FST/ Race	Treatment	Results	Side effects and recurrence
Sim et al. [42]	Low-fluence QS Nd:YAG	50	Asian	Weekly, 15 sessions 2.8 J/cm2, 10 Hz, 8 mm	Based on physician assessment, 59% of subjects demonstrated good (50–75%) improvement and 42% demonstrated excellent (75–100%) improvement	Erythema, transient burning, mild edema No PIH or hypopigmentation
Wattanakrai et al. [43]	Low-fluence QS Nd:YAG Split-face, investigator-blinded RCT: 1. QS Nd:YAG laser +2% HQ 2. 2% HQ	22	II–V	Weekly, 5 sessions 3–3.8 J/cm^2, 6 mm	92.5% improvement in relative lightness and 75.9% improvement in mMASI in laser group vs. 19.7% and 24% improvement, respectively, in HQ-only group	Mottled hypopigmentation (13.6%) and rebound hyperpigmentation (18%) on laser-treated side At least partial recurrence in all subjects at 12-week follow-up
Jeong et al. [44]	Low-dose QS Nd:YAG Split-face, crossover, RCT: 1. TCC then QS Nd:YAG 2. QS Nd:YAG then TCC	13	III–IV	Weekly, 8 sessions 1.6–2.0 J/cm^2, 7 mm, 2 passes	Mean MASI decreased significantly after laser treatment compared with TCC cream Side 1: mean MASI improved from 3.42 to 3.0 after TCC cream and to 2.09 after 8 weeks of laser Side B: mean MASI score decreased from 3.20 to 1.74 after laser and increased to 2.22 with TCC	Mild pain and erythema. No PIH or hypopigmentation Relapse seen in 85% at 11-month follow-up
Vachiramon [45]	Low-fluence QS Nd:YAG Split-face, investigator-blinded, RCT: 1. QS Nd:YAG 2. QS Nd:YAG +30% GA peel	15	III–V	Weekly, 5 sessions 2.2–2.8 J/cm^2, 10 Hz, 6 mm	52.3% improvement in mean RLI and 37.6% decrease in MASI at 4-week follow-up in combination group (vs. 37.6% and 14.6% reduction, respectively, in laser monotherapy group)	Burning, stinging, erythema, edema Guttate hypopigmentation (8%), PIH (17%) Rebound increase in RLI and mMASI score, but not complete relapse, at 16-week follow-up
Polnikorn [46]	QS Nd:YAG	35	NA	Weekly, 10 sessions followed by monthly, 2 sessions 3–3.4 J/cm^2, 10 Hz, 6 mm, 10 passes, 10% overlap	After 6 months of treatment, 30% of subjects demonstrated excellent clearance (>81% reduction of melasma) and 36.7% demonstrated good clearance (51–80% reduction)	Discomfort, erythema, whitening of fine hair, urticaria Mottled hypopigmentation (8.57%) Recurrence of melasma in 5.71% at study completion

Kang et al. [18]	Dual-toning QS Nd:YAG	30	IV	Bimonthly QS mode: 1.2 J/cm^2, 5 ns, 8 mm, multiple passes Micropulsed mode: 7 J/cm^2, 300 μs, 5 mm, multiple passes	67% of subjects with fair to excellent improvement, 23% with visible improvement, and 10% with little or no improvement	Erythema, stinging No recurrence at 6-week follow-up
Yue et al. [47]	Fractional-mode QS Nd:YAG	30	III–IV	Bimonthly, 8 sessions 2.6–3.6 J/cm^2, 8.5 mm, 42.4% coverage	Mean MASI decreased from 12.84 to 7.29, and mean MI decreased from 56.52 to 32.75 after treatment	Slight burning, tingling, and erythema No PIH or hypopigmentation Partial recurrence in 40% patients at 3 months and 82.4% at 6 months after last treatment
Kim et al. [48]	Low-fluence photoacoustic twin pulse (PTP) mode Nd:YAG	22	III–IV	Bimonthly, 5 sessions 2.5 J/cm^2, 7 mm, 5–7 passes	Significant improvement in melasma in 59.1% of subjects based on physician assessment and 86.4% based on subject assessment Mean MASI scores decreased by 20.4%	Erythema, dryness, pain, and itching No PIH or hypopigmentation Partial relapse in 18%
Jang et al. [49]	Low-dose fractional QSRL (694 nm)	15	III–IV	Bimonthly, 6 sessions 2–3 J/cm^2, 40 ns, 7.1 mm, 300 μm, 27.7% coverage	MASI decreased from 15.1 ± 3.3 before treatment to 10.6 ± 3.9 at 16 weeks	Transient erythema, mild pain Slight increase in MASI between 4 and 16 weeks' post-treatment
Picosecond lasers						
Choi et al. [50]	Picosecond Nd: YAG (1064 nm and 595 nm) Split-face, unblinded RCT: 1. Picosecond +2% HQ 2. 2% HQ	40	III–V	Weekly, 5 sessions **1064 nm** 1.5 J/cm^2, 5 or 10 Hz, 7–10 mm, 2–4 passes **595 nm** 0.55 J/cm^2, 2 or 5 Hz, 750 ps, 5 mm	At 1 week post-treatment, RLI decreased by 76.92% in the laser group and 2.56% in the HQ group. There was greater improvement in mMASI and better treatment satisfaction in the laser group at this time point Only RLI remained significantly improved on the laser-treated vs. HQ side at 12-week follow-up	Mild dermatitis, pain, and erythema

Table 53.1 (continued)

Author	Device	n	FST/ Race	Treatment	Results	Side effects and recurrence
PDL						
Passeron et al. [51]	PDL (595 nm) Single-blind, split-face, RCT: 1. PDL + TCC 2. TCC	17	II–IV	Every 3 weeks, 3 sessions 1st pass: 7 J/cm^2, 1.5 ms, 10 mm 2nd pass: 10 J/cm^2, 20 ms, 7 mm, 10% overlap	In the entire cohort, there was a greater decrease in MASI in the PDL group (6.20 ± 3.02–2.79 ± 2.70) vs. TCC only group (6.76 ± 3.25–4.35 ± 2.76). When stratified by FST, patients with FST II–III demonstrated significantly greater improvement with PDL + TCC. There was no difference in treatment response for FST IV	Transient irritation from TCC PIH only in FST IV (18%)
IPL						
Bae et al. [52]	Low-fluence, short-pulse IPL (550 nm–800 nm) Double-blinded RCT: 1. IPL with 10 J/cm^2 fluence 2. IPL with 13 J/cm^2 fluence	20	IV–V	Weekly, 6 sessions 10 J/cm^2 or 13 J/cm^2, 70 μs, 2 passes	Statistically significant decrease in MASI and MI compared to baseline at weeks 2–9 in both groups Slightly greater numeric improvement in melasma with 13 J, but this was not statistically significant	Transient erythema, burning
Figueiredo Souza and Trancoso Souza [53]	IPL (560 nm) Evaluator-blinded, open-label, RCT: 1. IPL + TCC 2. TCC alone.	62	II–V	1 session 12–22 J	49.4% reduction in MASI at 6 months and 44.9% at 12 months in IPL + TCC group Significantly better response in the IPL + TCC group than TCC alone	Pain, microcrusts, mild transient erythema PIH (25%)
Goldman et al. [54]	IPL (560 nm) Split-face RCT: 1. IPL + TCC 2. IPL + inactive cream	56	I–IV	Monthly, 2 sessions 14–18 J/cm^2, 3.0–3.5 ms, 2 pulses, delay of 20 ms (II) or 30 ms (III–IV)	Physician-rated improvement of clear or almost clear in 57% of patients with IPL plus TCC vs. 23% with inactive cream	Skin erosion, erythema, scaling, dryness, burning, edema, telangiectasia
Wang et al. [55]	IPL (570 nm–615 nm) RCT, 2 groups: 1. IPL + 4% HQ 2. 4% HQ	17	III–IV	Monthly, 4 sessions 26–33 J/cm^2, 3–5 ms, 2 pulses, 30–35 ms delay	39.8% improvement in relative MI in IPL + HQ group (vs. 11.6% in HQ group) at week 16 35% of patients had >50% improvement in melasma severity	Erythema, microcrusts, pain PIH (12%) Recurrence in 2 patients in IPL group at 24 weeks' post-treatment
Li et al. [56]	IPL	89	III–IV	Every 3 weeks, 4 sessions	Mean MASI decreased from 15.2 to 4.5 Investigator evaluation demonstrated 75.3% improvement after 4 sessions and 77.5% improvement at 3-month follow-up	Transient erythema, slight edema, microcrusts PIH (4.5%)

Chung et al. [57]	IPL Split-face RCT: 1. IPL + topical 2% tranexamic acid (TA) 2. IPL + vehicle	13	NA	Monthly, 4 sessions 8.0–9.4 J/cm^2 2.5 ms Double pulse 10 ms pulse delay	MI and mMASI decreased significantly from baseline to 12 weeks after the last IPL treatment on the topical TA side only	Rebound prevented by continued TA use at 3-month follow-up
Chung [58]	Pulse in pulse (PIP) IPL (550–800 nm) Split-face RCT: 1. PIP IPL 2. IPL + low-fluence QS-Nd:YAG (IPL/NDY)			Group 1: **IPL** Bimonthly, 7 sessions 12–15 J/cm^2, 2–3 passes Group 2: **IPL** 1 session 9.0–9.4 J/cm^2, 2.5 ms double pulse, 10 ms delay, 1 pass **Nd:YAG** Bimonthly, 6 sessions 1.0–1.2 J/cm^2, 10 ns, 8 mm, multiple passes	54.4% vs. 50.0% reduction in mMASI score in the PIP-IPL and IPL/NDY treatment groups, respectively, at 2 weeks after last treatment	No significant recurrence of melasma at 6 months' post-treatment

n number of patients, *FST* Fitzpatrick skin type, CO_2 carbon dioxide, *QSAL* q-switched alexandrite laser, *MASI* melasma area and severity index, *mMASI* modified melasma area and severity index, *PIH* post-inflammatory hyperpigmentation, *Er:YAG* erbium:yttrium aluminum garnet, *Er:glass* erbium:glass, *TCC* triple combination cream, *RCT* randomized controlled trial, *QSRL* Q-switched ruby laser, *QS Nd:YAG* q-switched neodymium-doped yttrium aluminum garnet, *HQ* hydroquinone, *GA* glycolic acid, *RLI* relative lightness index, *PDL* pulsed dye laser, *IPL* intense pulsed light, *TA* tranexamic acid

  - Red light—quality-switched ruby (QSRL) (694 nm), quality-switched alexandrite (QSAL) (755 nm)
  - Near-infrared—quality-switched neodymium-doped yttrium aluminum garnet (QS-Nd:YAG or QSNYL) (1064 nm)
- Picosecond laser (532 nm Nd:YAG, 755 nm alexandrite, 1064 nm Nd:YAG)
- Pulsed dye laser (PDL) (595 nm)

Ablative lasers emit a high wavelength that targets water and, through indirect tissue vaporization, reduces the number of melanocytes and overall melanin content within the epidermis and dermis [23]. These are not widely utilized in the treatment of melasma due to considerable recovery periods and a high risk of dyspigmentation or scarring, especially in higher Fitzpatrick skin types. Fractional resurfacing using non-ablative fractional lasers is a newer technology that, rather than causing full-thickness epidermal wounds, creates microscopic treatment zones (MTZs) that result in a reduction in melanocytes and number of melanin granules in keratinocytes without as much inflammation and pigmentary sequelae [33]. Quality-switched lasers, also referred to as "laser toning" devices, use photoacoustic and photothermolytic effects to destroy melanosomes [22]. Multiple passes of a low-fluence laser (i.e., 1.6–3.5 J/cm^2) over a large spot size (i.e., 6–8 mm) optimize energy delivery while minimizing tissue damage [22, 42]. Pulsed dye lasers (PDLs) are preferentially absorbed by hemoglobin within cutaneous vessels, thereby allowing this laser to target the vascular component of melasma [51]. Picosecond lasers are a newer class of lasers that use shorter pulse durations, which results in a greater photoacoustic (rather than photothermolytic) effect and thereby minimizes thermal injury to adjacent tissue [59, 60].

Intense pulsed light, a spectrum of light ranging from 500 to 1200 nm applied over a long pulse width (milliseconds), is another treatment option for melasma [52]. Research on monopolar radiofrequency devices [61] and light-emitting diodes (LED) [62] is limited, and, therefore, these modalities will not be addressed in this chapter. The most widely used energy-based devices for melasma are non-ablative fractional lasers (especially the 1927 nm wavelength), QSNYL, and IPL.

Effectiveness of Treatments

Fractional Resurfacing

Fractional resurfacing is currently the only FDA-approved laser treatment for melasma and, therefore, is widely used for this indication. Yet research on these lasers has yielded mixed results, with some studies even suggesting that TCC may be superior (2b) [30, 31, 34].

An early pilot study using 1550 nm Er:glass laser without hydroquinone pretreatment demonstrated 75–100% clearing of melasma in six out of ten patients after 4–6 treatments, although long-term follow-up was lacking (2b) [31]. Subsequent small observational studies demonstrated between 20% and 75% improvement in melasma in all subjects, with better results seen in those with skin type III as opposed to darker phototypes (2b) [29, 33].

A pilot study of 1540 nm Er:glass laser alone in ten subjects with FST II–VI showed at least 50% improvement in all who completed the study, although two subjects withdrew due to second-degree burns (2b) [34]. A larger trial studying 1540 nm plus TCC in Indian females demonstrated > 50% improvement in 46 out of 76 subjects at 1 month post-treatment and only 16 out of 76 at 6 months [35].

Similarly, 1927 nm thulium and 1927 nm diode lasers have been shown to result in at least 50% improvement in almost half of individuals treated with laser alone, with a statistically significant 51% reduction in MASI at 1 month post-treatment (2b) [36, 37]. Brauer et al. found no relapse at 3 months post-treatment with 1927 nm diode, while Polder et al. found a marginal increase in severity at 3 and 6 months post-treatment with the thulium laser, although melasma remained improved from baseline [36, 37].

Interestingly, randomized controlled trials comparing fractional laser (+/− concurrent TCC) to TCC alone have failed to demonstrate superi-

ority of laser therapy (1b) [30, 32, 63]. Wind et al. performed a split-face study of 1550 nm plus TCC versus TCC alone and found relative worsening of hyperpigmentation on the laser-treated side compared to the topical therapy side [30]. After two or more laser sessions, 31% of the patients developed post-inflammatory hyperpigmentation (PIH). Although treatment density (rather than fluence) of fractional lasers is most closely related to the development of PIH, the authors attributed the high rate of PIH to the use of high fluence in combination with springtime treatment (and subsequent high sun exposure) [64]. Kroon et al. randomized patients to either 1550 nm laser or TCC and found no difference in physician global assessment between the two groups [32]. Nonetheless, mean treatment satisfaction was higher in the laser group at 3-week follow-up [32].

Data on the frequency of relapse after treatment success with fractional resurfacing is inconsistent. Overall, there appears to be partial recurrence by 6-month follow-up, although often patients maintain some benefits of laser therapy at this time point [32, 35, 36].

Ablative Lasers

There are few studies evaluating the efficacy of ablative lasers in the treatment of melasma, and those that exist are limited by small sample sizes. Initial studies using 10,600 nm CO_2 laser plus Kligman's formula to treat dermal melasma demonstrated complete resolution of melasma within a test spot in all subjects. No recurrence was seen at 6-month follow-up; however, 75% of the subjects experienced either post-inflammatory hypo- or hyperpigmentation (level 4) [24]. The small sample size (four subjects) and small test spot treated limit the quality of these results. A high risk of PIH at 3–6 weeks' post-treatment has also been observed with Er:YAG 2940 nm lasers [23, 26]. One case series of ten females demonstrated that, after just one laser treatment, mean MASI decreased from 19.1 at baseline to 10.6 at 6 months, although MASI increased to >20 at weeks 3 through 6 due to the occurrence of PIH (2b) [26]. A recent observational study similarly showed a statistically significant decrease in MASI at 6-month follow-up, with 50–100% improvement in the majority of subjects; however, recurrence was seen in 33.3% (2b) [23].

Fractional Er:YAG and CO_2 lasers appear to have limited efficacy in the treatment of melasma, albeit mitigating the risk of PIH compared to traditional ablative lasers. A study of fractional Er:YAG in ten patients with FST III–V demonstrated mild-to-moderate clinical improvement in 70% of patients, although the reduction in MASI score was not statistically significant. PIH was observed in one out of ten subjects (2b) [27]. Trelles et al. demonstrated 90% efficacy of fractional CO_2 laser in achieving good-to-excellent results at 1 month post-treatment in skin types II–IV; yet all results were lost at the 10-month follow-up (1b) [28]. Nonetheless, use of fractional CO_2 laser in combination with anti-pigment cream was associated with 80% efficacy at 10 months' post-treatment, and the results were maintained at 12-month follow-up. Of the 30 females studied, none developed PIH [28].

A retrospective study of 48 Koreans treated with fractional long-pulsed alexandrite laser was associated with 42.7% improvement in epidermal melasma and 16.5% improvement in dermal melasma (2b) [65].

Quality-Switched Lasers

Quality-switched lasers, particularly QSNYL, are the most commonly used lasers for the treatment of melasma [66]. Initial observational studies using QSRL (694 nm) and QSNYL (1064 nm or 532 nm) in the treatment of melasma demonstrated unchanged or worsening pigmentation (2b) [38, 39]. A significant risk of PIH and hypopigmentation was observed, especially with the use of high fluences [38].

More recently it has been suggested that repetitive subthreshold-pulsed 1064 nm QSNYL is more effective in the treatment of refractory melasma than traditional Q-switched lasers (level 4) [67]. Zhou et al. studied the use of low-fluence QSNYL in 50 patients with skin types III–IV and

demonstrated a mean decrease in MASI of 61.3% after nine weekly treatments (2b) [40]. Brown et al. observed 25–100% lightening of melasma in 19 out of 20 subjects after 8 weekly treatments (2b) [41]. In a cohort of 50 Asians, 42% demonstrated excellent (75–100%) improvement and 59% demonstrated good (50–75%) improvement in melasma based on physician assessment after 15 weekly treatments (2b) [42]. Research on low-fluence photoacoustic twin pulse (PTP) mode, dual-toning QSNYL, and fractional mode QSNYL has also indicated positive results (2b) [18, 47, 48].

Randomized, controlled studies have shown that combined low-fluence QSNYL and topical therapy (hydroquinone and TCC) is more effective than topical therapy alone (1b) [43, 44]. It is typically believed that laser therapy plus topical therapy is superior to laser alone, although studies to prove this are needed.

Data on the use of QSRL in melasma is lacking, although a recent study in 15 Korean patients showed promising results (2b) [49]. After treatment with low-dose, fractional QSRL, mean MASI decreased significantly from baseline to week 16 (15.1 ± 3.3–10.6 ± 3.9), with the lowest MASI observed at 4 weeks' post-treatment (2b) [49]. A retrospective study of 25 Caucasians with FST I–III treated with QSRL showed a 72.3% reduction in MASI after 1–3 treatments; however, PIH and recurrent melasma occurred in 28% and 44% of patients, respectively, at 3-month follow-up (2b) [68].

While Q-switched lasers appear to be effective in reducing melasma severity, prior studies suggest that optimal results only can be expected to be maintained for approximately 4–6 months' post-treatment [18, 41]. Most studies have demonstrated at least partial relapse of melasma by 12 weeks' post-treatment [40, 43, 45, 47, 49], with approximately 80% relapse after 6–11 months [44, 47].

Picosecond Laser

Picosecond lasers are being used increasingly for the treatment of pigmentary disorders, including melasma, and have been shown to be efficacious and safe, even in highly pigmented skin [50, 69–71]. A recent split-face, randomized controlled trial of dual-wavelength picosecond laser (1064 and 595 nm) plus topical hydroquinone 2% versus hydroquinone monotherapy in 40 Korean females (FST III–IV) demonstrated the superiority of combination picosecond laser therapy [50]. One week after final laser treatment, there was greater than 50% improvement in melasma in 76.92% of the subjects on the laser-treated side versus 2.56% on the topical-only side. There was a significant improvement in mMASI and relative lightness index (RLI) on the laser-treated (compared to topical only) at 1 week post-treatment, and RLI continued to be significantly improved at 12-week follow-up. The rate of melasma recurrence was similar on both sides of the face [50].

Pulsed Dye laser

Pulsed dye lasers (PDLs), which target the vascular component of melasma, have been shown to be effective in reducing melasma severity and recurrence [51, 72]. Passeron et al. conducted a randomized, single-blind, split-face clinical trial of PDL plus TCC versus TCC alone in 18 white women (FST II–IV). They found that PDL plus TCC was beneficial in treating melasma in skin types II and III, but not skin type IV given that 50% of subjects with FST IV developed PIH [51]. A later case report of a woman enrolled in the aforementioned study suggested that, in addition to reducing melasma severity, PDL may also help minimize rebound of melasma within the treated areas [51]. Further studies of PDL in the treatment of melasma, particularly in darker skin types, are needed to quantify the degree of improvement that can be expected with the use of vascular-targeting therapies.

IPL

Conventional IPL is thought to have a limited effect on melasma [56]. Low-fluence and short-

pulse duration IPL, however, appears to be more effective [52, 56]. In one study, treatment with IPL was associated with a 77.5% improvement in melasma severity at 3 months' post-treatment without concurrent use of anti-pigment cream (2b) [56]. Bae et al. evaluated 20 Korean subjects with FST IV–V and demonstrated moderate to marked improvement in 55% of the subjects treated with 10 J and in 65% of the subjects treated with 13 J; the difference in improvement between the fluences was not statistically significant (1b) [52].

The efficacy of IPL appears to be increased when combined with hydroquinone, TCC, or topical tranexamic acid (1b–2b) [53–55, 57]. One randomized, split-face study of IPL plus TCC versus IPL plus inactive cream demonstrated physician-rated improvement of clear or almost clear in 57% who received TCC as compared to 23% who received inactive cream (1b) [54]. In another split-face study, Chung et al. demonstrated a statistically significant decrease in mMASI (14.77–9.38) on the side treated with IPL plus topical tranexamic acid, but no statistically significant change on the IPL plus vehicle side (1b) [58]. The use of topical tranexamic acid following IPL was also thought to help prevent rebound of melasma at 3-month follow-up [53, 57]. Figueiredo et al. demonstrated maintenance of IPL results at 12 months' post-treatment (MASI reduction of 49.4% at 6 months and 44.9% at 12 months) with continued use of TCC [53].

The response to IPL is better in subjects with epidermal melasma (rather than dermal) and those without forehead involvement; frontal and malar melasma do not appear to respond as well to IPL (2b, 1b) [53, 55].

Chemical Peels

The majority of research on chemical peels in melasma has focused on Glycolic Acid (GA) peels (Table 53.2). Javaheri et al. evaluated the efficacy of 50% GA peel plus nightly 10% GA in the treatment of 25 Indian females with epidermal and mixed melasma and demonstrated improvement in MASI in 90% of the subjects (2b) [74]. Average MASI decrease was 46.7% in epidermal-type and 27.8% in mixed-type melasma [74]. Rendon et al. similarly showed improvement in 90% of subjects treated with GA peel plus TCC at 12 weeks, with 65% rated as clear or almost clear (2b) [79].

Randomized controlled trials and observational studies have evaluated GA peels following or in conjunction with hydroquinone, topical GA, TCC, modified Kligman's formula, azelaic acid, and adapalene. Several studies suggest that serial 20–70% GA peels plus topical therapy are superior to topical therapy alone [73, 75, 78]. However, one prospective, split-face study showed no significant difference between combined peel and 4% hydroquinone versus hydroquinone alone (2b) [76]. A single-blind, split-face, randomized controlled trial of ten Asian females showed greater improvement in melasma and fine wrinkling with the use of 20–70% GA peel plus topical 10% GA/2% hydroquinone than topical therapy alone (1b) [73]. Although it is difficult to compare the relative efficacy of these combinations due to differences in study design, it can be concluded that the use of pre- and post-peel topical lightening agents enhances the efficacy of GA peels and decreases the risk of post-treatment pigmentary sequelae [73, 78].

Based on current data, one could expect to see an improvement in melasma in approximately 90% of subjects treated with GA peels and skin lightening agents (2b) [74, 79, 80] with improvement in MASI ranging from 46.7% to 79.99% (1b) [78, 83]. Some suggest that the efficacy of GA is inversely proportional to the duration of disease (1b) [84], while others have found no effect of age of onset and duration of melasma on treatment response [74]. One author suggests that a minimum of four chemical peels should be performed before pursuing a different peel or therapeutic modality (level 5) [21]. Few studies have reported on recurrence of melasma after chemical peel, although one study demonstrated relapse in 5.9% of patients at 3-month follow-up [84].

GA peels are most effective for epidermal melasma, followed by mixed-type, and are unlikely to have effect in dermal melasma (2b) [74, 77]. Although concentrations of 20–30%

Table 53.2 Studies evaluating glycolic acid and salicylic acid chemical peels in melasma

Author	Study design/ treatment	Concentration and regimen	n	FST/ race	Results	Side effects and recurrence
Glycolic acid						
Lim and Tham [73]	Single-blind, split-face 1. GA peel +10% GA + 2% HQ 2. 10% GA + 2% HQ BID	20–70% GA 4–5 min Every 3 weeks 8 treatments	10	IV–V Asian	Greater improvement in melasma and fine facial wrinkling on peel side ($p = 0.06$) 60% lightening on peel side in 4/10 vs. 1/10 on topical only side	Stinging Redness Burning Transient hyperpigmentation
Javaheri et al. [74]	Observational GA peel + 10% GA	50% GA 2–5 min Monthly 3 treatments	25	Indian	MASI improved in 90% of patients Average decrease in MASI was 46.7% in epidermal-type melasma vs. 27.8% in mixed-type	Mild hyperpigmentation (1/25)
Sarkar et al. [75]	Open-label, pilot 1. GA peel + modified Kligman's (2% HQ, 0.05% tretinoin, 1% hydrocortisone) 2. Modified Kligman's	30–40% GA 1–3 min Every 3 weeks 6 treatments	40	III–V Indian	Greater decrease in MASI score at 12 and 21 weeks in combined group (week 21: 79.99% vs 63.14%, $p < .01$)	Mild cutaneous erythema and burning Superficial desquamation Persistent erythema (10%) Superficial vesiculation PIH (10%)
Hurley et al. [76]	Single-blind, split-face 1. GA peel + 4% HQ 2. 4% HQ	20–30% GA 3–5 min Bimonthly 4 treatments	21	IV–V Hispanic	Decrease in MASI and lightening of pigmentation in both groups. No significant difference between peel + HQ versus HQ alone	Significant erythema (4/21)
Grover and Reddu [77]	Observational GA peel + tretinoin 0.025%	10–30% GA Bimonthly 7 treatments	15	III–V	Good to fair response in patients with epidermal and mixed melasma. No significant improvement in dermal melasma	Mild discomfort and irritation of skin PIH (13.2%) GA-induced hypopigmentation (6.7%)
Erbil et al. [78]	Randomized, single-blind 1. GA peel + azelaic acid + adapalene 2. Azelaic acid 20% BID + adapalene 0.1% QD	20%–70% GA 3–5 min Bimonthly 8 treatments	28	NA	83.08% decrease in MASI in peel group vs. 69.34% decrease in MASI in control group Better results when GA concentration is >50%	Moderate-to-severe epidermolysis with PIH (10.7%)
Rendon et al. [79]	Pilot GA + TCC (fluocinolone acetonide 0.01%, HQ 4%, and tretinoin 0.05%)	Bimonthly 5 treatments	20	II–VI	Hyperpigmentation significantly reduced on spectrophotometric measurement, with 65% of subjects rated as clear or almost clear at 12 weeks 90% of subjects showed improvement by 12 weeks	Erythema Desquamation Pruritus Burning sensation

Table 53.2 (continued)

Author	Study design/ treatment	Concentration and regimen	n	FST/ race	Results	Side effects and recurrence
Godse and Sakhia [80]	Observational study GA peel + TCC (tretinoin 0.05%, HQ 4%, mometasone furoate 0.1%)	57% GA 2–6 min Every 3 weeks 4 treatments	20	IV–V Indian	Significant reduction in melasma with 50% physician-rated improvement in 10/20 subjects and 75% improvement in 3/20	Irritation and hyperpigmentation (5%)
Salicylic Acid						
Kodali et al. [81]	Single-blinded, split- face 1. SA peel + 4% HQ 2. 4% HQ	SA 20–30% 4–5 min Bimonthly 4 treatments	20	III–V Hispanic	No statistically significant difference in MASI improvement or melasma severity between the 2 groups	Erythema Burning Peeling
Grimes [82]	Observational SA peel + 4% HQ	20–30% SA Bimonthly 5 treatments	6*	V–VI African American/Hispanic	Moderate to significant improvement in melasma in 66% of patients	Temporary crusting Hypopigmentation Transient PIH

n number of subjects, *FST* Fitzpatrick skin type, *GA* glycolic acid, *HQ* hydroquinone, *MASI* melasma area and severity index, *TCC* triple combination cream, *PIH* post-inflammatory hyperpigmentation, *SA* salicylic acid
*6 out of 25 patients studied had a diagnosis of melasma

should be used initially, 50–70% GA is most effective in decreasing the severity of melasma [73, 74, 76, 78]. In this author's experience (AFA), patients will typically demonstrate improvement by the third or fourth peel; patients who do not respond by the fourth peel are unlikely to demonstrate a clinically meaningful response [74].

Data on the use of salicylic acid (SA) peels in the treatment of melasma is limited [1, 85]. One study suggests that peels containing 20–30% SA within an ethanol base are effective when used in conjunction with daily application of hydroquinone 4% cream (2b) [82]. However, a subsequent single-blinded, split-face study comparing combination SA peel and 4% hydroquinone to hydroquinone alone showed no statistically significant difference in MASI or spectrophotometer-measured hyperpigmentation between the two groups (1b) [81].

It is important to note that many of the studies on chemical peels have been performed in Indian populations, which may limit the applicability of the results to other skin types, particularly darker-skinned individuals of African descent [74, 75, 77, 80, 83, 84]. Several studies have been performed in Hispanic and Middle Eastern populations [78, 79, 81].

Other Procedures

Tranexamic acid (TA) microinjections and microneedling have recently been studied in the treatment of melasma. A randomized, open-label, split-face study in 60 dark-skinned patients with moderate-to-severe melasma demonstrated 38% and 44% improvement in MASI scores with the use of TA microinjections and microneedling followed by topical TA (Dermaroller MS4), respectively (1b) [86]. No adverse events were reported in this study. Another split-face study of rucinol and sophora-alpha depigmentation serum with and without microneedling in office (Dermaroller CIT 8) and at home (Dermaroller C8) demonstrated greater improvement in MASI with the use of a microneedling device (1b) [87]. Microneedling (Dr. Roller®) followed by daily TCC and sunscreen has also demonstrated good results with the maintenance of skin lightening at 24 months in all patients who followed up at this time point (11/22 subjects) (level 4) [88].

Comparative Effectiveness of Common Treatments

Relative Effectiveness of Lasers

Due to the limited number of studies comparing laser modalities, it is difficult to develop strong evidence-based conclusions regarding the relative efficacy of different lasers. Additional randomized controlled trials, particularly split-face studies, are needed to further evaluate this question. Relevant studies are discussed below.

A randomized, split-face study of QSNYL versus QSRL demonstrated a clinical decrease in melasma severity in both treatment groups, with faster recurrence of melasma on the QSRL side (1b) [89]. Histological examination of biopsy specimens taken from skin treated with each laser suggested that QSNYL leads to a decrease in the number of melanin granules without significantly altering the cellular architecture, whereas QSRL induces greater epidermal and dermal damage that may contribute to subsequent melanogenesis [89]. Omi et al. concluded that QSNYL yields superior results with a longer recurrence-free interval [89].

A randomized, investigator-blinded, split-face study comparing low-fluence QSNYL and low-fluence QSAL in 20 subjects with FST I–IV demonstrated no difference in mMASI or subjective patient assessment between the two sides, although it is important to note the absence of skin types V–VI in this study (1b) [90].

A single RCT of 40 females with symmetric melasma suggested the superiority of low-power fractional CO_2 laser over low-fluence QSNYL. Based on patient self-assessment, there was complete improvement in 62.5% and 15% of patients treated with fractional CO_2 laser and QSNYL, respectively. At 2 months' post-treatment, the reductions in MI and mMASI score were significantly greater on the side treated with fractional CO_2 laser for subjects with both epidermal and dermal melasma (1b) [91]. The incidence of side effects was equal on both sides, and there were no cases of post-inflammatory hypo- or hyperpigmentation [91].

Several studies have also suggested that the combination of certain lasers may be superior to laser monotherapy. Early research on CO_2 lasers in melasma demonstrated the superior efficacy of combination CO_2 laser plus 750 nm QSAL. More specifically, CO_2 laser followed by 750 nm QSAL appeared to be more effective than either laser alone without additional risk of post-inflammatory dyspigmentation or other side effects (2b) [24, 25]. This has been attributed to the fact that, in addition to destroying hyperactive melanocytes, the CO_2 laser removes the epidermis, allowing for better activity of the QSAL on remaining, deeper dermal pigment [25]. It is important to note that CO_2 lasers are not suitable for treating melasma in FST IV–VI due to a high risk of pigmentary complications in this population. A report of two cases also suggests that a combination of fractional 2940 nm followed by 1064 nm QSNYL leads to rapid improvement in melasma with sustained results at 6-month follow-up; however, larger studies involving a broad range of skin types are needed to confirm this (level 4) [92]. Treatment with PDL followed immediately by 1927 nm fractional diode laser was suggested to be effective in a single case report [72]. While the synergistic targeting of vascular and melanin components is compelling, further research is needed to confirm the efficacy and safety of combined treatment (level 4). Current evidence does not support the combination of QSNYL plus 1550 nm, as one study demonstrated no substantial benefit over the use of QSNYL alone (1b) [93].

Relative Efficacy of Lasers Versus Chemical Peels

Although there are few direct comparison studies of lasers and chemical peels, overall the literature suggests that the efficacy is similar between the two treatments [94–96]. A split-face study in Asian women showed no difference in outcome, adverse events, or recurrence rate between 1550 nm fractional thermolysis and 15% TCA chemical peel (1b) [94]. Another study randomly

assigned 75 Indian patients to either high-fluence QSNYL, low-fluence QSNYL, or 30–75% GA peel and found that improvement of melasma was best in the low-fluence QSNYL group, followed closely by the GA group (1b) [95]. The low-fluence laser also was associated with a lower risk of erythema, burning, and PIH [95]. Unfortunately, MASI scores increased in all groups at week 12. Lastly, a study of 30 patients treated with either 1550 nm Er:glass or 70% GA peel demonstrated equivalent improvement in melasma with both procedures. Recurrence was seen in the majority of patients at 6-month follow-up regardless of treatment group (2b) [96].

Combination of Lasers and Chemical Peels

Two studies have suggested that low-fluence QSNYL in combination with 30% GA peels may be more effective than laser therapy alone (1b) [45, 97]. Vachiramon et al. demonstrated a 52.3% improvement in mean RLI and 37.6% decrease in MASI at 4-week follow-up in men treated with monthly laser and weekly chemical peels, as compared to 37.6% decrease in mean RLI and 14.6% reduction in MASI with laser monotherapy [45]. Park et al. performed a randomized, split-face study in which they studied six weekly sessions of QSNYL on the entire face and three biweekly sessions of 30% GA on just one side. The combined therapy side demonstrated an average improvement in MASI of 37.4% as compared to 16.7% on the laser-only side [97]. It is important to note the use of 30% GA in these studies, which is lower than the 50–70% concentration typically used for monotherapy.

Combination of Lasers and IPL

In a study of Chinese patients with melasma, the combination of three successive sessions of QSRL followed by one session of IPL was shown to result in mild-to-moderate improvement of melasma in 73.6% of Chinese patients, with significant decrease in mean MASI from 14.66 to 5.70 after treatment (2b) [98]. One IPL treatment followed by four weekly sessions of low-fluence QSNYL was associated with a 59.35% improvement in MASI in patients with mixed-type melasma in one retrospective review (2b) [100]. A randomized, split-face study of 18 subjects treated with QSNYL (five weekly treatments) and IPL (three biweekly treatments) or QSNYL alone demonstrated more rapid improvement in mMASI and relative lightness on the combined side. However, recurrence was more frequent on the combined side (33%) than the monotherapy side (11%) at 12-week follow-up (1b) [46].

Combination of Lasers and Other Procedures

A study of 26 patients treated with fractional QSRL (4–6 treatments) and sonophoresis with vitamin C demonstrated a 35% decrease in MASI at 3 months' post-treatment (2b) [101]. A split-face study of QSNYL plus ultrasonic application of vitamin C versus laser therapy alone showed better fading of melasma with combined therapy (60–80% versus 40–60% improvement, respectively) (2b) [102]. A retrospective study of QSNYL followed by vitamin C sonophoresis similarly showed excellent outcomes in 91.3% of patients treated (1b) [103].

Low-fluence QSNYL plus microdermabrasion has been attempted successfully in an observational study, but has not been compared to either treatment individually (2b) [104].

Relative Effectiveness of Chemical Peels

GA is typically considered the peel of choice for treatment of refractory melasma, although numerous studies have demonstrated non-inferiority of other peeling agents (Table 53.3) [19]. Research suggests that 10–20% TCA is as effective as 20–35% GA, with decrease in MASI of 73–79%

Table 53.3 Studies comparing chemical peeling agents for the treatment of melasma

Author	Study design/ treatment	n	FST/ race	Results	Side effects and recurrence
Kalla et al. [84]	Design unclear, 2 groups 1. 55–75% GA 2. 10–15% TCA	100	Indian	Response to TCA was rapid and produced better results than GA GA was more effective with onset of melasma <1 year, and TCA was more effective with onset of melasma >1 year	Relapse was more common in the TCA group (25%) than in the GA group (5.9%) TCA was associated with more local irritant effects, i.e., tingling, burning, and post-peel cracking than GA
Khunger et al. [105]	Open-label, split-face 1. 70% GA 2. 1% tretinoin	10	III–V Indian	A significant decrease in mMASI was observed on both facial sides, with no significant difference observed between the two sides	GA: vesiculation (30%) and PIH (10%) Tretinoin: erythema and superficial desquamation (20%)
Kumari and Thappa [106]	Randomized, single-blinded 1. 20–35% GA 2. 10–20% TCA	40	Indian	79% reduction vs. 73% reduction in MASI at 12 weeks with GA and TCA peels, respectively TCA showed more rapid initial improvement	GA: mild burning (95%) TCA: moderate-to-severe burning (75%), post-peel cracking (35%)
Puri [107]	Unclear design, 2 groups 1. 20–35% GA 2. 15% TCA	30	Indian	Both peels associated with significant reduction in MASI scores (82% in GA and 79% in TCA), although there was no statistically significant difference between the two groups	GA: burning (6.6%), erythema (10%), pain (3.3%), PIH (6.6%) TCA: burning (26.6%), erythema (20%), pain (6.6%), PIH (13.35%), post-peel cracking (6.6%)
Faghihi et al. [108]	Randomized, double-blinded, split-face 1. 70% GA 2. 1% tretinoin	63	III–IV	31% reduction in MASI in tretinoin group and 29% reduction in GA group	Post-procedure discomfort was significantly lower with tretinoin
Lawrence et al. [109]	Randomized, single-blinded, split-face 1. 70% GA peel 2. Jessner's peel	16	II–VI	Similar improvement in lightness was observed on both sides	All side effects were observed on the GA side: extensive epidermolysis leading to PIH (6.25%), persistent erythema (12.5%), scattered crusting (37.5%)
Sarkar et al. [83]	1. 35% GA 2. 20% salicylic and 10% mandelic acid (SM) 3. 50% phytic acid (PA)	90	Indian	At 12 weeks, reduction in MASI was 62.36% in GA group, 60.98% in SM group, and 44.71% in PA group There was no statistically significant difference between SM and GA, but both were better than PA	GA: mild erythema and desquamation (19.2%), hyperpigmentation (15.4%), persistent erythema (15.4%) SM: burning sensation (25%) PA: burning sensation (31.8%), HSV (18.2%)

n number of subjects, *FST* Fitzpatrick skin type, *GA* glycolic acid, *TCA* trichloroacetic acid, *mMASI* modified melasma area and severity index, *MASI* melasma area and severity index, *PIH* post-inflammatory hyperpigmentation, *SM* salicylic-mandelic acid, *PA* phytic acid, *HSV* herpes simplex virus

versus 79–83%, respectively (2b) [96, 107]. It is important to note, however, that this low concentration of GA is not as effective as higher concentrations [78]. The faster onset of results and superior efficacy in the treatment of chronic pigmentation (duration > 1 year) makes TCA an appealing option [84]. Yet there appears to be a higher risk of relapse and hyperpigmentation in those treated with TCA peels (25% in TCA vs. 5.9% in GA) as well as increased risk of local irritant effects including prolonged erythema, tingling, burning, and post-peel cracking of the skin [84, 96, 107].

While there are no comparative studies of GA and SA alone, a study of 35% GA versus

combination 20% SA/10% mandelic acid (SM) demonstrated that the reductions in MASI of 62.36% and 60.98%, respectively, were not significantly different (1b) [83]. Both GA and SM were shown to be more effective than phytic acid, which demonstrated a 44.71% decrease in MASI [83].

Research suggests that tretinoin 1% peel is as effective as 70% GA peel in the treatment of melasma with lower risk of post-procedure discomfort and adverse events, such as erythema and superficial desquamation (2b,1b) [105, 108]. A recent randomized, double-blind, split-face study showed reduction in MASI of 31% versus 29% with tretinoin 1% and GA 70% peels, respectively (1b) [108]. Similarly, use of Jessner's solution and 70% GA are associated with comparable improvement in melasma based on change in colorimeter-measured light reflectance, with fewer adverse events seen with the former (2b) [109].

Lastly, a study by Sobhi et al. suggests that combination of 70% GA and iontophoresis with vitamin C is more effective than GA peel alone (2b) [110].

Preoperative Evaluation and Patient Selection

Wood's lamp examination to determine melasma depth remains the first step in evaluation, as the depth of melanin pigment, whether epidermal, mixed, or dermal, affects the efficacy of available therapies. For example, chemical peels are most effective in epidermal melasma and are less efficacious in dermal melasma [74, 77]. For those with dermal pigmentation, management with lasers such as non-ablative fractional or low-fluence QSNYL would likely offer greater efficacy, although efficacy with all modalities is generally less than that with epidermal melasma [23, 24, 49, 65, 67].

Additionally, patients should be evaluated for concomitant disease of the face, including acne, rhytides, or photodamage that may indicate superiority of a particular therapeutic modality. Fractional resurfacing is FDA approved for treatment of periorbital rhytides, pigmented lesions, acne scars, and surgical scars, and would be an appropriate choice for patients who also seek treatment of these conditions [111]. Chemical peels would have additional benefits for patients with oily skin, acne, acne scars, fine wrinkling, and texturally rough skin [85]. SA is typically used for the treatment of acne alone and may be more effective and better tolerated than the traditional GA peel for acne and post-acne scarring [112]. Nonetheless, several studies have demonstrated significant improvement in inflammatory and non-inflammatory lesions as well as atrophic acne scarring with serial GA peels [113, 114].

Skin pigmentation and ethnicity also play a large role in choice of treatment, as darker skin tones have a higher risk of PIH after laser and chemical peel procedures [115]. Traditional laser resurfacing devices, including ablative CO_2 and Er:YAG, result in high rates of dyspigmentation and even scarring in dark-skinned patients and, therefore, should be avoided [115]. IPL appears to be effective in the treatment of melasma in Asian skin when used at conservative settings, but should be avoided in skin types IV–VI due to a high risk of PIH [116]. PDL should also be avoided in FST IV+ due to a high risk of PIH [51]. Non-ablative and fractional lasers are thought to be safer for use in pigmented skin; however, lower treatment densities are recommended to minimize the risk of pigmentary sequelae (2b) [63, 64, 114, 115]. Lasers with ultrashort-pulse durations, including picosecond lasers, have also been associated with a lower risk of pigmentary sequelae [70, 71, 117].

Like with lasers, low concentrations and duration of chemical peels should be used in darker skin types and titrated up slowly and carefully to avoid excessive peeling, burning, or frosting that may result in PIH or hypopigmentation [21]. Given the relative paucity of studies evaluating the safety and efficacy of laser treatment of melasma in FST V–VI, the decision to use a laser for melasma in this cohort should be based on careful evaluation of the potential risks and benefits.

Lastly, medical and medication history as well as history of sensitivity or allergies are important considerations when evaluating a patient for therapy. Chemical peels should be avoided in subjects

with active dermatitis at the peeling site, acute viral infection (involving the treatment area), skin malignancies (involving the treatment area), pregnancy (category C) and contact allergy to salicylates (for salicylic acid) [85]. For those with a history of herpes simplex infection (not active infection), prevention with an antiviral should be considered post-peel. Subjects should be asked about history of keloids, which may put them at unacceptable risk of scarring from any procedures. For those taking isotretinoin, procedures should be avoided or postponed until 3–6 months after discontinuing treatment [85].

Impact of Patient Preference

Patient preferences regarding pain, post-procedure downtime, frequency of office visits, and risk/benefit ratio play an important role in choosing a procedural therapy for melasma.

For patients with low pain thresholds or who would like to avoid painful procedures, chemical peels would generally be preferred over laser/light therapies. Most studies have demonstrated at least mild-to-moderate pain in subjects treated with lasers and IPL [23, 30–32]. Therefore, superficial chemical peels would be a superior initial choice for these patients.

As for post-procedure downtime, non-ablative fractional lasers (especially the low energy, low density 1927 nm diode) and low-fluence QSNYL appear to have the shortest downtime, with resolution of erythema and edema usually occurring within 24 h after treatment [40, 48]. Erythema from resurfacing may take up to 4 days to resolve [30, 35]. Transient facial redness due to ablative lasers and IPL may last up to 7 days and may be associated with crusting, edema, and oozing [23, 28, 53]. Persistent erythema has been reported in approximately 15% of patients treated with GA peels [83].

Most laser, light, and chemical peel procedures require four to eight treatments spaced every 2–4 weeks, depending on the depth and severity of melasma. Patients who are unable to attend at least monthly office visits may not be good candidates for procedural therapy. One study suggests that a single treatment with IPL followed by TCC is associated with significant improvement in melasma up to 1 year post-treatment (superior to TCC alone), although further studies are needed to confirm this [53]. At this time, topical therapies would be the best choice for such patients.

Side effects associated with each procedure, and patients' willingness to endure these side effects, are also important to consider. These will be discussed further below. Post-inflammatory hypo- and hyperpigmentation are the most concerning sequelae. Although there is limited data comparing the prevalence of pigmentary sequelae between different procedures, ablative lasers should be avoided in darker-skinned patients due to the high risk of dyspigmentation [24].

Typical Treatment Plan

A 45-year-old Indian woman with FST IV presents to your dermatology clinic with a 4-year history of hyperpigmentation of the bilateral cheeks and forehead that has been worsening over time. She has tried over-the-counter skin brightening creams without success and notes significant embarrassment due to the pigmentation on her face. She reports a history of hypothyroidism for which she takes levothyroxine and is otherwise healthy. Upon examination of the skin, she has hyperpigmented dark brown patches on the bilateral malar cheeks and forehead that are consistent with a diagnosis of melasma.

The first step in the management of this condition should be educating the patient about risk factors and preventative measures, including the role of UV light in the progression of melasma and the importance of using sun protection [2]. The patient should be instructed to use broad-spectrum sunscreen with SPF 30 or higher on a daily basis and to use protective clothing, such as a hat, when in the sun for extended periods of time.

Initially, she should be started on a topical agent that targets melanogenesis with the goal of reducing the severity of hyperpigmentation. Our first-choice agent would be TCC (i.e., 4% HQ,

0.05% tretinoin, 0.01% fluocinolone), as this compounded medication has been shown to be most effective in the reduction of melasma severity [118]. Hydroquinone 4% alone would also be an appropriate choice. The patient should be advised that it may take up to 3–6 months to see an optimal effect and that she should return to clinic in 6–8 weeks for follow-up to review compliance, response, and possible side effects.

This patient returns to clinic for a second visit after 2 months. She has been using the TCC twice daily and, although she sees a slight reduction in her melasma, she is still very bothered by the dark spots on her face. For this patient, second-line therapy would be chemical peels. GA would be the best option given the strength of data supporting its efficacy in the treatment of melasma. Initially, 20–30% GA should be applied for approximately 2–3 min with the goal of titrating up by about 10–20% and increasing the time by 1–2 min with each subsequent peel (up to a maximum of 70% for 4–5 min). Typically, about six to eight peels every 3–4 weeks will be required for optimal results. The patient should be instructed to continue use of TCC after the peels to minimize the risk of PIH. TCC is discontinued 72 h prior to each peel to avoid irritation from concomitant use of topical retinoids (e.g., tretinoin found in TCC).

If this patient still has not responded appropriately to chemical peels, laser and light therapies would be the next step in the treatment ladder. For this woman with a darker skin type, nonablative fractional resurfacing (e.g., low-energy, low-power 1927 nm diode or 1550 nm erbium-doped laser with low density) provides the best safety profile and good efficacy data. Low-fluence Q-switched Nd:YAG used weekly for six to eight sessions would be another appropriate choice. Ablative lasers should be avoided due to high risk of post-inflammatory pigmentary abnormalities.

Safety

Lasers and chemical peels are commonly used in clinical practice and typically are associated with a low risk of adverse events when tailored to patients' skin types and treatment preferences. Although studies have not looked at the frequency of adverse events in the treatment of melasma specifically, a retrospective review of 362 Korean patients (FST III–IV) treated with non-ablative fractional thermolysis for any reason demonstrated significant adverse events in approximately 5% of patients (2b) [119]. These included prolonged erythema (1.8%), PIH (1.1%), aggravation of melasma (0.9%), herpes simplex outbreak (0.6%), and acneiform eruptions (0.2%). Transient erythema, burning, and edema were not considered adverse events [119].

Nonetheless, burning sensation, erythema, and mild edema immediately after laser treatment are the most commonly observed side effects of laser therapy, regardless of the device used [30, 32, 42, 44, 47, 48, 50, 51, 117]. With use of low-energy, low-density 1927 nm diode laser, QSNYL, and picosecond lasers, these findings tend to be mild and typically resolve within 2–24 h [40, 48, 50, 117]. Fractional resurfacing with Er:glass laser, however, has been reported to cause sunburn-like erythema in 99% of subjects that may take up to 4 days to resolve [30]. Erythema due to ablative lasers may last up to 7 days and may be associated with crusting, edema, and oozing [23, 28].

Although pain can occur during any laser treatment, studies demonstrate a numerically higher level of pain with Er:glass and CO_2 lasers than QSNYL or picosecond lasers, with average pain scores of 5.4–6.4 out of 10 [23, 30–32, 50]. A study by Wattanakrai reported an average pain score of 4.7/10 with QSNYL [43], and others have demonstrated absence of pain in the majority of patients treated with this modality [48]. A study of picosecond 1064 nm/595 nm laser in melasma demonstrated only mild (<4/10) pain during treatment [50]. Nonetheless, there are no comparative studies to corroborate the higher pain level with certain lasers compared to others.

The greatest concern with the use of lasers is the risk for pigmentary alterations as a result of post-laser inflammation and/or damage to melanocytes. Fractional resurfacing devices have a therapeutic window and using a high density (or inappropriate fluence) may result in undesired

pigmentary sequelae [22]. The majority of studies using low-fluence QSNYL have failed to demonstrate immediate or long-term dyschromias [40, 42, 44, 47, 48], although some suggest that PIH and guttate hypopigmentation may occur in as many as 16–18% and 8–14% of patients, respectively. [43, 45] The rate of PIH is also inconsistent in studies of non-ablative fractional lasers, including 1550 nm, 1540 nm, and 1927 nm. Rates of PIH range from 0% to 31%, with the majority of studies demonstrating no PIH at all [29–33, 36, 37]. Typically, the use of lower fluences and lower densities is thought to decrease the risk of PIH in darker-skinned patients (2b) [30, 119, 120]. A recent retrospective study of 37 Chinese patients treated with fractional resurfacing demonstrated no significant difference in the rate of PIH with use of high-energy/low-density versus low-energy/high-density settings, although density seems to be more associated with the development of PIH (2b) [64, 120]. Ablative non-fractional lasers may result in PIH in up to 50% of subjects [24, 25]. Fractional and CO_2 lasers may be associated with a slightly reduced risk of hyperpigmentation, although several studies have not commented on presence/absence of PIH [27, 28]. Picosecond Nd:YAG and alexandrite lasers demonstrate a low rate of PIH, with studies demonstrating PIH in 0–7% of patients [50, 70, 117].

For all lasers, the risk of PIH is higher in individuals with higher skin phototypes and may be reduced by using conservative settings [23, 25, 43, 64, 120]. Further, the risk increases with each laser treatment and, for QSNYL, may be more common in those receiving ten or more treatments [43]. Fortunately, mottled hypopigmentation and hyperpigmentation typically resolve within a few months with appropriate treatment [67].

Similar to lasers, side effects from IPL include mild-to-moderate pain, mild transient erythema, burning, edema, microcrusts, skin erosion, dryness, and scaling [52–54, 56]. Crusting has been documented to last up to 1–2 weeks after treatment [55, 56]. PIH may occur in up to 25% of patients treated with high fluences, with PIH more commonly seen in those with higher Fitzpatrick types [53]. Nonetheless, the majority of studies have demonstrated lower rates ranging from 0% to 12% [52, 55, 56].

GA and SA peels are associated with minor side effects in approximately 15–20% of patients [82, 83, 121]. Patients commonly experience mild erythema, discomfort, stinging, or burning of the skin [73, 75, 77, 80–82]. Minor peeling or a pulling sensation of the skin may occur [82, 83, 121]. Less common adverse events include moderate-to-severe epidermolysis, superficial vesiculation, and superficial burns, which ultimately result in the development of PIH [73, 75, 78, 83, 121]. As with lasers, PIH is usually self-limited and resolves after ~2 months [73].

TCA peels are associated with more local irritant affects than GA, including tingling, burning, post-peel cracking, and erythema [84, 96, 107]. Puri et al. also demonstrated a higher rate of PIH in the 15% TCA versus 20–35% GA groups [96]. Conversely, tretinoin 1% peel is associated with significantly lower post-peel discomfort, although there is debate about whether tretinoin is a peeling agent at all [105, 108].

Studies directly comparing the adverse events associated with lasers and GA peels are limited [45, 94, 97]. A study of 75 Indian patients treated with either high-fluence QSNYL, low-fluence QSYNL, or 35–70% GA peel demonstrated the fewest adverse events in the low-fluence QSYNL group. GA peels were also well tolerated [95].

In terms of combination therapy, one study suggests that combination of QSNYL and 30% GA peel is associated with a higher risk of burning, stinging, erythema and edema, but not hyperpigmentation or hypopigmentation [45]. Another study, however, showed no increased risk of adverse events with use of QSNYL and 30% GA [97]. Hong et al. performed a split-face, comparative study of 1550 nm plus 15% TCA versus 15% TCA alone and demonstrated no significant difference in adverse events, including PIH [94]. Combination of low-fluence QSNYL with 1550 nm or microdermabrasion similarly does not appear to be associated with an increased risk of adverse events [93, 97]. Combination of CO_2 laser and QSAL is associated with higher rates of PIH, despite greater improvements in melasma severity [25].

Postoperative Care and Follow-Up

The monitoring schedule for melasma varies based on what mode of treatment is chosen and the frequency with which it is performed. Typically, lasers and chemical peels are performed every 2–4 weeks. Patients should follow the recommended schedule in order to achieve optimal results.

Once the patient has attained satisfactory improvement in melasma, maintenance therapy with topical agents should be initiated. Follow-up is recommended every 3 months to monitor adherence to maintenance therapy and evidence of recurrence. Typically, recurrence will be seen by 6–12 months after laser or light therapy, although some studies have suggested recurrence as early as 12 weeks after treatment [27, 28, 32, 35, 36, 43–45, 47, 55]. There is limited data on relapse with chemical peels [84]. When relapse occurs, patients may be restarted on topical depigmenting agents, if they are not already using one, or repeat procedure(s) could be considered.

Observations and Recommendations

Evidence based summary: Grading of Recommendations Assessment, Development, and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
Glycolic acid is the most efficacious peeling agent for the treatment of melasma	B
Chemical peels should be used in combination with a topical depigmenting agent to maximize efficacy and minimize the risk of pigmentary sequelae	A
Fractional resurfacing has been associated with moderate improvement in melasma when lower fluences and treatment densities are used	B
Low-fluence QSNYL, fractional resurfacing, and IPL may have benefit in the treatment of melasma when combined with topical depigmenting agents	B
There is insufficient evidence to support the use of ablative lasers (fractional and non-fractional) in the treatment of melasma	C
A combination of lasers and chemical peels may play a role in the treatment of melasma, but further studies are needed to evaluate optimal combinations and to outline which patients would particularly benefit	C
Patients should be counseled on the risk of PIH and relapse after treatment with chemical peels, lasers, and light therapies	A
The importance of post-procedure sun protection and maintenance therapy with topical agents must be emphasized	A
There is a paucity of data pertaining to the treatment of melasma in Fitzpatrick skin types V and VI	C

Self-Assessment Questions

1. Which of the following laser modalities is considered to be safe and effective in the treatment of melasma in skin types IV–VI?
   (a) Low-fluence 1064 nm Nd:YAG laser
   (b) 1550 nm Er:glass laser
   (c) 2940 nm Er:YAG laser
   (d) 755 nm Q-switched alexandrite laser
   (e) a and b
   (f) All of the above
   (g) None of the above

2. The efficacy of IPL in the treatment of melasma may be enhanced by the addition of which topical therapy:
   (a) Tretinoin 0.025%
   (b) Hydrocortisone 2.5%
   (c) Tranexamic acid 2%
   (d) Hydroquinone 2%
   (e) Glycolic acid 10%

3. A 32-year-old Indian female with melasma of the bilateral malar cheeks presents to your office after failing multiple prescription and over-the-counter topical skin lightening agents. She is interested in more aggressive interventions and would like to know what the most effective treatments are. When counseling the patient on available treatment options, which of the following would be an appropriate statement regarding the efficacy of procedural therapies for melasma?
   (a) The use of quality-switched Nd:YAG lasers is associated with complete resolution of melasma in the majority of patients after five to seven sessions.
   (b) GA chemical peels are a good choice for the treatment of melasma and should be started at a concentration of 50–70% given the increased efficacy of peels at this concentration.
   (c) Research suggests that, overall, laser modalities are more effective than chemical peels, and, therefore, fractional resurfacing or QSNYL should be the next step in management of this patient.
   (d) It would be appropriate to start with either low-fluence QS-Nd:YAG lasers or GA peels initially, and these two modalities may be combined in the future with additional improvement.
   (e) Fractional resurfacing is associated with at least 25% improvement in most patients, and those results are maintained up to 1 year after the last treatment.

4. The above patient decides to pursue laser therapy. What directions would you give her regarding the use of her topical skin lightening agents?
   (a) Discontinue use of skin lightening agents, as there is a higher risk of adverse events when lasers and topical therapies are used in conjunction.
   (b) For optimal results, continue daily use of triple combination cream prior to and following laser therapy.
   (c) For optimal results, continue your current skin over-the-counter brightening regimen prior to and following laser therapy.
   (d) You may continue to use topical lightening agents, but it is unlikely that you will attain additional benefits from their use.
   (e) Additional improvement may be seen if you use triple combination cream up until laser treatment, but you should discontinue use immediately after to avoid excessive skin lightening.

5. What is the most common side effect of fractional resurfacing when used for melasma?
   (a) Sunburn-like erythema
   (b) Post-inflammatory hyperpigmentation
   (c) Post-procedure pain
   (d) Oozing and crusting
   (e) Herpes simplex outbreak

Correct Answers

1. e: Low-fluence 1064 nm Nd:YAG laser and fractional resurfacing devices, including 1550 nm Er:glass, are considered to be safe for use in darker skin types and have been associated with improvement in melasma severity. Ablative lasers, including Er:YAG and CO_2 lasers, are associated with a significant risk of PIH and, therefore, should be avoided in skin of color. There is insufficient research on QSAL to support its use in skin of color.
2. c: Use of topical 2% tranexamic acid (or hydroquinone 4% or TCC) in combination with IPL has been shown to be more effective than IPL alone in the treatment of melasma. Tranexamic acid is also thought to help prevent rebound of melasma. The other topical compounds above have not yet been studied in conjunction with IPL.
3. d: Both lasers (QSNYL or laser resurfacing) and chemical peels (particularly GA peel) are effective in the treatment of melasma, and current research does not support the superiority of one treatment over another. Therefore, either would be an appropriate next choice. If optimal results are not achieved, it would be reasonable to combine the two treatment modalities. Studies suggest that combination of low-fluence QSNYL and 30% GA is more effective in the treatment of melasma than QSNYL alone.
4. b: Numerous studies suggest that use of triple combination cream prior to and following laser therapy is associated with better improvement in melasma than laser therapy alone. There is no increased risk of adverse events with the combination of laser and TCCs; in fact, the rate of PIH appears to be slightly reduced. Hydroquinone 4% is also considered to be a good adjuvant to laser therapy, but over-the-counter brightening agents have not been adequately studied.
5. a: Fractional resurfacing with Er:glass laser has been reported to cause sunburn-like erythema in 99% of subjects. Burning sensation and mild edema immediately after laser treatment are also commonly observed and self-resolve within a few hours to days after treatment. A retrospective review of 362 patients treated with non-ablative fractional thermolysis for any reason demonstrated prolonged erythema (1.8%), post-inflammatory hyperpigmentation (1.1%), aggravation of melasma (0.9%), herpes simplex outbreak (0.6%), and acneiform eruptions (0.2%).

54 Postinflammatory Hyperpigmentation

Renee C. Sheinin, Henry W. Lim, and David M. Ozog

Abstract

Postinflammatory hyperpigmentation (PIH) is an acquired hypermelanosis due to overproduction of melanin from cutaneous inflammation or injury. PIH can occur in all skin types and can be very difficult to treat. Treatment can be medical or procedural. Medical therapies include topical depigmenting agents such as hydroquinone, azelaic acid, kojic acid, and licorice extract, as well as topical retinoids, vitamin C, and sunscreens. Procedures that may be used to treat PIH include chemical peels, blue light photodynamic therapy (PDT), and various lasers including but not limited to the Q-switched ruby laser, the Q-switched Nd:YAG laser, and the fractional laser. The data available in the literature is limited to scarce case reports and case series. More studies need to be carried out to determine the overall effectiveness of each of the laser treatments described above.

Epidemiology

Postinflammatory hyperpigmentation (PIH) is an acquired hypermelanosis due to the overproduction of melanin resulting from cutaneous inflammation or injury (level 5) [1]. Inflammatory mediators including leukotrienes (LT-C4 and LT-D4), prostaglandins (PG-E2 and PG-D2), thromboxane-2, interleukin (IL)-1 and IL-6, tumor necrosis factor (TNF)-alpha, epidermal growth factor, reactive oxygen species, and nitric oxide have been shown to stimulate melanocyte activity (level 1a, 5, 5) [2–5]. Ongoing inflammation and additional ultraviolet light exposure can worsen PIH (level 5) [6].

PIH affects all age groups and can occur anywhere on the body (level 4) [7]. The affected areas are determined by the location of underlying causative dermatoses. It shows no gender predilection; however, it is more common in darker Fitzpatrick skin types. The lesions are irregularly shaped macules and patches and can vary in color from light brown to bluish gray depending on the level of deposition of pigment in the skin (level 3a) [8]. PIH can be localized in the epidermis, the dermis, or both. Epidermal PIH involves increased production of melanin and its transfer to keratinocytes; it is characterized by tan to dark brown macules or patches in the same distribution as that of the preceding inflammatory process [2]. Dermal PIH involves melanin that transgresses a damaged basement membrane,

© Springer Nature Switzerland AG 2019
M. Alam (ed.), *Evidence-Based Procedural Dermatology*, https://doi.org/10.1007/978-3-030-02023-1_54

which is then phagocytosed by macrophages, or macrophages that transgress the basement membrane to phagocytose melanin and then regress to the dermis (level 5) [9]; the pigment appears gray-blue or gray-brown (level 5) [9, 10].

Common instigators include acne, pseudofolliculitis barbae, insect bites, atopic dermatitis, contact dermatitis, psoriasis, pityriasis rosea, lichen planus, lichenoid drug reactions, lupus erythematosus, herpes zoster, fixed drug eruptions, irritants, burns, trauma, or cosmetic procedures including laser treatments (level 2c) [2, 3, 8, 11, 12]. PIH of the epidermis resolves spontaneously in most patients within months to years without therapy [2]; however, dermal PIH is persistent and can be recalcitrant to therapy (level 3a) [2, 13].

PIH can occur in all skin types; however, there is a higher frequency and severity in people of skin of color (skin types IV, V, VI (level 3a) [14]) compared to Caucasians (level 2c, 2b) [15, 16] such as in African Americans, Hispanics/Latinos, Asians (level 2c) [17], Native Americans, Pacific Islanders, and those of Middle Eastern descent (level 3a, 2c, 1b) [2, 15–25]. Furthermore, the degree of an individual's constitutive pigmentation may indicate a higher propensity for PIH [17]. The exact incidence of PIH is unknown. There is a reported prevalence of PIH of 5.8% for children of Middle Eastern descent (level 2c) [26]. The prevalence of pigmentary disorders in the United States ranges from 9% to 19.9% for blacks [16], 0% to 1.7% for whites, 6% to 7.5% for Hispanics/Latinos, and 56.4% to 55.9% for Arab Americans [15, 16, 23, 25]. The prevalence of pigmentary disorders outside of the United States has been reported to be 0.7–15.3% for blacks [19, 21, 24], 0.1% for whites [21], 0.42% for Arabs [19], 26.8% for Middle Eastern descent [26], 1.8% for Chinese [17], 2.7% for Malay [17], 0.3–2.3% for Indian [17], and 0.5% for mixed race [17]; no data were available for Hispanics/Latinos outside the United States.

Treatment Overview

PIH can be very difficult to treat. Treatment can be medical or procedural. Medical therapies include topical depigmenting agents such as hydroquinone, azelaic acid, kojic acid, and licorice extract, as well as topical retinoids and vitamin C [8]. These agents can be used alone or in combination with other therapies and work best for epidermal PIH [6]. Additionally, photoprotection including application of a broad-spectrum sunscreen with sun protection factor (SPF) greater or equal to 30, sun avoidance, and the use of photoprotective clothing should be recommended to all patients to prevent worsening of PIH [18].

Procedures that may be used to treat PIH include chemical peels, blue light photodynamic therapy (PDT), and various lasers. Importantly, all of these procedures used to treat PIH also have the probability to worsen it if they produce excessive inflammation. Chemical peels including salicylic acid peels and glycolic acid peels have been shown to be effective for the treatment of PIH in darker skin types. In a study of five patients with skin types V and VI, Grimes demonstrated that superficial salicylic acid peels are safe and effective in the treatment of PIH (level 4) [27]. In a randomized controlled trial, Burns et al. showed that serial glycolic acid peels in addition to a topical regimen consisting of 2% hydroquinone/10% glycolic acid gel twice daily and 0.05% tretinoin cream at night was more effective in treating PIH in skin types IV, V, and VI than the topical regimen alone. Both treatment groups had improvement in PIH, but the peel group had a faster and greater improvement as well as increased lightening of the normal skin (level 1b) [28]. Blue light PDT is an established treatment for acne vulgaris. One case report of a black female with acne vulgaris treated with blue light PDT described an improvement of not only her acne lesions but also her PIH, thereby proposing blue light PDT as an effective treatment for PIH (level 4) [29].

Lasers are another therapeutic modality used in the treatment of PIH. They need to be used with caution as they can exacerbate PIH inadvertently. It is important to note that efficacy data for using lasers to treat PIH are limited to case reports and small case series. The lasers used to treat PIH that have been described in the literature include the Q-switched ruby laser (QSRL), the Q-switched Nd:YAG laser, and the fractional laser (both erbium:YAG and CO_2 lasers).

The Q-switched ruby laser has been shown to have variable results. Taylor et al. showed no improvement in eight patients with either melasma or PIH treated with the Q-switched ruby laser with the following settings: 694 nm wavelength, 40 ns pulse duration, and fluences of 15–7.5 J/cm^2 (level 4) [30]. However, Tafazzoli et al. reported an improvement of 75–100% in 58% of patients with post-sclerotherapy hyperpigmentation who were treated with the Q-switched ruby laser (level 4) [31].

The Q-switched Nd:YAG laser has been demonstrated to be an effective treatment for PIH. Cho et al. reported a series of three patients with PIH who were successfully treated with five sessions of Q-switched Nd:YAG laser at fluences of 1.9–2.6 J/cm^2 (level 4) [32]. These treatments required minimal downtime, and there was no posttreatment bleeding or crusting. The authors postulated that the longer 1064 nm wavelength leads to less risk of developing PIH after the laser treatment due to its depth of penetration [32]. Another study that evaluated 20 patients with acne and PIH showed a greater than 50% statistically significant improvement in PIH after treatment with the 1064 nm Q-switched Nd:YAG laser (level 1b) [33]. Further studies are necessary to determine the efficacy and safety of the Q-switched ND:YAG laser for the treatment of PIH.

Fractional lasers have had mixed results in treating PIH. Katz et al. described a case of one patient with post-traumatic hyperpigmentation who was successfully treated with the 1550 nm erbium-doped Fraxel laser. The patient achieved near-complete resolution with three treatment sessions using a density of 880–1100 MTZ/cm^2 [7]. Furthermore, the 1927 nm fractionated thulium laser was described to achieve near-complete resolution of post-inflammatory hyperpigmentation caused by cupping in a 26-year-old female (level 4) [34]. Rokhsar et al. reported a case of one patient with PIH induced by CO_2 nonablative laser resurfacing who was treated with the 1550 nm Fraxel laser at densities of 2000–3000 MTZ/cm^2. They described an improvement of 50–75% after five sessions over a 2-month period with no adverse events (level 4) [35]. Another case depicted successful treatment with complete resolution of refractory PIH with two sessions, each 1 month apart, of fractional CO_2 laser in a 24-year-old female with skin type III (level 4) [36]. However, Kroon et al. reported that fractional laser was not effective for PIH as evidenced by a series of six patients, who each had a total of five treatments (level 4) [37].

Effectiveness of Treatments

The data available in the literature is limited to scarce case reports and case series. More studies need to be carried out to determine the overall effectiveness of each of the laser treatments described above as well as whether or not the effectiveness varies based on demographics such as age, gender, and ethnicity. It is unknown whether the effectiveness has changed over time and how long the results will last. Longitudinal studies have yet to be performed. The degree of improvement reported ranges from 50% to 100% in the case series and case reports mentioned above.

Comparative Effectiveness of Common Treatments

There is a paucity of data comparing the effectiveness of one treatment modality against another. One study evaluated the treatment of pigmented lesions with the Q-switched ruby laser and the frequency-doubled Q-switched Nd:YAG laser. The authors measured clinical lightening of the lesion 1 month after a single treatment. At least 30% of lightening was achieved in all 20 patients with either the Q-switched ruby laser or the Q-switched Nd:YAG laser. The Q-switched ruby laser had a slightly better outcome than the Q-switched Nd:YAG laser. Neither treatment modality caused side effects of scarring or textural change of the skin. Patients reported more pain during the treatment with the Q-switched ruby laser; however, they reported more posttreatment discomfort with the Q-switched Nd:YAG laser (level 4) [38].

To our knowledge, there were no other studies in the literature examining relative effectiveness, combination treatments, or prognosis. There is

likely some variability of outcome based on patient demographics, as well as condition-specific factors such as severity, type, or anatomic location. However, more studies need to be carried out to evaluate whether or not these factors will play a role in the effectiveness of treatment.

Most treatment paradigms begin with hydroquinone, photoprotection, and avoidance of the initial inflammatory process if possible. This is commonly done, although there is a lack of clinical trials demonstrating efficacy. Chemical peels are most commonly added at this point with salicylic acid, which is particularly useful for skin types IV–VI in a setting of inflammatory acne as a causative factor. Much less common is the use of lasers due to mixed results in a small number of case series studies, higher cost compared to medical therapies and chemical peels, and limited availability of devices in practice.

Preoperative Evaluation and Patient Selection

The preoperative evaluation is very important in selecting the right treatment for an individual patient. One such tool that can aid in determining what kind of PIH the patient has is the Wood's lamp. It can be a useful tool to differentiate between primary epidermal melanosis and primary dermal melanosis. This is most helpful in patients with skin types I–IV. Primary epidermal melanosis under Wood's lamp appears as well-circumscribed pigmentation with accentuated borders, whereas primary dermal melanosis is poorly circumscribed and is not accentuated under Wood's lamp illumination [13]. Based on the location of the pigment, the treatment plan can be tailored for optimal results.

PIH tends to improve slowly over time. Therefore, treatment is not necessary for all patients. Medical therapy and/or procedural therapy can be limited to patients who desire accelerated resolution of hyperpigmentation. Procedural therapy can also be considered for those patients whose PIH is refractory to medical treatments.

There are many factors that can influence the outcome of treatment. The location of the increased pigment within the skin is one example. Medical therapies work better for epidermal pigment than they do for dermal pigment. They reduce the production or distribution of epidermal pigment. Patients with increased melanin within the dermal macrophages are less likely to respond well to medical treatment [6]. Laser treatments can be used for either epidermal or dermal hyperpigmentation.

Impact of Patient Preference

A patient's propensity to choose to proceed with any given procedure depends on many factors including cost, discomfort during and after the procedure, adverse events, number of treatments required, and likelihood of improvement or resolution of their condition. The procedures described above vary considerably with regard to postoperative care and expected side effects. Superficial chemical peels require minimal immediate postoperative care. A thin coat of petroleum jelly or Aquaphor ointment is applied after most peels. If the patient has a more robust reaction, a topical steroid can be used. Additionally, in patients with skin type IV or greater, a topical steroid may reduce the risk of developing PIH from the procedure itself. Patients can expect their newly peeled skin to develop mild-to-moderate erythema in the first few days and superficial desquamation in the subsequent few days. The patient should be instructed to cleanse the peeled skin twice daily with gentle soap and water and to resume his or her normal skincare routine once the skin is back to baseline. This can take anywhere from 1 day to 1 week depending on the depth of the peel. If the patient has a history of facial herpes simplex outbreaks, it is best to prescribe prophylactic antiviral therapy. Photoprotection is of utmost importance in the post-procedural period, and broad-spectrum sunscreen with SPF $\geq$30 should be applied as soon as the skin can tolerate it [39].

Laser therapy requires immediate postoperative cooling with ice packs. This can reduce post-procedure perifollicular edema, which typically lasts for up to 48 h, and erythema, which can

persist up to 1 week, as well as reduce postoperative discomfort. If erythema persists beyond 10 days, a low- to mid-potency topical steroid can be applied. Some patients can develop an urticarial reaction, which is best managed with oral antihistamines. Crusting can develop and last from 7 to 10 days. This can be treated with twice-daily application of petroleum jelly or Aquaphor ointment. Patients should avoid picking or scratching the area. Similar to superficial peels, photoprotection and the use of sunscreen is highly recommended after the procedure. Analgesics are typically not required as long as the appropriate cooling measures are in place before, during, and after the laser treatment [39].

The fractional ablative lasers have a slightly longer downtime as compared to other lasers and superficial chemical peels and require more extensive wound care in the post-procedural period. The fractional Er:YAG resurfacing laser can cause erythema and swelling that lasts for an average of 3 days, whereas the fractional CO_2 laser has a downtime period of about 1 week on average and includes hemorrhagic crusting, swelling, and erythema. Wound care for proper re-epithelialization includes an occlusive dressing placed on the treated area for the first few days. The patient should cleanse the affected area daily. Alternatively, lukewarm water soaks can be performed to minimize crusting. As in the other procedures, liberal use of emollients such as petroleum jelly is necessary. It is important to note that erythema can persist even after re-epithelialization and the patient should be advised accordingly [39].

Given the variable efficacy for all of the procedures and medical treatments described above, patients select a treatment plan based on the combined variables of personal distress with their situation and available time and financial resources for the treatments.

Typical Treatment Plan

A 47-year-old female with skin type III presents to the clinic with facial PIH secondary to acne vulgaris. Her acne is under good control and her face is clear with the exception of the PIH that remains. She is interested in pursuing treatment for PIH. The gold standard for the treatment of this patient is topical hydroquinone. The data are limited for PIH, but hydroquinone has been extensively studied in patients with melasma. Second-line treatment options include topical retinoids, Tri-Luma (compounded topical retinoid, topical steroid, and hydroquinone), azelaic acid, and superficial chemical peels. There are insufficient data to determine their relative efficacy and how they compare to hydroquinone. The efficacy data of peels was described above; salicylic acid peel would be the next step of treatment for this patient.

For refractory PIH, lasers should be considered. Anesthesia is typically not required. Most patients describe the discomfort as being analogous to a rubber band snapping the skin surface. If a patient is particularly sensitive, a topical lidocaine 5% cream or an EMLA cream can be applied prior to treatment. Immediately after the laser treatment, the patient may experience sensations of pain or stinging. Postoperative cooling and occlusive dressings can help mitigate these symptoms. When using a Q-switched laser, the clinical endpoint is immediate skin whitening. This will typically resolve within 20–30 min. The treated area can become temporarily hyperpigmented and crusts can form. Daily application of petroleum jelly or other occlusive ointments and daily cleansing with a gentle soap and water will help promote healing of the treated area; crusts will usually fall off within 7–10 days. Photoprotection including the use of sunscreen is strongly recommended.

Novel Treatments

Although oral tranexamic acid has been reported as a successful treatment for melasma, it was not effective as prophylaxis for laser-induced PIH. The study included 32 patients who underwent QSRL treatment of lentigines, and all patients were divided into two groups: one that received oral tranexamic acid 750 mg daily and one that did not. The PIH appeared on average

about 4 weeks after the laser treatment in both groups. There was no difference observed among the two groups showing that oral tranexamic acid did not prevent induction of PIH (level 1b) [40]. Although the results of this study did not support the use of oral tranexamic acid in the treatment of PIH, it is important to appreciate this innovative approach by using oral therapies in expanding out-treatment armamentarium of PIH.

Safety

In general, lasers have an overall favorable safety profile when operated correctly. The most severe but rare adverse effect is retinal injury and ultimately blindness. This can be avoided with the use of the proper eye protection. The laser operator and everyone in the treatment room must wear safety goggles that are specific to the wavelength of that laser. The patient should be instructed to close his or her eyes and to wear external goggles that are not transparent. If the periocular area is being treated, metal eye shields should be inserted into the eye for protection. Other more common, less severe adverse events include blistering, bruising, dyspigmentation, and scarring. Both lasers and chemical peels may cause worsening of the PIH if an undetermined threshold of injury is reached resulting in undefined "excessive" inflammation.

Postoperative Care and Follow-Up

Often, one treatment is not sufficient to produce desirable results. Both chemical peels and laser treatments are performed as often as every 4–6 weeks, but this is an arbitrary timeframe. It is difficult to predict how many treatments an individual patient will need given the lack of evidence available in the literature. One important factor to consider when determining a treatment schedule is skin type. Patients with darker skin types should have longer intervals between treatments to help minimize adverse events. Some patients have been reported to have complete resolution of their PIH with the treatments described above. Others showed significant improvement but were unable to achieve complete clearance of their PIH.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
Procedural therapy can be considered for those patients whose PIH is refractory to medical treatments	C
All of the procedures used to treat PIH, including chemical peels, blue light photodynamic therapy (PDT), and various lasers, have the capacity to worsen PIH if they produce excessive inflammation	C
Chemical peels including salicylic acid peels and glycolic acid peels have been shown to be effective for the treatment of PIH in darker skin types	B
The Q-switched ruby laser has been shown to have variable results in the treatment of PIH	C
The Q-switched Nd:YAG laser has been demonstrated to be an effective treatment for PIH	C
Fractional lasers (including erbium, thulium, and CO_2) have had mixed results in treating PIH	C
Oral tranexamic acid is not recommended as prophylaxis for laser-induced PIH	B

Self-Assessment Questions

1. Which of the following is true regarding PIH?
   (a) PIH is more common in the elderly
   (b) PIH is more common in females
   (c) PIH is more common in darker Fitzpatrick skin types
   (d) PIH is localized to the epidermis only
   (e) PIH is more common on the forearms
2. All of the following have been used to treat PIH except:
   (a) Topical depigmenting agents such as hydroquinone
   (b) Red light photodynamic therapy
   (c) Chemical peels
   (d) Q-switched Nd:YAG laser
   (e) Fractional CO_2 laser
3. Which of the following is false?
   (a) Medical therapies work better for dermal pigment than they do for epidermal pigment
   (b) PIH tends to improve slowly over time
   (c) Laser treatments can be used for either epidermal or dermal hyperpigmentation
   (d) Epidermal melanosis under Wood's lamp appears as well-circumscribed pigmentation with accentuated borders
   (e) Dermal melanosis is poorly circumscribed and is not accentuated under Wood's lamp illumination
4. All of the following can be observed in the postoperative period after a laser treatment for PIH except
   (a) Perifollicular edema
   (b) Perifollicular erythema
   (c) Urticarial reaction
   (d) Crusting
   (e) All are correct
5. Which of the following is the most severe albeit rare adverse effect of laser therapy?
   (a) Blistering
   (b) Bruising
   (c) Dyspigmentation
   (d) Retinal injury
   (e) Scarring

Correct Answers

1. c: PIH affects all age groups. It shows no gender predilection. PIH can be localized in the epidermis, the dermis, or both. It can occur anywhere on the body. The affected areas are determined by the location of underlying causative dermatoses.
2. b: All of the above have been used in the treatment of PIH except B. Blue (not red) light PDT is another effective treatment for PIH.
3. a: All of the above statements are correct except A. Medical therapies work better for epidermal pigment than they do for dermal pigment. They reduce the production or distribution of epidermal pigment. Patients with increased melanin within the dermal macrophages are less likely to respond well to medical treatment.
4. e: All of the above can be seen in the postoperative period after a laser treatment.
5. d: All of the answer choices listed are possible adverse effects of laser therapy. However, answer D, retinal injury, is the most severe adverse effect as it can lead to blindness. This is a very rare adverse effect but a very important one that the clinician must be aware of.

Vitiligo

55

Jorge A. Hinojosa, Andrea Tovar-Garza, and Amit G. Pandya

Abstract

Vitiligo is a chronic autoimmune disorder of the skin in which melanocytes are destroyed resulting in patchy areas of skin depigmentation. This disease occurs in approximately 1% of the world's population without predilection for sex, race, or ethnicity (5) (Ezzedine et al., Lancet 386:74e84, 2015). Vitiligo can be classified into three major categories: segmental vitiligo, which has a unilateral distribution, non-segmental or generalized vitiligo, and mixed vitiligo, which is a combination of the former two (Ezzedine et al., Lancet 386:74e84, 2015). Approximately half of those affected with vitiligo develop their first lesion before the age of 20 (Ezzedine et al., Lancet 386:74e84, 2015). Vitiligo can be disfiguring, especially in dark-skinned individuals, and can have a significant psychological and social impact with major consequences on the quality of life for those affected (4) (Kostopoulou et al., Br J Dermatol 161:128–133, 2009). Other autoimmune disorders, including thyroid disease, pernicious anemia, Addison's disease, systemic lupus erythematosus, and alopecia areata, have been associated with vitiligo (2c) (Alkhateeb et al., Pigment Cell Res 16(3):208–214, 2003).

Introduction

Epidemiology

Vitiligo is a chronic autoimmune disorder of the skin in which melanocytes are destroyed resulting in patchy areas of skin depigmentation. This disease occurs in approximately 1% of the world's population without predilection for sex, race, or ethnicity (5) [1]. Vitiligo can be classified into three major categories: segmental vitiligo, which has a unilateral distribution, non-segmental or generalized vitiligo, and mixed vitiligo, which is a combination of the former two [1]. Approximately half of those affected with vitiligo develop their first lesion before the age of 20 [1]. Vitiligo can be disfiguring, especially in dark-skinned individuals, and can have a significant psychological and social impact with major consequences on the quality of life for those affected (4) [2]. Other autoimmune disorders, including thyroid disease, pernicious anemia, Addison's disease, systemic lupus erythematosus, and alopecia areata, have been associated with vitiligo (2c) [3].

Treatment Overview

Unfortunately, there are currently no FDA-approved therapies for repigmentation of vitiligo lesions. Off-label therapies that are often used alone or in combination include topical and systemic corticosteroids, topical immunomodulators, and phototherapies such as PUVA and NBUVB. While these treatments can result in complete repigmentation of lesions in some patients, rates of repigmentation are variable and usually do not result in complete repigmentation of all affected areas (2a) [4]. Patients with recalcitrant lesions that have been stable for 1–2 years after failed medical therapy may benefit from surgical methods of repigmentation (5) [5]. These surgical techniques can be divided into two groups: tissue grafting and cellular grafting. Autologous tissue grafting methods include suction blister epidermal grafts (SBEG), split-thickness grafts (STSG), and punch grafts (PG), also called mini-grafts. Cellular grafting techniques include non-cultured epidermal suspension (NCES) grafts, also called the melanocyte-keratinocyte transplantation procedure (MKTP), and cultured melanocyte transplantation (CMT). Other surgical methods that are less commonly used in the surgical treatment of vitiligo and will not be discussed in this review are microneedling, laser ablation as monotherapy, and hair follicle/outer root sheath transplantation. Regardless of the surgical approach, the aim of all of these methods is the same – to introduce melanocytes from non-affected melanocyte-rich tissue into a vitiligo lesion devoid of melanocytes. Because there is a risk of destruction of the transplanted cells due to inflammation at the recipient site, the most important factor for successful transplantation is to ensure disease stability or quiescence prior to undergoing any of the aforementioned procedures [5]. While there is no consensus on the definition of disease stability, the Vitiligo Global Issues Consensus Conference has stated that a 12-month period of photographically assessed stability is necessary for the purposes of surgical treatment (5) [6]. Contraindications to vitiligo surgery include a personal history of keloid diathesis and presence of the Koebner phenomenon (5) [5, 7]. Each technique has its own advantages and disadvantages, and thus the most appropriate surgical approach depends heavily on the size and location of the lesion(s) being treated, physician preference and experience, patient preference, and affordability and availability of required materials (Table 55.1).

Effectiveness of Treatments

Blister Grafting

Suction blister epidermal grafting (SBEG), or, simply, blister grafting, was first described by Falabella in 1971 (4) [8]. Since then, various modifications have been made to the original technique but the basic design remains the same; autologous epidermal blister roofs from a non-affected donor sites are transplanted onto de-epithelialized vitiligo lesions. To harvest the epidermal graft tissue, a negative pressure device is placed at the donor site (most commonly the thigh, abdomen, or arm) and set to −200 to −400 mmHg. This results in separation at the dermo-epidermal junction after 1–2 h (4) [9]. Heating the donor site to 42 °C can hasten the process and result in blister formation after just 45–60 min) (4) [10, 11]. Many negative pressure devices ranging from simple syringes to custom-made suction devices can be used, depending on availability, affordability, and physician preference. Once formed, the blister roofs are cut off at the edges, and the graft is placed onto the de-epithelialized recipient site which is typically first denuded by either dermabrasion, laser ablation, freezing with liquid nitrogen, suction blistering, or PUVA (5) [12].

Like other methods of melanocyte transplantation, successful repigmentation using blister grafting depends mostly on patient selection and vitiligo subtype. Indeed, patients with segmental or focal vitiligo have been shown to have higher rates of successful repigmentation than those with non-segmental vitiligo using SBEG (4) [13]. In addition, success rates are higher in patients younger than 20 years compared to older patients [13]. Nonetheless, repigmentation efficacy using SBEG is generally good. In a systematic review

Table 55.1 Summary

	Minigraft	Blister graft	Split-thickness graft	Cultured cellular transplant	Non-cultured cellular grafting
Melanocyte source	Punch biopsy graft	Suction blister	Thin dermo-epidermal sheets	Shave biopsy	Shave biopsy Suction blister
Size of lesions treated	0–50 cm	<20 cm	100–250 cm	100–500 cm^2	100–500 cm
Repigmentation area extension	6–12 mm	10–25 mm	n/a	n/a	n/a
Duration of procedure	45 m to 2 h	2–3 h	2–4 h	>24 h	45 m to 4 h
Immobilization/ dressing period (days)	7–14	7–14	7–14	7	7
Advantages	Easy and least expensive	Easy, inexpensive, excellent cosmetic results	Highest percentage of repigmentation	Large amount of cells from small sample	– Large areas treated by using a small donor area – Reduces cell preparation time and need for laboratory – One-day procedure
Disadvantages	Time-consuming in large areas	– Time-consuming – Color mismatch		– Expensive – Requires two visits – Specialized laboratory	– High cost – Higher level of training required – Specialized instruments
Side effects	Cobblestoning Polka-dot appearance Milia Scarring Color mismatch	Color mismatch	Color mismatch Milia Scarring Hematoma	Color mismatch Safety concerns of culture media	Color mismatch

of ten case-series studies using blister grafting, 301 out of 347 (87%) [95% CI 83–90%] of patients showed >75% repigmentation (4) [14]. In a retrospective review of 1100 patients by Li et al., 227 (20%) patients achieved complete repigmentation, while 568 (52%) achieved >50% repigmentation of lesions (4). Only 43 (3.9%) showed no repigmentation after treatment. Of the 227 patients with complete repigmentation, 16 (7%) patients developed depigmentation at the site of the transplants after 1–5 years. Most of these patients had generalized or acrofacial vitiligo. There was no recurrence of vitiligo in patients with segmental vitiligo. Success rates (defined as >50% repigmentation) for segmental (89.7%) and focal (76.5%) subtypes were significantly higher than in those with acrofacial (52.4%) or generalized (52.1%) subtypes. Lesions on the face, neck, and limbs showed higher success rates than other locations, while the scalp and hands had the lowest success rates (4) [15].

Survival of suction blister grafting using SBEG is considered high when in hands of an experienced physician. Success rate of up to 86.8% have been reported (4) [16]. As mentioned for other procedures, graft survival correlates indirectly with age; patients younger than 20 years have an excellent (100%) survival rate compared to a lower (75–78%) rate in patients older than 40 years. Regarding recipient sites, the face and neck have been shown to have the highest degree of pigment spread, doubling the size of the original graft [16].

Mini-punch Grafting

Mini-punch and punch grafting are similar techniques that differ only in the size of punch instrument used. Mini-punch grafts are 1 mm in diameter, while punch grafting refers to grafts that are 1.5–2 mm in diameter. Before performing extensive punch grafting procedures, all patients should first undergo a punch grafting test or trial [5]. This is done by implanting four mini-punch grafts in a depigmented lesion. If spreading of the pigment occurs within 8 weeks, then the patient could undergo the final, more extensive punch grafting procedure (4) [17].

When performing the procedure, the donor and recipient areas are both infiltrated with 1% lidocaine/epinephrine. The preferred donor site is typically a non-affected pigmented area of the thigh, hip, or buttocks. Donor skin using mini-punch biopsies reaching into the papillary dermis is obtained from the donor site and transplanted onto the recipient site. The recipient site should be prepared by removing skin with a punch biopsy instrument of the same diameter down to the subcutaneous fat [5, 17]. The recommended distance between each defect at the recipient site is 5–8 mm, at a depth of 2–3 mm [5]. Grafts can be spaced further apart in patients with darker skin types, since pigment spread is usually more robust in these patients. After placing the mini-punch grafts in the recipient area, hemostasis is achieved by applying pressure with saline-soaked gauze over the area. Both donor and recipient sites are then covered with small strips of tape (Steri-Strips®) [17].

Approximately 57% of patients achieve repigmentation which can be first observed between 14 and 32 days (mean 20.6 days) post-transplant. The repigmentation may continue to spread to maximum of 12 mm in diameter, but the average spread is 6.5 mm (4) [18]. Fifty-one percent of patients have good to excellent repigmentation (>65% repigmentation). Patients with segmental vitiligo typically demonstrate even better repigmentation overall with 89% of patients having good to excellent repigmentation [17]. *Malakar et al.*, found that 65.6% of patients with stable and recalcitrant vitiligo achieved repigmentation rates of 90–100% (4) [19]. Maximal repigmentation is observed at 3 months on the face and 2 months in other sites. Disease duration has not been shown to affect the repigmentation response (4) [20].

Higher rates of repigmentation of up to 86.7% are seen when NB-UVB is started immediately after the removal of the dressing at approximately 7 days post-surgery [20]. Other adjuvant phototherapies such as PUVASOL have shown repigmentation of up to 10 mm in diameter (4) [21]. Because of its lower cumulative dose, Excimer laser may be preferred in children or those with history of UV-induced phototoxicity. Nonetheless, NB-UVB is still the preferred choice as it is more feasible, less time-consuming, and more effective than other forms of phototherapy (4) [22].

The graft survival rate varies, depending on patient selection and surgical expertise and experience of the physician. Mini-punch grafting is an effective and easy to perform procedure, with an 87% graft survival rate. As we have mentioned, age and body site are important predictive factors for outcome, and patients younger than 20 years and grafts performed on the neck and trunk achieve better repigmentation. Additionally, inappropriate immobilization of acral regions and joints account for a poor outcome in these body sites (4) [23]. Other negative prognostic factors include active disease and presence of the Koebner phenomenon. Indeed, patients with stable disease show significantly higher rates of repigmentation (77–88%) compared to those with active disease (39–48%) ($p < 0.05$) (4) [17, 24]. Other factors such as acral distribution, extensive disease, and other types of leukodermas (such as nevus depigmentosus, herpes-induced lip leukoderma) are usually nonresponsive to mini-punch grafting [18]. Overall, the best results in patients undergoing mini-punch grafting occur in those with segmental and focal vitiligo and those younger than 20 years old [20].

Split-Thickness Grafts

In this method, grafts containing epidermis and papillary dermis are harvested from a non-affected site (typically the lateral thigh or gluteal region) using a dermatome or shaving blade and then transplanted onto an abraded recipient site

which has been previously prepared. The graft is then held in place using pressure and an appropriate dressing [5]. *Al-Mutairi et al*. performed this procedure on 17 patients with focal and segmental vitiligo who were clinically stable for at least 1 year. The size of the treated lesions ranged from 2 to 55 cm^2. The grafted area was then treated with excimer laser twice per week. At 16 weeks post-surgery (after 32 sessions of excimer), 12 out of the 17 patients had an excellent outcome, and the remaining 5 patients had good outcome. At 1-year follow-up, all 17 patients exhibited excellent repigmentation which remained for up to 4 years (4) [25]. Similarly, in a case series of 32 lesions in 21 patients, *Agrawal et al*. found that 100% repigmentation was achieved in 68% of lesions and 90–95% repigmentation was achieved in the remaining lesions. Importantly, satisfactory color match was not seen until 3–9 months (Average = 6.3 months) (4) [26].

In a systematic review by Njoo et al. which evaluated the results of 13 studies on split-thickness grafting, successful repigmentation (>75% repigmentation) was achieved in 87% [95% CI, 82–91%] of patients [14]. This was the highest rate of repigmentation among surgical techniques evaluated. Likewise, a systematic review by *Mulekar and Isedeh* found split-thickness grafting to have the highest repigmentation rates among the various grafting techniques (4) [27].

Cultured Melanocyte Transplant

The method of obtaining the donor tissue for cultured melanocyte grafts is similar to other methods. Typically, either a Silver skin grafting knife or suction blisters are used to obtain donor skin in non-cosmetically important areas like the thighs, buttocks, or waist (4)(4) [28, 29]. The skin graft is immediately transferred to a melanocyte culture laboratory for isolation of cells; the optimum time for successful culturing takes 1–3 weeks. After 3 weeks, the cell count is raised 50–100-fold after primary culture and subcultures are performed (4) [30].

The melanocyte-keratinocyte culture medium (MK medium) used most often in this form of grafting contains basic fibroblast growth factor, bovine pituitary extract, 10% fetal bovine serum, and penicillin-streptomycin, among others (4) [28, 29, 31]. The surgical procedure to graft the cultured cells onto the recipient site is similar to that described in non-cultured epidermal suspension grafting (4) [30–32].

This entire procedure requires a well-equipped laboratory and skilled technicians, which increases the patient's cost. There are also long-term safety concerns due to the use of bovine supplements, growth factors, and antibiotics during the cell culture process. In addition, the transplant procedure takes much longer than other forms of grafting due to an initial visit for harvesting donor cells and a second one approximately 3 weeks later for the actual melanocyte transplant procedure.

NCES/MKTP Grafting

Non-cultured epidermal suspension transplantation (NCES) was first described by *Gauthier et al.* in 1991. First, donor graft tissue was obtained from the scalp through superficial shaving with a dermatome and then immersed in a solution containing 0.25% trypsin for 18 h resulting in separation at the dermo-epidermal junction. At the same time, the recipient site was prepared by inducing blister formation with liquid nitrogen. Once the incubation of the donor graft tissue was complete, the epidermal side of the graft tissue was isolated by mechanical separation in order to obtain a cellular suspension consisting of a higher proportion of basal layer cells. This suspension was then injected directly into the blisters at the recipient site. The roof of the intact blister served as a natural dressing, holding the transplanted cells in place (4) [33]. In 1998, *Olsson et al*. modified the technique by using the gluteal region as the donor area, reducing trypsinization time to 50 min by incubating the donor tissue at 37 °C, and preparing the recipient site with dermabrasion (4) [34].

Modifications of this procedure continue to be made. For example, the fixation of the liquid suspension at the recipient area was thought to be a problem; therefore, hyaluronic acid was added as a carrier to increase the viscosity (4) [35]. Other methods of recipient site preparation have been adapted such as erbium/YAG or carbon dioxide

(CO_2) laser (4) [36]. Additionally, epidermal suction blisters have also been used to obtain donor cells (4) [37]. The benefits of this method include no need to separate epidermis from the dermis since the grafts are made of pure epidermis, a more cosmetically acceptable scar at the donor site and the use of blister fluid as a natural trypsin inhibitor [37]. The preferred technique will depend on the choice of the surgeon.

A double-blind placebo controlled study established that repigmentation was in fact induced by the transplanted melanocyte suspension and not simply a result of dermabrasion (3b) [38]. In an open-label, single-center study comparing dermabrasion and CO_2 laser to prepare the recipient site, both techniques resulted in similar rates of repigmentation; however there was a higher risk of temporary hyperpigmentation in recipient sites prepared with CO_2 laser (39% vs. 18%) (3b) [39]. *Silpa-Archa et al*. also compared the use of collagen dressing to petrolatum gauze for wound dressing and found there to be a slightly greater but insignificant improvement in repigmentation in the collagen dressing group [39]. Indeed, collagen dressing is preferred by most authors, as it provides an optimal environment for cellular growth and vascularization and holds transplanted cells in place (4) [40].

Like other methods of transplantation, the best results are observed in patients with stable segmental vitiligo and piebaldism which show repigmentation rates of 85% and 90%, respectively. Mean repigmentation rates in the treatment of halo nevi and generalized vitiligo are 91% and 70%, respectively. Patients with mixed vitiligo have shown the lowest rates of repigmentation (37%), causing them to be inappropriate candidates for NCES. Patients with stable disease have mean repigmentation rate of 88.6% (95% CI 83.2–94%) compared to 48.4% (95% CI 27–59.7%) in patients with active disease. Additionally, patients with Koebner phenomenon show lower rates of repigmentation (17%) compared to patients without this sign ($p = 0.015$) (4) [41].

The location of the recipient site can also influence successful repigmentation. The face and neck tend to have the highest success rates with 19% of lesions exhibiting excellent repigmentation (≥95% repigmentation) and 50% exhibiting good repigmentation (65–94% repigmentation). The extremities (excluding elbows and knees) show the second highest rates of repigmentation with 13% of lesions exhibiting excellent repigmentation and 25% exhibiting good repigmentation. Repigmentation rate in the trunk is highly variable, as 20% of lesions show excellent repigmentation but 80% of lesions show poor repigmentation (0–24% repigmentation). Lesions on the joints show a significantly lower response rate compared to the trunk and extremities ($p = 0.017$, $p = 0.0091$) [41]. Fingertips and distal toes do not improve with NCES. While a small number of patients may show initial improvement in these areas, they tend to relapse quickly. Large lesions (1000 cm^2) and multiple smaller lesions distributed on different anatomic locations may also have a poor prognosis (5) [42]. Transplantation of the lips is not encouraged due to the difficulty of appropriate dermabrasion and the constant trauma this area undergoes after grafting [40].

In children, focal and segmental vitiligo subtypes have shown better repigmentation rates than non-segmental vitiligo. In a retrospective, long-term follow-up study (9–54 months), 75% of focal vitiligo patients had excellent repigmentation (≥95% repigmentation). Sixty-two percent of those with segmental vitiligo had excellent repigmentation, 15% had good repigmentation (65–95% repigmentation), and only 8% had fair repigmentation (25–64% repigmentation) (4) [43]. Lastly, patients with lip and finger and toe tip involvement have been associated with poorer surgical outcomes; therefore, other treatment options should be pursued for these patients (4) [44].

As with other transplant procedures, adding phototherapy post-NCES grafting increases the repigmentation rate when compared to NCES alone and nontreatment. The median percent reduction of depigmentation in excimer and NCES in combination was 41.9% compared to 15.9% for NCES alone and 0.1% in untreated patches (3b) [45].

Importantly, studies have shown that repigmentation occurs for an average of 10 months after NCES transplantation (range 0–72 months). Therefore, reevaluation for repeating the proce-

dure should not occur until 1 year post-transplant (4) [41]. A 5-year follow-up study showed that repigmentation was sustained in those with stable disease [40].

Comparative Effectiveness of Common Treatments

Blister Grafting Versus NCES and CMP grafting

Budania et al. compared SBEG to NCES in a randomized study of 41 patients with 54 stable vitiligo lesions. Twenty-one patients with 28 lesions were treated with NCES and 20 patients with 26 lesions were treated with SBEG. At 16 weeks postsurgery, excellent repigmentation (90–100%) was observed in 20 of 28 (71%) of lesions treated with NCES compared to only 7 of 28 (27%) of lesions treated with SBEG (p = 0.002). Good repigmentation (≥75%) was achieved in 25 of 28 (89%) lesions in the NCES group compare to 25 of 26 (85%) lesions in the SBEG group (p = 0.61). Importantly, while Dermatology Life Quality Index (DLQI) [46] scores improved in both groups, there was a greater improvement in those who received NCES grafting compared to those who received SBEG (p = 0.045). Both groups showed excellent color match (2b) [47].

Czajkowski compared the effectiveness of cultured autologous melanocytes plus PUVA (CMP), SBEG plus PUVA (SBP), cryotherapy plus PUVA (CP), and PUVA alone (OP) in 20 patients with focal or acrofacial vitiligo of the dorsum of the hands and lower limbs. No significant difference was found between the number of successful transplants (100% repigmentation) between CMP and SBP. CP and OP methods were found to be ineffective (4) [48].

Suction Blister Grafting Versus Punch Grafts

Gupta et al. compared epidermal suction blister grafting to punch skin grafting in 49 patients. After 4–7 months, successful repigmentation (>75% repigmentation) occurred in 67% of the lesions in the punch graft group and in 82% of the lesions in the epidermal suction blister group. While the difference between groups was not significant, the group that received SBEG achieved cosmetically better results due to lower frequency of adverse effects such as cobblestoning and superficial scarring (4) [49].

Babu et al. compared the efficacies of punch grafting and suction blister epidermal grafting in patients with stable vitiligo of the lip. A total of 18 patients were included, of whom 8 (44.4%) patients had focal lip vitiligo, 9 (50%) patients had lip-tip vitiligo, and only 1 (5.6%) patient had generalized vitiligo. Punch grafting was done using a 1.5 mm instrument and each graft was placed 3–4 mm apart. Suction blister grafting was performed by obtaining 2 cm blisters after which the recipient site was prepared by manual dermabrasion until punctate bleeding was achieved. Blisters were placed 3–4 mm apart from each other. Of the punch grafting group, six (75%) of the patients achieved good to excellent (>50%) repigmentation compared to six (60%) patients in the suction blister grafting group. The color match was significantly better in the punch grafting group when compared to the suction blister grafting group (p = 0.02). Focal lip vitiligo patients had better outcome when compared to lip-tip vitiligo patients. The most common side effect in the recipient sites was cobblestoning in the punch graft group, whereas hyperpigmentation and thickening of grafts was the most common adverse effect in the suction blister group. There was no significant difference in repigmentation outcome in regard to age, sex, type of vitiligo, and disease duration. The authors concluded the preferred surgical treatment for stable lip vitiligo is punch grafting due to higher repigmentation, milder side effects, and better color match (4) [50].

NCES Grafting Versus CMT Grafting

In a study by *Verma et al.,* similar lesions on the same patient were transplanted with either NCES or CMT. Two target patches were grafted with 1500 cells/mm^2 with NCES and equal number of cells with CMT. The recipient site was prepared by dermabrasion until the appearance of pinpoint bleeding was achieved for both techniques. Repigmentation was evaluated by three-dimensional

analysis (3-D), transparent graph paper, and two-dimensional (2-D) computerized analysis. Excellent repigmentation (>75%) was observed in significantly higher number of lesions treated with CMT as compared to NCES as early as 8 weeks post-surgery. At the end of the 12-week period, four (100%) patients with segmental vitiligo achieved more than 90% repigmentation with CMT compared to 40% repigmentation with NCES. Overall 66% of lesions showed >70% repigmentation with CMT. A possible explanation for a better response could be due to the fact that pure melanocytes are transplanted in CMT allowing faster and better repigmentation compared to melanocytes from NCES, in which the number of melanocytes is lower (1 melanocyte:10–36 keratinocytes) (4) [51].

Cultured Melanocyte Grafting Versus Split-Thickness Grafting Versus NCES Grafting

In a retrospective case series of 124 patients with vitiligo, *Olsson and Juhlin* compared the long-term (1–7 years post-transplant) efficacy of autologous cultured melanocyte transplantation, split-thickness grafting, and NCES grafting. Of the 15 patients with segmental vitiligo, 5 were treated with cultured melanocytes, one was treated with split-thickness grafting, and 8 were treated with NCES grafting. All but one patient showed 95–100% repigmentation of their lesions. The remaining patient, who was treated with cultured melanocyte transplantation, had 85% repigmentation. Two patients with focal vitiligo treated with NCES grafting showed 100% repigmentation. In the 107 patients (369 anatomical sites treated) with non-segmental vitiligo, those who underwent cultured melanocyte transplantation (277 anatomical regions) achieved mean 42% repigmentation; those who underwent split-thickness grafting (40 anatomical regions) achieved mean 59% repigmentation; and those who underwent NCSE (52 anatomical regions) achieved mean 49% repigmentation. In the non-segmental group, patients with shorter disease duration, smaller affected areas, and younger age tended to response best to transplantation. The authors concluded that split-thickness grafting was the method which achieved better overall repigmentation but was also associated with worst outcome on the knees and elbows (4) [52].

Preoperative Evaluation and Patient Selection

The single and most important prerequisite prior to considering surgical intervention for vitiligo is to ensure disease stability. While there is no consensus regarding the minimum period of stability, the absence of new lesions, lack of progression of old lesions, and lack of signs of activity, such as the Koebner phenomenon, over the last year is the most commonly accepted definition of stability (4) [7, 53]. Some authors recommend test grafting in order to ensure disease stability [5]. While likely unnecessary in all cases, this method should be considered when there is doubt about stability or the patient's history is not entirely reliable. This method consists of placing four to eight mini-punch grafts and then observing the treated area for 12 weeks; if repigmentation is observed beyond 1 mm from the border of the graft, the test is positive and is considered a marker of disease stability (4) [54]. The Vitiligo Disease Stability Activity Score (VIDA) is another subjective method of establishing disease stability that relies heavily on patient recall. Surgery is recommended only in patients with VIDA scores of −1 or 0 (stable for at least 1 year and/or presence of spontaneous repigmentation) (4) [55].

While some studies suggest better surgical outcomes in younger patients, there is no consensus regarding the minimum age for surgery (4) [43]. Therefore, this decision should be left to the physician's judgment, taking all aspects of the disease and its impact on the patient and family into consideration. Lastly, the need for concomitant medical therapy, especially NB-UVB phototherapy, should be emphasized to the patient, as this can help repigmentation postoperatively.

Impact of Patient Preference

The choice of surgical intervention should be individualized. It is important to consider the type of vitiligo, location/size of depigmented

patches, downtime, and cost-effectiveness of the procedure. Small depigmented areas may achieve successful repigmentation with mini-punch grafting and blister grafting. Punch grafting is considered to be the easiest, fastest, and least expensive treatment modality. Mini-punch and blister grafting are the fastest procedures, whereas non-cultured cellular grafting takes up to 4 h. This should be explained to the patient when discussing the different treatment options. In large recipient areas, interventions like split-thickness grafting and cellular grafting should be considered. Split-thickness grafting might leave a less cosmetically acceptable scar in the donor area, compared to cellular grafting performed with blisters. Donor areas will usually have post-inflammatory hyperpigmentation, which usually resolves in a matter of months to 1 year. All cellular grafting comes with higher cost, therefore, cost of therapy should be discussed when proposing different surgical interventions to the patient (4) [56].

Typical Treatment Plan

A 23-year-old South Asian female presents to your clinic with a 16-year history of segmental vitiligo of her right chin and neck. The patient has been treating the areas with topical tacrolimus 0.1% twice daily and NBUVB phototherapy three times per week for over 1 year without any noticeable improvement. She would like further evaluation and management and would like to pursue surgical treatment options. There is no family history of vitiligo and no personal history of keloid diathesis.

Physical exam reveals a depigmented patch on her right chin extending to the right anterior neck approximately 5 × 10 cm in area, and leukotrichia is present throughout most of the lesion. There are no signs of repigmentation or signs of disease activity such as confetti-like depigmentation, trichrome depigmentation, or Koebner phenomenon. There are no other lesions on other areas of the body.

Segmental vitiligo is highly responsive to surgical therapies and should be considered when a patient has recalcitrant vitiligo despite 1 year of nonsurgical therapies. Given the size of the lesion in this case, the most appropriate surgical options to consider are autologous cultured transplant procedures and non-cultured epidermal suspension grafting. The patient is informed of the costs, possible risks, and efficacy of both procedures and elects to undergo NCES grafting, as she prefers to only miss 1 day of work. The patient is scheduled to undergo NCES grafting in 2 weeks and is told to continue NBUVB up until the day of procedure. Because the patient has a history of multiple herpes labialis outbreaks per year, she is prescribed oral valacyclovir 500 mg PO twice daily to be initiated 1 day prior to the procedure.

On the day of the procedure, the patient is consented for treatment, and the possible risks are explained, such as infection, scarring, incomplete repigmentation, and hypo-/hyperpigmentation. The steps of the procedure are explained to the patient and all remaining questions are addressed. The lesion to be treated is outlined using a 1 cm transparent grid paper, and the number of blisters necessary to cover a 50 cm^2 recipient area is calculated. The donor site is properly cleansed and suction blistering is initiated on her left lateral thigh with a negative pressure system. While the blisters are forming, the recipient area is prepared by first anesthetizing with lidocaine and then denuded using erbium/YAG laser with enough passes to produce pinpoint bleeding at the recipient site. Once formed, the blisters are prepared for suspension with trypsin and centrifugation and then transplanted onto the recipient site.

The recipient and donor sites are dressed appropriately, and the patient is instructed to leave the recipient site dressing in place for 7 days. She is also instructed to re-initiate NBUVB phototherapy thrice weekly the day after removal of the dressing. The patient is told to follow-up in clinic in 3 months, with the expectation that 25% repigmentation would be seen at this time. At her 2-month follow-up appointment, only 20% repigmentation is seen; however, the patient admits to inconsistent phototherapy adherence. The patient is informed of the importance of phototherapy post-transplantation and is encouraged to increase adherence as final repigmentation results are not seen until approxi-

mately 1-year post-transplantation. At her 1-year follow-up, 75% repigmentation is observed. Further surgical options, such as further NCES grafting, SBEG, and mini-punch grafting, are offered to the patient in order to cover any residual depigmentation; however, the patient is satisfied with her current progress and does not desire any further intervention.

Safety

Blister Grafts

Suction blistering is a relatively safe procedure without any serious adverse events reported in the literature [13]. Hyperpigmentation of both the donor and recipient sites is the most common adverse event using this technique. Rates of hyperpigmentation at the recipient site vary between 16.5% and 38% [13]. Hyperpigmentation of the donor site can be expected in most patients as a result of post-inflammatory hyperpigmentation, but this typically resolves 6 months post-surgery (4) [57]. Other less common side effects and their reported frequency include Koebner phenomenon of the donor site (2%) [95% CI 1–4%], imperfect color match (4%) [95% CI 4–10%], infection (1%) [95% CI 0–3%], and scar/keloid formation (1%) [95% CI 0–3%] [14]. Importantly, suction blistering has been safely and successfully used to treat adolescents (4) [58].

Split-Thickness

Milia and partial loss of grafts are the two most common adverse effects with split-thickness grafting, occurring in 13% [95% CI, 8–18%] and 11% [95% CI, 7–15%] of patients, respectively. Scar formation at the donor site occurs in approximately 12% [95% CI, 34–47%] of patients. Hyperpigmentation at the donor site can also be seen [14].

Punch Graft Safety

Complications of this procedure are most likely to be cobblestone-like appearance, which occurs in 27–31.8% of treated lesions. This side effect can be ameliorated by using smaller grafts (1–1.2 mm) [17, 18]. Polka dot appearance and color mismatch can be seen in 43% and 34%, respectively [19]. Hemostasis is essential, since graft protrusion caused by excessive bleeding often leads to milia formation [20].

It is important to consider that the smaller the punch graft, the better the cosmetic result and the faster the repigmentation rate; while the bigger the punch, the longer the repigmentation time and the greater the risk of cobblestone-like scarring (4) [59]. Fortunately, 87% of patients feel the transplant has had a positive impact on their quality of life [24].

Autologous Cultured Melanocyte Transplantation

The risk of infection at the donor and recipient site is relatively low, ranging from 7.4% to 11%. This procedure usually does not cause milia or scarring [30]. The presence of the Koebner phenomenon has been reported after CMT in 4% of patients. Safety concerns of culture media and supplements used to cultivate the melanocytes is a main concern. High concentrations of mitogenic factors that are used for melanocyte culture accelerate the growth cycle, potentially increasing the risk of carcinogenesis of transplanted cells. However, studies using different concentrations of culture media have not shown gene mutations in specific signaling pathways. Long-term follow-up studies are needed to assess this risk (4) [60].

NCES/MKTP Grafting

Common side effects seen in a retrospective study were color mismatch (hypo-/hyperpigmentation) in 80%; however, this was found to be non-concerning in 79% of treated patients. Furthermore color mismatch tends to improve improves after sun exposure ($p = 0.012$). Only 7% experienced some loss of pigment at follow-up, all with generalized vitiligo [41]. Less common side effects include mild scarring in 3% [44].

Postoperative Care and Follow-Up

Once post-transplant would healing has occurred, patients should be seen at regular 3–4-month intervals for up to a year after transplantation to ensure they have not had recurrence of disease

and to ensure adherence of any postoperative treatments (e.g., phototherapy). Final results of the transplantation procedure are not seen until after about 1-year post-transplantation in most cases. At this point, patients should be reevaluated and considered for an additional transplantation procedure if necessary.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
General	
Disease stability of over 1 year is associated with higher success rates for vitiligo grafting procedures	C
Test grafting with mini-punch grafts should be considered when the status of disease stability is unclear	C
Patients with focal and segmental vitiligo have better outcomes compared to those with generalized vitiligo	C
Distal extremities have a poorer outcome compared to the head, neck, and trunk	C
Younger patients tend to have better results compared to older patients	C
Postoperative phototherapy is associated with higher rates of repigmentation	C
Continued repigmentation of the recipient site is seen for up to a year after transplantation in some cases	C
Repeat procedures or combination of procedures may be required in order to obtain complete repigmentation	C
SBEG	
The majority of patients have over 50% repigmentation of treated lesions	C
Regarding recipient sites, the neck and face have been shown to have the highest degree of pigment spread	C
SBEG has been safely and successfully used to treat adolescents	C
Mini-punch grafting	
The majority of treated patients have good to excellent repigmentation of treated lesions	C
Patients with darker skin types tend to have larger areas of recipient site graft spread	C
Smaller punch grafts are associated with better cosmetic results	C
Split-thickness skin grafts	
Success rate is high with split-thickness skin grafts	C
Side effects include scarring and color mismatch	C
Cultured melanocyte transplants	
While usually successful, CMT requires a well-equipped lab and 1–3 weeks to prepare the cells prior to transplantation	C
Long-term safety concerns may be present due to additives in the culture medium	C
NCES/MKTP grafting	
The majority of treated patients have good to excellent repigmentation of treated lesions	C
Maximum repigmentation occurs at a mean of 10 months after surgery	C
Relative efficacy of procedures	
NCES grafting is more efficacious than SBEG grafting	C
SBEG grafting has lower risk of adverse effects compared to punch-grafting	C
Punch grafting is more efficacious than SBEG for lip vitiligo	C

Self-Assessment Questions

1. True or False: PUVASOL and NB-UVB phototherapy are contraindicated in patients after undergoing mini-punch and epidermal blister grafting, due to a lower graft survival rate.
2. All of the following patients are good candidates for surgical procedures, EXCEPT:
   (a) A 10-year-old South Asian female, with segmental vitiligo in her left trunk diagnosed at age 5, who has tried topical steroids, tacrolimus, and NB-UVB phototherapy for 3 years.
   (b) A 30-year-old Hispanic male, with a depigmented 5 cm patch on his jawline, who has tried NB-UVB phototherapy for 3 years, which has resulted in 75% repigmentation.
   (c) An 18-year-old Caucasian male, with depigmented macules and patches on his face, chest, knees, and arms, which have responded to topical steroid and phototherapy achieving a 50–75% repigmentation in 14 months. He is interested in a surgical procedure only his forehead and cheek since those lesions are more visible.
   (d) A 29-year-old Caucasian female, with depigmented patches on her face and trunk; she has treated the areas with NB-UVB phototherapy and tacrolimus for 2 years and is very compliant with treatment. She denies any new lesions. On physical exam she has generalized vitiligo, with 4% BSA involvement, trichrome, and confetti-like lesions.
   (e) A 40-year-old African-American female with a depigmented patch on her left forehead since age 10. She states she tried phototherapy for 1 year but she did not see any repigmentation over 3 years ago. On physical exam you observe leukotrichia.
3. The appropriate depth that should be reached when preparing the recipient defect for punch grafts to minimize adverse effects is:
   (a) papillary dermis
   (b) upper reticular dermis
   (c) lower reticular dermis
   (d) subcutaneous tissue
   (e) none of the above
4. Punch grafting testing is a good method to determine disease stability when there is uncertainty. Patients are considered "stable" if there is a 1 mm spread of pigment at ____ post-transplant.
   (a) 6 weeks
   (b) 12 weeks
   (c) 20 weeks
   (d) 30 weeks
   (e) 40 weeks
5. You perform a non-cultured epidermal suspension graft in a 30-year-old South Asian female who presented to your clinic for segmental vitiligo on the chest. At her 6-month follow-up visit, you observe she has 40% repigmentation. The patient is very anxious. What would be your next approach?
   (a) Schedule her for a second NCES grafting on your next available date
   (b) Suggest performing a mini-punch grafting in the rest of the area, since it has been shown to have higher success rates than NCES grafting
   (c) Encourage the patient to continue her phototherapy and reassure her that improvement is usually until 1 year after the procedure is performed
   (d) Discuss with the patient she will not be a candidate for any surgical procedure at any point
   (e) Discuss with the patient the transplant was a failure since we except at a least 90% repigmentation by 6 months

Answers

1. False: Phototherapy post-transplantation have been shown to increase the repigmentation rate in patients with vitiligo compared to the surgical procedure alone.
2. d: The patient has active disease, due to the presence of trichrome and confetti-like lesions; therefore she is not a candidate for any surgical procedure.
3. b: The donor punch should reach the subcutaneous tissue to avoid a cobblestone effect postsurgery.
4. d: When in doubt regarding the presence of active disease, test grafting can be performed. The test is positive and considered a marker of disease stability if after placing four to eight punch grafts, repigmentation beyond 1 mm from the border of the graft at 12 weeks is observed.
5. c: Studies have shown that repigmentation occurs up to 10 months after NCES grafting. A second procedure could be considered and discussed with the patient after 1 year post-transplantation.

Morphea and Scleroderma

56

Rachel Kyllo and Martha Laurin Council

Abstract

Morphea and scleroderma are a spectrum of autoimmune connective tissue disorders hallmarked by tissue fibrosis. Morphea is localized to the skin, subcutaneous tissues, and occasionally, deeper, directly underlying structures such as muscle and bone. In contrast, scleroderma is characterized by systemic involvement, including the vasculature and internal organs (1a) (Fett, Clin Dermatol 31:432–437, 2013). Treatment largely depends upon the extent of disease, with minor cases of morphea requiring observation and systemic sclerosis requiring potent immunosuppressive medications. Although an exhaustive discussion of medical therapies for this spectrum of diseases is beyond the scope of this chapter, surgeries and laser therapy are important components of comprehensive care of these patients. The cosmetic and functional sequelae of morphea and scleroderma can be extensive, and the procedural dermatologist is in a unique position to reverse some of the manifestations of these debilitating diseases.

Introduction and Epidemiology

Morphea and scleroderma are a spectrum of autoimmune connective tissue disorders hallmarked by tissue fibrosis. Morphea is localized to the skin, subcutaneous tissues, and occasionally, deeper, directly underlying structures such as muscle and bone. In contrast, scleroderma is characterized by systemic involvement, including the vasculature and internal organs (1a) [1]. Treatment largely depends upon the extent of disease, with minor cases of morphea requiring observation and systemic sclerosis requiring potent immunosuppressive medications. Although an exhaustive discussion of medical therapies for this spectrum of diseases is beyond the scope of this chapter, surgeries and laser therapy are important components of comprehensive care of these patients. The cosmetic and functional sequelae of morphea and scleroderma can be extensive, and the procedural dermatologist is in a unique position to reverse some of the manifestations of these debilitating diseases.

Morphea is a distinct clinical entity characterized by sclerosis of the dermis and subcutaneous fat. Rarely, deeper tissues such as fascia,

muscle, tendon, or bone, directly beneath the involved skin and subcutaneous tissue, may also be involved. Several clinical variants of morphea exist (2a) [2, 3]. The most common type is plaque-type morphea, featuring an erythematous, indurated plaque that becomes sclerotic over time, often with resulting post-inflammatory hyperpigmentation. Guttate morphea is characterized by smaller, more numerous lesions, otherwise similar in morphology to plaque morphea. Deep morphea has involvement of the deep dermis and subcutaneous fat, sometimes resulting in dystrophic calcification. Nodular morphea presents with keloidal papules and plaques. Linear morphea often involves the underlying fascia, tendons, and muscles, which can result in painful joint contractures and immobilization. Morphea *en coup de sabre* is a variant of linear morphea involving the forehead (Fig. 56.1); Parry-Romberg syndrome is a severe variant that results in hemifacial atrophy and significant cosmetic disfigurement.

The estimated prevalence of morphea in the United States is 2.7 per 100,000 population (2b) [4]. There is a female predominance of approximately 3:1 (2a, 2b) [3, 5]. Children and adults are affected at equal frequencies; the most common variant in adults is plaque-type morphea, while linear morphea is the most common presentation in children (2b) [4–7].

Fig. 56.1 En coup de sabre morphea. (Image courtesy of Dr. Lesley Lawley)

Scleroderma has a worldwide distribution and can affect all ages and races (2b, 1a) [8, 9]. The prevalence of scleroderma in North America is estimated at between 3 and 24 per 100,000 persons [9]. There is a strong predilection for the female gender; the incidence in women is approximately four times higher than in men (1a) [10]. The average age of onset is in the 4th–6th decades [9].

Scleroderma is divided into two clinical categories: limited systemic sclerosis, characterized by fibrosis limited to the face and peripheral extremities, and diffuse systemic sclerosis, in which fibrosis of the skin spreads to involve proximal extremities and the trunk (2a, 2b) [11, 12]. CREST syndrome is a variant of limited scleroderma characterized by calcinosis cutis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasias (Fig. 56.2). Most patients with scleroderma (90%) will have a positive antinuclear antibody (ANA); other associated autoantibodies include the anti-centromere antibody, which is associated with CREST syndrome, and the anti-topoisomerase antibody, which is associated with diffuse scleroderma (1a, 1b, 1b) [13–15].

Scleroderma has numerous cutaneous manifestations (1a) [16–18]. As fibrosis of the peripheral extremity progresses, patients often develop painful digital ulcerations. Dyspigmentation is common, with both hyperpigmentation and hypopigmentation possible. Mat-like telangiectasias develop on the face, lips, and palms, which are cosmetically displeasing. Dystrophic calcification is possible, particularly on the digits. Scleroderma is one of the leading causes of secondary Raynaud's phenomenon, which can have a dramatic impact on patient quality of life (3a) [19].

Patients with scleroderma are best managed in conjunction with a multidisciplinary team of rheumatologists, pulmonologists, gastroenterologists, and nephrologists. The leading cause of mortality from systemic sclerosis is pulmonary disease [9]. Internal manifestations of sclero-

derma are myriad and include pulmonary arterial hypertension, pulmonary interstitial fibrosis, esophageal dysmotility and reflux, scleroderma renal crisis, and congestive heart failure [16, 17]. Patients are often placed on immunosuppressive medications to prevent progression of internal organ involvement.

Treatment Considerations: Morphea

First-line treatments for plaque morphea include topical and intralesional corticosteroids, topical calcineurin inhibitors, and phototherapy (3a) [20]. Linear morphea tends to have an aggressive clinical course, and treatment with pulsed systemic corticosteroids as well as methotrexate appears to reduce the frequency of late-stage sequelae such as joint contractures, which lead to limited range of motion and functional disability. Importantly, variants of linear morphea that affect the face (morphea en coup de sabre and hemifacial atrophy) can dramatically affect facial symmetry. The resultant cosmetic defects can be pronounced, causing psychosocial distress to affected patients.

Morphea en coup de sabre affects the forehead or paramedian scalp, often leaving depressed linear scars. Various methods to cosmetically restore the resultant soft tissue deficit have been reported, including hyaluronic acid (HA) filler (4) [21, 22], polymethylmethacrylate (PMMA) (4) [23], polyacrylamide hydrogel (4) [24], and autologous fat transplantation (4) [25–27]. Progressive hemifacial atrophy (also known as Parry-Romberg syndrome) often involves the deeper soft tissues, cartilage, and bone, leading

to pronounced facial asymmetry. Surgical techniques that have been used to correct this asymmetry include autologous fat transplantation, bone and cartilage grafts, osteotomies with bone repositioning, pedicled and free flaps, and hair transplantation.

Practitioners must recognize the theoretical risk that injection of filler or other material into the area of a quiescent morphea plaque could result in reactivation of the patient's morphea. The typical time course of linear morphea involves a period of intense activity for 3–5 years, after which the disease typically becomes quiescent. However, the time course of the disease is variable, and reactivation has been reported decades after initial diagnosis (2b) [28]. Ideally, clinicians wait to perform any cosmetic restoration on patients with linear morphea until the disease has been quiescent (asymptomatic with no progression and no changes in size or color) for a period of at least 3–5 years. Regardless, patients should be counseled regarding the theoretical risks of reactivation of their underlying morphea prior to cosmetic restoration attempts.

Hyaluronic acid fillers are United States Food and Drug Administration (FDA) approved for the correction of facial rhytides and have been used for decades with an acceptable safety profile. Rare complications of hyaluronic acid filler injection include tissue necrosis or embolization due to inappropriate injection of filler into blood vessels, allergic reactions, and granuloma formation. Injection of hyaluronic acid has been utilized in multiple case reports to fill the atrophic defects left by morphea en coup de sabre and hemifacial atrophy (4) [21, 22, 29].

Notably, these procedures involve injection of hyaluronic acid into the forehead and medial cheek, where most clinicians have little experience injecting filler. One should be especially cautious not to inject in or near blood vessels which could result in tissue necrosis. In general, physicians performing hyaluronic acid filler injection in unfamiliar areas should aspirate before injecting to ensure appropriate needle positioning (outside of any blood vessels), and low volumes should be used (1.0 cc or less at a time) to avoid these complications. With these precautions, hyaluronic acid injection is a noninvasive option for replacing the soft tissue defects left by morphea en coup de sabre and hemifacial atrophy. Appropriate pretreatment counseling regarding the theoretical risk of reactivation of their underlying morphea is an absolute necessity. Patients should also be counseled regarding expected posttreatment bruising and edema and the probable need for repeat treatments as the hyaluronic acid is dissolved over time.

Alternatives to hyaluronic acid filler injection include permanent fillers such as polymethylacrylate and polyacrylamide hydrogel. Polyacrylamide and polymethylacrylate are permanent fillers that have primarily been used to treat Human Immunodeficiency Virus-associated lipoatrophy. Polyacrylamide filler has been used successfully in the treatment of progressive hemifacial atrophy in a single case report [24], while polymethylmethacrylate has been used successfully in the treatment of morphea en coup de sabre of the forehead in a single case report [23]. Only experienced injectors should consider use of permanent filler, as injection techniques must be impeccable to avoid overcorrection.

Autologous fat grafting is another procedure that has been used for the treatment of linear morphea (4, 4, 4, 4, 3b) [25–27, 30, 31]. The fat graft is typically harvested from an area with high adipocyte density (such as the abdomen, hip, or buttocks). The adipocytes can either be injected directly into the area of atrophy [26, 31] or the graft can be harvested en bloc and inserted into a pocket created by a linear incision along the atrophic defect [27, 31]. Overcorrection of the defect is recommended, as the graft will flatten naturally with resorption over time. Injected fat grafts tend to require multiple treatments over time to achieve an acceptable cosmetic result [25, 26, 31]. One study involving 20 patients with linear scleroderma of the face showed 51–75% long-term correction of forehead lesions after an average of 4.2 treatments [31].

Advantages of autologous fat grafting include the wide availability of donor tissue in most individuals, and the biocompatibility of the graft, with decreased risk of granulomatous or allergic reactions compared to injection of foreign materials. As with hyaluronic acid injection, rare reports of tissue necrosis or embolization of injected

material to cerebral or retinal vessels have been reported after autologous fat injection (3a) [32]. Patients should also be counseled regarding expected postoperative bruising, edema, scarring (if the en bloc technique is used), and risk for infection. Overall, autologous fat grafting appears to be an acceptable option for the restoration of atrophy associated with linear morphea of the face. Existing evidence for the procedure is limited to case reports and case series. No studies comparing hyaluronic acid filler with autologous fat grafting for this indication exist.

Patients with severe disfigurement due to progressive hemifacial atrophy or larger defects of morphea en coup de sabre may require more aggressive plastic surgery under general anesthesia for repair. Localized pedicled flaps or free flaps can be used to replace the soft tissue volume of the affected side of the face (4) [33–35]. A recent systematic review comparing free flaps, localized pedicled flaps, and structural autologous fat grafting found that free flaps were superior, with the lowest complication rate (8.4% compared to 12.4% for localized flaps) and reoperative rate (0.7% compared to 7.1% for fat grafting) (2a) [36].

Osteotomies with subsequent bone repositioning may be necessary in cases with significant involvement of the facial bones. Autologous bone grafts (4) [37], demineralized bone matrix [33], and calcium phosphate hydroxyapatite cement (4) [38] have been used when bony repositioning is insufficient to fill the defect. Defects of the nasal ala may be repaired using composite grafts, and scalp grafts can be used to replace the hair of the eyebrow [37]. In general, preoperative imaging with a computerized tomography (CT) scan of the face to delineate the extent of bone and muscle involvement is prudent.

Often, extensive plastic surgery is carried out over the course of multiple operations, with less invasive techniques such as filler or autologous fat grafting used to perfect the final cosmetic result only after the patient has fully healed from the operation. As expected, major facial plastic surgeries have increased risks compared to noninvasive techniques. Patients should be counseled regarding the possibilities for postoperative bleeding or hematoma, wound infection, flap necrosis or atrophy, nerve damage, and hardware failure. A recent report including 43 patients who underwent plastic surgery for progressive hemifacial atrophy reported a 6% complication rate (3b) [39].

Treatment Considerations: Scleroderma

Raynaud's Phenomenon

Raynaud's phenomenon is a painful condition in which vasoconstriction leads to reduced blood flow to the distal fingers or toes, causing characteristic color changes from pallor (white), to cyanosis (blue), to rubor (red) as the episode resolves. Scleroderma is the leading cause of secondary Raynaud's phenomenon, and more than 95% of scleroderma patients suffer from Raynaud's (1a, 1b, 1b) [40–42]. The pathophysiology of Raynaud's phenomenon is abnormal vascular thermoregulatory control related to hyperactivation of the sympathetic nervous system and endothelial cell dysfunction (1a) [43]. Raynaud's phenomenon is typically treated with cold avoidance and oral calcium channel blockers such as nifedipine (1a) [44]. Second-line therapies include phosphodiesterase type 5 inhibitors (1a) [45] and topical nitrates.

Surgical intervention can be considered for cases of treatment-resistant Raynaud's phenomenon with recalcitrant digital ulcers or digital ischemia. Chemical sympathectomy, achieved by injection of local anesthetic in the proximity of the affected sympathetic ganglia, can induce relief of symptoms (3b, 4, 4) [46–48]. Unfortunately, this may result in compensatory decreased blood flow on the contralateral side, and symptomatic relief is only temporary [48].

Endoscopic thoracic sympathectomy may be used to surgically disrupt the sympathetic chain between the T2 and T4 levels and reduce sympathetic hyperactivation to the hands. A 2011 meta-analysis of thoracic sympathectomy of 15 non-randomized trials found that thoracic sympathectomy resulted in long-term benefit for 58%

of patients with Raynaud's related to underlying scleroderma (2a) [49]. Digital ulcer healing occurred after thoracic sympathectomy in 81% of patients. There is substantial risk of postoperative compensatory sweating (between 45% and 99% reported risk) or ipsilateral Horner syndrome (up to 7% of patients). Overall, thoracic sympathectomy is an invasive surgical procedure with significant risks and should only be undertaken in refractory cases that have exhausted all other treatment options at significant risk for digit auto-amputation.

A less invasive approach is local digital sympathectomy, in which the nerves providing sympathetic innervation are stripped from the arteries providing blood flow to the affected digits. This procedure is not associated with risk for Horner syndrome or compensatory sweating (4) [50]. A retrospective review found that 32/38 (84%) of patients treated with digital sympathectomy for digital ulcers associated with scleroderma had ulcer healing after the procedure (2a) [51]. A 2015 clinical case series of 31 cases of digital sympathectomy found that 86% of patients experienced relief of ischemic pain, and 83% of patients had decreased incidence of digital ulceration after 5 years of postoperative follow-up (4) [52]. Digital sympathectomy is a less invasive procedure with fewer risks than thoracic sympathectomy, although 37% of patients have reported postoperative complications [50] (level 4, grade C).

Recently, several case reports and case series have shown encouraging results on the use of injected botulinum toxin-A (BTX-A) in Raynaud's phenomenon. BTX-A has been shown in animal studies to block sympathetic nerve conduction, providing a mechanistic explanation for its utility in reducing vasoconstriction in patients suffering from Raynaud's (5) [53]. Typically, 100 units of BTX-A is injected locally into the hand, with injections concentrated on neurovascular bundles of digits and the superficial palmar arch (3b) [54]. A 2016 review of 11 case series found that between 85% and 100% of patients reported decreased pain after BTX-A injection, with the majority of patients experiencing immediate relief (2a) [55]. The duration of treatment effect averaged to 4–6 months (3b, 2a, 4, 2b, 2b, 2b) [54, 56–59]. Healing of digital ulcers was noted in 48–100% of patients.

BTX-A has an excellent safety profile, with risk for allergy or anaphylaxis quite low. The main adverse event associated with BTX-A injection in these areas is weakness of the intrinsic muscles of the hand, which is typically transient and mild. Therefore, BTX-A may be a safe and effective second-line treatment for secondary Raynaud's phenomenon, with improved pain and healing of digital ulcerations with minimal side effects. BTX-A injection is less invasive than surgical sympathectomy, and its effects are transient. A blinded, randomized controlled trial on the efficacy of BTX-A injection in secondary Raynaud's is needed.

Calcinosis Cutis

Calcinosis cutis is characterized by dystrophic deposition of calcium in the soft tissues. Calcinosis is a frequent occurrence in patients with scleroderma and is associated with significant morbidity due to pain, overlying ulceration, and subsequent functional disability. In addition, the calcium deposits are often visible and may be cosmetically displeasing to some patients. Medical treatment options are disappointing. Treatment of calcinosis with low-dose warfarin, bisphosphonates, diltiazem, minocycline, and rituximab has been reported in the literature, but treatment effects are minimal, particularly for long-standing or larger lesions (4) [60, 61]. Surgical excision or curettage of calcinosis cutis is effective for both small and large lesions and is the treatment of choice for idiopathic calcinosis cutis [61]. Surgical excision has been used successfully in the treatment of calcinosis secondary to scleroderma (4) [62]. However, patients with scleroderma frequently have issues with prolonged wound healing, making surgical excision a less attractive option in these patients (2a) [63].

Carbon dioxide (CO_2) laser has also been used as an ablative therapy to vaporize calcinosis

cutis in scleroderma (4, 3b) [64, 65]. The largest case series reported at least moderate improvement in 17/21 (81%) lesions treated with CO_2 laser, with a recurrence rate of 10% after median follow-up of 20 months [65]. The main risk associated with CO_2 laser treatment is postoperative infection, and patients can be placed on prophylactic antibiotics posttreatment for prophylaxis if desired [64]. Scleroderma patients treated with ablative CO_2 laser may experience delayed wound healing as with other surgical treatments for calcinosis. CO_2 laser is likely an effective therapy for calcinosis cutis and can be considered for patients with calcinosis who prefer to avoid surgical excision or curettage of lesions.

Extracorporeal shock wave lithotripsy (ESWL), in which acoustic shock waves are used to break up calcium deposits, has also been reported as a treatment for calcinosis cutis in one case report and one small cohort (4, 2b) [66, 67]. In the largest case series reported, patients were treated with three 20-min sessions of ESWL to the affected areas of the skin. Pain reduction was seen in five of seven patients, and six of nine treated lesions showed reduced surface area after three treatment sessions, while no patients experienced an adverse effect [67]. Contraindications to ESWL include pregnancy, chronic renal insufficiency, and presence of a pacemaker. ESWL is more effective for calcinosis lesions that have already ulcerated [60]. ESWL appears to be associated with decreased pain compared to surgical procedures; however, it is likely less effective. Studies directly comparing ESWL to ablative therapies will need to be done before the procedure can be recommended routinely over surgical procedures.

Telangiectasias

The mat-like telangiectasias of scleroderma commonly affect cosmetically sensitive areas of the face, neck, upper trunk, and distal upper extremities. Many patients find the appearance of their telangiectasias cosmetically disfiguring. The 585 nm pulsed dye laser (PDL) was first reported as a treatment for the telangiectasias associated with scleroderma in 1996 (2b) [68]. PDL works by inducing selective photothermolysis of the ectatic vessels that make up the telangiectasia, as the oxyhemoglobin within the vessel wall preferentially absorbs that wavelength of light. In general, patients are treated with a 585 or 595 nm pulsed dye laser at fluences of 5.5–7 J/cm^2 with a 5–7 mm spot size. Each lesion is treated with 1–2 pulses to a treatment end point of mild purpura (3b) [69].

More recently, intense pulsed light (IPL) has been described as a treatment modality for telangiectasias associated with scleroderma. IPL emits noncoherent, broad-spectrum white light, which induces some degree of photothermolysis of vessels via absorption of the radiation throughout the entire depth of the vessel (2b) [70]. In general, patients treated with IPL receive 1–2 passes of intense pulsed light (550–1100 nm wavelength) at a fluence of 24–36 J/cm^2 after skin preparation with ultrasound gel to facilitate light-tissue coupling [70]. Fluence and pulse duration should be selected based on patient's skin type, with more conservative (lower fluence) values chosen for initial treatment in darker skin types. Both PDL and IPL have been reported as successful treatment modalities for telangiectasias associated with scleroderma (2b, 3b, 2b, 1b) [68–71].

Posttreatment purpura and edema are expected side effects after PDL treatment. Scarring is a very rare but cosmetically disfiguring complication. Intense pulsed light has fewer side effects but may be less effective. A within-subject randomized trial in which patients received IPL to one side of the face and PDL to the other demonstrated significant improvement with decreased number of telangiectasias bilaterally. PDL resulted in greater clinical improvement but with greater adverse effects (bruising) [71].

Histopathologic analysis of skin samples has shown that, relative to normal skin controls, the telangiectasias of scleroderma patients have

thicker vessel walls and collagen fibers. The telangiectasias associated with scleroderma have been shown to be more resistant to standard laser treatments used for essential telangiectasias, requiring an average of twofold the number of treatments to clearance of individual lesions [69]. Patients should therefore be counseled pretreatment regarding expectations and the likely need for repeat treatments. Overall, both PDL and IPL appear to be effective treatments for telangiectasias associated with scleroderma (level 2b, moderate). PDL appears to be more effective but with greater risk for adverse effects such as bruising and complications.

Conclusions

In summary, morphea and scleroderma encompass a wide spectrum of diseases with several dermatologic manifestations. Although some patients will be treated with observation, topical therapy, or systemic therapy, dermatologic surgery plays a role in managing the characteristic cutaneous signs of disease. The rare nature of these diseases and the continued advances in technology assure that new therapies will continue to emerge for these difficult conditions.

Evidence-based procedural correction of morphea and manifestations of systemic sclerosis

Dermatologic condition	Procedural treatment (quality of evidence)
Morphea	
En coup de sabre	HA filler (moderate evidence) PMMA (low evidence) Polyacrylamide hydrogel (low evidence) Autologous fat (moderate evidence)
Hemifacial atrophy	Surgery, including fat transfer, bone and cartilage grafts, hair transplant, and local tissue flaps (moderate evidence)
Systemic sclerosis	
Raynaud's	Chemical sympathectomy (low evidence) Endoscopic thoracic sympathectomy (low evidence) Local digital sympathectomy (low evidence) Botulinum toxin (moderate evidence)
Calcinosis cutis	Surgical excision or curettage (low evidence) CO_2 laser (low evidence) Extracorporeal shock-wave lithotripsy (low evidence)
Telangiectasias	Pulsed dye laser (moderate evidence) Intense pulsed light (moderate evidence)

Self-Assessment Questions

1. A 50-year-old woman with scleroderma and secondary Raynaud's syndrome is considering botulinum toxin-A (BTX-A) injection for treatment of her Raynaud's. Which of the following regarding BTX-A treatment in this situation is not true?
   (a) BTX-A treatment will often speed healing of digital ulcers.
   (b) A typical treatment for Raynaud's of the hands involves injection of 100 units of BTX-A.
   (c) Repeated BTX-A injections are usually necessary to maintain treatment effect.
   (d) Animal studies have shown that BTX-A blocks parasympathetic nerve conduction, which provides a pathophysiological explanation for its use in Raynaud's.
   (e) Patients should be warned regarding possible weakness of hand intrinsic muscles after injection of BTX-A.

2. A 55-year-old woman with diffuse scleroderma presents with painful calcinosis cutis of the right third digit. The calcium deposit measures approximately 0.8 cm in size. She is interested in the simplest, most effective treatment option. Although you discuss various medical and surgical interventions with her, what procedure will you ultimately recommend for the treatment of this lesion?
   (a) Medical therapy with warfarin
   (b) CO_2 ablative laser
   (c) Simple excision
   (d) Extracorporeal shock wave lithotripsy

3. A 36-year-old woman with a 10-year history of CREST syndrome presents to your office. Physical examination is notable for scattered mat-like telangiectasias of the face, upper chest, and neck. She would like to discuss options for laser removal of these telangiectasias. She is interested in obtaining maximum clinical benefit with fewer treatments if possible and is not bothered by postoperative bruising. What is the best laser treatment option for her?
   (a) Intense pulsed light
   (b) 585 nm pulsed dye laser
   (c) CO_2 ablative laser
   (d) Erbium-YAG resurfacing laser

4. A 14-year-old boy with a 2-year history of morphea en coup de sabre affecting his left paramedian forehead presents for discussion of treatment options to fill the resultant atrophic defect. What treatment do you recommend at this point?
   (a) Medical treatment alone
   (b) Structural fat grafting
   (c) Hyaluronic acid filler injection
   (d) Local pedicled flap
   (e) Free flap

5. A 26-year-old woman with a 15-year history of progressive hemifacial atrophy presents to discuss treatment options. She has already undergone multiple facial plastic surgeries to correct the underlying bony deformities and is interested in discussing less invasive treatment options to smooth out her facial contours. She wants "a natural look," with no overcorrection, and does not mind coming in for repeat treatments. She does not want another procedure that would leave her with a scar. Which of the below treatments would you recommend?
   (a) Hyaluronic acid filler
   (b) Polymethylacrylate filler
   (c) En bloc autologous fat grafting
   (d) Local pedicled flap
   (e) Free flap
   (f) Observation

Answers

1. d: Botulinum toxin-A has been shown in animal studies to block sympathetic nerve conduction, not parasympathetic nerve conduction. The remaining answers are correct.
2. c: Simple excision remains the most appropriate treatment for a single, large lesion of calcinosis cutis. Medical therapies are not particularly effective for the treatment of calcinosis cutis. ESWL requires multiple treatments and is more effective for smaller lesions that have already ulcerated. CO_2 ablative laser could be considered in this situation but remains relatively untested for larger lesions of calcinosis cutis; also, this particular patient is interested in the simplest treatment option.
3. b: The 585 nm pulsed dye laser and intense pulsed light have both been reported as effective treatment options for the telangiectasias associated with scleroderma. PDL is slightly superior to IPL in efficacy, although PDL is associated with higher rates of postoperative edema and ecchymosis.
4. a: In general, patients undergoing elective repair of cosmetic defects for linear morphea of the face should have quiescent disease for at least 3 years prior to repair. This patient should have methotrexate +/− pulsed dose corticosteroids, pending a discussion with her rheumatologist and/or general dermatologist, and be re-evaluated 3–5 years after disease quiescence.
5. a: Hyaluronic acid filler is the best treatment option for this patient. Her desire to avoid overcorrections makes her a poor candidate for permanent filler such as polymethylacrylate, and her desire to avoid additional scars makes her a poor candidate for en bloc autologous fat grafting. Local pedicled or free flaps are invasive procedures that would be too aggressive for the subtle facial contouring that the patient is requesting. She is more than 5 years out from disease quiescence, and observation alone would be inappropriate.

Port-Wine Birthmark and Hemangioma

57

Leah K. Spring and Andrew C. Krakowski

Abstract

Port-wine birthmarks (PWB) and infantile hemangiomas (IH) typically present, respectively, at birth to within weeks of birth and represent two of the most common types of vascular anomalies in children. Without treatment, port-wine birthmarks follow an expected evolution of hypertrophic change and bleb development (usually around the third decade of life) with associated physical and psychosocial comorbidities. Conversely, infantile hemangiomas typically follow a process of predictable involution that begins at approximately 1 year of life; despite the overall positive clinical outcome of most infantile hemangiomas, permanent sequelae such as telangiectasia, atrophic wrinkling, and redundant skin with fibro-fatty residua may be observed in up to 50% of patients after "spontaneous resolution," a consideration that should be included in long-term prognosis and patient expectation discussions. Myriad medical and procedural treatment options exist for both PWB and IH and their associated complications, and patients may seek intervention at any age (i.e., infant to adult). It is therefore incumbent on all dermatologists and plastic surgeons to keep abreast of evolving treatment technologies and therapeutic approaches in order to deliver optimal clinical outcomes. This chapter reviews the published evidence regarding clinical evaluation and efficacy of available procedural interventions for PWB and IH and offers a practical approach based on that data.

Introduction

Two major categories of vascular anomalies are recognized by the International Society for the Study of Vascular Anomalies: vascular malformations

© Springer Nature Switzerland AG 2019
M. Alam (ed.), *Evidence-Based Procedural Dermatology*, https://doi.org/10.1007/978-3-030-02023-1_57

and vascular tumors. Cutaneous capillary malformations (commonly referred to as *port-wine stains* or, preferably from a patient advocacy perspective, as *port-wine birthmarks*) represent a relatively common pediatric type of vascular malformation. Infantile hemangiomas, quite distinctly, are the most common benign vascular tumor of infancy [1].

Port-Wine Birthmark

Port-wine birthmarks (PWB) are congenital low-flow vascular malformations caused by a somatic activating mutation in GNAQ, occurring in an estimated 0.3–0.5% of newborns [2, 3]. Males and females are affected equally, and there is no difference in prevalence between premature and full-term infants. The overwhelming majority of PWB are present at birth (i.e., congenital), occur on the head and neck, and grow proportionately with the child; very rarely, however, this type of vascular malformation can be acquired following trauma. Though facial PWB have been classically described as overlying the trigeminal nerve (ophthalmic, maxillary, and mandibular regions), recent evidence supports distribution following the embryonic vasculature of the face [2].

A rare and serious disorder associated with PWB—and associated with the same mutation in GNAQ—is Sturge-Weber syndrome (SWS), which may manifest clinically with seizures, mental retardation, glaucoma, hemianopsia, and hemiparesis [2, 3]. Forehead and eye involvement of a PWB confers risk of SWS. An ophthalmologic examination for any infant with eyelid involvement and neuroimaging (brain MRI with gadolinium contrast) for those with specific signs or symptoms or extensive bilateral, hemifacial, or median forehead PWB may be recommended [2, 4].

Other congenital syndromes associated with PWB, bony overgrowth, and soft tissue hypertrophy include Klippel-Trenaunay and Parkes-Weber. Cobb syndrome is described as PWB with underlying arteriovenous malformations of the spinal cord.

Left untreated, a PWB follows a predictable evolution attributable to chronic progressive vascular ectasia. Well-defined pink to red patches gradually darken to violaceous or deep purple. These lesions may be associated with the Meyerson phenomenon, an inflammatory component characterized by scaling, oozing, and crusting resembling an overlying eczematous dermatitis. More worrisome are the hypertrophic changes that include diffuse thickening and development of nodules or "blebs," most commonly in the V2 distribution; these findings typically begin to present around the third decade of life, eventually affecting 65–71% of all patients over the age of 50 [5] (Fig. 57.1). Early-onset hypertrophy (before the age of 15) has been reported and often accompanies soft tissue and bony overgrowth. In these individuals, the lips are the most frequently affected site, and odontologic problems (enlarge-

Fig. 57.1 Port-wine birthmark with blebs on the lateral scalp, neck, and face. Treatment with PDL 595 nm has begun (with mild lightening) on the upper posterior third of the lesion

ment of the maxilla causing open bite deformity) have been reported in 40% of the cases [6, 7].

Hypertrophic development in PWB is associated with disfigurement of normal tissue architecture, an increased risk of spontaneous bleeding, development of pyogenic granulomas and non-melanoma skin cancers, and functional impairment all leading to decreased quality of life. Given that most PWB are found on the head and neck, it is not surprising that they are often associated with psychosocial impairment. It is recommended by many experts that all patients with PWB receive early intervention to prevent morbidity and achieve optimal results [8].

Infantile Hemangioma

Infantile hemangiomas (IH) are benign proliferations of endothelial tissue occurring in 4–10% of infants and children [9, 10]. Increased incidence is seen in Caucasians (as many as 10% within their first year of life), females (three times that of males), premature infants (23% incidence in those weighing <1000 g at birth), and infants of mothers who underwent chorionic villus sampling (21% incidence) [11]. Hispanic infants with IH are more likely to have segmental lesions associated with "PHACES" (posterior fossa brain malformations, facial hemangiomas, arterial anomalies, cardiac anomalies, eye abnormalities, sternal clefting and/or supraumbilical raphae) syndrome as well as mucosal involvement [12] (Fig. 57.2).

Over 50% of IH occur on the head and neck (particularly along embryologic fusion lines), but the lesions may also be found on the trunk and extremities [12]. Large segmental hemangiomas should raise concern for "PHACES" or "LUMBAR" (lower body hemangioma, urogenital anomalies, ulceration, myelopathy, bony deformities, anorectal malformations, arterial anomalies, and renal anomalies) syndromes [13–15]. Superficial or deep IH in the "beard distribution" (i.e., the lower lip, mandible, chin, and neck) may portend concomitant upper airway or subglottic involvement, which manifests as stridor, a hoarse cry, and increasingly "noisy" breathing [16] (Fig. 57.3). Potential complications of all hemangiomas include ulceration (5–13% of all IH), bleeding, pain, visual and airway compromise, as well as permanent disfigurement and scarring [12, 17].

Most infantile hemangiomas are recognized around 2 weeks of life and enter a rapid proliferative phase that peaks in velocity between 5.5 and 7.5 weeks [13, 18] and can continue for up to 18 months. Those relatively rare lesions that pose serious risks to patients are now treated, first-line, with systemic beta-blockers (e.g., oral propranolol) with tremendous success [19]. Left untreated, hemangiomas typically enter an involution phase that begins around 1 year of life and may last more than 2–6 years. Involution may be heralded by a color change from bright to dull red. A grey to white hue may also be noted centrally and expand peripherally. The surface flattens and softens, and the volume of the lesion

Fig. 57.2 Large segmental hemangioma associated with PHACES involving the entire left face including the orbit. Oral propranolol was initiated with tremendous success; pulsed dye laser was utilized as adjuvant treatment to help with areas of active and pending ulceration

Fig. 57.3 Deep hemangioma in the "beard distribution" of a pediatric patient with skin of color. The lesion was most appreciable when the head was placed in the gravity-dependent position. This patient originally presented to his pediatrician as a young infant with stridor and increased work of breathing

Fig. 57.4 Ulcerated hemangioma on the right cheek of an infant. This lesion will almost certainly leave a permanent scar in a cosmetically sensitive area. It is also at risk for infection

decreases. Gradually, fibro-fatty tissue deposits around the blood vessels.

It is estimated that about half of children with hemangiomas will have normal skin after involution of the lesion. Of course, the other way to consider this axiom is that "half may not," and, thus, up to 50% of children may have permanent sequelae such as telangiectasias, atrophic wrinkling, anetoderma, yellow or hypopigmented discoloration, alopecia, and redundant skin with fibro-fatty residua [20]. Ulceration, untreated infection, and bleeding are additional risk factors for permanent scarring (Fig. 57.4). Consequently, even in this modern era of systemic beta-blockers, some hemangiomas require treatment with interventional modalities. If the potential for permanent physical disfigurement, functional impairment, negative self-image, and lack of self-confidence are real concerns, then aggressive management of these lesions utilizing a full armamentarium (and the guiding principle of "do no harm") should be the goal.

Preoperative Evaluation of the Patient

The patient's Fitzpatrick skin type, age, location of anatomic involvement, functional compromise (present or future), associated symptoms (bleeding, infection, or pain), and a history of prior treatment must be documented. These features guide the treatment modalities that should be selected, as well as the specific parameters to be utilized.

A thorough physical examination of the lesions themselves is essential at every appointment. The long and short axis of each lesion should be measured and documented, and special attention should be paid to color and thickness, as well as the presence of blebs, ulceration, or scars. Standard photographs (to include both anterior-posterior and lateral angles) should be taken.

While most port-wine birthmarks and infantile hemangiomas are diagnosed by history and physical exam alone, some lesions may require

further evaluation by imaging or lab work. When possible, management of complex PWB or IH should be coordinated through a multidisciplinary team to help rule out any associated comorbidities and to optimize the short- and long-term treatment plans.

Imaging Studies

If an arterial, venous, or lymphatic anomaly is suspected, imaging may be performed to help distinguish "high-flow" (i.e., hemangiomas, arteriovenous malformations, and arteriovenous fistulas) from "low-flow" (i.e., venous, lymphatic, or capillary malformation) lesions. Both ultrasound (US) and magnetic resonance imaging (MRI) are superior to radiographs and computed tomography (CT) in the evaluation of vascular lesions [21].

US may be selected as an initial screening method as it is readily available, inexpensive, and safe. Sedation is generally not needed on patients able to hold (or be held) still, and there are no absolute contraindications to its use [22]. Ultrasound provides good soft tissue contrast and basic anatomy information, and, in expert hands, it can help determine vascularity and flow dynamics. This modality is best utilized for superficial vascular anomalies and is suboptimal in the evaluation of deeper vascular lesions particularly when muscle or bone involvement is suspected [21].

MRI can also help determine vascularity and flow dynamics, as well as provide superior spatial resolution and detailed superficial and deep soft tissue evaluation [23]. MRI, usually in conjunction with magnetic resonance angiography (MRA), is the preferred study if ultrasound has provided insufficient information, or it may be chosen as a first-line modality if deeper or more complicated vascular anatomy is suspected [21]. Contraindications to MRI include the presence of implanted devices (e.g., cardiac pacemakers, defibrillators, wires, or metal parts) or certain patient populations: pregnant, claustrophobic, morbidly obese, unstable, or those with renal failure [24, 25]. An important consideration for the pediatric patient undergoing MRI is that of sedation (and the potential inherent risks of anesthesia), as this study typically requires that patients remain still for prolonged periods of time in an enclosed space.

Ultimately, the decision to image a vascular anomaly should be reserved for those cases where the additional information would be helpful to confirm the diagnosis, rule out associated co-morbidities, or determine an optimal management strategy [21].

Specialty Consultation

Neuroimaging (brain MRI with gadolinium contrast) may be recommended for any symptomatic patient or infants with extensive bilateral, hemifacial, or median forehead PWB, keeping in mind that forehead and eyelid involvement confer the greatest risk for SWS [2, 4]. An ophthalmologic examination to rule out glaucoma is recommended for any infant with upper and lower eyelid involvement, bilateral PWB, episcleral hemangioma, iris heterochromia, or choroidal hemangioma [26, 27]. Referral to pediatric dermatology, cardiology, ophthalmology, and neurology for infants with large segmental hemangiomas may be indicated to rule out a diagnosis of PHACES [21]. If general anesthesia is required during planned procedural intervention, then the anesthesiologist must assess the patient prior to the procedure.

Setting the Standard

As this textbook is driven by evidence-based reporting, it must be mentioned that our ability to evaluate the relative efficacy of port-wine birthmark and infantile hemangioma interventions is complicated by several factors. At the bench, reliable animal models for both lesions are lacking, hampering in vivo research. Likewise, there are no universally accepted and validated assessment tools to grade clinical improvement of port-wine birthmarks or hemangiomas before and after intervention. There are also no universally

accepted "expert consensus" recommendations, policy papers, or definitive treatment guidelines, and long-term, rigorously controlled studies are nearly absent in the pediatric peer-reviewed literature.

Seeking Comparative Studies

It is interesting to try to explain the deficiency in the number of "head-to-head" interventional comparisons in the peer-reviewed literature. Practically speaking, we might start by acknowledging that, given the overall competitiveness of the laser surgery field and the reputations (and egos) involved, there may be a lack of incentive – and even a disincentive – to publish "negative" studies. There are also fundamental access issues to the numerous interventional modalities that could and should be considered. For example, a well-known laser surgeon may enjoy direct access to 30 or more lasers, each with a different wavelength representing a potentially different chromophore and different depth of penetration. The pediatric dermatologist, on the other hand, may have limited access to a pulsed dye laser and, if fortunate, one or two other devices. That same pediatric dermatologist, on the other hand, may enjoy the benefit of working within a tertiary or quaternary healthcare facility and may have access to pediatric anesthesia services and a multidisciplinary vascular lesions team; the private practice laser surgeon may be limited to in-office topical pain management and the plastic surgeon down the street. The concept of "use what you got" is a pervasive confounding factor in the real-world treatment (and assessment of treatment) of these skin lesions.

Seeking Consensus

Given the variations in clinical photographic technique and lighting, a standardized photography protocol for these lesions would better permit comparison of pre- and posttreatment images with one another and from one study to the next. A blue background should be adopted whenever possible, and photography without flash is recommended to help prevent color "washout" of the clinical images. As PWB and hemangioma are vascular (i.e., gravity-dependent) lesions, patient position must be consistent as well. Ambient temperature may also affect clinical photography, as a chilly operating room may be associated with more superficial vasoconstriction as compared to a warm patient exam room.

A validated visual grading scale for vascular lesions would be the next logical step to assist both clinicians and researchers alike. Likewise, expert consensus on timing of treatments, time interval between treatments, the total number of treatments performed, the type of anesthetic (topical and general) used, the definition of "long-term follow-up," Fitzpatrick skin type, the use of cooling, posttreatment wound care, and some attempt to capture patient (or, more likely, parent) satisfaction and cost-effectiveness would also be helpful.

Seeking More Objective Assessment

Attempts to quantify pre- and posttreatment changes using noninvasive technologies are evolving. For example, epidermal thickness and depth of PWB upper boundary have been associated with treatment outcomes [28]. These clinical characteristics likely play a key role in guiding therapy; however, they are difficult to accurately predict, even on multiple sites of the same patient. Consider the even greater inherent variability between different patients (e.g., age, skin type, etc.) and different lesions themselves (e.g., anatomic location, history of prior treatment, size of vessels, ratio of oxy- to deoxy- and methemoglobin, etc.) and the range in providers' proficiency with each device being compared; it becomes clear why a definitive review of the published evidence is so difficult.

Both reflectance spectrophotometry and colorimetry have proven useful for the objective

assessment of pre- and posttreatment erythema [29]. Sometimes utilizing more than 40 or more sensors, spectrophotometers provide highly accurate quantitative measurements of the color and intensity of reflected light at each wavelength over the visible and near-infrared portions of the electromagnetic spectrum. Less complex is colorimetry, which seeks to account for the wide variability inherent in human color perception by quantifying the three primary colors (red, green, and blue) for which the human eye possesses receptors. Colorimetry assumes that all colors are perceived as some mixture of these three primaries, the components of which are referred to as X-Y-Z coordinates. Typically, three photocells acting as receptors capture the red, green, and blue data and convert them to saturation and light intensity, representing the relative amounts of erythema and skin pigmentation, respectively [30]. Cross-polarized diffuse reflectance color imaging is another technique that is helpful for quantitatively assessing erythema and melanin in vascular lesions, especially when large areas are involved [31].

In terms of evaluation of PWB and hemangioma ultrastructure, reflectance confocal microscopy employs a low-power, near-infrared laser to noninvasively produce in vivo tissue images to a depth of 200–300 microns. Similarly, optical coherence tomography utilizes light to produce high-resolution, three-dimensional, in vivo images to a depth of up to 1 mm. Both techniques are highly user dependent and are limited by their depths of penetration. However, they offer tremendous potential for diagnosing and better characterizing vascular anomalies in vivo, a step toward the standardization of treatments of these lesions.

Perfusion through a lesion, measured in blood perfusion units, may be objectively and noninvasively quantified using laser Doppler flowmetry (LDF). Similarly, laser speckle imaging (LSI) can be used to detect the relative motion of red blood cells (i.e., the speckle pattern) through the lesion. Both techniques may prove useful for objectively quantifying the degree of photocoagulation pre- and post-laser treatment [32].

Pushing Forward

In short, a limited number of randomized controlled trials, a lack of general expert consensus, and limited objectively quantifiable data make head-to-head comparisons of one modality to the others extremely difficult. High-quality, long-term studies are required to evaluate relative efficacy, and physicians should be encouraged to adopt objective tools that decrease the subjectivity inherent in this topic. Doing so could, ultimately, allow for improved direct objective comparison of treatment options for these vascular lesions and help reduce the total number of treatments (and the number of costly, painful procedures) necessary for patients to optimize clinical outcomes.

Approach to Treatment

Because the interventional modalities used to manage both PWB and hemangiomas may themselves be associated with certain side effects and complications (e.g., pain, ulceration, skin dyspigmentation, scarring, etc.), treating physicians should approach their patients with humility and the guiding principle of “do no harm” in mind. Intervention should begin as early as possible, when the vascular lesions are smaller and typically more superficial; it is assumed (not proven) that these characteristics may lend themselves to improved response to intervention, thus decreasing the total number of treatments necessary and the likelihood of long-term complications.

Treatment of Port Wine Birthmark

Many procedural interventions have been utilized in the treatment of port-wine birthmarks, including myriad lasers (e.g., carbon dioxide, alexandrite, Nd:YAG, argon, copper vapor, etc.), intense pulsed light (IPL), photodynamic therapy (PDT), surgical excision, dermabrasion, cryotherapy, sclerotherapy, radium implants, X-ray therapy, electrocautery, tattooing, and cosmetic camouflage.

Laser Treatment

Numerous lasers have historically been used to treat PWB. The ruby laser was first, as pioneered by Dr. Leon Goldman, in 1963. The argon laser, with peak emissions around 488 and 514 nm (i.e., the blue-green section of the electromagnetic spectrum), also demonstrated a high absorption coefficient for hemoglobin. The continuous wave carbon dioxide laser, emitting at 10,600 nm, was utilized to non-selectively treat vascular lesions. However, these original devices were associated with pulse durations (i.e., continuous wave) that were longer than the thermal relaxation time of the targeted blood vessels. In the absence of epidermal cooling, their utility proved to be very user dependent, and even in expert hands these devices were associated with a high risk of scarring and dyspigmentation.

Pulsed Dye Laser (Table 57.1)

Laser treatment of vascular lesions was revolutionized by the development of the yellow light-emitting flashlamp-pumped pulsed dye laser (PDL). PDL was the first laser to be specifically developed with the principle of "selective photothermolysis" in mind. It was pioneered by Anderson and Parrish, who were driven to develop a laser for the treatment of pediatric port-wine birthmarks, in the 1980s [33]. First-generation PDL utilized yellow light emitting at wavelength 577 nm to target oxyhemoglobin (roughly 70% of total hemoglobin, the remainder being mostly deoxyhemoglobin and methemoglobin), a chromophore with absorption peaks located around 418, 542, and 577 nm. This wavelength laser caused selective thermal destruction of the abnormally dilated blood vessels with minimal to no

Table 57.1 Pulsed dye laser treatment of port-wine birthmark

Author	Level of evidence	# Patients	Laser parameters	Clinical outcome
Smit et al. [34]	1a	71 prospective, objectively measured, and/or controlled studies	Varied	PDL is the most studied, most commonly used "gold standard" treatment for PWB
Faurschou et al. [35]	1a	5 RCT, 103 patients	Varied	PDL leads to clinically relevant clearance of PWB
Yung and Sheehan-Dare [36]	2b	18 with PWB	585 nm: 7 mm, 15 J/cm^2, 1.5 ms 595 nm: 7 mm, 15 J/cm^2, and 1.5 ms, 6 ms, or 20 ms	Efficacy of 585 nm = 595 nm
Greve and Raulin [37]	2b	15 with PWB	585 nm: 7 mm, 5.5 J/cm^2, 0.5 ms 595 nm: 7 mm, 5.5 J/cm^2, 0.5 ms; 7 mm, 13 J/cm^2, 20 ms	Efficacy of 585 nm > 595 nm, but with higher rate of side effects (purpura, pain, and crusting)
Chapas et al. [42]	2b	49 infants with PWB	595 nm: 7.75–9. 5 J/cm^2	88.6% average clearance after 1 year (best improvement along V1)
Reyes and Geronemus [44]	2b	73 (3 months to 14 years) with PWB	557 or 585 nm: MPD, 360 or 450 microseconds, 5 mm	53–95% lightening
Fitzpatrick et al. [45]	2b	133 with 140 PWB	585 nm: 5.5–7.5 J/cm^2	Positive clinical response: pink PWB, located on head and neck, patients <10 years old Negative clinical response: purple PWB, lesions on distal extremities, patients >50
Yu et al. [48]	2b	13 with PWB	595 nm: 12 J/cm^2, 1.5 ms, 7 mm	Lateral face blanching rate: 34.01% Central face blanching rate: 8.68%

collateral damage of surrounding cutaneous structures. Eventually, 585 nm and 595 nm wavelength devices were developed because they combined still-precise absorption with slightly deeper penetration through cutaneous tissue and enhanced dye life. The addition of surface cooling devices permitted improved treatment of darker skin and the use of higher fluences with larger spot sizes.

A literature review of 71 prospective, objectively measured, and/or controlled studies from 1993 to 2003 found the pulsed dye laser (PDL) to be the most studied, most commonly used, and widely considered "gold standard" for a variety of cutaneous vascular lesions, including PWB [34]. Similarly, a Cochrane review through 2010 identified five randomized clinical trials with 103 participants and concluded that PDL leads to clinically relevant clearance of PWB but that patients marginally preferred treatment with the 1064 nm Nd:YAG because of a shorter duration of posttreatment purpura [35].

Both the 585 nm and 595 nm wavelengths appear efficacious, without definitive published statistical advantage of one over the other [36, 37]. Lightening of PWB is directly related to the number of PDL treatments, with the majority of PWB requiring six or more laser sessions to achieve stable improvement [38]. Fluences of 6–12 J/cm^2 at 8-week intervals have been reported to result in an average of 12% lightening per treatment [34]. Spot sizes of 7 mm and 10 mm are ideal and result in similar therapeutic outcomes. The 10-mm spot is considered by some to be more efficacious, as the larger beam penetrates deeper into the skin, targeting larger vessels. Additionally, the 10-mm spot allows for lower radiant exposure (i.e., less joules) and reduced treatment time [39]. When using the 595 nm laser, clinical outcomes from pulse durations of 20 ms are comparable to 1.5 ms, and both were superior to 6 ms [36].

The most apparent side effect of PDL treatment of PWB is purpura, which should be used to determine if a therapeutic endpoint has been achieved. Purpura limited to the selected spot size should occur immediately following the typical PDL settings (7–10-mm spot size, 6–9 J/cm^2, 0.4–3 ms). Purpura reaches maximal intensity 1–2 days after treatment, and it gradually fades over the next 7–10 days [40]. Brauer et al. recently reported statistically significant improvement in ecchymosis by using subpurpuric PDL settings (10 mm, 7.5 J/cm^2, 6 ms) 48 h after treatment of PWB [41].

Pigmentary alterations have been reported in 3–24% of patients, most commonly in those with darker skin types [35]. Other reported complications include pain, crusting, blistering, and scarring, with most side effects resolving within several weeks [34, 35].

Treatment with PDL appears to be most successful when initiated within 3 months of birth, as the overall lesion is small, and vessels are smaller and more superficial [8, 42, 43]. Reyes et al. reported 55% lightening after a single treatment in patients 3 months to 6 years of age, which decreased to 48% in patients older than 7 years of age [44]. In another study, 90% of children 0–10 years of age experienced "good to excellent" responses, whereas only 67% of patients older than 50 had the same clinical response [45]. Early treatment of PWB also prevents hypertrophic evolution of the lesion, which in its natural history occurs in 20% of patients at a median age of onset of 31 years [46].

PWB located on the lateral face and neck responds more favorably to treatment with PDL than to central facial lesions [47]. Histologic investigation suggests that variations in vessel location and diameter (more superficial vessels are found in lateral PWB) are responsible for this treatment response [48].

Treatment of PDL-Resistant or Hypertrophic PWB (Table 57.2)

Though most PWB lighten with PDL treatment (the "gold standard"), only 40% of patients achieve "good" lesional clearance. Suboptimal clearance has been reported in 20–46% of patients, and 14–40% of patients are considered "PDL resistant" [49]. Additionally, PWB can recur following treatment with PDL via angiogenesis, with reported recurrence rates of 11% after "sev-

Table 57.2 Treatment of PDL-resistant PWB or hypertrophic PWB

Author	Level of evidence	# Patients	Laser parameters	Clinical outcome
Tierney and Hanke [58]	1b	8 with PDL-resistant PWB	755 nm: 8–12 mm, 40–60 J/cm^2, 3 ms, 60/40 DCD	56.3% improvement of color, 60% improvement in skin texture, and 59.4% improvement in overall cosmetic outcome
Izikson et al. [28]	2b	20 with hypertrophic or PDL-resistant PWB	755 nm: 8–12 mm, 35–100 J/cm^2, 3 ms, 60/40 DCD 755 nm (as above) + concurrent or alternating sessions of PDL	Hypertrophic PWB: Significant lightening (3/3 patients). No complications except expected posttreatment purpura, edema, erythema, and discomfort Resistant PWB: Significant lightening (1/17 patients), moderate lightening (12/17), mild lightening (3/17), no response (1/17). 2 patients with scars after blistering, 1 patient with hypopigmentation
Grillo et al. [59]	1b	21 with PDL-resistant PWB	755 nm: 10 mm, 35–55 J/cm^2, 3 ms	Mean global improvement 2.28. Mean patient satisfaction 8.5. Minimal scarring & blistering in 1 patient
Carlsen et al. [60]	1b	16 with PDL-resistant PWB	755: 8 mm, fluence titrated to effect, 3–10 ms	3 ms pulse duration superior in both clearance and safety
McGill et al. [56]	1b	18 with PDL-resistant capillary malformation	755, KTP, and Nd:YAG IPL & PDL as control	Alexandrite induced largest mean improvement in color, but with highest risk of hyperpigmentation and scarring (4 patients) KTP and Nd:YAG were least effective
Li et al. [57]	1b	11 with PWB	755 nm vs PDL	PDL most appropriate for flat, pink PWB Hypertrophic, purple PWB respond best to 755 nm
Yang et al. [52]	1b	17, split lesion study	1064 nm: 5 & 7 mm, Fluence determined by MPD (widely varied), 3–15 ms PDL 595 nm: 7 mm, 8 J/cm^2, 1.5 ms	PDL resulted in >75% clearance (3 patients), 51–75% clearance (6 patients) Nd:YAG @ 1 MPD resulted in >75% clearance (1 patient), 51–75% clearance (5 patients) Hyperpigmentation, hypertrophic scar, and pyogenic granuloma reported
Van Drooge et al. [62]	2b	32 with PWB	1064 nm	Majority of patients with good or excellent improvement, with > 60% improvement in color. Hypertrophic responded more favorably than color. Mild to moderate scars in seven patients, hypopigmentation in one
Kono et al. [63]	1b	10 with hypertrophic PWB on lips	1064 nm	80% with good to excellent improvement without complications
Chang et al. [64]	4	4 with blebbed PWB	1064 nm: 5–6 mm, 120–150 J/cm^2, 30 ms	80–100% improvement of blebs
Alster and Tanzi [65]	1b	25 with recalcitrant PWB treated with dual wavelength laser	595 nm: 10 mm, 6.5–9 J/cm^2, 6 or 10 ms 1064 nm: 10 mm, 30–50 J/cm^2, 10–20 ms	25–50% improvement in 48%. Mild purpura. No PIPA or scarring
Wang et al. [66]	1b	61 with PWB treated with dual wavelength laser	595 PDL: 10 mm vs 595 + 1064 DWL: 10 mm	No treatment advantage, higher rate of scarring with DWL than PDL
Kwiek et al. [69]	2b	44 with facial CM	532 nm: 5–10 mm, 8–11.5 J/cm^2, 5–9 ms	At least 25% improvement: All patients At least 50% improvement: 77.3% At least 75% improvement: 38.6% At least 90% improvement: 13.64%

Table 57.2 (continued)

Author	Level of evidence	# Patients	Laser parameters	Clinical outcome
Al-Dhalimi et al. [68]	1b	14 with facial PWB	1064 vs 532 (split-lesion comparative study)	532: 57.2% with moderate to good improvement; 28.6% with excellent improvement. 1064: 7.1% with moderate to good improvement; 0% with excellent improvement No scarring or hyperpigmentation after 3 months of the last session
Al-Janabi et al. [70]	1b	16 with PWB	532 nm	Mild improvement = 6.25% Moderate improvement = 12.5% Good improvement = 31.25% Excellent improvement = 50%
Reddy et al. [55]	1b	5 with PWB, lesion split into 4 quadrants	532 nm: 6–10 mm, 4.8–9 J/cm^2, 3–6 ms	12/20 quadrants: 1–25% improvement 3/20 quadrants: 26–50% improvement 5/20 quadrants: 51–75% improvement
Latkowski et al. [71]	1b	155 with PWB	532 nm	Fair improvement: 23% Good improvement: 27% Excellent improvement: 31% Trunk and limb PWS most resistant to treatment. No scarring or persistent PIPA
Pence et al. [72]	1b	89 with PWB	532 nm: 2–6 mm, 9.5–20 J/cm^2, 15–50 ms	50–74% improvement: 44% 75–90% improvement = 38% >95% improvement = 13% Transient hyperpigmentation (2.25%), hypopigmentation (1.12%), and "hypotrophic" scarring (1.12%)

eral years" [50], 16% after at least 1 year [51], and up to 50% 5 years after treatment [52].

The limited success of PDL is attributed to incomplete photocoagulation of the target vessels. PDL's yellow light penetrates 1–2 mm deep into a lesion than can extend 3–5 mm into the skin, targeting vessels between 55 and 150 μm. Larger and deeper vessels remain patent [49, 53]. In addition to vessel depth and diameter, variable vessel density, anatomic location of the lesion, and high epidermal melanin content make uniform and predictable treatment outcomes a therapeutic challenge.

PDL-resistant PWB or hypertrophic PWB in adults may respond to the 755 nm alexandrite and the 1064 nm neodymium:yttrium-aluminum-garnet (Nd:YAG) lasers, which are preferentially absorbed by deoxyhemoglobin over oxyhemoglobin (HbO_2). Additionally, these lasers are less absorbed by melanin than the yellow wavelengths and penetrate 50–75% deeper into the skin. Both the 755 nm and 1064 nm lasers require higher fluences to achieve sufficient photocoagulation, which is associated with a higher risk of scarring and permanent pigmentary change [49, 54]. Alternatively, the frequency-doubled 532 nm Nd:YAG laser can also be used in select cases to reduce both vessel number and size, with penetrating depths of 0.35–4 mm into the skin [55].

Alexandrite Laser (755 nm)

The 755 nm wavelength provides two theoretical advantages over the 1064 nm laser: a greater absorption coefficient of deoxyhemoglobin over HbO_2 (preferentially damaging veins more than arteries) and a less pronounced effect of methemoglobin (an oxidized species that appears during laser-induced heating of blood vessels; methemoglobin has a much stronger absorption than either deoxyhemoglobin or HbO_2 at 1064 nm, producing an "all or nothing" fluence-response relationship) [54].

The 755 nm laser was the most effective treatment modality, with the highest associated risk (hyperpigmentation and scarring), in a direct comparison study of 18 patients with PDL-resistant capillary malformations treated with either the 755 nm alexandrite, 532 nm KTP, 1064 nm Nd:YAG lasers, or intense pulsed light (IPL). The KTP and Nd:YAG lasers were least effective in this study [56]. Another comparative study of 11 patients treated with either the 755 nm alexandrite or PDL suggested that the PDL was most appropriate for flat, pink PWB whereas hypertrophic, purple PWB responded best to 755 nm [57].

Three case series detailing a total of 49 patients with PDL-resistant PWB treated with the 755 nm alexandrite laser demonstrated "moderate to significant" lightening in 80% of patients [54] and 50–60% improvement of color, skin texture, and overall cosmetic appearance [58], and both mean global improvements and good patient satisfaction [59]. In addition to the expected post-laser effects (purpura, edema, erythema, and discomfort) experienced by all patients, more serious sequelae (blistering, scarring, and hypopigmentation) were also noted. All authors cautioned that the potential risk for adverse effects and very narrow therapeutic index mandate conservative parameters and close observation of the treated tissue [54, 58, 59].

A study of 16 patients (14 of whom had failed PDL treatment) treated with the alexandrite 755 nm laser at 8 mm and fluence titrated to effect revealed that a 3 ms pulse duration was superior to both 5 ms (*P* 0.016) and 10 ms (*P* 0.004) in both clearance and safety. The authors concluded this treatment modality is best suited for patients with purple, hypertrophic PWB and should be "restricted to experienced personnel due to particularly narrow therapeutic window" [60].

Treatment Pearls for the 755 nm Alexandrite Laser

- Best suited for purple, hypertrophic PWB or PDL-resistant PWB;
- Treatment should be performed by only experienced laser physicians because of the narrow therapeutic window and risk for scarring;
- Treat the darkest part of the PWB first and closely monitor for the desired endpoint: A subtle grey-blue darkening that transitions over several minutes to lasting purpura [54];
- If no response, increase fluence by 5–10 J/cm2 and treat the unresponsive areas [54]; and
- Complete treatment with one pass (no double pulses), minimal to no overlap.

Neodymium-Doped Yttrium-Aluminum-Garnet Laser (1064 nm)

As with the 755 nm alexandrite laser, the 1064 nm Nd:YAG laser penetrates more deeply into the skin than PDL, causing complete constriction and immediate blood vessel disappearance in up to 60.6% of vessels ranging in diameter from 30 to 300 μm [61]. Higher fluences are required to achieve this desired response, and nonselective bulk heating can occur. Significant scarring can result when fluences greater than 1.2 times the minimal purpura dose (MPD) are used, making treatment of the anatomically heterogeneous PWB lesion challenging [53]. Short pulse durations (<10 ms) should be utilized to minimize collateral tissue damage [61]. Ultimately, however, the Nd:YAG should only be used by experienced clinicians who can successfully navigate its narrow therapeutic window.

Multiple studies have demonstrated good to excellent (50–75%) improvement of PWB, PWB blebs, and hypertrophic PWB, with risks of pigmentary alteration and mild to moderate scarring reported in up to 20% of patients [53, 62–64]. Hypertrophy appears to respond more favorably than color. What is most impressive, however, is the wide variability of MPD elicited by the Nd:YAG as reported by Yang et al., demonstrated in Table 57.3.

Disparate reports of the dual-wavelength laser (DWL) (595 nm PDL + 1064 nm Nd:YAG) have found this treatment modality to be both effective and without adverse effects [65], as well as demonstrating no advantage in efficacy over the PDL but associated with a significantly higher rate of scarring [66]. Post-DWL biopsies have demonstrated maximum vessel wall damage and epidermal sparing when the 10-mm spot size is used, PDL pulses are shorter than 10 ms, and a second pass with PDL only is performed [67].

Table 57.3 Minimal purpura dose in patients treated with the Nd:YAG [53]

PWS color	Fluence	Pulse duration	Spot size
Pink	90–250 J/cm^2	6–15 ms	7 mm (<100 J/cm^2) 5 mm (>100 J/cm^2)
Red	50–130 J/cm^2	4–8 ms	7 mm (<100 J/cm^2) 5 mm (>100 J/cm^2)
Purple	40–60 J/cm^2	4 ms	7 mm

Treatment Pearls for the 1064 nm Nd:YAG Laser

- Best suited for purple, hypertrophic PWB or PDL-resistant PWB.
- Treatment should be performed by only experienced laser physicians because of the narrow therapeutic window and risk for scarring.
- Determine the MPD: Perform test pulses in rows of three pulses, starting at 30 J/cm^2; fluence is increased by 20% increments until a subtle darkening (purpura) lasting beyond 15 min is appreciated [53].
- Complete treatment with one pass (no double pulses), minimal to no overlap.

Frequency-Doubled Neodymium-Doped Yttrium-Aluminum-Garnet Laser (532 nm)

A split-lesion, randomized study comparing the long-pulsed Nd:YAG 532 nm and 1064 nm laser in the treatment of 14 patients with facial PWB showed an overwhelming greater therapeutic efficacy with the 532 nm laser ($P = 0.001$). Over 50% of patients treated with 532 nm laser experienced moderate to good improvement compared to 7.1% of patients treated with the 1064 nm laser. No patients developed scarring, and the solitary incidence of hyperpigmentation resolved with hydroquinone cream [68].

Multiple studies confirm the safety and efficacy of the 532 nm laser in the treatment of PWB, reporting an average of 50–75% improvement in the 380 patients treated [55, 69–73]. PWB on the face responded most favorably, whereas lesions on the trunk and extremities were often recalcitrant to treatment [71]. Post-inflammatory hyperpigmentation was reported in patients with Fitzpatrick skin types III to IV but was a rare occurrence in lighter-skinned individuals [68, 72, 73]. "Hypotrophic scarring" was reported only in one study (1.12%) [72].

Treatment of PWB in Skin of Color (Table 57.4)

The treatment of vascular anomalies (specifically PWB) on over 1500 patients with skin types III–V has been reported to be moderately effective and generally well tolerated.

Chinese patients (Fitzpatrick skin types III–IV) with PWB treated with the 585 nm laser, 595 nm laser, Nd:YAG 532 nm laser, or both 585 nm and 532 nm laser demonstrated moderate efficacy (more than 60% with 25% clearance) [73], a "favorable response" (69.9%) [74], or "excellent" improvement (62%) [75], irrespective of the laser system used. Post-procedural hyperpigmentation was most commonly reported at rates of 13% [73], 4% [74], or 6% [75], and it typically resolved in 3–6 months. Less common side effects included focal textural changes (1.6%), hypopigmentation (2.2%), and hypertrophic scarring (one patient) [75].

Patients under 1 year of age experienced the best results (93.9% responded, 18.2% with complete resolution), and those over 50 were noted to have the least response (25% responded, 0% with complete resolution) [74].

Indian patients (Fitzpatrick skin types IV and V) with PWB demonstrated 25–75% lightening when treated with the 585 nm PDL [76] and 54% mean lightening of flat PWB and 40% mean lightening of hypertrophic PWB when treated with the 595 nm PDL [77]. Children experienced a superior and faster response (61–80% improvement was noted in 70% of children compared to 50% of adults after 8–10 sessions). The poorest response was noted in adult patients with thick, non-blanching PWB and PWB located on the upper cutaneous lip [78]. A greater therapeutic effect was demonstrated after ten sessions (58.6%) than four sessions (41.8%). Post-procedural hyperpigmentation occurred in

Author	Level of evidence	# Patients	Laser parameters	Clinical outcome
Liu et al. [75]	1b	184 (Chinese) with PWB of face, neck, trunk, limbs	595 nm: Variable	62% with "excellent" improvement, 20% with "good" improvement Prominent hyperpigmentation (6%), hypopigmentation (2.2%), focal textural changes (1.6%), hypertrophic scarring (1 patient)
Woo SH et al. [80]	2b	237 (Korean, skin types III to V) with nevus flammeus, telangiectasia, hemangioma	595 nm: variable, depending on lesion type	Nevus Flammeus: 48% with good to excellent results Telangiectasias: 78% with good to excellent results Hemangiomas: 54.1% with good to excellent results Transient hyperpigmentation (21.3%), hypopigmentation (3.3%), cutaneous atrophy (1.7%), hypertrophic scarring (0.8%)
Shi et al. [74]	2b	848 (Chinese, skin types II–IV) with PDL-resistant PWB	595 nm: 8–12 J/cm^2, 1.5–10 ms	69.9% favorable response, with patients under 1 year of age experiencing the best results (93.9% responded), those over 50 with least response (25% responded) Hyperpigmentation (4%), resolved in 3 months
Khandpur and Sharma [77]	2b	98 (Indian, skin types IV and V) with PWB	Flat PWB: 595 nm: 7 mm, 8–10 J/cm^2, 1.5–3 ms Hypertrophic PWB: 595 nm: 7 mm, 8–12 J/cm^2, 1.5–6 ms	Mean lightening: 54% (flat), 40% (hypertrophic) Hyperpigmentation (40.5% of flat PWB, 29.2% of hypertrophic PWB), post-laser burning (13%), pain (25%), honeycombing (8.1%), erythema, blistering, hypopigmentation, and atrophy
Sharma and Khandpur [76]	4	27 (Indian, type IV and V) with PWB	585 nm: 7 mm, 5–7.5 J/cm^2, 0.45 ms	60% with 25–75% lightening Hyperpigmentation (26%), hypopigmentation (3%). No textural change or scarring
Bae et al. [79]	4	2 (African American) with PWB	595 nm: 10 mm, 7–8.25 J/cm^2, 1.5 ms	Resolution of PWB, no side effects
Ho et al. [73]	2b	107 (Chinese) with PWB	585 nm 532 nm 585 nm + 532 nm	More than 60% of patients experienced >25% clearance 13% with complications (most commonly pigmentary changes)
Thajudheen et al. [78]	1b	75 (Indian) with PWB	595 nm: 7–10 mm, 6–12 J/cm^2, 0.45–10 ms x 10 sessions @ 4 week intervals	70% of children with 61–80% improvement 50% of adults with 61–80% improvement Hyperpigmentation (30%), superficial scarring attributed to pulse stacking

26% [76], 30% [78], and 40% [77] of patients. Strict photoprotection (all patients), hydroquinone (select patients), and time (6–8 weeks [78] up to 6–9 months [77]) resolved all undesired pigmentary alteration. Other side effects included pain (25%), honeycombing (8.1%), transient hypopigmentation (3%), erythema, and blistering [77]. No textural change or scarring was appreciated except in an isolated case of pulse stacking [78]. No significant benefit or difference in side effect profile was seen between the two PDL wavelengths [76, 77].

Two African American pediatric patients (Fitzpatrick skin types IV and V; age 1 month

and 4 years) experienced resolution of their PWB without complication when treated with 595 nm PDL [79].

Nevus flammeus, telangiectasias, and hemangiomas on Korean patients with skin types III to V have also responded favorably to PDL. Over 50% achieved good to excellent improvement of their vascular skin lesions. Transient hyperpigmentation occurred in 21% of patients. Others experienced hypopigmentation (3.3%), cutaneous atrophy (1.7%), and hypertrophic scarring (0.8%) [80].

Sufficient evidence has demonstrated that darker-skinned patients with PWB and other vascular neoplasms can benefit from laser intervention. These patients generally require more treatment sessions to achieve the desired result. Post-inflammatory hyperpigmentation is the most common reported sequelae of treatment, and it generally resolves in weeks to 9 months with strict sun protection. A detailed informed consent discussion regarding expectations of a moderate response and associated risks (emphasizing pigmentary alteration) is necessary prior to treatment.

Treatment Pearls for Patients with Skin of Color

- Start with conservative settings.
- Single pulses with minimal to no overlap (avoid pulse stacking).
- 6–8-week intervals between treatments.
- Delay additional treatment until any post-inflammatory hyperpigmentation has resolved.
- Strict photoprotection for at least 3–4 weeks following each treatment.

Emerging/Experimental Treatments for PWB

Photodynamic therapy (PDT) has emerged as a potential alternative to laser treatment, and today it is most commonly performed in China. Targeted destruction of PWB blood vessels occurs when a photosensitizer (photocarcinorin, hemoporfin, benzoporphyrin derivative monoacid ring A, or talaporfin sodium) within the blood vessel is excited, generating cytotoxic singlet oxygen that causes direct endothelial cell damage, thrombosis, and vascular collapse [49, 81]. Similar to laser (where efficacy is dependent upon selection of the correct wavelength, fluence, pulse duration, and spot size), PDT's success depends on a variety of factors such as choice of photosensitizer, wavelength and light intensity, and exposure time [49]. Efficacy appears similar or even superior to PDL, and fewer treatments are necessary to achieve clearance (on average 1–4) [82–86]. Patients 5–20 years old have been observed to have the greatest response to PDT treatment (in contrast to PDL which is most effective in younger patients) [84]. Side effects can include blistering, swelling, severe pruritus, pigmentary alteration, scarring, photoallergy, and photo-thermal injury. Strict sun avoidance is necessary for 2–4 weeks after treatment [82–86]. Clinical trials are ongoing; however, researchers postulate that PDT could potentially be used in the future either as a solitary or synergistic treatment modality for PWB [87].

Intense pulsed light (IPL) is an option when non-purpuric treatment is desired or when access to PDL is limited. IPL produces broadband, non-coherent light between 390 nm and 1200 nm using a xenon flashlamp. Filters are available to adjust the wavelength range that is delivered to the PWB, conferring a wider "target" range. Limitations include pigmentary changes (hypo- and hyper-pigmentation) that may result and an overall reduced efficacy in comparison to PDL.

Treatment of Infantile Hemangioma (Table 57.5)

As most hemangiomas pose no threat to life or function, a viable treatment strategy may be to simply adopt a "wait and see" approach. For those relatively rare lesions that do pose serious risks to patients, first-line treatment with systemic beta-blockers (e.g., oral propranolol) has produced tremendous results and volumes of well-controlled published studies. A plethora of procedural interventions—the focus of this chapter—have been utilized to treat hemangiomas and

Table 57.5 Treatment of infantile hemangioma

Author	Level of evidence	# Patients	Laser parameters	Clinical outcome
Admani et al. [88]	4	5	585/595 nm PDL: 7–12-mm spot; 5–10 J/cm^2; 0.45–1.5 ms pulse duration; dynamic cooling 30/10–30 ms; treatments repeated 2–8 weeks until desired effect	No adverse events reported
Chinnadurai et al. [89]	1a	29 studies (4 RCT, 8 retrospective cohort, 17 case series)	PDL, Nd:YAG, CO_2 were included; specific parameters varied across studies	Long-pulse PDL, at 585/595 nm, with epidermal cooling was most commonly utilized device; variations in treatment protocols and parameters did not allow for identification of a single method's clinical superiority
Kwon et al. [90]	2b	40 children (age 9.6 at initiation of treatment and 18 at completion); 47 hemangiomas (32 superficial, 15 mixed)	595 nm PDL with dynamic cooling: 10-mm spot; 7–10 J/cm^2; pulse duration 3–6 ms; dynamic cooling 30/10; treatments repeated at 1–4 week intervals	Mean number treatments 4.6; treatment was more effective in superficial lesions than mixed; hyperpigmentation was reported as an adverse event
Chen et al. [91]	2b	43 patients with infantile hemangiomas on the hand	595 nm PDL: 7-mm spot; 10–13 J/cm^2; pulse duration 20–40 ms; epidermal cooling 20/40	Hemangiomas were treated effectively; confounding factor was that the mean age of patients at initial treatment was 8.92 months, coinciding temporally with the expected natural transition to involution
Zhong et al. [93]	2b	794 Chinese patients (900 hemangiomas); mean age 3.6 months	Long-pulse Nd:YAG with contact cooling copper plate for up to five treatments: superficial and mixed lesions treated with 3–5-mm spot; 120–235 J/cm^2; 10–30 ms pulse duration Deep lesions treated with 7-mm spot; 65–120 J/cm^2; 20–30 ms pulse duration	Most superficial lesions responded in 1–2 treatments; mixed and deeper lesion response was poor until propranolol was added. Adverse events include blistering (82%), change in skin (8.4%), hyperpigmentation (4.3%), atrophic scarring (2%), postoperative secondary ulcer (0.5%), hypopigmentation (0.1%)
Batta et al. [94]	1b	60 superficial early hemangiomas	585 nm PDL: 3–5-mm spot; 6–7.5 J/cm^2; 0.45 ms pulse duration	25 patients had complete clearance or minimum residual signs. Adverse events include ulceration (7%), painful ulceration (5%), bleeding (3%), infection (3%), and need for oral steroid (2%)
David et al. [89]	2b	78 children with ulcerated hemangiomas (147 lesions total; mean size 21 cm^2)	585 PDL: 5–7-mm spot; 5–6.8 J/cm^2; 3–4 week treatment intervals (average two treatments)	71 patients showed good response with no adverse events reported
Cerrati et al. [96]	4	20 patients (average age 2.69 years) with residual telangiectasia following hemangioma involution	532 nm diode laser: 0.7–2-mm spot; 10.2–25 J/cm^2; 36–44 ms pulse duration; pulse frequency 3–5 Hz	Complete response (73%), near-complete response (23%) in patients

Table 57.5 (continued)

Author	Level of evidence	# Patients	Laser parameters	Clinical outcome
Alcántara González et al. [97]	2b	12 patients with atrophic scar or fibro-fatty residua	2790 nm ablative fractional yttrium-scandium-gallium-garnet: 300-μm spot; 120–200 mJ; density level 3; 600-μm pulse width. Treatment with 595 nm PDL or combined sequential 595 nm PDL and 1064 nm Nd:YAG applied if telangiectasias or residual vascular component present	Mean parent satisfaction was 6.75 (scale from 0 to 10); mean improvement was 1.58 based on 3 dermatologists rating photographs on scale of 0–4; "discrete punctate pattern" noted in e patients as long-term adverse event
Brightman et al. [98]	4	5 patients (age 4.5–13 years at initial treatment)	Ablative fractional CO_2: 20–40 mJ; 0.29–80 kJ total energy; 20–40% coverage; 2–13 treatments; 2–10 month average treatment interval	On average, patients experienced 50%–75% improvement in color, texture, and overall appearance
Feng et al. [99]	4	1 patient (age 2 years; Fitzpatrick skin type IV)	755 nm alexandrite laser: 15-mm spot; 25–30 J/cm^2; 3 ms pulse duration; cryogen spray cooling with spurt duration of 40 ms; pulses stacked (3–5 per area) at approximately 1 pulse delivered every 3–4 s to minimize epidermal damage	"Vessel darkening" was obtained and clinical outcome was excellent
Daramola et al. [100]	2B	92 patients (average age 36 months) with 94 hemangiomas (mostly head/neck with mean surface area 7.75 cm^2)	Surgery	Head and neck lesions were more statistically likely to require multiple modality treatment

their sequelae. Laser surgery, surgical excision, intralesional therapy, cryotherapy, electrocautery, and embolization are all modalities that have been used with reported effect.

Laser Treatment

Laser treatment has been demonstrated to be both safe and effective in the management of infantile hemangiomas. Small, thin, superficial lesions are the best candidates when specific complications (or the risk of complications) are not driving the clinical decision to laser. Patients who are excluded from utilizing systemic beta-blockers or those patients who cannot tolerate beta-blockers may also benefit from laser surgery. Several studies comparing laser with systemic beta-blockers or in combination with beta-blockers tend to report greater clinical improvements in combination arms versus beta-blockers alone; these additive effects suggest that laser treatment should retain an important role in the management of refractory hemangiomas [88].

A 2016 systematic review of multiple databases including MEDLINE® and EMBASE, from 1982 to June 2015, identified 29 studies addressing the use of lasers for infantile hemangiomas. A total of 4 randomized controlled trials, 8 retrospective cohort studies, and 17 case series were identified by two investigators working independently to assess risk of bias and strength of evidence. Parameters varied widely across studies in terms of laser type, pulse width, or cooling materials. Overall, the long-pulse PDL, at 585 nm or 595 nm, with epidermal cooling was

the most commonly utilized device. These lasers allow for a depth of penetration of approximately 1–2 mm into the target vasculature. However, variations in treatment protocols and parameters did not allow for identification of a single method's clinical superiority [89].

At least one retrospective study of 40 children with 47 hemangiomas reported early intervention with PDL (average age at initiation of treatment was 9.6 weeks) to be effective in helping to prevent further hemangioma growth, as well as utility in accelerating the transition to "plateau" or "involution" phase [90].

PDL may also be used on areas specifically at risk for significant functional or psychological impact. A complication of some hand hemangiomas, for example, is the increased risk for overlying skin maceration secondary to "infant sucking." For the same reason, hand hemangiomas may inadvertently transform a topical medication into a systemic one, making management strategies in this anatomic location difficult. In these cases, laser offers an alternative approach. A 2014 retrospective review of 43 patients with infantile hemangiomas on the hand supported the role of PDL (595 nm) with fluence 10–13 J/cm^2, pulse duration 20–40 ms, 7-mm spot, and epidermal cooling 20/40 to treat hand hemangiomas effectively. However, a confounding factor was that the mean age of patients at initial treatment was 8.92 months, coinciding temporally with the expected natural transition to involution [91].

A 2014 retrospective interdisciplinary study involving 77 hemangiomas reported that combination treatment with pulsed dye laser (595 nm) and Nd:YAG laser (1064 nm) was also an effective management strategy. The study utilized ultrasound to more objectively assess hemangioma thickness. Overall, parents reported that treatment results were "good" or "very good" in most lesions. Transient blistering was the main side effect noted [92].

With its depth of penetration to around 4–6 mm, the long-pulsed Nd:YAG (1064 nm) laser has also shown promising results for the treatment of hemangiomas. A 5-year study involving 794 Chinese patients demonstrated greatest efficacy in superficial lesions and older patients (as would be expected by the natural course of infantile hemangiomas). Interestingly, efficacy did not depend on anatomic location of the lesions themselves [93].

Ulceration and pain are specific indications for consideration of laser, though physicians are reminded that laser treatment itself may worsen ulceration, particularly when treating deep or combined superficial and deep lesions. Large, rapidly growing hemangiomas, especially segmental ones on the head and neck, are more likely to ulcerate. Anatomic location (e.g., scalp, lip, and perineum) may also help predict ulceration risk. Rapid reepithelialization—sometimes as early as a few days after initial treatment—has been reported after PDL treatment. Recommended treatment intervals have been based largely on anecdotal reports and range from "weekly" to "every two weeks" [94]. A larger retrospective review of 78 children with ulcerated hemangiomas requiring treatment (mean size of 21 cm^2) followed a protocol using PDL at mean energy 6.6 J at 3–4-week intervals until healing occurred. Seventy-one of the 78 patients responded to PDL alone (mean number of 2 treatments; mean number of 173 pulses per treatment) [95].

Recently, a great deal of attention has been paid to utilizing laser for "hemangioma residua." This refers to the telangiectasias, erythema, and fibro-fatty textural changes that may be left behind after hemangiomas involute. PDL has been demonstrated to be effective in helping to clear residual telangiectasias. Similarly, a 2015 case series involving 20 patients (average age 2.69 years) suggested that treatment with a 532 nm diode laser was effective, with more than half of patients showing a complete response [96].

For fibro-fatty residua, specifically, a 2012 retrospective study of 12 patients with atrophic scar or fibro-fatty tissue demonstrated that ablative fractional yttrium-scandium-gallium-garnet laser could treat these sequelae of involuted hemangiomas with mixed results [97]. A separate observational study suggested that patients could experience at least 50–75% improvement in color, texture, and overall appearance following ablative laser resurfacing [98]. Most likely,

a multimodal approach will prove best, as it often does in the world of pediatrics. Supporting this belief is a single case report, published in 2017, that demonstrated successful treatment of hemangioma residua utilizing a combination of 755 nm alexandrite laser and ablative fractional laser resurfacing with a carbon dioxide laser. Interestingly, the pediatric patient was Fitzpatrick skin type IV who had been previously treated with 6 months of oral propranolol. The protocol utilized the following parameters: 755 nm alexandrite laser at 15-mm spot, fluence 25–30 J/cm^2, 3 ms pulse duration, and cryogen spray cooling with spurt duration of 40 ms. Crucially, pulses were stacked (3–5 per area) at approximately 1 pulse delivered every 3–4 s to minimize epidermal damage. The clinical endpoint was "vessel darkening." A single ablative fractional laser resurfacing treatment was also performed, and the overall clinical outcome was excellent [99].

Surgery

The role of surgery in the management of infantile hemangiomas has been greatly reduced since the advent of beta-blockers as systemic and topical therapeutic options. Rapidly proliferating hemangiomas at risk for hemorrhage, ulceration, functional impairment, and disfigurement remain lesions for which surgery may be an option. Likewise, surgery could be considered in any nonhealing, recalcitrant hemangioma in which case a scar may be a reasonable option to replace the primary lesion. Surgery may also be helpful in repairing the cutaneous defects associated with involuted hemangiomas. In one large retrospective review performed at a tertiary pediatric hospital, a subset of 92 patients (average age of 36 months) underwent surgery for a total of 94 infantile hemangiomas. Most lesions were located on the head and neck, and the mean surface area was 7.75 cm^2. These head and neck lesions were more statistically likely to require multiple modality treatment, reaffirming that a multidisciplinary approach that includes a skilled surgeon may prove beneficial [100].

Intralesional Therapies

The use of intralesional treatment for hemangiomas was much more common in the era preceding systemic beta-blockers; however, interest has recurred with the discovery of laser-assisted delivery of medications. Corticosteroids, propranolol, bleomycin, and bleomycin A5 (pingyangmycin) have all been utilized intralesionally. Many providers prior to the era of systemic beta-blockers utilized intralesional corticosteroid for complicated hemangiomas, especially intraocular lesions. This technique, while effective, may be associated with systemic side effects including adrenal suppression, as several case series have reported [101, 102].

At least one retrospective study of 18 patients (average age 8.6 years) found bleomycin A5 to be "not safe" for infantile hemangiomas because of the medication's association with soft tissue atrophy [103].

Repeated injection with intralesional propranolol was found to be safe but not effective in treating small, noncomplicated hemangiomas in areas of cosmetic concern [104].

In 2014, a prospective feasibility study evaluated the use of fractional carbon dioxide laser-assisted drug delivery of topical timolol in deep hemangiomas. Nine patients, ages 1–6 months, underwent fractional ablative laser resurfacing at 1-week intervals, after which topical timolol maleate 0.5% ophthalmic solution was applied under occlusion for 30 min, four to five times per day for an average of 11.6 laser treatments over an average of 14.2 weeks. Plasma timolol levels were not detected after the first administration of topical timolol, and eight out of nine patients showed good or excellent regression. The authors report that small sample size, lack of a control group, and lack of ultrasonographic assessment of the change in size of hemangiomas after treatment severely limit the general applicability of this study; however, the novelty of the delivery is commendable [105].

Other Treatments Modalities

Electrocautery has historically been utilized for treatment of hemangiomas, especially for superfi-

cial lesions; however, its association with scarring makes it less than ideal in this modern treatment era. Likewise, cryosurgery was utilized as an option for superficial lesions in the 1960s; however, the complications of scarring scars, dyspigmentation, and milia have limited its use. Some renewed interest in cryotherapy developed after a case series of 19 young patients with 24 hemangiomas treated with a device with a constant applicator tip temperature of −32 °C was published in 2000 [106]. Sclerotherapy consists of injecting a sclerosing substance, such as polidocanol, sodium tetradecyl sulfate, or ethyl alcohol, directly into the lesion. Radiation and radioisotope therapy has been used rarely for cases where hemangiomas imminently threaten life or function. Further rigorously controlled studies are needed to better evaluate these treatment modalities and compare them directly to the now-accepted first-line use of systemic beta-blockers.

Treatment Pearls for Infantile Hemangiomas

- Systemic beta-blockers are first-line therapy for complicated lesions;
- Early treatment with laser, either concurrently with beta-blockers or alone, may help prevent rapid growth;
- Ulcerated hemangiomas may benefit from laser;
- Lasers are useful in the treatment of hemangioma residua (telangiectasias, erythema, and fibro-fatty textural changes);
- Surgery has a diminished role in management but remains useful for complicated hemangiomas in specific anatomic locations; and.
- A multidisciplinary approach, when possible, may lead to better clinical outcomes.

Safety and Sequelae Mitigation

When using lasers, wavelength-specific eye protection must be worn by the physician, patient, and all medical personnel in the room. Ocular risks (corneal burns or retinal pigment loss) are devastating but a very controllable risk when diligent safety procedures are practiced [107]. Standard goggles usually suffice for adults but frequently do not fit infants and small children. In these cases, white gauze may be used to ensure that the entire periorbital area is completely covered. If laser surgery is planned in proximity to the eye, then metal corneal shields are necessary. Even then, metal eye shields may not offer complete protection (i.e., they may be incorrectly fitted or placed), and there is at least one report of ocular damage from unexpected heating of the metal eye shield itself after treatment of an eyelid hemangioma with a long-pulsed 1064 nm Nd:YAG laser [108].

Flammability is a concern whenever lasers are utilized near or around a source of supplemental oxygen (i.e., the operating room). Wetting hairs with a water-based lubricant or protecting areas with water-soaked draping may help reduce the risk of combustion.

The most common cutaneous side effects of laser treatment of hemangiomas and PWB are transient and, typically, include pain, erythema, edema, and purpura. The pulse of the lasers has been described as feeling like the "snap of a rubber band." In the authors' opinions, this is a gross underestimate. Nevertheless, procedural discomfort is generally tolerable for teens and adults and, if it is not, these patients are physically capable of saying so. Pediatric patients are a more vulnerable population and may require the use of general anesthesia to facilitate a safe, well-tolerated, controlled laser treatment by minimizing discomfort, emotional stress, and unexpected movement.

Post-laser erythema and edema typically resolve over hours, but may occasionally persist up to days or weeks. If permissible for the procedure, ice and patient positioning (propping the head up with an additional pillow at bedtime) may help to dramatically reduce these symptoms.

Purpura is an expected (and often desired) immediate post-laser finding, as PWB and infantile hemangiomas are typically treated at settings that induce bruising for more effective results. Patients can be reassured that most purpuras typically fade over 1–2 weeks. Lasing without cooling, double-pulsing, or overlapping pulses can lead to blistering and crusting, which should be treated with application of petrolatum ointment at least thrice daily until healed [107].

Permanent side effects are rare and include hyperpigmentation and hypopigmentation (either

from post-inflammatory pigmentary alteration and/or damage to melanosomes) or hypertrophic or atrophic scarring (reported risk of less than 1%) [109, 110]. These risks can be mitigated by selecting the appropriate laser wavelength matched to the patient's Fitzpatrick skin type and thickness of the targeted lesion, the use of epidermal cooling (either cryogen or Zimmer forced air cooling), strict photoprotection prior to and after treatment, and the use of test spots for treatment-naïve individuals. Hair loss, either permanent or temporary, may also be observed after lasing in hair-bearing areas like the scalp or eyebrow.

Risks of General Anesthesia

A recent focus on the risks of neurocognitive deficits associated with prolonged or repeated exposure to general anesthesia has developed, based on findings from young animal studies [111–113]. While no firm conclusions have been demonstrated in human studies, several studies have been published that offer insight into this debate. A sibling-matched cohort study of 105 sibling pairs (one exposed to a single anesthetic episode at a mean age of 17.3 months, one unexposed) demonstrated no statistically significant difference in IQ scores in later childhood [114]. A much larger cohort (33,514 anesthesia-exposed children compared to 159,619 unexposed children) demonstrated that 0.41% and 0.97% of anesthesia-exposed children had lower school grades and lower IQs, respectively [115].

Three retrospective chart reviews inform our understanding of the risks of general anesthesia in the specific setting of laser-treated pediatric patients with vascular lesions. In 1997, Grevelink et al. published the outcomes of 179 patients, aged 5 weeks to 18 years old, who underwent a total of 745 treatments: 78% in office and 22% in the same-day surgical unit. No side effects were observed in 76% of patients. The two most common reported side effects—laryngospasm upon emergence from general anesthesia and nausea/vomiting—were experienced by 10% and 6% of patients, respectively. The overwhelming majority of patients reported a positive experience. Overall, general anesthesia was shown to be effective in minimizing pain and discomfort associated with laser treatment, and, moreover, more pulses per treatment could be performed [116].

A multicenter retrospective review of 881 procedures performed on 269 children revealed 90% of patients experienced no clinically relevant complications. Nausea was the most commonly reported side effect (4% of patients). The authors postulated that the low complication rate of general anesthesia in elective dermatologic cases was secondary to the good baseline health of their patients, short procedural duration, the elective nature of the procedures, and the use of pediatric anesthesiologists [117].

A recent retrospective study of 33 patients averaging 6.7 laser treatments under general anesthesia before the age of 4 found no increased risks of neurodevelopmental abnormalities. The prevalence rates of speech and language disorders, attention-deficit hyperactivity disorder, anxiety, behavior disorders, and motor disorders were similar to those reported in the US population [118].

Based on available evidence in humans, one-time use of general anesthesia for the laser treatment of pediatric patients appears to be safe with a low rate of complications. Less data exists for serial treatments under general anesthesia, and it is unclear if there is a critical point at which the risks outweigh the benefits. Long-term, rigorous studies are underway, the results of which should provide the laser surgeon with some much-needed guidance.

Patient Preference and Informed Consent

Treatment of vascular lesions often requires multiple sessions over months to years. A physician-patient-parent partnership founded in trust and understanding of the process, duration of treatment, expected outcomes, and risks is essential to ensuring compliance as well as good medico-legal outcomes. Discussing preferences of the patient and/or parents can help achieve this relationship and should be considered in any discussion concerning which treatment modality to use.

Any Informed consent discussion should emphasize the commitment to the treatment process and the risks and benefits associated with the specific modality being utilized. Patients and

parents of children with PWB and infantile hemangiomas should carefully consider the holy grail of "total resolution" against the very real risks of pigmentary alteration, ulceration, scarring, blistering, and textural abnormalities associated with laser therapy. It is even more important to consider these risks against the expected natural progression of the lesions themselves, specifically, a tendency for PWB to hypertrophy and bleb with time and an expectation for most infantile hemangiomas to involute at least to some degree with time. Patients and parents should also be aware of the possibility that treatment (particularly of deep or complicated hemangiomas) may not lead to any appreciable improvement at all and may only result in adverse events [119].

Cost of intervention should also be a consideration for patients, their families, and the health system at large. Though most insurance companies cover pulsed dye laser therapy of infantile hemangioma and PWB, variability does exist between carriers, and the determination of medical necessity is sometimes dependent on anatomic location (face and neck appear to be preferentially covered) and/or the presence of bleeding, infection, pain, ulceration, or documented functional impairment. Presence of any of these signs and symptoms should be well-documented to ensure a positive prior authorization review.

Conclusion

Myriad treatment options for port-wine birthmarks and infantile hemangiomas exist, with no universal consensus on what constitutes the safest and most efficacious treatment modalities. Even less is certain regarding the use of these interventions in the pediatric and adolescent populations due to a lack of controlled trials within these age groups. Nevertheless, much progress has been made in the last several years with multimodal therapy yielding tremendous clinical improvements and technological enhancements. The emergence of specific therapies that target specific molecular and cellular pathways—used alone or in combination with procedural interventions—represents a promising future in the management of these vascular lesions.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Treatment recommendations for PWB and hemangiomas

PWB treatment recommendations	**Level of evidence**
PDL (585 nm or 595 nm) is the preferred treatment of flat PWB for patients with all skin types. Best results are achieved when treatment is initiated early, ideally within the first year of the patient's life	B
755 nm alexandrite and 1064 nm Nd:YAG lasers are the preferred treatment for PDL-resistant and hypertrophic PWB. Treatment should be performed only by physicians with extensive laser experience	B
755 nm alexandrite, 1064 nm Nd:YAG, 532 nm Nd:YAG, and PDT can be considered as second-line treatment modalities for PWB. Treatment should be performed only by physicians with extensive laser experience	B
Hemangioma treatment recommendations	**Level of evidence**
Systemic beta-blockers are the preferred treatment for complicated hemangiomas	A
PDL can be considered for the following situations: Patients who cannot tolerate beta-blockers Small, thin, superficial lesions Lesions with ulceration and associated pain Hemangioma residua	B
Fractional ablative laser alone or in combination with 755 nm alexandrite laser can be used to improve color, texture, and overall appearance of hemangioma residua	C
Surgery can be considered as part of a multidisciplinary approach to complicated hemangiomas (lesions at risk for hemorrhage, ulceration, functional impairment, and disfigurement)	C

Self-Assessment

1. Port-wine birthmarks and Sturge-Weber syndrome share a common mutation (GNAQ). What anatomic locations of PWB confer the highest risk for SWS?
   (a) Forehead
   (b) Eyelid
   (c) Temple
   (d) Cheek
   (e) A & B
2. What techniques can be used to limit post-inflammatory hyperpigmentation when using lasers to treat a patient with skin of color?
   (a) Double-pulsing with 20% overlap
   (b) Single-pulsing with minimal to no overlap
   (c) 4–6-week treatment interval
   (d) Strict photoprotection for 3–4 weeks after treatment
   (e) B & D
3. When counseling a patient with PWB and the family about pulsed dye laser, which of the following is **INCORRECT**?
   (a) Lightening of the PWB is directly related to the number of treatments. Most patients require six or more treatments.
   (b) One expected side effect is purpura, which reaches maximal intensity 1–2 days after treatment, and gradually fades over the next 7–10 days.
   (c) 50% improvement in color can be seen after the first treatment. On average, over 75% of patients will have complete resolution of their PWB.
   (d) Treatment is most successful when initiated within 3 months of life.
   (e) Central facial PWB tend to be more resistant to PDL treatment than lesions on the lateral face and neck.
4. Factors that may contribute to the lack of good comparative data for the evaluation of different modalities in the treatment of port-wine birthmarks and infantile hemangiomas include:
   (a) A lack of reliable animal models that has hampered in vivo research.
   (b) A lack of universally accepted, validated assessment tools that makes grading clinical improvement of port-wine birthmarks or hemangiomas before and after intervention difficult.
   (c) There are no universally accepted "expert consensus" recommendations or definitive treatment guidelines.
   (d) Authors may be disincentivized to publish "negative" results.
   (e) All of the above.
5. First-line treatment of a rapidly growing periocular hemangioma should include an assessment to initiate which therapy?
   (a) Radiation
   (b) Intralesional corticosteroid
   (c) Systemic beta-blockers (oral propranolol)
   (d) Oral corticosteroids
   (e) Nd:YAG (but only with metal eye shields in place)

Answers

1. e: Forehead and eye involvement of the PWB confer risk of SWS. An ophthalmologic examination is recommended for any infant with eyelid involvement and neuroimaging (brain MRI with gadolinium contrast) for those with extensive bilateral, hemifacial, or median forehead PWB.
2. e: Conservative settings administered via single pulses with minimal to no overlap, avoidance of pulse stacking, longer treatment intervals (6–8 weeks), strict post-laser photoprotection, and delaying additional treatment until any post-inflammatory hyperpigmentation has resolved are all essential components to minimize risk of hyperpigmentation when treating darker-skinned individuals.
3. c: On average, 12% improvement can be appreciated with each PDL treatment. Only 40% of patients achieve "good" lesional clearance, the rest experience suboptimal or even no improvement.
4. e: All of these stated factors may confound the ability to perform rigorous head-to-head comparisons of interventional modalities for port-wine birthmarks and infantile hemangiomas. There is much clinical and technological progress to be made!
5. c: Systemic beta-blockers (oral propranolol) are now the first-line therapy of choice for complicated hemangiomas. This rapidly growing lesion could compromise function, so a quick-acting, reliable therapy is necessary. If the lesion proves recalcitrant to systemic beta-blocker therapy, then additional modalities could also be considered.

Rosacea

58

Shlomit Halachmi

Abstract

Rosacea is a chronic inflammatory disorder of the skin that develops in adults and progresses with age. Treatment is guided for each subtype based on its major presenting clinical features: erythema, inflammation, and tissue hypertrophy. A 2015 Cochrane Database Review showed that most high-level evidence studies address topical and oral therapies used for papulopustular rosacea. This chapter surveys peer-reviewed studies of ten or more subjects reporting outcomes of energy-based, surgical, and injection procedures. The erythematous and papular components of rosacea respond well to light in the near-infrared range (532–1064 nm), with response rates of 55–96% after a series of sessions, but relapse is high. Studies comparing response to different light sources reveal minimal differences in their effectiveness. Phymatous changes respond to destructive and surgical modalities, including electrocautery, CO_2, and surgical debulking, with comparable outcomes. Photodynamic therapy has been proposed but does not provide significant benefit. Low-level evidence suggests possible effects of intradermal microdroplet botulinum toxin injections.

Telangiectasia · Electrocautery · Rhinophyma

Epidemiology

Rosacea is a chronic inflammatory disorder of the skin that develops in adults and progresses with age. Epidemiological studies have shown rates of 2–22% prevalence of rosacea depending on the populations studied. The relatively wide range is likely attributable to regional variation in skin phototypes and environment, but most studies point to a prevalence of 10% in the United States and Europe. Risk factors include European or Celtic heritage and lighter skin types.

Rosacea can further be exacerbated in susceptible individuals by any element that can cause flushing:

- sun exposure
- heat
- consumption of spicy food, hot beverages, or alcohol
- physical exertion
- emotional flushing

The nearly ubiquitous Demodex mites, estimated to reside in the skin of 80–100% of adults, have also been suggested as an underlying factor in rosacea. This theory is supported

Table 58.1 Rosacea subtypes

	Main clinical features	Targets for treatment
Erythematotelangiectatic rosacea (ETR)	Facial erythema, flushing, telangiectasia	Vascular structures
Papulopustular rosacea (PPR)	Central facial erythema, acneiform papules, and pustules	Inflammation
Phymatous	Hypertrophy and irregular cobblestoning of the nose	Hypertrophic tissue
Ocular	Blepharitis, Meibomian gland dysfunction	Inflammation

by several studies of Demodex prevalence in rosacea-affected skin and by the response, in some cases, to antiparasitic treatment.

To guide management, rosacea is classified into subtypes based on the major presenting clinical features (Table 58.1). These in turn drive the main treatment target.

As reported in a 2015 Cochrane Database Review of interventions for rosacea, most of the high-level evidence studies from randomized controlled studies (RCTs) address topical and oral therapies used for papulopustular rosacea (PPR) (1a) [1]. The Review concludes that laser- and light-based device studies are of low quality and summarizes a few. This chapter, in complement to the medical therapies review, addresses only manual interventions and includes procedures, whether energy-based, surgical, or injectable, of treating ETR, PPR, and phymatous rosacea. The studies are not amenable to pooling due to wide variation in methodology and lack of standardized core outcomes [2]. For this chapter, studies that include ten or more subjects are included regardless of methodology.

Treatment Overview: Energy-based Devices

Erythematotelangiectatic (ETR) and phymatous rosacea are most amenable to procedural interventions. Technologies that target hemoglobin-rich targets, including laser, intense pulsed light (IPL), and electrocoagulation (EC) can be used to treat either diffuse erythema or discrete telangiectasia. Phymatous changes of the nose can also be treated with debulking procedures for reduction of hypertrophy and improvement of texture. The favored technologies for treating ETR are primarily those that emit light in the visible and near-infrared range (532–1000 nm), while those used to treat phymatous rosacea are nonspecific long-wavelength ablative lasers.

The sources of energy reported in the treatment of rosacea include:

ETR and PPR

532 nm	Potassium titanyl phosphate laser (KTP)
585–595 nm	Pulsed dye laser (PDL)
1064 nm	Neodymium doped:yttrium-aluminum-garnet laser (Nd:YAG)
400–1200 nm	Intense pulsed light systems (IPL), with variable filters

Phymatous Rosacea

10,600 nm	Carbon dioxide laser (CO_2)
Electrodessication	

Rosacea commonly affects individuals whose skin has low background melanin levels and limited ability to generate melanin in response to ultraviolet light. In skin that tans easily, ultraviolet (UV)-induced damage triggers melanin production, protecting the skin from further UV-induced damage. In lighter skin types, the skin cannot mount this response and therefore is more susceptible to UV damage, manifested in part by inflammation and vasodilation, leading to redness. Further, in lighter skin the reedness is more visible because there is little melanin to mask the redness.

Treatment of redness in rosacea rests on targeting of hemoglobin in the superficial blood vessels. Since rosacea tends to develop in lighter skin phototypes, treatment with lasers is aided by the relatively higher ratio of hemoglobin to melanin. The higher density of the target chromophore, hemoglobin, and the relatively lower density of the competing chromophore, melanin, improve

the therapeutic window when lasers emitting visible light are used. Due to the wavelength-dependent penetration of light into skin, the use of shorter wavelengths, including those that are well absorbed by hemoglobin, can provide adequate vascular coagulation with lower energy doses. Therefore, it may be anticipated that visible light would have a wider therapeutic window than some of the longer-wavelength lasers or electrocoagulation, which penetrate more deeply and which may produce greater nonspecific tissue heating due to absorption in water.

Lastly, rosacea occurs on the central face, an area that is rich in sebaceous glands and is capable of rapid healing with lower risk of scarring than other sites. Therefore, aggressive debridement of hypertrophic tissue, as is seen in phymatous changes of the nose, is remarkably safe and effective on the nose, allowing the use of ablative lasers.

Effectiveness of Commonly Available Methods for Treating ETR and PPR

Vascular lasers used to treat the erythema or telangiectasia of ETR are effective, most often after a series of treatments. Larger spot size lasers or IPL are appropriate for treating diffuse erythema, while discrete vessels are targeted with small laser spot sizes. Pulse duration and power are selected based on provider and patient preferences of the desired immediate visible endpoint, which may be erythema or purpura. The relative effectiveness of purpuric vs. nonpurpuric treatment has been assessed in a few studies, but the choice is made ultimately by the patient's willingness to bear purpuric lesions on the face for 7–10 days.

Treatment is repeated after a variable interval until the desired response is achieved. As the erythema and telangiectasia improve, treatment parameters can be adjusted for the clinical presentation.

The signs of rosacea invariably recur because procedure-based treatments target the signs of rosacea but do not alter the underlying predilection. Avoidance of known triggers can delay recurrence. The time to recurrence may be months or years and is not routinely monitored in studies or in clinical practice. Additional treatments, if needed, can be performed at the time of recurrence.

Potassium Titanyl Phosphate Laser (KTP), 532 nm

Studies of KTP in the Treatment of Erythematotelangiectatic Rosacea (ETR)

Maxwell et al. assessed 14 patients with ETR in a prospective randomized blinded clinical trial (1c) [3]. One side of the face was treated with 532-nm laser. A subset of patients was also instructed to apply retinaldehyde to the face. Patients underwent six treatments over 3 months. Patients and five blinded evaluators scored digital images using a 5-point improvement scale to assess reduction of overall redness and of telangiectasia, difference between the treated and untreated hemiface, and skin texture improvement. All patients reported mild-to-moderate improvement. However, blinded evaluators could identify correctly the treated and untreated sides only 47% of the time. Due to the use of a topical treatment in a subset of subjects, it is not possible to pool all laser-treated hemifaces. Therefore, the number of subjects in each treatment group does not support statistical conclusions.

Insufficient data is available for rates of adverse events in treatment of rosacea with KTP. The expected adverse events include edema, purpura, blistering and scabbing, and pigmentary changes, and the risk is dose-dependent. Pigmentary changes might be less common due in rosacea than in other vascular lesion treatments due to the higher proportion of rosacea in lighter skin types. Scarring has been reported for KTP treatment of superficial vascular lesions, but accurate rates in rosacea are not available (4) [4].

Pulsed Dye Laser (PDL)

Studies of PDL in Erythematotelangiectatic Rosacea (ETR)

The largest portion of clinical studies evaluates the safety and effectiveness of PDL. The studies are not amenable to pooling, but all support PDL's effectiveness and safety. The primary outcome for most studies is degree of improvement,

largely assessed by subjective scales, and at times aided by device-based measurements of erythema. Some studies directly examine impact on quality of life (QoL).

Tan et al. published a retrospective study of 40 consecutive patients whose facial erythema was treated with PDL at purpuragenic parameters (585 nm, 0.45 ms, 5.4–6.5 J/cm^2, spot sizes 5 or 7 mm). Telangiectasia were treated with an additional pass using 3-mm spot and fluence 6.5–7.5 J/cm^2 (4) [5]. The average number of treatments was 2.4 [range 1–10] and the average follow-up time was 2 years [range 6 months to 4.5 years]. Subjects, family members, and 10 hospital staff rated improvement on a 5-point scale (1 = worse; 2 = no improvement; 3 = slight improvement; 4 = moderate improvement; 5 = marked improvement). Subjects and families rated improvement at 4.4 and 4.3, respectively, and the mean score of the judges was 3.7. During the treatment and follow-up, three patients experienced exacerbations requiring antibiotics; six developed post-inflammatory hyperpigmentation; and three developed recurrent erythema after 6, 16, and 52 months. Study limitations include the use of a nonsymmetric improvement scale (2/5 is the neutral score, with 1 score to assess worsening and 3 scores to assess improvement) and the pooling of all subjects despite wide variation in the number of treatments without a dose-response analysis correlating improvement and the number of treatments.

Jasim et al. assessed response to subpurpuragenic PDL in 12 subjects with rosacea-associated telangiectasia (4) [6]. A single treatment was performed at 595 nm, 6 ms, and fluence 7–9 J/cm^2 titrated to produce transient violaceous change. Pretreatment images were compared to images taken 6–8 weeks after treatment, and the percent reduction, in quartiles, was subjectively assessed. Two of the 12 subjects (17%) scored improvement of >75%, two subjects (17%) improved 50–75%, and five (42%) improved 25–50%. No subjects developed purpura or adverse events. These improvement rates are slightly lower than those reported in other PDL studies, perhaps reflecting the use of a single treatment session. However, the overall positive response to a single treatment combined with an absence of purpura generates a net positive benefit:risk ratio and supports offering this option to patients.

A similar study by Bernstein et al. in 2008 reported the response of 20 subjects with linear telangiectasia and diffuse facial erythema (4) [7]. Telangiectasia were treated with a 595-nm, long-pulse, elliptical spot, followed by full-face treatment with short-pulse circular spots. Parameters were adjusted for each patient. Severity was graded on a 0–6 scale before and 8 weeks after the last treatment. All subjects experienced some improvement, and no severe adverse events were reported. The mean severity score by blinded physician observers was 2.3 ± 1.3 at baseline and 1.4 ± 0.9. The mean per-patient change in score is not reported. The study is limited by the lack of untreated controls, partial blinding, and variable parameters. The low mean baseline score of 2.3/6 supports benefit of the approach for mild-to-moderate rosacea; the response of more severe rosacea is not addressed.

Studies of PDL in Papulopustular Rosacea (PPR)

Lowe et al. assessed the effects on PPR in 27 patients who had been treated for telangiectasia and erythema with 585-nm flash lamp-pumped dye laser (FPDL) (4) [8]. Of the 27 patients, 24 had improved erythema after one to three treatments. Papular and pustular activity decreased in 59.2% of the patients, and those with severe pre-treatment PPR exhibited the greatest degree of improvement.

In a similar study, Berg et al. treated ten subjects with erythema and telangiectasia using FPDL and then followed them for change in papulopustular activity (4) [9]. Ten months after treatment, five subjects had fewer lesions of PPR, three were unchanged, and two had more lesions.

The outcomes reported in these studies are similar: 50–59% of subjects treated for the vascular component had additional benefit in the papulopustular component. However, the authors summarize their findings differently: Lowe et al. propose that the response to FPDL is significant, while Berg et al. state that FPDL is of limited

value. A fair conclusion may be that FPDL is best suited for ETR and that some patients (approximately half) may also experience reduction in PPR.

Neodymium Doped:Yttrium-Aluminum-Garnet Laser (Nd:YAG)

Studies of Nd:YAG for Papulopustular Rosacea (PPR)

Lee et al. treated 30 Korean subjects with PPR using long-pulsed Nd:YAG (4) [10]. Group A (22 patients with mild-to-moderate PPR) were treated with laser only, and Group B (8 patients with severe PPR) were treated with laser and doxycycline 100 mg BID. Three treatments were provided (1064 nm, 10 mm, 50 ms, 40–50 J/cm^2, with dynamic cooling) at 4-week intervals. Three dermatologists assessed blinded photographs after 4 weeks using a 4-point severity scale. Laser alone yielded good improvement in 17 of 22 subjects (77%), while laser and doxycycline yielded good response in 7 of 8 (88%). All tolerated treatment well. Due to the small number of subjects in group B, and the inclusion of severe PPR only in group B, the two groups cannot be compared. The study suggests that long-pulse Nd:YAG is safe and effective, though no conclusions can be drawn regarding added benefit or risk of cotreatment with doxycycline.

Intense Pulsed Light (IPL)

Studies of IPL for ETR and PPR

Taub et al. report a study of 32 adults with facial erythema refractory to medical management who underwent treatments with IPL (2.4/4.0 ms double pulse with 20 ms delay, 32–36 J/cm^2 at 570-nm filter or 27–32 J/cm^2 at 560-nm filter) (4) [11]. Twenty-eight subjects completed the study, with a mean of 3.6 treatments per patient and mean follow up of 3.7 months. Three subjects experienced adverse events (purpura, peeling, or post-inflammatory hyperpigmentation). Most patients reported improved redness (83%), improvement in flushing (75%), and reduction of acneiform lesions (64%). Two subjects reported no benefits.

Kawana et al. treated 12 adults (6 with ETR and 6 with PPR) with rosacea using IPL (550–670 nm) for a total of 3 sessions at 4-week intervals (4) [12]. Spectrophotometer measurements showed that skin color approached those of unaffected skin in 6/6 ETR and 5/6 PPR subjects (total response rate 91.6%), with greater mean reduction in erythema in ETR.

Taub and Devita treated 21 patients with moderate-to-severe rosacea with either three or five monthly full-face treatments using IPL 470–980 nm combined with radiofrequency (4) [13]. Patient- and physician-reported improvements in flushing, erythema telangiectasia, and global severity indicated improvement after three treatments, with marginal additional improvement after five treatments. The study does not compare results with IPL alone, at comparable light dosing. The treatment was well-tolerated, but the greater penetration depth of RF than of visible light could lead to heating in deeper, nontarget tissues.

Kassir et al. evaluated the effects of IPL fluence, pulse duration, and pulse stacking on treatment response (4) [14]. IPL was used to treat 102 patients with mild-to-severe rosacea using 2.5/5 ms pulses, with one, two, three, or four stacked pulses delivered with 20–30 ms delay. ETR was treated with 530-nm filter and fluence 10–30 J/cm^2, while PPR was treated with 420 nm filter and fluence 10–20 J/cm^2. Patients underwent a mean of 7.2 treatments at 1–3-week intervals. Digital analysis of images showed that 80% of patients had reduced erythema. In patient-reported outcomes, 78% reported reduced flushing and 72% reported reduced papular lesions. The authors conclude that the parameters used describe optimal settings. Considering the multiple permutations (two wavelengths, variable fluence, and 1–4 pulses stacked) and the application to two patient types, the study does not provide sufficient power for any single parameter set to determine that its outcome defines the ideal protocol. The data do, however, support effectiveness and safety of IPL for treatment of ETR and PPR.

Liu et al. compared the effectiveness of IPL (540–950 nm) in treating different elements

of erythema associated with rosacea (3b) [15]. Sixteen patients with ETR and 16 with PPR underwent three treatments at 3-week intervals. Improvement in erythema was assessed by two dermatologists using a quartile grading scale [0, ≤25% improvement; 1, 26–50% improvement; 2, 51–75% improvement; 3, 76–100% improvement]. Patients reported satisfaction with treatment outcomes using a 10-point scale. All 30 subjects completing the study improved, with the PPR subjects showing higher mean improvement scores (2.1 ± 0.7 vs. ETR group, 1.4 ± 0.5; $p = 0.003$) and >75% improvement in 5/15 PPR subjects vs. 0/5 ETR subjects ($p = 0.026$). Patient satisfaction was higher (6.9 ± 1.5 PPR vs. ETR group, 5.6 ± 1.5; $p = 0.026$). It should be noted that for PPR the improvement cited was in perilesional erythema, and not in the number of papules or pustules. Therefore, this study may be assessing the response of discrete (and transient) erythematous lesions in PPR to that of more global erythema and telangiectasia of ETR.

Combination Treatments

Studies of Combination Treatments for Erythematotelangiectatic Rosacea (ETR)

Kim et al. sought to increase the available chromophore in rosacea by pretreating the face with topical niacin to induce flushing (3b) [16]. Eighteen subjects underwent split-face treatment with 585-nm PDL after application of niacin to one side. Both sides of the face were treated with the same PDL parameters using subpurpuragenic setting for three sessions at 3-week intervals. Erythema was assessed by polarization color imaging, as well as by three blinded dermatologists and by the subjects. Subjects and blinded evaluators rated improvement as better on the niacin-treated hemiface ($p = 0.007$ and 0.0050), but imaging measurements showed no significant difference between the two sides. The reasons for this discrepancy are not clear. A limitation of the study is that the treatments were performed on flushed vs. non-flushed hemifaces, but the evaluation was done in the absence of the same stimulated flushing. It is possible that niacin leads to dilation of smaller capillaries that are not visible in the absence of a flushing trigger, but has a lesser effect on already dilated pathological vessels that are visible "at rest." In such a case, the niacin treatment could increase laser absorption in the "triggerable" background vessels, resulting in reduced flushing upon stimulation. Such effects may not be visible at rest. Perhaps this explains the perception of patients, who experience less flushing on the niacin-treated side, but the absence of objective differences in static erythema at rest.

Karsai et al. assessed the benefits of combined treatment with PDL and Nd:YAG, on the premise that 595-nm exposure leads to temporary conversion to methemoglobin, which has particular affinity for 1064-nm light (3b) [17]. The split-face study assessed the application of sequential dual wavelengths (595 nm then 1064 nm) versus 595-nm PDL or 1064-nm Nd:YAG alone in 20 subjects. Telangiectasias on one side of the nose were treated with PDL (595 nm, 7 mm, 10 ms, 10 J/cm^2) followed immediately (100 ms delay) by Nd:YAG (1064 nm, 7 mm, 15 ms, 70 J/cm^2). The other side of the nose was treated with either PDL or Nd:YAG. Four weeks after a single treatment, blinded assessment of before and after photos showed greater improvement after dual laser than after 595 nm or 1064 nm alone ($p < 0.05$). There was no significant difference between 595 nm and 1064 nm alone. The authors conclude that sequential delivery of 595-nm and 1064-nm laser can provide a synergistic approach to treatment. Study limitations include lack of controls for total light dose (total power delivered) and for evaluation of additive vs. synergistic effects of 595 nm and 1064 nm. The former limitation could be assessed in part with a control study arm in which hemifaces were treated with dual-pulse 595 nm/595 nm or 1064 nm/1064 nm at the parameters of the sub-pulses in the active arm. The latter could be assessed by reversing the order in which 1064-nm and 595-nm light were delivered or by delivering 595 nm/1064 nm with ultrashort interpulse delay vs. long interpulse delay; either approach would reveal whether pre-exposure to 595 nm immediately prior to 1064 nm provides increased benefit to other combinations in the treatment of rosacea.

Other Procedures

Photodynamic Therapy (PDT)

A consensus panel statement published in 2006 provided recommended light sources for use with 5-aminolevulenic acid (ALA) in photodynamic treatment of rosacea, based on the experience of the panel members (5) [18]. The consensus report recommends the use of ALA with PDL using pulse stacking, or with visible light sources (blue, green, yellow, red). A recommended protocol is two treatment sessions at 2–5-week intervals, with increased ALA incubation times in the second treatment.

Calzavara-Pinton et al. assessed the response to PDT with methyl aminolevulinate (MAL) in a retrospective chart review of 20 hospitals in Italy who used the procedure for off-label indications (4) [19]. Although acne responded well, rosacea was less responsive and PDT did not appear to be a viable treatment.

Botulinum Toxins

Dayan et al. treated 13 patients with intralesional microdroplet injections (0.05 cc) of onabotulinumtoxinA, reconstituted as 100 units in 7 cc saline (4) [20]. Intradermal injections totaling 8–12 units per cheek resulted in reduced erythema after 1 week, sustained for 3 months.

Bloom et al. enrolled 25 subjects with ETR, injecting 15–45 units of abobotulinumtoxinA into the dermis over the nasal tip, ridge, and alae (4) [21]. Fifteen subjects completed the study. The treatment resulted in reduced mean erythema severity scores at 1, 2, and 3 months after treatment ($p < 0.05$, $p < 0.001$, and $p < 0.05$, respectively). Pairwise comparison of 3-month erythema score to baseline showed statistically significant reduction at all time points.

Effectiveness of Commonly Available Methods for Treating Phymatous Rosacea (Rhinophyma)

Abundant literature is available for procedures used to treat rhinophyma. However, most reports include small case series, and all are retrospective, non-blinded, and non-controlled. Reports that include ten or more patients are summarized below.

Carbon Dioxide Laser (CO_2)

Karim et al. report their experience from 1983 to 1993 in treating 18 patients with good results and safety and durability of response which they defined as "curative" (4) [22]. El-Azhary et al. report 30 patients treated by CO_2 ablation from 1986 to 1989 (4) [23]. If rhinophyma was severe, CO_2 excision was used for debulking prior to vaporization. Treatments were generally well tolerated, with infrequent hypopigmentation, scarring, and a single case of alar lift.

Madan et al. review their experience with 124 cases of treating rhinophyma with CO_2 under local anesthetic (4) [24]. The approach applied CO_2 in continuous mode to debulk, followed by reshaping the contours using either defocused 2–3 mm beam or resurfacing mode (scanner) with 4–7 mm spot. Most patients (118) experienced good outcomes with no serious adverse events. Six patients had scarring, hypopigmentation, or dilated pores.

Corradino describe their results in 14 men treated with a similar approach, the "downward steps" technique, in which high-power CO_2 is used for initial debulking, followed by progressive reduction of power for coagulation and finer shaping in a single procedure (4) [25].

Electrosurgery

Clark and Hanke report the use of electrosurgery to treat 13 patients with severe rhinophyma (4) [26]. The technique was particularly well suited for patients with lobular rhinophyma. In contrast, patients with generalized hypertrophy of the nasal tissue had poorer outcome and higher risk of scarring. The authors cite the lower cost of equipment as a significant benefit over laser treatment.

Relative Effectiveness of Procedures

Few comparative studies evaluate the benefits of one energy-based device over another. Due to the variability of treatment settings and baseline severity, there is insufficient evidence to render a clear distinction between the available devices.

ETR: PDL Versus Nd:YAG

Alam et al. compare the effectiveness of nonpurpuragenic 595-nm PDL with 1064-nm Nd:YAG for diffuse facial erythema in a split-face, double-blind randomized controlled trial (1b) [27]. Cheeks were treated with either PDL or Nd:YAG monthly for four treatments. In 14 evaluable subjects, spectrophotometer readings showed PDL led to greater improvement than Nd:YAG (8.9% vs. 2.5%), correlating with better subject-reported improvements with PDL than Nd:YAG (52% vs. Nd:YAG 34%). Both treatments were safe, though PDL was perceived as more painful than Nd:YAG. The authors suggest that Nd:YAG may have a relative benefit in darker-skinned patients, particularly due to less pain.

Similarly, Salem et al. reported a split-face study comparing the response to PDL and Nd:YAG in 15 patients with ETR (1c) [28]. After three monthly sessions, 73% of Nd:YAG-treated patients had significant reduction in erythema and telangiectasia vs. 53.3% of PDL-treated patients. Substance P staining in skin biopsies showed lower substance density after Nd:YAG than PDL, correlating with clinical response. This study was performed in Egypt, where sun exposure and skin phototype effects may have affected parameters' selection for each device. This appears to be in agreement with the suggestion posed by Alam et al. that Nd:YAG may have an advantage in darker phototypes [27].

ETR: PDL Versus IPL

Neuhaus et al. report a randomized, controlled, single-blind, split-face trial comparing nonpurpuragenic PDL treatment, IPL, and untreated control (1b) [29]. Twenty-nine subjects underwent 3 monthly treatment sessions (PDL, 10 mm, 6 ms, 7 J/cm^2, with cryogen cooling; IPL, 560-nm filter, 2.4/6.0 ms pulse train with 15 ms delay, 25 J/cm^2). Evaluation measures included spectrophotometric erythema scores, blinded investigator grading, and patient assessment of severity and associated symptoms. Both nonpurpuragenic PDL and IPL reduced erythema and telangiectasia in spectrophotometric analyses and blinded evaluations, with equivalent safety and effectiveness.

Rhinophyma: Scalpel Versus CO_2

In 1993, Har-el et al. retrospectively review the charts of 23 patients treated surgically for rhinophyma: 16 had undergone CO_2 laser ablation, and 7 had sharp blade excision (4) [30]. No differences were identified in the length of surgery, preservation of normal tissue, pain, outcome, or adverse events, although the laser procedure was easier for the providers and support staff.

In 2013, Lazzeri et al. reported their long-term results in 67 patients treated by either tangential scalpel excision (N = 45) or CO_2 (N = 22) (4) [31]. Outcomes were comparable. They conclude that the accuracy and precision of the lasers are not justified by cost of the device.

Preoperative Evaluation and Patient Selection

Papulopustular rosacea (PPR) is generally managed by medical therapies, including topical and oral antibiotics, often with good outcomes. Procedures are not first-line therapies for PPR. As described above, laser-based procedures targeted at ETR may offer some benefit to PPR in addition, but patients should be advised that the treatments are not intended to reduce the papular/pustular activity.

The flushing, fixed erythema, and telangiectasia of ETR are the visible sequelae of vascular pathology. Unlike PPR, the changes visible in ETR are anatomic and do not respond to medical therapies. Vascular lasers can coagulate the structures visible in ETR with excellent results. However, the underlying causes of the vascular change are not affected by the procedure. Consequently, erythema nearly always recurs.

Rhinophyma is best treated with ablative modalities. Mild or early cases, particularly in younger adults, are best treated by mild ablative means ("vaporization"), whereas larger, lobular hypertrophic areas require excision, either by ablative laser or scalpel. Few larger studies are available to compare scalpel and CO_2 excision. Two summarized above conclude that there are not significant differences in patient outcomes, though the laser approach may be preferable to providers.

Impact of Patient Preference

Patients being treated for ETR may be able to choose among IPL, purpuragenic PDL, non-purpuragenic PDL, and Nd:YAG. The literature summarized above suggests that results are comparable for effectiveness overall, though Nd:YAG may be a better option for darker phototypes due to reduced absorption by melanin at 1064 nm. Patients may have a strong preference, however, between purpuric and nonpurpuric PDL, given the profound visual appearance of PDL-induced purpura on the face.

Due to variable treatment parameters in the studies, there is no data regarding a correlation between the choice of device and recurrence rates. However, all procedures share a common goal of reducing the density of vascularity in the skin, and treatment is concluded when that endpoint is achieved. It is reasonable to predict, then that the visible reductions in erythema are accurate measures of vascular reduction at an anatomic level and that regardless of the means for achieving the reduction in vascularity, the rate at which future erythema will develop is more closely dependent on the substrate (the patient's genetics and environment) than on the technical energy parameters used.

Typical Treatment Plan

Patients referred with a diagnosis of rosacea should be evaluated first to confirm the diagnosis and identify the subtype. Typically, rosacea affects adults, particularly those with Fitzpatrick skin types I–III. Rosacea affects primarily the midface but can also include the chin and lateral cheeks, particularly over the malar eminences. Involvement that spares the midface, or which is primarily located in the periphery of the face and jawlines, may suggest other acneiform disorders. Rosacea, in contrast to acne vulgaris, does not exhibit comedones. Upon history, patients may confirm family history of rosacea, symptoms of flushing, and gradual worsening over time.

Papules and pustules point to PPR. This is best treated with topical or oral prescription medications. More severe cases may require treatment with isotretinoin. Recent use of isotretinoin should be elicited prior to beginning any procedure, as there have been reports of increased risk of hypertrophic scarring when procedures are performed within 6 months of isotretinoin use.

Redness in the absence of papules, whether fixed or "flushing," is associated with ETR. The erythema and telangiectasia, especially of the nose, chin, and cheeks, can remain despite well-managed PPR.

Trophic changes to the nose, including increase in bulk or cobblestone texture, are hallmarks of phymatous rosacea.

Patients with ETR are likely to benefit from vascular light-based treatments. Smaller areas or discrete telangiectasia can be treated with lasers with a small spot size. Larger areas of erythema can be treated with larger spot sizes (10 mm or larger), long pulse durations (10 ms), and lower power (titrated to temporary color change in the treated spot). Pulsed dye laser is a common first-line choice. As summarized above, some articles cite the effectiveness of nonpurpuragenic settings (pulse durations 6 ms or higher, with fluence titrated to visible vasospasm). Other providers state that their experience guides them to offer purpuragenic treatment parameters (pulse duration 1.5 ms or shorter) with the possibility of requiring fewer treatments to reach clearance. The appearance of purpura, as prominent circles of purple on the face for a week to 10 days, should be clearly explained to the patient, preferably with photographs, to support decision-making.

Treatment with PDL is associated with a mild stinging sensation with each pulse. The use of cryogen to precool the skin aids in pain reduction. Topical lidocaine can be used in advance of treatment, though its application causes some vasoconstriction and could reduce the effectiveness of treatment. Therefore, treatment without lidocaine is preferred when the patient can tolerate the procedure.

Postoperative Care and Follow-Up

Post-procedure care involves gentle cleansing and application of emollient as needed, with aggressive sun avoidance measures. Treatment may be repeated after 4–6 weeks, when residual rosacea can be assessed. Parameters are adjusted as needed at each treatment. The endpoint for a treatment course is visual clearance that is deemed satisfactory to the patient and provider.

Education regarding rosacea triggers can be reinforced during and after the treatment course. Avoiding or mitigating triggers that are within a patient's control may slow the progression of new erythema in the future.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
Treatments for ETR and PPR	
PDL is most commonly studied for treatment of ETR	N/A
Nd:YAG may have benefit in darker phototypes	C
Nonpurpuragenic PDL settings may be more acceptable to patients while offering efficacy	B
IPL has been shown effective in treating facial erythema	B
Small, non-controlled studies suggest that intradermal microdroplet botulinum toxin injections can provide temporary benefits	D
Studies have demonstrated noninferiority in pairwise comparisons of IPL, PDL, and Nd:YAG	B
Variability in parameters, procedures, and metrics precludes defining a single technology as superior	N/A
Treatments for rhinophyma	
CO_2 treatment applies laser to excise bulk and then to contour the nose	N/A
Outcomes are very good and can last for years	C
Patients' outcomes are similar with scalpel and CO_2; convenience and cost may impact the provider	D

Self-Assessment Questions

1. The target of pulsed dye laser (595 m) in rosacea is thought to be
   (a) The epidermis
   (b) The dermis
   (c) The sebaceous gland
   (d) Demodex mites
   (e) Blood vessels

2. In treating rosacea, CO_2 laser has the most utility in improving
   (a) Nasal telangiectasia
   (b) Diffuse redness
   (c) Papules and pustules
   (d) Ice pick scars
   (e) Hypertrophic tissue

3. Recurrence after treatment is least common with
   (a) KTP
   (b) PDL
   (c) Nd:YAG
   (d) IPL
   (e) CO_2

4. The first line of treatment for papulopustular rosacea is
   (a) KTP
   (b) PDL
   (c) IPL
   (d) All of the above
   (e) None of the above

5. Studies presented in this chapter state the following based on their results: relative to PDL, IPL is
   (a) Better because it is more cost-effective
   (b) More dangerous because its use is regulated differently
   (c) More effective because of its wider light spectrum
   (d) Comparable in safety and effectiveness
   (e) All of the above

Correct Answers

1. e: PDL targets hemoglobin and therefore damages blood vessels by heat coagulation of the vessel walls. While there may be an effect on Demodex mites and heating of the dermis or sebaceous glands, these are not the main reason PDL reduces erythema.
2. e: CO_2 is used for debulking hypertrophic tissue in rhinophyma. While it may improve telangiectasia, redness, and new papules, it is not primarily intended for these endpoints. CO_2 can be used for treating acne scar, but ice pick scars are not generally caused by rosacea.
3. e: Rhinophyma treatments (with CO_2) results in much longer time to recurrence.
4. e: PPR is treated with topical or oral prescription medications.
5. d: Cost, user regulation, and the benefits of coherent light vs. IPL can be debated, but the controlled studies cited in his chapter demonstrated similar outcomes after PDL and IPL treatment.

Androgenetic Alopecia

59

Maria Colavincenzo and Stefan G. Vanderweil

Abstract

Androgenetic alopecia (AGA) is a common, non-scarring form of hair loss characterized by progressive miniaturization of terminal hair follicles on the scalp. First-line therapy for AGA consists of medical therapy with topical minoxidil and oral anti-androgens. Two emerging procedural therapies, platelet-rich plasma (PRP) injections and low-level light therapy (LLLT), represent novel therapeutics for the management of AGA. The details of these procedural treatment modalities are discussed within this chapter.

Keywords

Androgenetic alopecia · Platelet-rich plasma
Low level light therapy

Introduction

Androgenetic alopecia (AGA) is a common, non-scarring form of hair loss characterized by progressive miniaturization of terminal hair follicles on the scalp. AGA encompasses what is commonly referred to as male pattern hair loss (MPHL) in men and female pattern hair loss (FPHL) in women. There is an abundance of data to suggest that AGA is an androgen-mediated process. Genetic predisposition is the main risk factor for the condition.

AGA is clearly the most common form of hair loss, though exact prevalence estimates are variable. Among men, age-dependent estimates range from 16% among young adults to as high as 96% in older adults [1]. Among women, estimates range from as low as 3% to as high as 38%, again with higher prevalence found in older age groups [2]. Racial disparities in prevalence are also recognized, with higher rates in Caucasians, lower rates in African Americans, and variable rates among different subsets of Asians [1].

Therapeutic Approach

First-line therapy for AGA consists of medical therapy with topical minoxidil and oral anti-androgens. There is strong evidence to suggest that topical minoxidil, in varying concentrations and vehicles, is effective in men and women with AGA. Oral anti-androgens, including finasteride and dutasteride, are heavily utilized in both genders, though robust data in support of efficacy are found for only male patients [3].

Procedural interventions for AGA are generally considered either as adjuvant treatments for medical therapies or appropriate when the former approach is intolerable or inefficacious. Hair transplantation is both widely practiced and highly effective and addressed elsewhere in the text. Two emerging procedural therapies, platelet-rich plasma (PRP) injections and low-level light therapy (LLLT), are discussed in detail in this section. PRP entails the injection of patient-derived plasma, while LLLT refers to the use of a light-emitting device.

Platelet-Rich Plasma (PRP)

PRP is a novel technology for the treatment of androgenetic alopecia. PRP is an autologous blood product containing high concentrations of platelets and rich in growth factors such as platelet-derived growth factor, vascular endothelial growth factor, and transforming growth factor beta. These components are thought to stimulate angiogenesis and tissue repair and have found multiple applications across regenerative medicine [4]. It is prepared from a patient's blood sample and then injected into the affected areas of the scalp. While this basic algorithm is universal, there are many different collection systems differing in their use of additives and other modes of preparation. The volume of PRP utilized and the frequency of dosing also vary widely. Therefore, the procedure is far from standardized.

PRP has recently been applied to the treatment of androgenetic alopecia (AGA), with mounting evidence for its efficacy. However, its mechanism of action remains somewhat unclear. Experimental data has shown that PRP is capable of stimulating the hair follicle's mesenchymal component, the dermal papillae, to proliferate and induce hair follicle cycling [5]. PRP has also been shown to facilitate the telogen to anagen transition [6]. Other hypotheses regarding its mechanism include the stimulation of hair follicle stem cells and the promotion of neovascularization [7].

While PRP gains more popularity among clinicians in the treatment of AGA, precise estimates of its utilization are lacking.

Effectiveness of PRP

In recent years, multiple placebo-controlled trials have demonstrated PRP's efficacy in treating AGA. A recent meta-analysis analyzed data from multiple randomized controlled trials and identified a significant impact of PRP on hair follicle density (1a) [8]. Although not statistically significant, the authors also identified other favorable trends including increased hair shaft thickness. Data also exists that shows improvement in other hair parameters resulting from PRP injections, including an increased proportion of anagen hairs and decreased rates of shedding (1b) [9, 10]. PRP has also been studied as an effective adjuvant therapy to hair transplantation, resulting in increased yield (1b) [11].

Effectiveness of PRP may vary by gender, with one report showing earlier onset of hair growth in men but higher hair counts in women [12]. A placebo-controlled trial identified several factors that may influence response to PRP, with statistically significant favorable outcomes associated with male gender, onset of AGA after 25 years of age, disease duration over 10 years, and a positive family history of AGA (1b) [9].

While robust comparisons of different PRP preparation modalities are lacking, there are some reports demonstrating differences among them. One study in particular showed the superiority of a collection system that did not utilize calcium-activated PRP when compared with one that did [13]. Given the mixed outcomes of various trials, each utilizing different PRP preparations, it is reasonable to conclude that preparation modality influences patient response.

The duration of response to PRP injections is variable and generally falls within months to roughly a year [14].

The relative efficacy among the procedural interventions is largely unknown, given the lack of comparative trials. One study on PRP compared the injections in combination with either finasteride or minoxidil with the same medical therapies alone and found that the addition of PRP resulted in statistically significant improvement in multiple hair growth parameters (1b) [9]. Another study also found PRP in combination with minoxidil to be more efficacious than minoxidil alone (2b) [15].

Preoperative Evaluation, Safety, and Adverse Effects of PRP

Overall, PRP has an excellent safety profile. PRP injections are inappropriate for those with diminished or dysfunctional platelets. Current infections, both systemic and localized to the treatment area, hematologic malignancy, immunosuppression, anemia, and recent NSAID use, have also been proposed as contraindications in orthopedic procedures utilizing PRP [16].

Appropriate preoperative tests include a complete blood count and coagulation tests.

Side effects from PRP injections are generally mild and include injection site pain, erythema, and edema. Other less common complications include headache, infection, and cutaneous hypersensitivity reactions [12].

Low-Level Light Therapy (LLLT)

Early observations in animal studies and of paradoxical hypertrichosis in laser therapy were among the first indications that light devices might indeed be useful toward promoting hair growth [17–20]. In the subsequent years, several light-emitting devices were developed for commercial use. Low-level light therapy (LLLT), also called low-level laser therapy, refers to the use of a visible light-emitting device for photobiomodulation. LLLT is referred to as "low level" because its energy density is low compared with other forms of laser treatments [21].

Red or near-infrared laser light is known to possess tissue repair properties, and LLLT has been used for regenerative purposes in treatment of a wide range of medical conditions, from wound healing and nerve regeneration to joint pain relief [22]. LLLT devices that emit coherent monochromatic red light have been developed for various skin conditions, including hair growth. Chromophores are the receptors in biological tissue that can absorb photons. Wavelengths in the range of 650–1200 nm have maximal tissue penetration in biologic tissue (the so-called optical window of tissue). LLLT devices employ light within this therapeutic range, in the red or near-infrared spectrum (600–950 nm) [22–23].

LLLT is thought to result in the absorption of light by chromophores contained in the protein of components of the respiratory chain of the mitochondria, in particular cytochrome c oxidase (CCO), which results in photodissociation of nitric oxide (NO), leading to greater production of ATP [21]. While the exact mechanism by which this promotes hair growth is uncertain, it is thought that release of NO from CCO may increase anagen hairs. NO is known to be a potent vasodilator, and increased blood flow was reported in several studies [22, 24–25]. Possible downstream effects on the hair follicle are thought to include anagen reentry of telogen hair follicles, with prolonged anagen duration and increased anagen growth rate [22, 26–29].

Based on the available data in support of the benefit of LLLT as a treatment for AGA, the Food and Drug Administration granted the first clearance for a device indicated for treatment of AGA in men in 2007, and the category was expanded to include treatment of women with AGA in 2011 [22, 30–32]. Current LLLT devices for hair loss, for the most part, utilize a wavelength of 655 nm [26], including the HairMax LaserComb (Lexington Int. LLT, Boca Raton, FL) and Apira iGrow helmet (Apira Science Inc., Boca Raton, FL) [28], which represent the few FDA-cleared commercially available LLLT devices with published clinical findings in peer-reviewed journals [26, 31–34]. However, in recent years, many additional companies have received FDA clearance for similar LLLT devices. Commercially available home-use LLLT devices come in comb, helmet, or cap form, with variable pricing (costing from a few hundred dollars and upwards) and variable treatment regimens (number of minutes per treatment, number of times per week) [26].

Effectiveness of LLLT

Building upon a strong basis of in vitro and animal studies, there are a rapidly increasing number of clinical studies evaluating the potential effects of LLLT on AGA, the vast majority of

which suggest a benefit for LLLT in treatment of male and female pattern alopecia. There are a total of five RCTS evaluating LLLT for AGA in men/women [31–35]. All were double-blinded and used blinded evaluators to report changes in hair density at 16–26 weeks with LLLT compared to sham devices [26]. All RCTs found improvements in hair density/hair count in LLLT-treated subjects compared to the sham-treated subjects (1a) [26, 31–35]. Three trials noted a range of relative increases in hair density of 15.27–19.8 hairs/cm [2] in treatment groups compared to controls [31, 34–35]. Two separate studies in males and females conducted by the same group also noted an increased hair count, by 35% in males and by 37% in females, compared to controls [28, 32–33].

One systematic review examined 11 clinical studies of LLLT for AGA which evaluated a total of 444 males and 236 females [28]. The studies assessed hair count/hair density as an end point, and nine found statistically significant improvements in both males and females following LLLT treatment (1a). In another review of nine clinical studies, five assessing comb devices and four regarding helmet/cap devices, the same positive findings for LLLT in treating AGA were noted (1a) [26], although criticisms included the small sample sizes in some of the individual studies, lack of intention to treat analysis in many cases, and a lack of reported visual evidence (only one RCT provided global photographs). Other concerns include a relatively short follow-up period, generally 6 months.

The authors also noted that the positive effects of LLLT in the available clinical data also raise further questions to be clarified. For example, it is unclear whether the number of light sources or the type of light sources is important for efficacy of LLLT – whether it is a laser-emitting diode (LED), a laser diode, or a combination that is affecting the target area of interest. (As opposed to LED light, laser light is monochromatic, collimated, and coherent.) Similarly, while most devices advocate treatment for 15–20 min every other day or three times a week, the optimum treatment regimen or dosage for LLLT is not known [26]. Thus, the decision of which device and regimen to recommend to a given patient is not straightforward at this time [28].

Relative Effectiveness of LLLT

Indeed, LLLT, along with minoxidil and finasteride, was found to be in the highest level of evidence for benefit in a recent systematic review and meta-analysis of treatments for AGA (1a) [3]. However, as noted by previous reviews, a limitation remains the relatively smaller number of trials and patients evaluated with LLLT as compared to traditional, pharmacologic hair loss therapy [26], thus solid conclusions about the relative efficacy of LLLT compared to other treatments cannot be made at this time. While in clinical practice, the most common treatment plan may include a range of modalities including topical and systemic therapy, there has been relatively little reported on comparisons among different modalities of treatment, or combinations thereof.

One study compared the use of LLLT monotherapy to LLLT combined with minoxidil and/or finasteride in males and females (2b) [36]. All showed improvement, although no group demonstrated significant advantage over the others. In a recent RCT among women with AGA, LLLT was compared to minoxidil topical (5% bid) and to a combination of both LLLT and minoxidil [37]. The most improvement, judged by hair counts and dermoscopic assessments as well as patient satisfaction, was in the combination group.

Given the generally high level of evidence for minoxidil and finasteride, these treatments are typically, together, considered as first-line treatment for AGA. But LLLT should also be considered in parallel, especially given the increasing evidence for potential benefit which has been reported in the last several years.

Safety of LLLT

Safety is a major plus to LLLT in general, with such devices considered exceedingly safe.

Compared to medical therapy and surgical therapy, the risks are very low – so far there have been no serious adverse events reported. A minority of patients have reported minor side effects, such as headache, pruritus, or warm sensation in the treatment site [28]. Initiation of telogen effluvium has been observed in only one study and resolved after 2 months of treatment [21]. Some other possible considerations are presence of any atypical, precancerous, or malignant lesions on the scalp which could, in theory, be stimulated to grow by proliferative effects of LLLT [22, 38–39]. However, in the conducted clinical studies, only one case of a basal cell carcinoma on scalp was reported, which the authors felt was not likely related to the LLLT. In summary, the very low incidence of side effects gives LLLT an excellent safety profile [21].

Patient Characteristics and LLLT

It has been noted that the success of any LLLT device may well depend on individual differences, including in physical characteristics such as hair color, length, and skin color [26]. Notably, LLLT devices are cleared for use in individuals with Fitzpatrick skin type I to IV. In computer models, darker skin decreases transmission of light, presumably due to melanin [26], yet one clinical study reported that patients with Fitzpatrick skin type IV demonstrated a greater response to the LLLT therapy than patients with Fitzpatrick I, II, and III skin types (2b) [40]. Any clinically significant differences based on skin type remain to be validated.

As to other relevant considerations, one prospective study found that patients with intermediate severity AGA (Hamilton-Norwood III and IV and Ludwig I and II) showed the maximal response to LLLT (2b) [28, 36]. It is thought that perhaps, in patients with rather full hair density at baseline, this hair might pose a barrier to light penetration, while at the other extreme of severe alopecia the condition may be less responsive. Another study found that older subjects tended to respond better than younger subjects (2b) [40]. In terms of location of the treatment area, although both sexes showed significant benefit in all areas, in one study there was a greater improvement in the vertex area in men and temporal area in women (4) [38]. Further research will be needed to characterize the difference in response to LLLT in subpopulations [28].

Patient Preferences and Treatment Approach to AGA

Given the lack of controlled trials gauging the relative efficacy of different treatment modalities for AGA, patient preference often dictates the management strategy. For those patients wishing to utilize the most data-driven approaches, medical therapies are most often appropriate as first line. Procedural interventions then become useful adjuvants or replacements to these when the improvement is insufficient or the side effects intolerable. Safety considerations may also influence patient preference.

LLLT and PRP appear to be very safe, with generally less side effect considerations than systemic anti-androgen therapy, and likely even in comparison to topical minoxidil. Some patients prefer to avoid pharmacologic interventions altogether, for whom LLLT and PRP may have a unique appeal. In the particular case of women of childbearing potential with AGA, LLLT may be a primary consideration due to its excellent safety profile. PRP injections can be painful, and, therefore, highly pain-averse patients may wish to avoid this approach. Cost considerations factor prominently in patient choice as well, given that most approaches require out-of-pocket expense. Medical therapies are often the most affordable, while both LLLT and PRP are more costly, and hair transplantation typically requires a considerable investment.

Medical therapies require indefinite use and are limited by patient adherence. Similarly, the at-home time commitment of LLLT makes this therapy less desirable for patients not willing to commit additional time to use the device regularly.

Among the different currently commercially available LLLT devices, there is a range of inconvenience – e.g., hands-free devices, while more expensive, may be strongly preferable to some patients. Patients preferring to minimize their at-home treatment commitments may favor interventional therapy with PRP and have a lower threshold for seeking hair transplantation. In summary, personal preference is a central consideration in treatment of AGA.

After a patient is diagnosed with AGA, a discussion of both medical and procedural therapies should ensue. Baseline photographs are crucial for monitoring patient response to treatment. A typical initial approach for a treatment-naïve patient would be the use of either or both minoxidil and finasteride. Assessment of the efficacy and tolerability of these interventions is then gauged after 6–12 months. If the therapies are intolerable or their results are unsatisfactory, the addition of or substitution with PRP and LLLT should be discussed. Concomitantly, candidacy for hair transplantation should be considered, as is discussed thoroughly elsewhere in this text.

Conclusions

PRP and LLLT are procedural interventions for AGA that are supported by the available evidence. Data from multiple randomized controlled trials show that PRP and LLLT are effective and well-tolerated. There are no head-to-head comparative trials between these modalities and traditional medical therapies. In the absence of these, considering the much more substantial amount of data supporting medical therapies, PRP and LLLT largely play an adjuvant or second-line role at this time. However, many patients find these traditional interventions to be intolerable or ineffective, and therefore, these procedural interventions can offer patients an additional, effective, evidence-based treatment modality.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development, and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
PRP increases hair density in AGA	B
LLLT increases hair density in AGA	B
Topical minoxidil and oral anti-androgens are first-line therapies for AGA in men and women	A
PRP in combination with minoxidil or finasteride may be more effective than medical therapy alone	C
LLLT in combination with minoxidil or finasteride may be more effective than medical therapy alone	D
PRP may improve the efficacy of hair transplantation for patients with AGA	C
PRP is safe and lacks significant adverse effects	A
LLLT is safe and lacks significant adverse effects	A
Patient preference factors prominently in the therapeutic approach to alopecia when considering among medical, surgical, and procedural therapeutic options	A

Self-Assessment Questions

1. Clinical studies have demonstrated that PRP significantly increases:
   (a) Hair follicle density
   (b) Hair shaft thickness
   (c) Hair shedding
   (d) Proportion of telogen hair follicles
   (e) Cutaneous vasoconstriction

2. Regarding treatment of AGA with LLLT:
   (a) Most devices utilize wavelengths of around 1000 nm
   (b) LLLT is known to be most effective in lightest skin types (Fitzpatrick skin type I and II)
   (c) LLLT is effective as monotherapy or combination therapy with topical minoxidil
   (d) LLLT is contraindicated in patients with a history of skin cancer, given the increased risk of scalp carcinogenesis
   (e) Comb-style devices lead to more effective light penetration compared to cap-style

3. Features of PRP and LLLT include:
   (a) Highly cost-effective
   (b) Decades of long-term outcome data
   (c) Highly powered trials compared to topical therapies
   (d) Excellent safety profile

4. A procedurally wary middle-aged male patient presents with moderate-to-severe AGA, having previously failed 1 year of treatment with topical minoxidil.
   (a) LLLT is the first-line treatment option.
   (b) PRP is the first-line treatment option.
   (c) Oral finasteride is the first-line treatment option.
   (d) Hair transplantation should be encouraged.

5. A female patient of childbearing potential not actively trying to conceive but not willing to practice contraception is distressed by progressive hair loss, diagnosed as AGA clinically after ruling out other possible contributing factors. She is using minoxidil topical but is not satisfied with the response after 6 months. You should:
   (a) Prescribe adjuvant oral anti-androgens such as spironolactone or finasteride.
   (b) Perform a hair transplant procedure so that additional or ongoing medical therapy will be unnecessary.
   (c) Recommend PRP given its excellent safety profile.
   (d) Recommend LLLT given its excellent safety profile.

Correct Answers

1. a: PRP has been shown to significantly increase hair follicle density and the proportion of anagen hair follicles. It has also been found to significantly decrease the rate of hair shedding. It may increase hair shaft thickness, though data from a clinical trial did not reach significance. Hypotheses regarding its mechanism include the stimulation of hair follicle stem cells and the promotion of neovascularization.
2. c: Clinical studies have demonstrated the effectiveness of LLLT both as monotherapy and in combination with medical therapy, though the relative effectiveness is still unknown. Most devices utilize wavelengths around 655 nm (within the red/near-infrared spectrum). The devices are FDA-cleared for use in individuals with Fitzpatrick skin type I to IV, and while some small studies have suggested a possible effect of skin type on response to LLLT, this remains to be clarified. LLLT is not considered a carcinogen or risk for patients with a history of skin cancer (though use would be deferred in the setting of any specific suspicious lesion within the treatment zone pending diagnosis and treatment). While it clearly affects patient preference and experience, the significance of device style (such as comb or cap or band) in terms of LLLT effectiveness, if any, is not known.
3. d: PRP and LLLT have excellent safety profiles, with a lack of significant reported adverse events. Considered together, they are effective therapeutic considerations for AGA but involve significant out-of-pocket expense for patients. While clinical trials support their use and potential benefit, there is a lack of long-term outcome data (with most trials averaging 6 months or less), along with generally lower sample sizes in comparison to trials which have evaluated medical therapies.
4. c: Medical therapy with minoxidil and oral anti-androgens are the most established treatments and should be offered/considered for all patients with AGA. After a detailed discussion of potential side effects, a decision can be made as to whether to pursue finasteride. Procedurally wary patients are not likely to seek hair transplantation or PRP injections, though these are treatment considerations for patients with inadequate response to minoxidil. LLLT would be a second-line consideration in the described patient, given its tolerability and effectiveness in clinical trials.
5. d: While safety studies in pregnancy are lacking for all therapies for AGA, in particular, medical therapies are not considered safe in pregnancy. Oral androgens are known teratogens and must not be prescribed to women who may become pregnant. Minoxidil topical should not be used in pregnancy. While hair transplantation surgery is a treatment consideration for women as well as men with AGA, it is best used in parallel with nonsurgical therapy, since it does not address the progressive nature of AGA and would be deferred in the setting of pregnancy. PRP and LLLT are both considerations for patients who cannot pursue and do not tolerate or respond to medical therapy; but in the setting of possible conception, the noninvasive nature of LLLT makes this the best choice for the described patient. In the setting of a known pregnancy, however, LLLT is usually deferred given the lack of explicit safety data in that setting, as is the case with many or most cosmetic treatments.

Cutaneous Carcinogenesis in Organ Transplant Recipients

60

Joyce T. Yuan, Amanda R. Twigg, and Sarah T. Arron

Abstract

Organ transplant recipients (OTR) have a high risk of skin cancer, and skin cancer in OTR tends to be more aggressive. Skin cancer risk varies with immunosuppressive regimen. Azathioprine and cyclosporine are most associated with skin cancer, while sirolimus has a protective effect. OTR have a higher burden of actinic keratoses. Field treatments found to be safe and effective in OTR include diclofenac, imiquimod, 5-fluorouracil, and photodynamic therapy. Studies on ingenol mebutate in OTR are ongoing. Skin cancer chemoprevention with acitretin or nicotinamide should be considered in OTR with frequent skin cancers. Mohs micrographic surgery is often indicated in OTR. Dermatologic evaluation and management of OTR should include a thorough history taking and incorporation of patient preferences. There are currently no evidence-based consensus guidelines for skin cancer screening in OTR. Expert opinion recommends at least annual screening. A screening protocol for OTR based on a patient's specific risk factors has been proposed.

Keywords

Skin cancer · Cutaneous carcinogenesis
Organ transplant recipients

Introduction

The field of organ transplantation has greatly evolved since its inception six decades ago. In the United States, since 1988, there have been 398,792 solid organ transplants, with 17,878 transplants in 2015 alone [1]. The most commonly transplanted organs are kidney, liver, heart, and lung [1]. With advances in immunosuppressive regimens, control of infectious diseases, and improved access to HLA-matched organs, organ transplant recipients (OTR) are now living longer, with increased graft survival (2b, 2b) [2, 3]. While chronic graft failure is still the leading cause of death in OTR, death from other causes, including malignancy, is increasingly common [2]. Because OTR have a high risk for skin cancer, and skin cancer in OTR tends to be more aggressive, vigilant dermatologic care is warranted. Regular dermatology visits, treatment of actinic keratoses, consideration of chemoprophylaxis, and medical and surgical treatment of skin cancers are recommended in this patient population.

Epidemiology

Organ transplant recipients (OTR) have a significantly increased risk of developing skin cancer, especially non-melanoma skin cancer (NMSC) (2b, 2b, 2b, 2b, 1b) [2, 4–7]. Chronic immunosuppressive medications in these patients impair immune surveillance mechanisms normally needed for eradication of precancerous skin lesions, and some may exert a direct carcinogenic effect [2]. Relative risk of NMSC in OTR has been reported as 108.6 in men and 92.8 for women [4], with sun-exposed areas more likely to be affected [4]. While basal cell carcinoma (BCC) is the most common skin cancer in the general population, squamous cell carcinoma (SCC) predominates in the OTR population [2, 5]. A single-center cohort study of heart and renal transplant recipients in Norway reported a 65-fold increased incidence of SCC compared to the general population, and the incidence of SCC of the lip was increased 20-fold [6]. Basal cell carcinoma incidence is increased tenfold in the OTR population [5]. Malignant melanoma incidence has been estimated as between twofold [7] and threefold in renal and heart transplant recipients (2b, 2b) [6, 8], although one large OTR cohort study did not find a significant increase in melanoma risk [4]. Other cutaneous malignancies, including Merkel cell carcinoma (MCC), seem to have an increased incidence in OTR as well (2b) [9]. While there are 65 melanomas for every one MCC in the general population, this ratio is decreased to 6:1 in OTR, suggesting that the chronically immunosuppressed posttransplant state decreases the threshold for developing MCC more than it does for melanoma [9].

Skin cancers in OTR are more aggressive, with a greater risk of local recurrence or metastasis (2b, 2b, 2b, 2b) [2, 8, 10, 11]. Risk of metastasis from SCC in OTR has been estimated at 7% [10]. Skin cancer mortality in OTR in the United States is at least 35.27 per 100,000 person-years (2b) [12], nine times higher than in the general population [12]. Organ transplant recipients at the highest risk of skin cancer, and also death from skin cancer, are white patients, men, thoracic transplant recipients, and patients at or above the age of 50 years at the time of transplant (2b, 2b, 2b, 1b) [8, 11–13]. Smoking history and increased ultraviolet (UV) radiation exposure also show a positive correlation with skin cancer in OTR (2b) [14]. Human papilloma virus (HPV) has been associated with SCC, although its biologic role in OTR cutaneous carcinogenesis is unclear (2b) [15]. Although SCC has a higher incidence than malignant melanoma in OTR, malignant melanoma in OTR is associated with higher mortality (11.48/100,000 person-years versus 4.94/100,000 person-years) [12]. Melanoma-specific mortality in OTR is about threefold higher compared to in non-OTR patients [8].

Medications and Skin Cancer Risk

Several medications have been studied and implicated with an increase in skin cancer risk in OTR. Short-term, intense immunosuppression, specifically with T-cell-depleting antibody agents, has been associated with late-stage melanoma (2b, 2b) [8, 16]. Maintenance immunosuppression with azathioprine in OTR seems to increase the risk of SCC (2b, 2b, 3b) [14, 17, 18], localized melanoma [8, 16], and MCC (2b) [19]. A proposed mechanism for this is synergism of azathioprine with ultraviolet radiation to promote carcinogenesis [8, 19]. Cyclosporine, a calcineurin inhibitor, has also been associated with NMSC in renal transplant recipients in multiple studies (2b, 2b, 1b, 2b) [6, 14, 20, 21]. These observations are supported by in vitro studies, in which cyclosporine was found to inhibit apoptosis and DNA repair in human keratinocytes exposed to UVB radiation (5, 5) [22, 23]. The observed effect of cyclosporine on skin cancer in renal transplant recipients appears to be dose-dependent, with fewer NMSC in patients on lower doses of cyclosporine [20]. Cyclosporine also increased the risk of MCC in OTR in one retrospective cohort [19]. The effects of cyclosporine

and the effects of azathioprine on MCC risk were found to be further increased in patients who had higher UV radiation exposure, as measured by lower latitude of residence [19]. A large 30-year cohort study of renal transplant recipients, however, did not find increased skin cancer risk secondary to azathioprine, cyclosporine, or tacrolimus (2b) [24]. Also, in heart transplant recipients, cyclosporine and tacrolimus were reported to have no effect on skin cancer incidence [17].

Mycophenolate mofetil was associated with a protective effect against SCC in heart transplant recipients [17] and in a cohort of solid OTR [18]. Prednisone has been associated with increased NMSC risk in non-OTR (3b, 2b, 3b) [25–27], but one prospective study found no such association (2b) [28]. In OTR, systemic corticosteroids have not been examined as an independent risk factor for skin cancer in OTR.

Voriconazole is frequently used in lung transplant recipients for antifungal prophylaxis. It carries a mortality benefit in lung transplant recipients who develop posttransplant *Aspergillus* colonization. Although one retrospective cohort study found no association between voriconazole exposure and NMSC risk in lung transplant recipients after statistically adjusting for demographic and clinical factors (2b) [29], voriconazole was independently associated with an increased risk of NMSC, and specifically SCC, in lung transplant recipients in several studies (2b, 2b, 2b, 2b) [30–33]. Risk of SCC was increased 2.6-fold with any voriconazole exposure in lung transplant recipients, and the risk was observed to be dose-dependent [31, 32]. In a majority of patients on voriconazole who develop SCC, acute phototoxicity in the first year of voriconazole exposure precedes development of actinic keratoses and progression to SCC (4) [34]. Especially in patients with signs of chronic phototoxicity [34] and in patients with risk factors for SCC, such as low Fitzpatrick skin type, high cumulative UV exposure, or older age, alternatives to voriconazole for antifungal prophylaxis should be considered [32].

Benefits of mTOR Inhibitor for Immunosuppression

Mammalian target of rapamycin (mTOR) inhibitors are newer immunosuppressants with reported antioncogenic effects; sirolimus and everolimus have been studied in OTR. Upregulated in SCC, mTOR is involved in the regulation of angiogenesis, cell proliferation, and survival (5) [35]. Mammalian target of rapamycin inhibitors increased MCC risk in OTR in one study [19]. However, overall, there has been strong evidence supporting the use of mTOR inhibitors in OTR for the secondary prevention of skin cancer. As concluded by two meta-analyses of randomized controlled trials and observational studies, in renal transplant recipients, conversion to a sirolimus-based immunosuppressive regimen, after the development of skin cancers, was associated with a reduced risk of NMSC (1a, 1a) [36, 37]. Switching from cyclosporine to sirolimus in particular had a protective effect [37]. While sirolimus was associated with decreased incidence of NMSC in clinical trials focused on kidney transplant recipients with a personal skin cancer history, findings may not be generalizable to the entire solid OTR population for primary prevention of NMSC (2b) [38]. In a large cohort study of solid OTR, risk of SCC was not associated with the use of sirolimus or with cumulative duration of sirolimus [38]. It has been suggested that in kidney transplant recipients, the observed beneficial effect of sirolimus may be due to the cessation of a calcineurin inhibitor, rather than a direct effect of sirolimus [38].

Although sirolimus was not associated with graft rejection, serious adverse events, such as pneumonitis, diarrhea, urinary tract infection, and unexplained fever, were more common with sirolimus than with calcineurin inhibitor in a phase III randomized clinical trial (1b) [39]. High rates of surgical site wound healing delay, 20–50%, have been reported in OTR on sirolimus; independent risk factors for sirolimus-related wound complications in renal transplant recipients were obesity, age greater than 40 years, acute graft rejection, thymo-

globulin for induction immunosuppression, and at least 35 mg of cumulative sirolimus by posttransplant day 4 (2b, 2b) [40, 41]. Waiting for transplant surgical sites to heal well prior to starting sirolimus is therefore advisable. While holding sirolimus prior to any major surgery is recommended based on current evidence, there is limited data to support stopping sirolimus for skin cancer surgery. In a retrospective review of dermatologic surgeries, OTR on sirolimus had a higher infection rate (19.2% vs. 5.4%) and more wound dehiscence (7.7% vs. 0%) compared with OTR not on sirolimus, but these values were not statistically significant (4) [42]. The morbidity of dehiscence and wound healing delay in dermatologic surgery is also low; therefore, the benefit-to-risk ratio favors continuing sirolimus in the setting of dermatologic surgery in most OTR.

Everolimus, an mTOR inhibitor with pharmacokinetics distinct from those of sirolimus (5) [43], has been associated with a reduced risk of NMSC mainly in kidney transplant recipients and also in heart and lung transplant recipients; these findings were based on case series and case reports (2b, 4, 5, 2b) [44–47]. Further clinical trials and prospective studies are warranted.

Management of Actinic Keratoses

Along with an increased risk of NMSC, OTR have an increased incidence of actinic keratoses (AK) (2b, 2b, 4) [15, 48, 49]. As in non-OTR, treatment of AK is indicated to avoid progression to SCC; the risk of malignant transformation in the general population has been reported as 0.60% at 1 year and 2.57% at 4 years (1b) [50]. Available management options are the same as those for the general population, although many agents are off-label in immunosuppressed patients (see Chap. 41 "*Treatment of Precancers with Topical Agents*"). In OTR, cryotherapy is frequently used for destructive treatment of individual AK. For increased numbers of AK, field treatment is warranted, especially since immunosuppressed OTR are more prone to wound healing delay and infection after undergoing destructive modalities [49]. For OTR with extensive areas of actinic dysplasia, field treatment is also helpful for increasing the signal-to-noise ratio, allowing for detection of persistent, cancerous lesions that would otherwise be difficult to distinguish in a field of uncontrolled AK. A proposed algorithm for AK management in OTR is presented in Fig. 60.1.

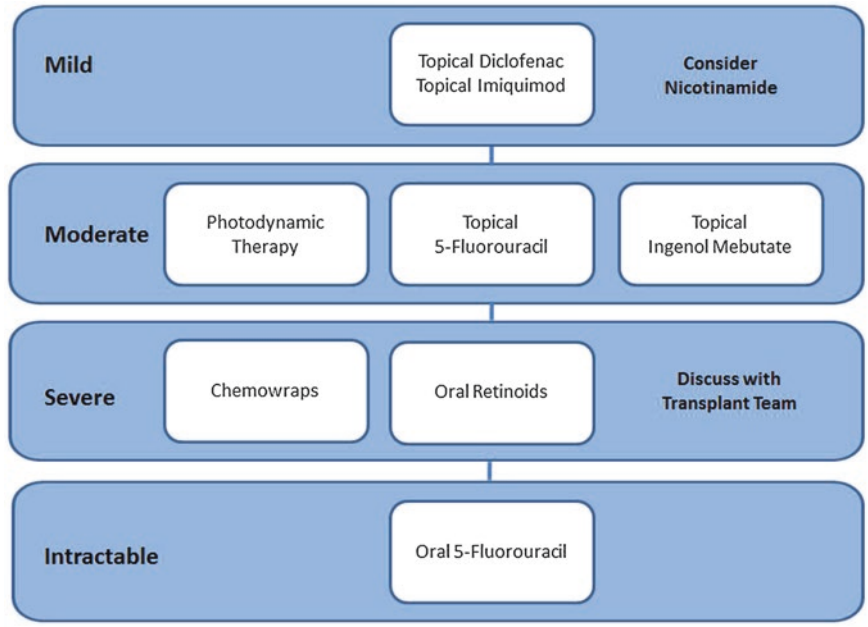

Fig. 60.1 Proposed algorithm for actinic keratosis management in organ transplant recipients

Safety and Efficacy

Topical field treatments studied specifically in OTR include diclofenac and imiquimod. Diclofenac 3% gel in 2.5% hyaluronic acid (Solaraze) is a nonsteroidal anti-inflammatory drug (NSAID), which is FDA-approved for the treatment of AK. In OTR, topical diclofenac was found to be safe, with no associated graft rejection, meaningful changes in laboratory values, or systemic side effects (4) [51]. In a placebo-controlled, randomized clinical trial of solid OTR, diclofenac 3% gel applied twice daily for 16 weeks resulted in complete clearance of AK in 41% of subjects, compared with 0% of subjects on the placebo regimen, 4 weeks after treatment (1b) [52]. Imiquimod modulates cellular immune responses through agonist activity at Toll-like receptor 7 (TLR7) (2b) [53]. It is FDA-approved for the treatment of AK, superficial BCC, and external genital warts, while use in immunosuppressed patients is currently off-label. Imiquimod is available as a 3.75% cream and as a 5% cream. Several studies in OTR have examined 16-week courses of imiquimod 5% cream, three times weekly; no graft rejections or laboratory evidence of graft dysfunction were noted (4, 2b, 2b, 2b) [49, 53–55]. Although clinical trials on imiquimod 5% cream in OTR have been small, varying efficacy in clearing AK has been confirmed in all studies [49, 53–55]. One multicenter, placebo-controlled, randomized clinical trial of 43 subjects found complete clearance of AK at 8 weeks posttreatment in 62.1% of subjects with imiquimod, versus 0% with placebo; and partial clearance of AK was achieved in nearly 80% of OTR subjects [54].

Topical 5-fluorouracil (5-FU) prevents DNA synthesis by competitively inhibiting thymidylate synthetase (2b) [56]. It is FDA-approved as a cream in 5% (Efudex), 0.5% (Carac), and 1% (Fluoroplex) formulations for the treatment of AK and is well studied in immunocompetent patients. In renal transplant recipients, 5-FU 5% cream applied to AK on the face twice daily for 3 weeks resulted in complete, 100% clearance of AK in 63% of subjects at 8 weeks, and in 0% of subjects at 12 months (4) [57]. Partial clearance rates (≥75%) were 100% at 8 weeks and 71% at 12 months [57]. Besides demonstrated efficacy, this medication was found to be safe and well tolerated in renal transplant recipients, with the only reported adverse event being mild hyperpigmentation, along with local skin reactions [57]. By anecdotal experience, for truly extensive field disease on the extremities in OTR, "chemowraps" with 20 g of 5-FU 5% cream applied topically under Unna boot occlusion and repeated weekly for 4–6 weeks are highly effective.

Ingenol mebutate gel (0.015% for the face and scalp and 0.05% for the trunk and extremities) is FDA-approved for the treatment of AK in immunocompetent patients. Ingenol mebutate is an off-label option for OTR, and a major advantage of this medication is its effectiveness (as studied in immunocompetent patients) with a short treatment course of 3 consecutive days on the face and scalp and 2 days on the trunk and extremities (1b) [58]. Two clinical trials to study the safety and efficacy of ingenol mebutate in OTR are currently in progress (ClinicalTrials.gov Identifier: NCT02866695, NCT02473848).

Photodynamic therapy (PDT), with either aminolevulinic acid (ALA) or methyl-aminolevulinic acid (MAL) as a topical photosensitizer, has been shown to be safe and effective in several trials in OTR (1b, 4, 1b, 4, 2b, 2b) [59–64]. In OTR, two treatments with MAL-PDT, spaced 1 week apart, resulted in a significant reduction in new AK lesions, with a complete response rate of 77% at 3 months in an open, intra-patient, randomized trial [59]. In a smaller trial of renal transplant recipients, two MAL-PDT treatments, with an interval of 2 weeks, resulted in a complete response rate of 72% at 3 months on the face and scalp and 40% on the dorsal hands [60]. In a randomized, blinded trial, one to two ALA-PDT treatments at a 6-month interval decreased the development of AK, but there was no observed reduction in the incidence of SCC at 2-year follow-up [61]. However, repeated ALA-PDT treatments at 4–8-week intervals for 2 years reduced the incidence of SCC in a case series of 12 OTR with high burden of disease at 1- and 2-year follow-up [62]. Methyl-aminolevulinic acid is not currently marketed in the United States.

Relative Efficacies

In a randomized, open-label, intra-patient study of eight OTR, two MAL-PDT treatments, with an interval of 1 week, was directly compared with 5-FU 5% cream, twice daily for 3 weeks, for the treatment of AK [63]. Subjects were evaluated at 1, 3, and 6 months posttreatment, and at all timepoints, MAL-PDT was found to be more efficacious than 5-FU in achieving complete resolution of AK (89% vs. 11%) and in reducing mean lesional area (100% vs. 79%); MAL-PDT was also superior in cosmetic outcome and patient preference [63]. In OTR, MAL-PDT has also been compared with routine spot treatment of AK, consisting mainly of cryotherapy, and excluding 5-FU and imiquimod [59]. Compared with routine spot treatment, MAL-PDT was more effective at preventing new AK lesions at 3 months after initial PDT treatment; at 27 months, the two treatments had similar efficacy, but MAL-PDT resulted in superior cosmetic outcome [59].

Skin Cancer Chemoprevention

Acitretin

Acitretin (Soriatane) is an oral retinoid, used off-label for the prevention of skin cancer in OTR (2b) [65]. Acitretin has been effective at decreasing SCC in OTR in several small clinical trials (2b, 2b, 2b, 2b) [65–68]; possible mechanisms of action include induction of apoptosis or growth arrest of tumor cells, immunomodulation, and promotion of normal cellular differentiation [65]. In a randomized, double-blind, placebo-controlled trial of renal transplant recipients, acitretin 30 mg oral daily for 6 months resulted in significantly fewer SCC during the treatment period; discontinuation of acitretin, however, resulted in relapse and loss of benefit within several months [66]. In an open, randomized 2-year crossover study of renal transplant recipients, significantly fewer SCC were observed during treatment with acitretin; reduction in BCC was also noted but did not reach statistical significance [67]. A retrospective study found that low-dose systemic retinoids (etretinate and acitretin) in OTR significantly reduced SCC during the first 3 years of treatment, and benefit for up to 9 years was observed [65]. However, in one trial of renal transplant recipients taking acitretin, no effect on skin cancer occurrence was noted; absence of a control group in this study may have accounted for the discrepancy [68].

Acitretin was found to be safe in OTR in all clinical trials; there was no association with graft dysfunction or major systemic side effects [65–68]. Common adverse effects reported in OTR were cheilitis, xerosis, palmoplantar desquamation, brittle nails, mild hair loss, epistaxis, hypertriglyceridemia, headache, and musculoskeletal symptoms [65–68]. Liver panel abnormalities were rare [67]; most studies did not report any effect on liver function tests [65–66, 68]. In two studies, side effects were significant in some subjects, requiring dose adjustments [68] or prompting subjects to withdraw from the trial [67]; in other studies, side effects were generally mild and well tolerated [65–66]. In a prospective cohort study of 29 OTR undergoing dermatologic surgery, 10–50 mg daily of oral acitretin was not associated with any increase in wound healing complications (1b) [69]. Doses of 0.2–0.4 mg/kg/day, with titration depending on results of lab monitoring and side effects, have been reported for chemoprevention in OTR [65]. Acitretin 30 mg oral daily was reported to be safe, well tolerated, and effective in renal transplant recipients [66]. George et al. (2002) observed the highest discontinuation rate (52.2%); of the subjects who continued with treatment, acitretin 25 mg daily or every other day was well tolerated and effective [67]. In the author's experience, starting at a low dose of 10 mg every other day and increasing to a goal of 25 mg daily or 0.4 mg/kg daily is advisable.

Nicotinamide

Oral nicotinamide, vitamin B3 in amide form, has been found to be effective for skin cancer chemoprevention in high-risk patients (1b) [70]. Nicotinamide is thought to boost levels of adenosine triphosphate (ATP) and indirectly aid in DNA repair and genomic stability (2b) [71]. Efficacy in immunocompetent, high-risk subjects, defined as having at least two NMSC

in the past 5 years, was demonstrated through a phase III, placebo-controlled, randomized trial; nicotinamide 500 mg twice daily resulted in a 23% reduction in NMSC at 12 months, which was statistically significant [70]. Actinic keratosis count was also observed to be significantly decreased at 3, 6, 9, and 12 months of treatment [70]. There was no benefit after discontinuation of the drug [70]. In OTR, only one small phase II clinical trial of nicotinamide 500 mg twice daily has been done; safety profile in OTR was excellent, and there was a 35% reduction in NMSC, although this value was not statistically significant (2b) [72]. Further phase III clinical trials are warranted in OTR. Meanwhile, considering the safety and observed efficacy, it is reasonable to prescribe nicotinamide in higher-risk OTR for modest skin cancer chemoprevention.

Skin Cancer Treatment

Skin cancer treatment options for OTR are the same as those for immunocompetent patients, following NCCN guidelines (for discussion of NCCN guidelines, please see Chaps. 4, 42–46 in this text). Surgical treatment options include electrodessication and curettage, wide local excision, and Mohs micrographic surgery. The Mohs Appropriate Use Criteria evaluates the evidence for benefit from Mohs surgery over other treatment modalities; Mohs is often recommended as appropriate for immunosuppressed patients [73], and the use of this guideline is recommended.

Managing Organ Transplant Recipients in Dermatology Clinic

When evaluating an OTR, a complete history should be taken, with questions that elucidate the level of skin cancer risk. These include the organ transplanted, date of transplantation, history of rejection episodes or complications, and, importantly, past and current immunosuppressive medications. A full medication list, including infection prophylaxis and any photosensitizing agents, should be reviewed. Personal and family history of skin cancer, previous dermatologic procedures and surgeries, and history of field treatments for AK, along with Fitzpatrick skin type, sun exposure history, and sun protection practices should be documented. A full-body skin exam should be performed, and patients should be counseled on their increased risk of skin cancer and on sun protection techniques. Depending on the severity of AK and frequency of NMSC, chemoprevention with nicotinamide or acitretin may be considered. Mohs preoperative evaluations in OTR are generally the same as those for immunocompetent patients. There is no evidence for routine wound infection prophylaxis with antibiotics in OTR undergoing Mohs.

Patient Preference

Dermatologic care of OTR should accommodate patient preference whenever possible. Organ transplant recipients often face treatment fatigue from numerous clinic visits, hospitalizations, and a long list of medications to manage. Discussing patient compliance, efficacy, and satisfaction with medications such as topical therapies can help guide treatment decisions. Photodynamic therapy and ingenol mebutate for field treatment of AK, for example, require much less patient compliance than 5-FU and imiquimod, which involve longer treatment courses. Insurance approval and cost may also play a role in treatment selection. Starting an agent such as acitretin for skin cancer chemoprevention requires patient agreement with lab monitoring and tolerance of side effects. As in immunocompetent patients, skin cancer treatment decisions should factor in patient preference after discussion of risks, benefits, and alternatives for each option; patient preference plays a greater role in skin cancer cases for which the appropriateness of Mohs is "uncertain" based on Mohs Appropriate Use Criteria.

Skin Cancer Screening

In the general population, the benefit of skin cancer screening has been debated. Skin cancer screening was implemented on a large scale in

Germany as part of the SCREEN (Skin Cancer Research to Provide Evidence for Effectiveness of Screening in Northern Germany) project; the study found that the incidence of invasive melanoma increased, and melanoma mortality decreased, with screening (1b) [74]. As a result of these findings, Germany started a national mandatory skin cancer early detection initiative [74]. However, major biases and limitations of the SCREEN project have been discussed (5) [75], and the quality of evidence reporting benefit from skin cancer screening has been deemed low (3a) [76]. The United States Preventive Services Task Force (USPSTF), after conducting a systematic evidence review, concluded that the value of skin cancer screening for reducing mortality was unclear (3a) [77]. The benefits of screening, which are reduced morbidity and mortality from skin cancer, should outweigh the risks, which include unnecessary biopsies, cost, and patient anxiety. The USPSTF and other groups have therefore called for further research to better define screening protocols, particularly for high-risk populations who are most likely to benefit from skin cancer screening, such as OTR [75–77].

There are currently no formal, evidence-based consensus guidelines for skin cancer screening in OTR. Expert opinion from the International Transplant Skin Cancer Collaborative (ITSCC) has guided dermatologists thus far, with a general recommendation for annual skin cancer screening in OTR and screening with increased frequency for OTR with a history of AK or skin cancer (5) [78]. The Transplant Skin Cancer Network (TSCN) has recently created the "Skin Cancer Risk Evaluation aftEr traNsplant" (SCREEN) score, an evidence-based scoring algorithm for skin cancer incidence after transplantation. The prediction model is based on posttransplant incidence data for SCC, melanoma, and MCC. Skin cancer incidences were collected for a large retrospective cohort of 10,649 patients, from 26 transplant centers in the United States, with up to 10 years of follow-up. Statistically significant risk factors for skin cancer were assigned point values based on relative hazard; identified risk factors were white race (5 points), pretransplant skin cancer (3 points), age ≥ 50 years at the time of transplant (2 points), male sex (1 point), and transplanted heart or lung (1 point) (2b) [79]. A four-tier risk prediction scoring system was proposed, with categories of Low risk (0–3 points), Medium risk (4–6 points), High risk (7–9 points), and Urgent risk (10–12 points). Skin cancer incidence in the Urgent risk group was 65.6%, while that in the Low risk

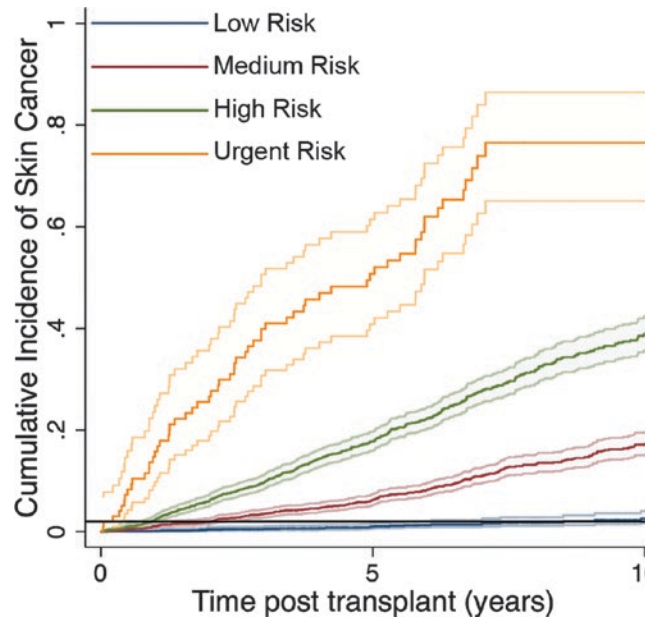

Fig. 60.2 Cumulative incidence function curves for the "Skin Cancer Risk Evaluation aftEr traNsplant" (SCREEN) Categories.

Table 60.1 Posttransplantation referral guidelines based on the "Skin Cancer Risk Evaluation aftEr traNsplant" (SCREEN) category

SCREEN risk category	Initial screening guidelines for referral to dermatology[a]
Low Risk	Problem/lesion focused (patient or provider initiated) at any time in the posttransplant period No routine posttransplant skin cancer screening recommended
Medium Risk	Problem/lesion focused (patient or provider initiated) at any time in the posttransplant period First posttransplant skin cancer screening by 5 years
High Risk	Problem/lesion focused (patient or provider initiated) at any time in the posttransplant period First posttransplant skin cancer screening by 2 years
Urgent Risk	Consider pretransplant skin cancer screening Problem/lesion focused (patient or provider initiated) at any time in the posttransplant period First posttransplant skin cancer screening by 6 months

[a]Referral to a specialized transplant dermatologist where available

group was 1.7% (Fig. 60.2). TSCN has proposed skin cancer screening guidelines based on expert opinion of these data. In Low risk patients, routine skin cancer screening is not recommended due to minimal skin cancer risk, but referral for evaluation of concerning lesions is recommended. Routine skin cancer screening, preferably by a transplant dermatologist, is recommended for Medium, High, and Urgent patients every 5 years, 2 years, and 6 months, respectively (Table 60.1) [79]. This decision support tool has been endorsed by ITSCC for use in the United States.

Hypothetical Case

A 65-year-old white male with a history of double lung transplant for idiopathic pulmonary fibrosis 3 years ago presents to dermatology clinic as a new patient; he was previously followed by an out-of-state dermatologist. A complete history reveals the following: He is Fitzpatrick skin type I. He grew up working on a farm and experienced multiple blistering sunburns as a child. Since his transplant, he has been vigilant about sun protection, wearing SPF 50 sunscreen and a broad-brimmed hat whenever outdoors; he also avoids the sun as much as possible. His skin cancer history consists of a BCC on the right nasal ala 5 years ago, and squamous cell carcinoma in situ (SCCIS) on his right forehead 2 years ago, status post Mohs and complex layered linear closure. One year ago, he had a left medial canthus SCC and left nasal sidewall SCC, both treated with Mohs and repaired by oculoplastics, and a right auricular helix SCC treated with Mohs and complex closure. He has no family history of skin cancer. He has been doing well with his lung transplant and has not had evidence of rejection. He has been maintained on an immunosuppressive regimen of tacrolimus 1 mg BID, prednisone 7.5 mg PO daily, and mycophenolate mofetil 500 mg PO BID. He has no history of field treatment for AK. He reports no recent skin changes or concerns. On exam, he has one 3 × 7 mm pink pearly papule on his chest concerning for malignancy; he also has 15 erythematous scaly papules on his face, consistent with AK. Otherwise, full-body skin exam is normal.

This patient is in a high-risk group for posttransplant skin cancer based on his age, sex, race, pigmentation, sun exposure, lung transplant, and history of skin cancer. He was extensively counseled on sun protection and on his risk of skin cancer. He was managed with the following: (1) cryotherapy of 15 AK lesions on his face, with PDT of the face and ears scheduled for within 2 months, (2) shave biopsy of the pink pearly papule on his chest, and (3) classification into SCREEN Urgent risk category based on his score of 12 points [79]. Accordingly, it was decided that he should be seen for routine skin cancer checks every 6 months or earlier as needed for new or concerning skin lesions.

Frequency of skin cancer was discussed with the patient's transplant team, who agreed to transition toward use of sirolimus for immunosuppression. The transplant team held mycophenolate mofetil, with plans to taper tacrolimus and

start sirolimus. From shave biopsy, pathology returned as a nodular BCC. Mohs Appropriate Use Criteria score was 5, defined as "Uncertain" evidence for benefit from Mohs micrographic surgery over other treatments. Electrodessication and curettage (ED&C) of the BCC was recommended and performed.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
OTR have an increased risk of skin cancer. They develop more aggressive skin cancers, with increased skin cancer mortality	A
Risk factors associated with skin cancer mortality in OTR include white race, male sex, transplanted heart or lung, and patients at or above 50 years of age	B
In OTR, azathioprine, cyclosporine, and voriconazole are associated with increased skin cancer risk	B
Sirolimus has been shown to reduce skin cancer risk in kidney transplant recipients with a personal history of skin cancer	A
Sirolimus has not been shown to be effective for primary prevention of skin cancer in OTR	C
Diclofenac is safe and effective for the treatment of AK in OTR	B
Imiquimod is safe and effective for the treatment of AK in OTR	A
5-Fluorouracil is safe and effective for the treatment of AK in OTR	B
Photodynamic therapy is safe and effective for the treatment of AK in OTR	A
Nicotinamide 500 mg BID is safe and appears to be modestly effective for skin cancer chemoprevention in OTR	C
Acitretin is safe and effective for non-melanoma skin cancer chemoprevention in OTR	A
For OTR, annual skin cancer screening, with increased screening frequency in patients with a history of AK or skin cancer, has been recommended based on expert opinion	D
A new evidence-based skin cancer screening protocol for OTR, with screening frequency directly based on a patient's risk factors for skin cancer, has been proposed	B

Self-Assessment Questions

1. Which of the following is *not* a reported risk factor for skin cancer incidence in OTR? (Choose all that apply.)
   (a) White race
   (b) Transplanted heart or lung
   (c) Age 50 years or older at the time of transplant
   (d) Female sex
   (e) Immunosuppression with azathioprine

2. Evidence for reduction in skin cancer risk with conversion to sirolimus-based immunosuppression is strongest in which of the following patient populations?
   (a) Renal transplant recipient with personal history of skin cancer
   (b) Renal transplant recipient without personal history of skin cancer
   (c) Heart transplant recipient with personal history of skin cancer
   (d) Heart transplant recipient without personal history of skin cancer
   (e) Bone marrow transplant recipient without personal history of skin cancer

3. Which of the following have been shown to be safe and effective for the treatment of actinic keratoses in OTR? (Choose all that apply.)
   (a) Diclofenac
   (b) Ingenol mebutate
   (c) Imiquimod
   (d) 5-Fluorouracil
   (e) Photodynamic therapy

4. Which of the following is most commonly reported as a dose-limiting side effect of acitretin in OTR?
   (a) Acne fulminans
   (b) Periorbital edema
   (c) Mucocutaneous side effects (cheilitis, dry lips, palmoplantar desquamation, etc.)
   (d) Lymphopenia
   (e) Elevation in liver function tests

5. Which of the following is true regarding nicotinamide?
   (a) Grade A evidence supports the use of nicotinamide for skin cancer chemoprevention in OTR.
   (b) Nicotinamide is not safe in OTR.
   (c) Nicotinamide 500 mg PO BID is well tolerated in immunocompetent patients but not in immunocompromised patients.
   (d) Nicotinamide should be used for primary prevention of skin cancer in all OTR.
   (e) Nicotinamide has been shown to be effective for skin cancer chemoprevention in patients with frequent NMSC.

Correct Answers

1. d: White race, thoracic organ transplant, age 50 years or older at the time of transplant, and male sex are risk factors for skin cancer incidence in OTR. Azathioprine has been associated with increased risk of skin cancer in OTR in multiple clinical studies. See *Epidemiology, Medications, and Skin Cancer Risk* and *Skin Cancer Screening*.
2. a: Two meta-analyses concluded that, in renal transplant recipients, conversion to a sirolimus-based immunosuppressive regimen, after the development of skin cancers, was associated with a reduced risk of NMSC. Findings may not be generalizable to the entire solid OTR population for primary prevention of NMSC. In one large cohort study of solid OTR, which included nonrenal transplant patients, the risk of SCC was not associated with the use of sirolimus or with cumulative duration of sirolimus. See *Medications and Skin Cancer Risk – Benefits of mTOR Inhibitor for Immunosuppression*.
3. a, c, d, e: (At the time of publication, phase I study of ingenol mebutate in OTR is in progress). Diclofenac, imiquimod, 5-fluorouracil, and photodynamic therapy have all been shown to be safe and effective for the management of actinic keratoses in OTR. Ingenol mebutate is FDA-approved for the treatment of actinic keratoses in immunocompetent patients. At the time of publication, phase I study of ingenol mebutate in OTR is in progress. See *Management of Actinic Keratoses – Safety and Efficacy*.
4. c: Mucocutaneous side effects of acitretin, including palmoplantar desquamation, xerosis, and cheilitis, are very common and may be dose-limiting. Liver panel abnormalities occur rarely with acitretin, and monitoring of liver function tests is therefore recommended. Acne fulminans, periorbital edema, and lymphopenia are not commonly reported adverse effects of acitretin. See *Skin Cancer Chemoprevention – Acitretin*.
5. e: Based on Grade C evidence, nicotinamide 500 mg PO BID is safe, well tolerated, and modestly effective for skin cancer chemoprevention in OTR. Nicotinamide has been shown to be effective for secondary chemoprevention in patients with frequent NMSC, but there are no studies to support its use for primary prevention of skin cancers. See *Skin Cancer Chemoprevention – Nicotinamide*.

Leg Veins

61

Sarah Hahn Hsu, Laura M. Schilling,
Margaret A. Weiss, and Robert A. Weiss

Abstract

There are multiple treatment modalities to address unwanted and/or symptomatic leg veins. When selecting treatment, variations in vessel size, depth, and type must be taken into consideration. Treatment options include sclerotherapy, endovenous ablation with laser or radiofrequency, ambulatory phlebectomy, transcutaneous lasers and intense pulsed light systems, as well as the more recently developed cyanoacrylate closure and mechanochemical ablation. This chapter reviews the effectiveness, safety, and appropriate selection of the above-listed procedures for treating leg veins.

Keywords

Sclerotherapy · Endovenous ablation
Phlebectomy · Venous insufficiency
Varicose veins · Reticular veins
Telangiectasias

Epidemiology

Leg veins can largely be divided into deep and superficial systems defined by their relationship to the muscular fascia. Deep veins lie beneath the muscular fascia, whereas superficial veins are located above this deep fascia. Perforating veins penetrate the fascia and connect the superficial and deep venous systems.

To ensure blood return from the lower extremities to the heart and lungs, a system of muscular pumps and valves allows blood to flow from superficial to deep and from distal to proximal. Any dysfunction in this system, such as valvular incompetence, muscular pump failure, or chronic venous obstruction, may result in impaired venous outflow and reflux.

The most common form of venous disease is venous insufficiency from valve incompetence. Deep venous insufficiency typically occurs when valves are damaged by deep vein thrombosis. Superficial venous insufficiency occurs when a high-pressure leakage develops between the deep and superficial systems or within the superficial system, followed by sequential failure of the venous valves within the superficial veins. Over time, incompetent superficial veins can present as dilated and tortuous varicose veins, blue reticular veins, venulectasias, and telangiectasias. Varicose veins are a common problem, with incidence reported to range from 20% to 64% [1–4]. Telangiectasias are also extremely

common and have been reported to affect up to 80% of the population [5].

Although specific genetic risk factors for varicosities are not known, heredity does seem to play an important role. One study demonstrated that the risk of developing varicosities was 20% with two unaffected parents, 25% for males and 62% for females with one affected parent, and 90% with two affected parents [6]. There is also evidence that geographic region and race may play a role. In particular, the prevalence of venous disease has been found to be higher in westernized and industrialized countries [7].

Other risk factors for the development of venous disease include gender and age, with greater incidence in women and with advancing age. Highlighting this difference, the Tecumseh community health study from Tecumseh, Michigan, found that varicosities were present in 72% of women aged 60–69 years but only 1% of men aged 20–29 years [8]. An exception to this trend is the blue reticular varicosities involving the lateral lower extremities. While they are more common in females, these tend to occur earlier in life and do not increase in incidence with advancing age [9].

Regarding the greater incidence of venous disease in women, pregnancy has been shown to be an important risk factor. A significantly higher age-adjusted prevalence of varicose veins, reticular veins, and telangiectasias has been demonstrated in parous women compared with nulliparous women [5]. Further, a positive correlation has been shown between the prevalence of varicose veins and the number of pregnancies [10]. Development of varicose veins has additionally been attributed to environmental factors. Studies repeatedly showing that certain occupations, especially those that require prolonged standing, are associated with a greater incidence of varicosities [11, 12].

With progressive venous insufficiency, complications include stasis dermatitis, edema, and ulceration. Further, many patients report associated symptoms including pain, soreness, burning, aching, throbbing, cramping, muscle fatigue, and restless legs. In one study, up to 53% of patients with leg telangiectasias attributed associated symptoms [13]. Therefore, not only cosmetically bothersome, venous disease of the lower extremities can be extremely debilitating.

Treatment Overview

Variations in vessel type, size, flow, and depth preclude the possibility of a single effective treatment modality. Vessel types include varicosities, reticular veins, venulectasias, and telangiectasias [14]. This distinction is generally made based on size with varicose veins being greater than 4 mm in diameter, reticular veins ranging from 2 to 4 mm, venulectasias ranging from 1 to 2 mm, and telangiectasias being less than 1 mm.

Among the treatments for leg veins, the longest-standing technique is phlebectomy. Its use dates back to ancient times, when it was first described by Aulus Cornelius Celsus (25 BC–45 AD) [14, 15]. In 1956, Dr. Robert Muller, a dermatology-trained phlebologist from Switzerland reinvented and refined the technique that we now know as ambulatory phlebectomy [15]. Ambulatory phlebectomy involves the removal of varicose veins through small incisions using hooks and forceps. It can be performed under local anesthesia in an office-based setting. Ambulatory phlebectomy is considered a safe and immediately effective procedure for the treatment of varicose veins, although its need has been greatly reduced with the discovery of foam sclerotherapy [15].

Sclerotherapy remains the treatment of choice for most leg veins less than 4 mm in diameter [14, 15]. It involves the injection of dilated veins with liquid or foam agents to damage the endothelial cells and cause fibrosis of the target vessel. Sclerosing agents can be broadly divided into three categories: detergents such as polidocanol and sodium tetradecyl sulfate (STS), osmotic or hypertonic solutions such as hypertonic saline, and chemical irritants including glycerin [14]. Concentrations of these agents may be adjusted according to the size of the vein being treated.

Transcutaneous laser therapy and intense pulsed light (IPL) systems may be valuable alternatives in specific situations where sclerotherapy

is not preferred. These devices cause endothelial injury by heating hemoglobin and ultimately obliterating the vessel lumen [14, 15]. In general, however, treatment of leg veins with lasers and IPL devices are less predictable as compared to sclerotherapy. Several reasons may contribute to the variable response. These include the variability in depth and location of the leg veins, as well as differences in vessel wall thickness and diameter. Further, blood in leg veins tends to have a reduced oxygenation state that leads to a violaceous instead of red color. Therefore, each telangiectasia may have a slightly different optimal wavelength of absorption based on its color, in addition to its relative size and depth [15].

For treatment of reflux present at the saphenous veins, endovenous occlusion has become a widely utilized, less invasive alternative to surgical ligation and stripping [14, 15]. This procedure is performed percutaneously with ultrasound guidance. The two most frequently used endovenous ablation techniques utilize either laser or radiofrequency. Endovenous radiofrequency ablation was FDA approved in 1999 and was quickly followed by the clearance of endovenous laser ablation in 2000 [15]. In addition to the use of radiofrequency and lasers, other endovenous procedures have been developed in recent years. These include steam vein sclerosis, mechanochemical ablation, and injection of cyanoacrylate glue [16].

Sclerotherapy

Studies repeatedly show that sclerotherapy is more effective than placebo injections for the treatment of telangiectasias, reticular veins, and varicose veins [17–20]. In a clinical trial comparing polidocanol 0.5–1%, STS 1%, and placebo for treatment of telangiectasias and reticular veins, significantly more patients were satisfied with polidocanol (88%) than with STS (63%) or placebo (11%) [1b] [20]. Another study compared polidocanol 0.25%, STS 0.5%, heparsal, and placebo for treating telangiectasias [2b] [21]. The lower extremities of each patient were divided into four quadrants, and each area was treated with a different agent. Although all the agents except placebo were effective, polidocanol was found to have the fewest adverse reactions and provided the greatest patient comfort. When patients were given the choice of a sclerosant to treat the placebo-injected area, polidocanol was favored by all 20 patients.

In two separate studies, polidocanol was shown to be significantly more effective than placebo injections in obliterating non-saphenous varicosities, with success rates varying between 76.8% and 88.6% [2b] [17, 19]. It should be emphasized that only those with competent saphenous veins were included in these studies. On the other hand, long-term efficacy with sclerotherapy is unlikely if underlying reflux is present. In a separate study, varicose vein recurrence was found to be over 90% at 6 years post-sclerotherapy in those with underlying saphenous vein incompetence [2b] [22].

A Cochrane review was conducted on sclerotherapy for telangiectasias [2a] [23], and a separate Cochrane review was performed on sclerotherapy for varicose veins [2a] [24]. In both reviews, there was no evidence suggesting superior efficacy of any one sclerosant over another. Sclerosing agents for treating telangiectasias included polidocanol, STS, chromated glycerin, hypertonic saline, and hypertonic dextrose. For treating varicose veins, polidocanol, STS, ethanolamine, and hypertonic saline were included. However, there was a discrepancy among these sclerosants regarding the risk of adverse events. For example, when treating telangiectasias, STS 1% was more likely to cause adverse reactions than polidocanol 0.5%. In another trial comparing polidocanol and hypertonic saline for treating telangiectasias and reticular veins, there were no significant differences in overall improvement between the two agents [2b] [25]. However, hypertonic saline caused 2.35 times as much pain during the injections, and there was a higher risk of tissue necrosis.

Also important in determining the risk of adverse events is the concentrations of the sclerosing agents. Polidocanol 0.25%, 0.50%, 0.75%, and 1% were compared with regard to clinical effectiveness and safety in treating telangiectasias

[2b] [26]. While there was no evidence of increased efficacy at any particular dose of polidocanol, hyperpigmentation was found to be more likely at a concentration of 1% when compared with lower concentrations. In the continued search for the "ideal" sclerosant concentrations, a recent study reviewed the effects of varying concentrations of STS and polidocanol. Based on both histologic evaluation and clinical correlation, STS 0.15% and polidocanol 0.31% were found to be the best concentrations for the treatment of leg telangiectasias from 0.8 mm to 1.0 mm [2b] [27]. However, no exact standard exists at this point. As for larger varicosities, polidocanol 1% and 3% foam were compared for treating great saphenous vein incompetence [1b] [28]. It was demonstrated that both concentrations had equivalent efficacy in treating veins less than 8 mm in diameter. At 2-year follow-up, reflux was absent in 69% of the 3% group and 68% of the 1% group. With the idea that the optimal sclerosant concentration depends on vessel size, most studies examining the effectiveness of sclerotherapy on variably sized varicosities tend to adjust the concentration of the sclerosant according to vessel diameter [19, 29].

Multiple studies have demonstrated that foam sclerotherapy, with ultrasound guidance if the varicosity is not readily visible from the skin surface, can be more effective than liquid sclerotherapy when treating larger vessels [18, 30–33]. In a crossover, randomized, controlled trial comparing foam and liquid sclerotherapy for treating varicose veins, total occlusion rates were significantly higher with foam sclerotherapy (92%) compared to liquid sclerotherapy (76%) [2b] [32]. These results are consistent with a subsequent study comparing foam and liquid sclerotherapy in combination with endovenous laser ablation [2b] [34]. There was no difference in terms of closure of the saphenous veins with endovenous laser ablation, but successful sclerosis of the varicose tributaries was significantly higher with foam sclerotherapy (92.7%) than liquid sclerotherapy (71.8%).

The greater effectiveness of foam is attributed to the fact that foam completely fills and displaces the blood in the vein, so that very little of the solution is diluted by blood. Therefore, the full strength of the sclerosant is in contact with the vein wall, maximizing endothelial injury. At the same concentration, foam is nearly four times as strong as its liquid counterpart [33, 35]. Ultimately, foaming allows one to use a lower concentration and less volume of sclerosant, which also translates to decreased side effects. For smaller vessels, however, foam runs the risk of rupturing the thin walls with risk of increased pigmentation and matting. Therefore, liquid sclerotherapy is preferred for these vessels. As a general rule, foam should be reserved for vessels that are larger than 1 mm, although there is no strict consensus on amount or concentration of sclerosant [5] [36].

Lasers and IPL Systems

While sclerotherapy remains the gold standard for treating most leg veins, transcutaneous lasers and intense pulsed light (IPL) devices may be indicated in select situations. Lasers for treating leg veins include the 532 nm potassium titanyl phosphate (KTP) laser, 585–595 nm pulsed dye laser, 755 nm alexandrite laser, various 800–980 nm diode lasers, and 1064 nm neodymium-doped yttrium aluminum garnet (Nd:YAG) laser. The evidence for using each device will be briefly discussed below.

The 532 nm KTP laser has high absorption by both hemoglobin and melanin and has a penetration depth of about 0.75 mm. Studies show that the KTP laser is mainly effective in treating leg veins smaller than 1 mm in diameter [37–41]. Clearing of over 50% of leg veins was noted after a single treatment session [38, 39] and over 75% of veins after two treatments [37]. Only a few studies investigated the efficacy of the KTP laser for the treatment of larger veins. One study reported good results for treating leg veins that are 1–2 mm in diameter [2b] [42]. After two treatment sessions, 67% of patients had a greater than 50% clearance. Other studies found no improvement after three sessions [43, 44].

Absorption by hemoglobin is also strong with the 585–595 nm pulsed dye laser although lower

than at 532 nm. However, there is deeper penetration at this longer wavelength with depth of vascular damage for a short-pulse duration estimated to be 1.5 mm. Like the KTP laser, studies show that the pulsed dye laser is more effective in treating veins smaller than 1 mm in diameter [45–49]. In a study demonstrating that efficacy decreases with increasing vessel size, vessels <0.2 mm showed the greatest response with 100% having complete clearance after two treatments [2b] [50]. For vessels 0.2–1 mm, 13% had complete clearance, while 78.3% had greater than 75% improvement. Vessels 1.1–2 mm were the least likely to respond with none showing complete clearance and only 22.2% showing greater than 75% improvement. In a few comparative studies, the pulsed dye laser has been demonstrated to be slightly superior to the KTP laser in the removal of leg veins [40, 41].

The 755 nm alexandrite laser has a high relative absorption by hemoglobin, although absolute absorption by hemoglobin is significantly lower than with the KTP and pulsed dye lasers. Its main advantage over the KTP and pulsed dye lasers is its penetration depth, which can theoretically reach up to 2–3 mm. Therefore, this laser may be useful for deeper and more resistant vessels. The alexandrite laser is considered to be the most effective for leg veins 0.4–3 mm in diameter [2b] [51].

Multiple diode lasers are available and include wavelengths of 800, 810, 900, 940, and 980 nm. Similar to the alexandrite laser, the various diode lasers are generally used for the treatment of larger vessels that are located deeper in the dermis. In one study, veins with a diameter of 3–4 mm showed the most response [2b] [52]. Another study examined the use of the diode laser for treating telangiectasias and venulectasias and found that only 13.3% of telangiectasias less than 0.4 mm had greater than 75% clearance [2b] [53]. On the other hand, 88.2% of vessels between 0.8 and 1.44 mm obtained more than 75% clearance. In a comparative study between 1064 nm Nd:YAG, alexandrite, and 810 nm diode lasers, the diode laser produced less predictable results and less clearance of leg veins up to 3 mm in diameter [2b] [54].

Among all vascular lasers, the 1064 nm Nd:YAG laser has been the most extensively studied for the treatment of leg veins. There is weak hemoglobin, melanin, and water absorption at this wavelength. However, it has the deepest penetration with a depth of more than 4 mm at its peak, making this laser a suitable treatment modality for more deeply located veins. The first report using the Nd:YAG laser to treat leg veins included veins ranging in size from 0.5 to 3 mm [2b] [55]. At 3 months follow-up, 75% improvement was noted at the treatment sites. In a subsequent study, 64% of patients achieved 75% or greater clearing of 0.2–4 mm diameter vessels after a maximum of three treatment sessions [2b] [56]. Overall, the Nd:YAG laser is considered to be better for veins larger than 1 mm in diameter, although good results have also been reported for smaller veins [43, 57, 58]. In a study including 21 lower extremity sites, 58% of 0.25–1 mm vessels, 83% of 1.1–2 mm vessels, and 100% of 2.1–4 mm vessels showed significant clearing after two treatments [2b] [58]. Recurrence after treatment with the Nd:YAG laser has been reported to be infrequent with less than 10% of leg veins recurring after 1 year [56, 59].

IPL systems emit a broad-spectrum light, from 500 to 1200 nm, although cutoff filters can be used to exclude certain wavelengths. Clinical evidence for IPL in the treatment of leg veins is scarce, but particularly, small vessels are believed to respond well to IPL treatment. In a multicenter trial of 159 patients, clearance rates of greater than 75% were found in 80% of vessels smaller than 0.4 mm, 87% of vessels 0.4–1 mm, and 61% of vessels 1–3 mm in diameter [2b] [60].

Endovenous Ablation

The two most commonly used endovenous ablation techniques are endovenous laser ablation and radiofrequency ablation. These will be the focus of this section.

Successful occlusion of the great saphenous vein following endovenous laser ablation has been reported to vary between 77% [61] and 99% [62] at 1 year. A recent meta-analysis of studies

with a 4- to 5-year follow-up for endovenous thermal ablation of the great saphenous vein found success rates of 84.8% with endovenous laser ablation and 88.7% with radiofrequency ablation [2a] [63]. Endovenous thermal ablation of the small saphenous vein has also demonstrated excellent results with success rates of 96.2–98.5% [64–66]. In a study that followed patients to 2 years after endovenous laser ablation of the small saphenous vein, 81.2% of patients had continued occlusion [2b] [65].

To reduce potential side effects, endovenous lasers with higher wavelengths have been introduced. Higher wavelength lasers (1320, 1470, 1500 nm) predominantly absorb water, as opposed to the lower wavelength lasers (810, 940, 980, 1064 nm) that more specifically absorb hemoglobin. These higher wavelength lasers have the theoretical advantage of contracting the vein with less heat generation and fewer risks than with the hemoglobin-absorbing wavelengths. A retrospective review was conducted on endovenous thermal ablation with an 810 nm diode, a 1320 nm laser, and a radiofrequency device to treat great and small saphenous vein incompetence [2b] [67]. Successful ablation rates were reported to be 80.8% with 810 nm, 93.7% with 1320 nm, and 78.2% with radiofrequency at 1-year follow-up. At 5-year follow-up, successful ablation rates were 65.7% with 810 nm, 84.7% with 1320 nm, and 61.7% with radiofrequency. Other studies show equal occlusion rates with the higher wavelength lasers when compared to lower wavelength lasers, although less postoperative pain has been reported with the higher wavelength lasers [68–71].

New endovenous laser fiber tips have also been developed to increase efficacy and reduce potential adverse events. The standard bare fiber creates unequal energy delivery at the vein wall resulting in local vein wall perforations and surrounding tissue destruction. New fibers have been designed to increase the heated surface area, resulting in the need for lower energy density [72, 73]. A randomized controlled trial reported fewer side effects and an equal occlusion rate using a newer tulip fiber compared with a bare fiber [1b] [73].

Overall, it appears that endovenous laser ablation and radiofrequency ablation have similar occlusion rates. However, a definitive conclusion cannot be drawn given the great variability in the devices and limited studies that compare across each of these variations. In addition to differences in laser fiber tips (bare fiber versus the newer fibers) and wavelengths, there are also variations in radiofrequency catheters (older ClosurePlus versus newer ClosureFast). In a short-term outcome analysis comparing the two generations of radiofrequency catheters, ClosureFast was found to be superior to ClosurePlus in terms of great saphenous vein obliteration (98% with ClosureFast versus 88% with ClosurePlus) [2b] [74]. To date, there are no trials comparing the use of the ClosureFast catheter with higher wavelength lasers and with the newer fiber tip design.

Ambulatory Phlebectomy

Phlebectomy may be performed as an adjunctive treatment to surgical stripping or endovenous ablation of the main refluxing truncal vein [75–77]. It may also be performed as an exclusive procedure for the treatment of branch varicosities [78, 79]. Most types of primary and secondary varicose veins may be removed by ambulatory phlebectomy, except when junctional saphenous incompetence is present. When any important sources of reflux are present, such as at the saphenofemoral junction or saphenopopliteal junction, these need to be corrected before any effort is made to address the end-branch disease with phlebectomy. Vessels most readily treated with phlebectomy include accessory saphenous veins of the thigh, reticular veins in the popliteal fold or on the lateral thigh or leg, veins of the ankle, and the dorsal venous network of the foot. Studies have shown that ambulatory phlebectomy is a safe and immediately effective procedure [78]. Development of new varicosities or recurrence following ambulatory phlebectomy has been found to range from 2% to 11% at a minimum of 6 months follow-up [78, 80, 81].

Compression After Venous Intervention

Some providers use compression stockings alone as initial treatment in the early stages of varicose veins without ulceration. Of note, while most studies report a subjective improvement of symptoms with compression, a 2013 Cochrane review reveals insufficient evidence to determine whether compression, as the sole intervention, is effective in the treatment of early varicosities [1a-] [82]. However, the recommendation of compression after other interventions for leg veins remains common.

Compression therapy is commonly used after endovenous thermal ablation. A randomized controlled trial demonstrated that the use of 35 mm Hg compression stockings for 7 days after endovenous laser ablation of the great saphenous vein significantly reduced pain and improved physical function when compared with use for 2 days [1b] [83]. Another randomized trial compared the use of thigh-high 23–32 mm Hg compression therapy for at least 2 weeks with no compression therapy following endovenous laser ablation of the great saphenous vein [1b] [84]. It was concluded that compression therapy reduced the severity of pain and edema during the first week post-procedure. However, there were no significant differences in the quality of life or in the mean time to return to work between the two groups.

Compression therapy is also routinely used after sclerotherapy. Studies show that post-sclerotherapy compression improves the clinical appearance of vessels and reduces post-sclerotherapy pigmentation and bruising [85, 86]. In one study, 3 weeks of continuous compression led to best results, although even 3 days of compression resulted in greater improvement than no compression [2b] [87]. The use of graduated compression stockings was shown to reduce the risk of post-sclerotherapy pigmentation, telangiectatic matting, and cutaneous necrosis, even when treating vessels less than 1 mm in diameter. However, when low compression profile (15–20 mm Hg) stockings were used after foam sclerotherapy of larger veins, there was no effect on efficacy, side effects, or satisfaction scores when compared with a control group without compression [1b] [88]. Most clinicians believe Class I (20–30 mm Hg) compression is necessary for treating telangiectasias, whereas Class II (30–40 mm Hg) or Class III (40–50 mm Hg) compression is indicated for larger varicosities [5] [36].

Most recently, an evidence-based review of the use of medical compression stockings in venous and lymphatic disorders was performed. A recommendation of early compression after GSV intervention, such as using thigh-length 20–40 mm Hg stockings for 1 week, was made to reduce post-procedure side effects (Grade 1B) [89]. No clear benefits were appreciated with compression periods of longer than 1 week. Additional eccentric compression along the treated vein may be beneficial in reducing side effects as well (Grade 1B). In terms of increasing efficacy of the treatment and improving outcomes, medical compression stockings were recommended after treatment of C1 veins with liquid sclerotherapy (Grade 2B), but not after treatment of the GSV [89]. However, there continues to be significant variations in clinical practice in terms of compression following leg vein interventions.

Incompetent Saphenous Veins: Surgery Versus Endovenous Ablation Versus Foam Sclerotherapy

In multiple recent studies comparing conventional surgery with endovenous thermal ablation and ultrasound-guided foam sclerotherapy for treating incompetent great saphenous vein, residual reflux has been found to be significantly more common after foam sclerotherapy compared with the other two treatments [62, 90–92]. In the trial with the longest follow-up of 5 years, success rates were 85% with surgery, 82% with endovenous laser ablation, and 41% with foam sclerotherapy [2b] [93]. The difference in success rates of surgery and endovenous ablation was not statistically significant.

A large trial including 798 patients compared surgery, endovenous laser ablation, and foam sclerotherapy (STS 3%) for the treatment of both

great and small saphenous vein reflux [1b] [94]. Complete success rate after 6 months was 78% for surgery, 82% for endovenous laser ablation, and 43% for foam sclerotherapy. Disease-specific quality of life was also significantly improved in all three groups after the intervention, although comparatively worse for foam sclerotherapy.

While few randomized controlled trials exist specifically comparing treatment modalities for small saphenous vein incompetence, a meta-analysis found success rates to be higher with endovenous thermal ablation as compared to surgery [2a] [64]. Anatomical success rates were 58% with surgery, 98.5% with endovenous laser ablation, 97.1% with radiofrequency ablation, and 63.6% with foam sclerotherapy. A recent Cochrane review further analyzed the available data to date. Three randomized controlled trials, comparing endovenous laser ablation and surgery, included 289 participants and revealed less frequent recanalization or persistence of reflux at 6 weeks in the endovenous laser ablation group with an odds ratio of 0.07 [1a] [95]. At 1 year, recurrence of reflux was less commonly seen in the endovenous laser ablation group, although no difference in clinical recurrence of reflux was appreciated. Insufficient data was available to distinguish a difference in recurrence or persistence of reflux between foam sclerotherapy and surgery.

Varicose Veins: Ambulatory Phlebectomy Versus Sclerotherapy

Although both sclerotherapy and ambulatory phlebectomy are useful tools in treating varicose veins, there are very limited studies comparing the two. In the most recent study comparing the recurrence rates of varicose veins after sclerotherapy and ambulatory phlebectomy, it was found that there were significantly fewer recurrences with ambulatory phlebectomy (1/48) when compared to liquid sclerotherapy (12/48) *at 1-year follow-up [2b]* [78]. At 2-year follow-up, six additional recurrences were found with sclerotherapy but none with phlebectomy. In a separate study, rate of recurrence or development of new varicosities was found to be similar between the two treatment modalities (11% with ambulatory phlebectomy versus 12% with sclerotherapy) [2b] [80]. In addition, there was no significant difference in patient satisfaction between the two groups.

Reticular Veins and Telangiectasias: Lasers and IPL Systems Versus Sclerotherapy

Studies comparing lasers and IPL systems with sclerotherapy are also scarce. Among the various devices, the Nd:YAG laser has been the most extensively studied. This is understandable as the Nd:YAG laser is considered the most effective, especially for treatment of larger leg veins. In a trial comparing Nd:YAG, diode, and alexandrite lasers for treating 0.3–3 mm leg veins, greater than 75% improvement was observed in 88% with the Nd:YAG laser, 29% with the diode laser, and 33% with the alexandrite laser [54]. Similarly, when compared to KTP, Nd:YAG has been found to provide superior clearance of vessels greater than 1 mm and comparable if not better clinical improvement of vessels less than 1 mm in diameter [40, 43]. However, the KTP laser may be preferred for treating smaller vessels given its more favorable side effect profile. Another study compared the clinical efficacy of Nd:YAG and IPL. Again, the results were in favor of the Nd:YAG laser [2b] [96].

In a prospective randomized trial comparing the Nd:YAG laser to sclerotherapy, 56 patients with telangiectasias and reticular veins were included and were followed up to 6 months [2b] [97]. It was demonstrated that both sclerotherapy and Nd:YAG laser have similar effectiveness with a significant clinical improvement of >70% after two treatment sessions of each. However, improvement was achieved more quickly with sclerotherapy, and the Nd:YAG laser was considered to be more painful. Prior smaller studies found similar results [98–101]. Overall, however, these studies lack long-term follow-up with the longest follow-up of 6 months. Therefore, a comparison of recurrence rates cannot be made.

Preoperative Evaluation and Patient Selection

A preliminary assessment is performed to understand whether there is an underlying source for the varicose veins and their regions of involvement.

After a thorough history is obtained, a complete examination of both legs needs to be performed. The physical exam serves to identify cutaneous complications of venous insufficiency and directs the need for noninvasive diagnostic imaging prior to treatment. In particular, cutaneous findings may provide clues as to whether there is an underlying source of reflux, such as from regions of the great saphenous vein, small saphenous vein, or lateral venous system. For example, evidence of chronic venous stasis, particularly of the medial ankles or lower legs, is a sign of great saphenous vein incompetence. On the other hand, skin changes or ulcerations on the lateral ankles are likely to be related to small saphenous vein insufficiency. Clues for reflux in the reticular veins of the lateral venous system include telangiectatic webs on the lateral and posterior thighs [102].

As a general rule, when a patient presents with bulging varicosities, complains of leg pain or swelling, has history of prior vein surgery, or has strong family history of varicose veins and presents with an abundance of veins in the area served by the saphenous veins, diagnostic imaging with Duplex ultrasound is indicated. The Duplex ultrasound can easily detect unusual venous anatomy, valvular incompetence, and venous obstruction [103–105]. The cutoff values defining valvular reflux during ultrasound examination are retrograde flow longer than 500 ms for the saphenous, tibial, and deep femoral vein, longer than 1 s for the femoral and popliteal vein, and longer than 350 ms for the perforating veins [106].

It should be noted that traditional clinical tests such as Trendelenburg and Perthes have proven unreliable in the mapping of venous incompetence [107, 108]. Therefore, have been largely replaced by diagnostic imaging.

If an underlying source of reflux is located, this should be treated prior to proceeding with treatment of branch varicosities and telangiectasias. If the area of reflux is left untreated, there is high risk of treatment failure and recurrence [22].

Procedure Selection

Incompetent Saphenous Veins: Surgery Versus Endovenous Ablation Versus Foam Sclerotherapy

For saphenous varicosities, endovenous occlusion using radiofrequency or laser is strongly preferred over surgical ligation and stripping and has now become the standard of care in the United States. There is comparable efficacy but significantly fewer side effects with endovenous ablation as compared to surgery [14, 15].

When comparing sclerotherapy and endovenous procedures, there is a higher recanalization rate with sclerotherapy [94]. However, foam sclerotherapy may be an attractive option to treat superficial incompetence in elderly and frail patients or those with venous leg ulcers. With sclerotherapy, patients would need to be informed that repeat treatment may be needed.

Varicose Veins: Ambulatory Phlebectomy Versus Sclerotherapy

Foam sclerotherapy or ambulatory phlebectomy can both be used to treat varicose tributaries. Phlebectomy may be preferred for patients who want to pursue a more definitive treatment for their varicose vein, as vessel removal by this method are gone permanently. In addition, results are immediate, so it may be preferable for patients who do not want to wait for sclerotherapy results. In the case of recurrent varicose veins after phlebitis or sclerotherapy, these may be particularly difficult to extract with phlebectomy because of adhesions and local scar tissue from prior inflammation. Therefore, sclerotherapy would be preferred in this case. Additionally, selection may be made based on vein wall thickness. Visible blue veins are an indication that the vein wall is so thin that blood is easily visualized within it. Removal with phlebectomy would easily shred these veins so sclerotherapy would be preferred.

Reticular Veins and Telangiectasias: Lasers and IPL Systems Versus Sclerotherapy

When considering smaller veins, a consideration is between sclerotherapy and lasers or IPL devices. Sclerotherapy is the gold standard for most of these leg veins as it is relatively safer, less expensive, and easier than laser therapy [15]. For example, when treating arborizing telangiectasias, injection of a sclerosing agent into the supplying vein is often sufficient, whereas the affected area needs to be treated vein by vein with laser therapy. In addition, the variability of leg veins among patients, and even within the same patient, means that laser settings need to be constantly adjusted, or a different laser modality may need to be used altogether [15]. Still, lasers may be preferred in patients who are needle phobic, have concerns of allergy to sclerosants, have severe hypercoagulability, have previously developed unwanted side effects from sclerotherapy, have failed sclerotherapy, or have telangiectasias that are so small in caliber that they cannot be cannulated even with the smallest of needles. In addition, laser therapy may be preferred in areas prone to ulceration, such as the ankle [14, 15].

Typical Treatment Plan

Case 1

A 40-year-old woman presents with leg veins that bulge and ache constantly. She also complains of leg pain and swelling after a long day at work as a waitress. Family history is notable for mother and sister with varicose veins.

On exam, prominent varicosities are present from her right medial knee extending over the posterior calf and down to the ankle, and a small varicosity is present on the left medial calf.

Duplex ultrasound is performed, revealing an incompetent right small saphenous vein and incompetent left great saphenous vein.

The right small saphenous and left great saphenous veins are treated with 1320 nm endovenous laser ablation. At 6-week follow-up, remaining superficial varicosities are treated with duplex-guided sclerotherapy with polidocanol 0.5% foam. The patient is advised to wear 30–40 mm Hg compression stockings for 2 weeks posttreatment.

Especially given the patient's young age and genetic susceptibility, she is advised to follow up annually to examine for recurrence and for the development of new varicosities.

Case 2

A 45-year-old woman complains of the appearance of veins on her lateral thigh. They appeared during pregnancy and have worsened over the past 10 years. No significant symptoms are noted.

On exam, a prominent blue reticular network with associated telangiectasias is noted on her left lateral thigh.

Duplex ultrasound is not performed as this patient presents with the commonly seen pattern of an abnormal lateral venous system without other venous abnormalities.

Two sessions are performed 6 weeks apart using polidocanol 0.5% foam for the prominent reticular veins and chromated glycerin 72% for the telangiectasias. The patient is advised to wear 20–30 mm Hg compression stockings for 2 weeks after each treatment.

Case 3

A 70-year-old woman presents with a red to violaceous spider telangiectasia on the ankle without associated symptoms.

On exam, an isolated spider telangiectasia is noted on the right medial ankle.

Duplex ultrasound is not performed as this patient presents with an isolated telangiectasia without signs or symptoms of underlying venous insufficiency.

The option of laser or low-concentration liquid sclerotherapy is discussed with the patient. Given her fear of needles and location on the

ankle, she opts for laser treatment. Resolution is achieved with a single session of the 1064 nm Nd:YAG laser.

Emerging Therapies

Few novel therapies for leg veins have recently gained acceptance. Endovenous cyanoacrylate closure (CAC) of the saphenous veins is now FDA approved and is a method that does not require tumescent anesthesia or post-procedure compression. The cyanoacrylate acts as an adhesive that seals off incompetent veins. Early studies showed high closure rates with mild procedural pain, limited side effects, and 98% patient satisfaction [2b] [109]. An initial study comparing cyanoacrylate closure to radiofrequency ablation in 222 patients showed noninferiority with a 1-month closure rate of 100% and 87% in CAC and radiofrequency ablation, respectively. At 12 months, the complete occlusion rate was 97.2% and 97.0% in CAC and radiofrequency ablation, respectively [1b] [110, 111]. Similarly, a retrospective comparison between CAC and endovenous laser ablation showed a 12-month closure rate of 98.6% and 97.3%, respectively, with less side effects in the CAC group [2b] [112].

Another novel therapy is known as mechanochemical endovenous ablation. This involves applying endovenous mechanical damage to the vessel wall using a rotating catheter tip, combined with the infusion of a liquid sclerosant from the catheter tip upon withdrawal, causing chemical damage. Again, tumescent anesthesia is not required and the process does not involve heat. An initial prospective, multicenter study of 126 patients with great saphenous vein reflux involving the saphenofemoral junction revealed closure rates of 100% at 1 week, 98% at 3 months, 95% at 12 months, and even 92% maintained at 24 months [2b] [113, 114]. Recent, larger studies have confirmed the procedure's efficacy in treating both the great and short saphenous veins [115]. Further comparative studies, with longer follow-up, are necessary to fully understand the role of these novel therapies in the treatment of leg veins.

Safety

Sclerotherapy

The most commonly encountered complications of sclerotherapy are telangiectatic matting, hyperpigmentation, and cutaneous necrosis. Other complications that are not minor but rare in incidence are inadvertent arterial injection and nerve injury.

Telangiectatic matting refers to tiny new red telangiectasias that appear after sclerotherapy or surgical removal of varicose veins. The incidence is between 15% and 24% [26, 116] and usually resolves spontaneously in 3–12 months [116, 117]. The precise cause of matting remains unknown although using the minimum concentration of sclerosant, small volumes, and low infusion pressure can reduce this complication [117–119]. The use of chromated or nonchromated glycerin also decreases the risk of matting [2b] [120].

Post-sclerotherapy pigmentation is a persistent pigmentation along the course of the vessel that has been treated with sclerotherapy. The etiology is thought to be from a combination of post-inflammatory hyperpigmentation as well as direct hemosiderin deposition. Its incidence ranges from 10% to 30% and may appear up to 12 weeks after treatment [117, 118, 121]. Spontaneous resolution occurs in 70% of patients by 6 months but may persist longer than 1 year in up to 10% of patients [121]. Pigmentation has been found to be more likely at higher sclerosant concentrations. For example, polidocanol 1% is more likely to cause pigmentation than 0.5% [2b] [117]. Likewise, the incidence of pigmentation at higher concentrations of STS is reported to be 30–80%, while the incidence decreases to 11% with STS at 0.1% [2b] [118]. Further, evidence suggests that glycerin is less likely to cause pigmentation compared to certain concentrations of STS, hypertonic saline, and polidocanol [120, 122].

Cutaneous necrosis occurs most commonly due to extravasation of sclerosant into perivascular tissues. It occurs commonly with hypertonic saline and rarely with polidocanol, STS, and glycerin.

Fortunately, it is infrequent and has been reported to affect 0.23% of patients treated with sclerotherapy [123]. It has usually been reported to occur after perivascular injection of sclerosants in higher concentrations and rarely after properly performed intravascular injections in various concentrations [118]. Cutaneous necrosis may also occur with direct intra-arterial injection, reactive vasospasm, and excessive compression of skin overlying the treated vein. Accidental intra-arterial injection, with and without ultrasound guidance, causing acute ischemia has been reported in at least 18 patients [123–132].

Neural injury may occur following direct injection into the nerve but also from perineural leakage of a sclerosant. The nerves most commonly affected are the saphenous and sural nerves, which lie close to the great and small saphenous veins, respectively [133].

Superficial thrombophlebitis may also occur after sclerotherapy and have been reported to occur in 4–7.5% of patients [134]. It occurs primarily after treatment of larger varicose veins and presents as an area of erythema, warmth, and tenderness over an indurated venous segment.

Overall, foam and liquid sclerotherapy have been associated with similar adverse events, except transient visual disturbances and headaches, which are more common with foam sclerotherapy. Particularly for patients with a patent foramen ovale, foam solution can communicate into the arterial system and cause neurological side effects. Two cases of stroke and one case of transient ischemic attack have been described during foam sclerotherapy, and all were found to have a patent foramen ovale [135, 136].

Lasers and IPL Systems

The most common sclerotherapy side effects of telangiectatic matting and hyperpigmentation have also been found to occur following laser therapy of leg veins [98, 99, 101]. A study was conducted comparing Nd:YAG laser and sclerotherapy with STS for treating small diameter leg veins [2b] [98]. The incidence of matting was 28% with laser and 17% with sclerotherapy, whereas the incidence of hyperpigmentation was 57% with laser and 67% with sclerotherapy. In another study comparing Nd:YAG laser and sclerotherapy with polidocanol 0.5% foam, incidence of matting was seen in 20% of patients with either therapy, while hyperpigmentation was more common with sclerotherapy (67.9% with sclerotherapy versus 39.3% with laser) [2b] [97].

Further, laser therapy has proven to be more painful than sclerotherapy and is associated with less favorable patient satisfaction scores [98, 99, 101]. Other risks inherent to lasers include hypopigmentation [137, 138], especially when treating patients with darker skin types, epidermal necrosis, scarring, and purpura. Understandably, the risks vary depending on the laser and settings used. When using infrared lasers, and particularly the Nd:YAG laser, there is a greater risk of bulk tissue heating and necrosis. Therefore, pulse stacking or overlap between pulses should be avoided. On the other hand, there is a greater risk of hypopigmentation with the shorter wavelength KTP and pulsed dye lasers, as these wavelengths have higher absorption by melanin. For IPL devices, the use of multiple wavelengths implies a significant risk of damaging nonvascular structures.

Endovenous Ablation

The most important factor in minimizing complications from endovenous thermal ablation is the use of tumescent anesthesia. It is injected around the target vessel to protect the surrounding tissue from heat generated during treatment. With this technique, postoperative complications from endovenous ablation are limited. Reported complications include thrombophlebitis (7%) [139], hyperpigmentation (5%) [139], paresthesia (1–2%) [140, 141], thermal skin injury (<1%) [139], bruising, and hematomas (0–7%) [140–143]. Given the proximity of the sural nerve to the small saphenous vein at the distal calf, access at the lateral malleolus results in a higher paresthesia rate compared with the mid-calf [2b] [144]. In line

with this, endovenous laser ablation of the small saphenous vein has been associated with a significantly higher incidence of sensory disturbance compared with ablation of the great saphenous vein [2b] [145].

When compared to surgery, patients treated with endovenous thermal ablation have less pain [61, 141–143, 146], swelling, bruising, paresthesia, and a faster return to normal activities [66, 147]. Additionally, surgically treated patients are more likely to develop complications such as wound infection (2–6% with surgery versus 0% with endovenous thermal ablation) [146] and hematomas (5% with surgery versus 2% with endovenous thermal ablation) [139]. However, the risk of superficial thrombophlebitis was found to be significantly higher with radiofrequency ablation than with surgery [2a] [146].

In a comparative study on the use of lower and higher wavelength endovenous lasers, the higher wavelength 1320 nm laser caused fewer side effects compared with the 940 nm diode laser [2b] [70]. There was significantly reduced ecchymosis and pain in those treated with the 1320 nm laser. In a subsequent randomized clinical trial, the higher wavelength 1500 nm endovenous laser was again found to cause fewer side effects than the 980 nm diode laser [2b] [71]. Patients treated with a 1500 nm laser had less induration around the treated vein, less need to take analgesics (1.8 days versus 2.9 days), and had a better postoperative quality of life.

In a meta-analysis, the incidence of deep vein thromboses was found to vary between 0.2% and 1.3% with endovenous thermal ablation and seemed to be higher in patients treated with radiofrequency than laser ablation [2a] [148]. However, it mainly included studies using the old radiofrequency ablation techniques and endovenous laser ablation with bare tip fibers and lower wavelengths. Development of thrombus extension at the saphenofemoral junction could be found in a limited number of cases, with case series reporting a frequency varying between 0.3% and 7.8% [149–151]. Pulmonary embolism has also been reported in up to 3% of patients after endovenous laser ablation [149, 151].

While foam sclerotherapy is associated with somewhat less postoperative pain than endovenous laser ablation, there was no significant difference in the rating of postoperative pain when radiofrequency ablation was compared with foam sclerotherapy [1b] [91].

Ambulatory Phlebectomy

In comparison to sclerotherapy, phlebectomy avoids the risks of intra-arterial injection, extravasation skin necrosis, and residual pigmentation. However, complications observed with phlebectomy include edema (5–17.5%), especially at the dorsum of the foot, hematoma formation (4.9–95%), superficial phlebitis (2.4–13%), temporary hyperpigmentation (1.2–3.3%), nerve injury (9.5–39%), and telangiectatic matting [152, 153]. Further, scar formation was found to be significantly more likely with phlebectomy (17%) than sclerotherapy (0%) [78].

Postoperative Care and Follow-Up

Studies suggest that clinical symptoms and findings on diagnostic imaging are not necessarily correlated. When a cohort of patients treated with endovenous laser ablation for great saphenous vein incompetence were followed up to 6 years, symptomatic clinical failures occurred in 11.6%, while echo-color-Doppler confirmed failures were present in 30% [2b] [154]. Among them, only 1.1% had both symptomatic clinical and echo-color-Doppler confirmed failures. Similarly, following ultrasound-guided foam sclerotherapy, 5-year recurrence rate on Duplex ultrasound was found to be 64%, whereas clinical recurrence was present in 4% [2b] [155]. Given the fact that reflux may be present at truncal veins without associated symptoms, it would be reasonable to follow patients at regular intervals to examine for recurrence. In particular, certain patients may be at greater risk for developing new varicosities and recurrence, such as those with a strong family history of varicosities or those who present

with venous disease at a younger age. For these patients, a closer follow-up may be warranted.

In general, however, there is little evidence regarding the appropriate schedule for monitoring patients for recurrence or for the development of new leg veins.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
Duplex ultrasound is the diagnostic test of choice to evaluate venous anatomy and to identify sources and patterns of reflux	A
Endovenous thermal ablation (with laser or radiofrequency) is safe and effective and is recommended over surgery and foam sclerotherapy for the treatment of incompetent saphenous veins	B
Phlebectomy or foam sclerotherapy is recommended for the treatment of varicose tributaries	B
Liquid or foam sclerotherapy is recommended for treating reticular veins and telangiectasias	A
Foam sclerotherapy should be reserved for treating vessels greater than 1 mm in diameter	D
The optimal treatment approach for sclerotherapy is to match a given vessel diameter with the lowest concentration of sclerosant to achieve the desired effect	B
Transcutaneous lasers may be indicated for treatment of reticular veins and telangiectasias, only when sclerotherapy is not an option	C
The 1064 nm Nd:YAG laser is the laser therapy of choice for leg veins, especially for those greater than 1 mm in diameter	B
Post-procedure compression is recommended following endovenous thermal ablation and sclerotherapy	A

Self-Assessment Questions

1. A 60-year-old woman presents with bulging varicosities along the right medial calf. What is the next diagnostic or therapeutic intervention?
   (a) Perform Trendelenburg test to determine whether the congestion is caused by superficial venous reflux or incompetence of the deep venous system
   (b) Perform Duplex ultrasound to examine for underlying sources of reflux
   (c) Immediately proceed with foam sclerotherapy to treat the patient's primary complaint
   (d) Immediately proceed with ambulatory phlebectomy to treat the patient's primary complaint
   (e) Explain that treatment would not be possible due to the size and extent of the varicosities

2. The patient from question 1 is found to have reflux of the great saphenous vein on Duplex ultrasound. What is the treatment of choice?
   (a) Endovenous thermal ablation with laser or radiofrequency
   (b) Surgical stripping and ligation
   (c) Ultrasound-guided foam sclerotherapy
   (d) Ultrasound-guided liquid sclerotherapy
   (e) No treatment is recommended for this patient

3. A patient presents with an isolated arborizing telangiectasia on the left lateral thigh. What is the treatment of choice?
   (a) Sclerotherapy with polidocanol 0.25% liquid
   (b) Sclerotherapy with hypertonic saline 23.4%
   (c) Sclerotherapy with STS 1% foam
   (d) Laser therapy with 1064 nm Nd:YAG
   (e) Laser therapy with 532 nm KTP

4. For the patient from question 3, which post-sclerotherapy compression therapy would be recommended, if any?
   (a) 15–20 mm Hg compression stockings
   (b) 20–30 mm Hg compression stockings
   (c) 30–40 mm Hg compression stockings
   (d) 40–50 mm Hg compression stockings
   (e) No compression therapy is recommended

5. A patient presents for treatment of blue reticular veins on the legs that are 2–3 mm in diameter and refuses any treatments that involve needles. Which laser is the treatment of choice?
   (a) 532 nm KTP
   (b) 585 nm Pulsed dye laser
   (c) 810 nm diode
   (d) 755 nm Alexandrite
   (e) 1064 nm Nd:YAG

Correct Answers

1. b: Duplex ultrasound allows for the examination for underlying sources of reflux, as well as evaluation of venous anatomy and evidence of obstruction. It has largely replaced traditional clinical tests such as Trendelenburg and Perthes. If there is underlying reflux, it should be treated prior to treating the varicose tributaries.
2. a: Endovenous thermal ablation has been demonstrated to be as effective but safer than surgery in the treatment of great saphenous vein incompetence.
3. a: For a given vessel diameter, the lowest possible concentration of sclerosant should be used to reduce potential side effects. In addition, foam sclerotherapy should be reserved for vessels greater than 1 mm in diameter, while hypertonic saline is associated with significant pain without increased effectiveness when compared to polidocanol. Laser therapy should be reserved for treating leg veins only when sclerotherapy is not an option.
4. b: 20–30 mm Hg post-sclerotherapy compression is recommended following treatment of telangiectasias, whereas 30–40 mm Hg or 40–50 mm Hg compression is indicated for larger varicosities.
5. e: For leg veins greater than 1 mm in diameter, the 1064 nm Nd:YAG laser is the preferred laser therapy. For leg veins less than 1 mm in diameter, the pulsed dye laser or KTP laser may also be effective.

Invasive Melanoma

62

David Panther and David G. Brodland

Abstract

Melanoma remains one of few malignancies with increasing incidence. Surgical removal of invasive melanoma is the first and most important therapeutic intervention. Historically, margins of up to 5 cm have been recommended for a wide local excision (WLE). However, randomized controlled trials comparing margin width have significantly narrowed the size of an appropriate WLE to 1–2 cm, depending on Breslow depth. Narrow margins have not been shown to worsen survival in these trials. More recently, refinements in Mohs surgery have allowed for the highest rate of local control when immunohistochemistry is employed, particularly for head and neck melanomas, which have a poor rate of local control with WLE. Perioperative issues include appropriate examination and counseling, consideration of sentinel lymph node biopsy, and taking patient preference into account. Safety of the various surgical modalities is related to the size of the excision and the delay between excision and repair, with advantages noted for smaller excisions and same-day repair.

Melanoma · Excision · Mohs · Surgery Complication

Epidemiology

The incidence of invasive malignant melanoma (IMM) has been steadily increasing in the USA by 1.4% each year (2c) [1], though recently declining incidence in those under age 50 may herald a coming stabilization or reversal in the overall trend (2c) [2]. Approximately 2.1% of men and women born today will be diagnosed with in situ or invasive melanoma of the skin at some point during their lifetime, based on 2011–2013 data, and the annual incidence now stands at 21.8 per 100,000 men and women per year. Upon initial diagnosis of IMM, 84% of patients have local disease, 9% have regional involvement, and 4% have distant metastases, with the other 3% being unstaged [2]. Mortality from IMM is 2.7 per 100,000 per year [1]. The 5-year melanoma-specific survival rate for patients whose IMM is diagnosed before detectable metastasis is 98%. This falls to 63% when regional metastasis has already occurred and

17% for those with distant metastasis at initial diagnosis [2]. The depth of invasion predicts prognosis, with increasing depth portending a poorer survival probability (Fig. 62.1) (2c) [3].

Based on 2009–2013 data, the median age at diagnosis is 63 [1], and age is one of many known risk factors for developing melanoma (2c) [4]. A white male over the age of 85 has a nearly ninefold higher risk for melanoma than one in the 45–49 age group, and more than 90 times the risk of one in the 20–24 group (Fig. 62.2) (2c) [5]. Although incidence is lower in the young, invasive melanoma represents a greater proportion of all cancers; melanoma is the second most common cancer in females in their third decade of life (2c) [6]. Other non-modifiable factors include male sex (except before age 50, when incidence is slightly higher in women (Fig. 62.2)), a personal or family history of melanoma, numerous clinically atypical melanocytic nevi, and lighter skin type (especially those who are unable to tan, have blonde or red hair, or have blue eyes), as well as more recently discovered heritable genetic mutations such as the CDKN2A gene (2a-3a) [7–11]. Each of the four main body sites (head and neck, trunk, upper extremity, and lower extremity) have their own unique incidence profile, which varies based on age and sex (Fig. 62.2b, c). Avoidable risk factors are the key to prevention efforts, and the most significant is ultraviolet radiation (UVR) exposure. One study estimated 86% of melanomas diagnosed in the UK were related to UVR from the sun

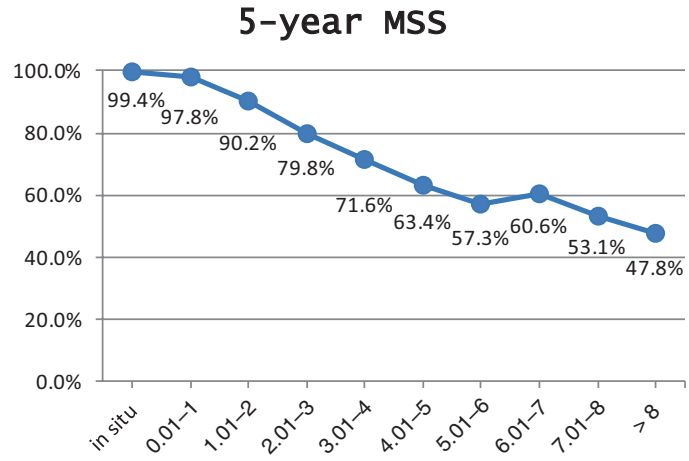

Fig. 62.1 Melanoma-specific survival (MSS) decreases with increasing Breslow depth of a primary melanoma, based on cases diagnosed between 2004 and 2008 and reported to SEER

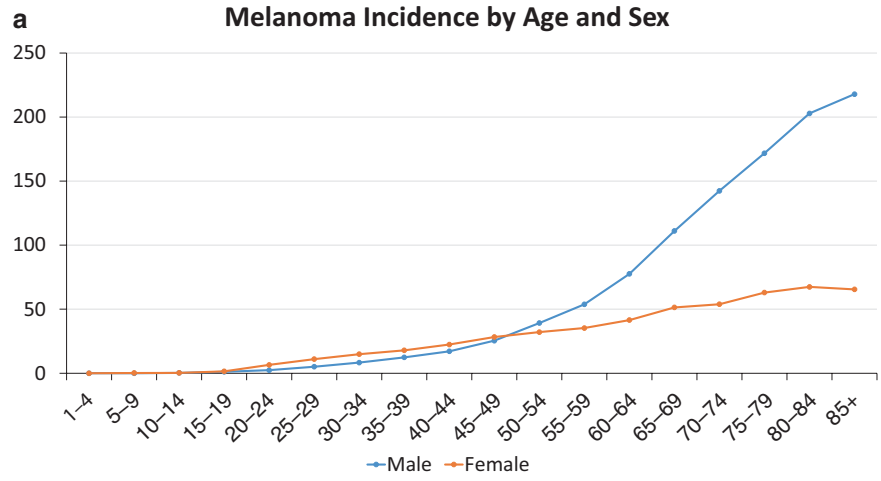

Fig. 62.2 Incidence increases with age and male sex. Incidence is reported in cases per year per 100,000 people

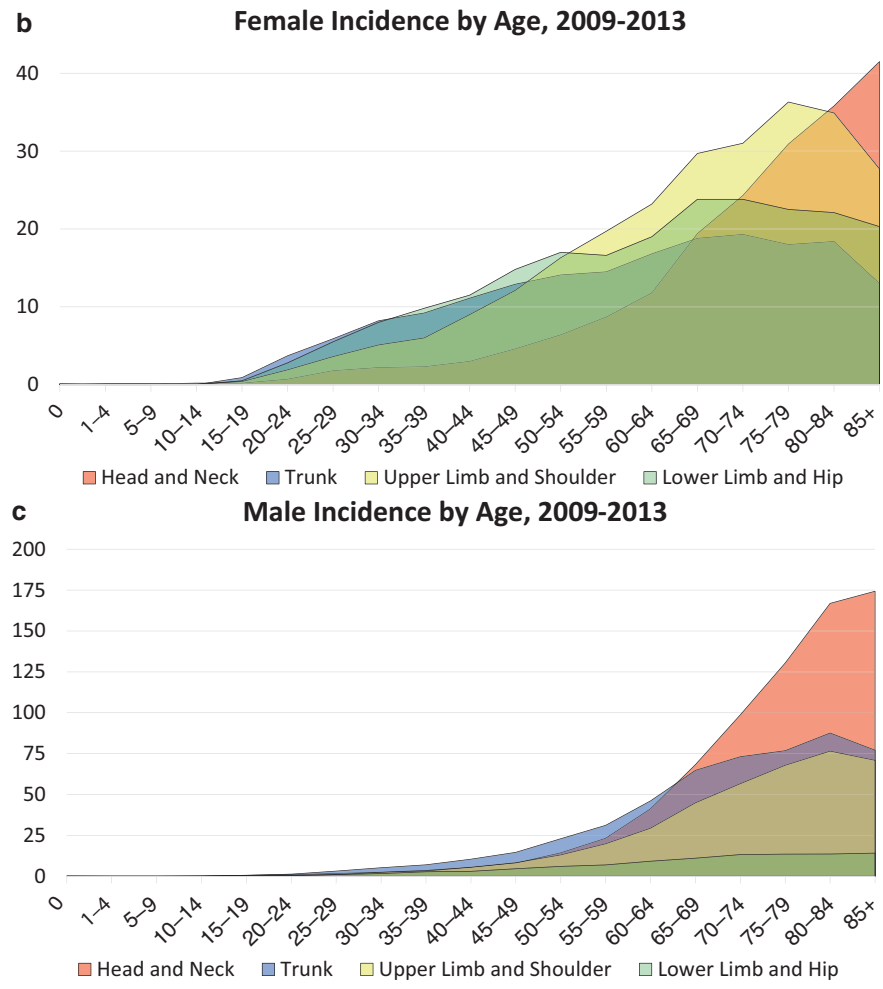

Fig. 62.2 (continued)

(2c) [12], and risk doubles with a history of more than five sunburns (2c) [13]. Indoor tanning has also been shown to have a strong association with melanoma incidence (2b) [14]. Reduction of UVR exposure by daily application of sunscreen was shown to be associated with halving the incidence of new melanomas in Australia (1b) [15].

Treatment Overview

Introduction

The backbone of treatment for primary cutaneous melanoma is complete surgical removal of the tumor [16]. This may be accomplished in a number of ways (Fig. 62.3), the most common of which is wide local excision (WLE). The visually delineated tumor, plus a predetermined (based on Breslow depth) safety margin of clinically normal skin (1b) [16–18], is removed and sent to a pathologist, and the wound is closed. The specimen is then sampled by sectioning perpendicular to the margin to give several cross-sectional views of the specimen. The histologic margin visualized by standard perpendicular sectioning is approximately 0.01% of the true margin [19], leading to the specter of a false negative if melanoma extends through the margin between the cross-sectional planes. There is no national standard for how melanoma is processed after WLE. Lab manuals often specify between 2- and

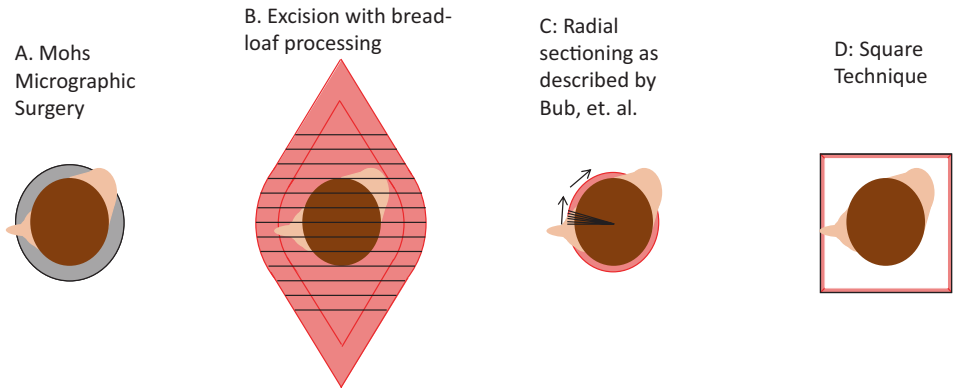

Fig. 62.3 Excisional techniques (first stage) compared for a 1.5-mm deep melanoma. Melanocytic lesion is brown and subclinical extensions are flesh-colored. Peripheral surgical margins are black when pathologically examined and red when not examined; deep surgical margins are gray where examined and pink where not examined. (**a**) MMS excision, with initial 6-mm margin and two areas of confirmed positive margins, which will be removed in subsequent 3 mm layers. 100% of peripheral and deep margins are examined, and immunostains are frequently used due to the small number of slides generated. (**b**) WLE, shown with both 1-cm and 2-cm margin options (reflecting range in guidelines for 1.01 – 2-mm deep melanomas). If 1-cm margins are chosen, the 1 o'clock peripheral margin is close but clear, while the area between 8 and 9 o'clock is biologically positive. Whether this will be seen as a positive margin on pathology depends on how the specimen is cut, which is not standardized. Some lab protocols dictate bread-loaf sections throughout the specimen at varying intervals, while others allow for "representative" margin sampling at larger intervals when specimens are very large. While a 2- cm margin will clear most melanomas regardless of thickness, the resulting defects are often substantially larger than those created by any other method. Immunostains are not typically done, due to the large number of slides generated. (**c**) Radial sectioning every 1 mm is likely to identify the vast majority of biologically positive margins, including those shown in this example. Subsequent surgeries remove 2–3 mm of tissue, until clear margins are obtained. Coupled with the described practice of reoperating when margins are only clear by 1–2 mm, this is a rigorous margin assessment, though a large number of slides are generated and immunostains are not used. (**d**) The square technique requires angular margins to allow for high-quality en face sectioning and examines 100% of the peripheral margin. The 1-cm initial margin is positive, which prompts another removal 0.5 cm beyond the original margin. Deep margins are sampled at the discretion of the surgeon and dermatopathologist, and the timing of this sampling depends on the clinical situation. Typically, only H&E stain is performed

5-mm intervals for specimens small enough to be completely embedded; very large excisions are difficult to embed entirely, and margin sampling is at the discretion of the physician or technician performing the work [20].

Mohs micrographic surgery (MMS) was developed and refined to assess 100% of the surgical margin for contiguous cutaneous tumors and has been successfully applied to invasive melanoma (2b-4) [21–24], allowing for complete, histologically confirmed tumor extirpation and reconstruction in a single day. A narrow margin of clinically normal skin is removed (3-mm–1-cm margins have been reported, depending on surgeon and tumor characteristics) [21, 24], and the entire peripheral and deep margin is laid flat and processed via frozen section immediately. This allows for 100% of the surgical margin to be visualized and mapped to define areas of remaining melanoma, which are selectively removed in a series of excisions until all margins are clear (Fig. 62.4). The central portion of the specimen containing any residual tumor is typically sent out for permanent sections to confirm staging, though some may opt to view them as frozen sections first, then thaw and send out for permanents [24]. Each round of specimen processing takes approximately 1 h when immunostains are used [25].

Variations of staged excision (SE) have been described to improve on WLE and ensure the entire surgical margin is visualized prior to delayed closure [26–30]. The term "margin-controlled excision" (MCE) will be used to lump all techniques that evaluate 100% of the surgical margin (such as MMS and some staged excision protocols). The basic premise of SE is to begin

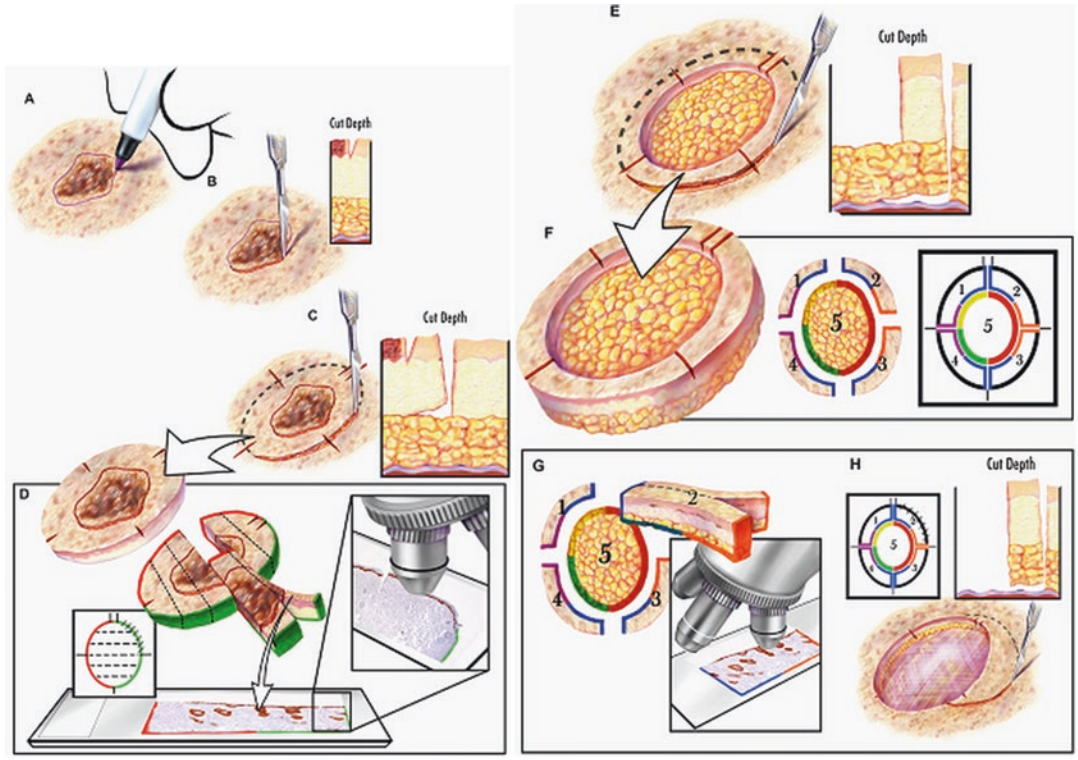

Fig. 62.4 Steps for Mohs micrographic surgery technique for melanoma at the Hospital of the University of Pennsylvania. (**a**) The scar and clinically visible residual melanoma at the site of the original biopsy are outlined. Additional pigmented lesions near the primary melanoma are also outlined and documented with photography in case they would collide with either the surgical margin or reconstruction. (**b**) An incision is made to the level of the papillary dermis at the exact clinical margin of the melanoma. (**c**) The visible tumor is excised to the superficial fat with a peripheral margin of at least 2–3 mm of clinically normal-appearing skin (larger margins may be excised for higher risk tumors). (**d**) The peripheral margins of the debulking specimen are inked with tissue dye and a map is drawn to record the grossing strategy. The debulking excision is grossly sectioned in breadloaf fashion at 2–3-mm intervals and vertical sections are cut for microscopic examination. The inset demonstrates tumor extending beyond the hash mark at the clinical margin of the tumor (made in step B) to the green-dyed edge. (**e**) The Mohs layer is excised around the entire defect from the debulking excision to the fascia with an additional peripheral margin of at least 2–3 mm of clinically normal-appearing skin (larger margins may be excised for higher risk tumors). Hash marks are made on the skin surface to maintain orientation relative to the patient. (**f**) The Mohs layer specimen is grossly sectioned to separate the epidermis, dermis, and a thin layer of subcutaneous fat from the deep fatty margin. Free cut edges of all grossly sectioned specimens are inked, and surgical maps are drawn to represent the method of gross sectioning. (**g**) Microscopic frozen sections are cut from the complete peripheral and deep margins for evaluation by the Mohs surgeon. In this example, piece 2, which corresponds to the site of the positive margin on the debulking excision (see step D), has tumor at the margin. (**h**) The presence of tumor at the margins is indicated on the Mohs map, and additional layers around the positive margin are excised until there is no evidence of microscopic disease. A minimum of a 2–3-mm peripheral margin was excised on subsequent stages, but larger margins were sometimes excised if the previous stage was strongly positive (Reprinted with permission from Etzkorn et al. [24])

with a relatively narrow margin (between 2 and 10 mm), with subsequent selective removal of melanoma found remaining at the margin. Excised tissue is usually oriented for en face (parallel along the true margin) overnight permanent sectioning, and subsequent removals and closure are done on separate days. One described variation of this technique involves radial (perpendicular) sections at 1-mm intervals with further removal warranted when melanoma approaches within 2 mm of the true margin, in an attempt to account for tumor extensions between the radial cuts (Fig. 62.5) [26]. "Peripheral incontinuity tissue examination" has been used to

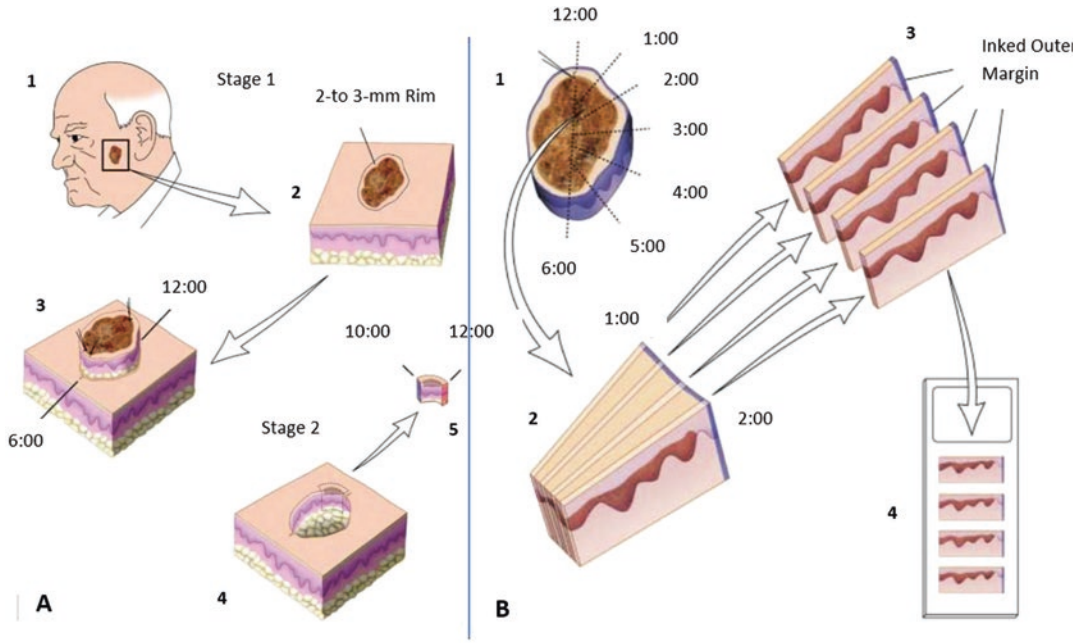

Fig. 62.5 (**a**) Staged excision. Stage 1: A 2–3-mm margin is demarcated around the tumor (2). A perpendicular incision is made into subcutaneous tissue and the specimen is oriented in respect to the face of a clock (3). Sutures in the specimen and incision nicks in perilesional skin demarcate 12 and 6 o'clock positions. The specimen is sent to pathology for radial sectioning (B). Stage 2: The patient returns the following day. In this example, tumor is present at the 11 o'clock position (4). A 2–3-mm rim is again demarcated, and tissue is excised with a perpendicular incision from approximately the 10–12 o'clock positions. To maintain orientation, the 10 and 12 o'clock margins are inked blue and orange, respectively (5). Further stages are performed until negative margins are achieved. (**b**) Pathology processing. 1, Margins are inked to maintain orientation; the specimen is bisected and then divided radially (like pieces of a pie) according to the numbers on a clock face. 2 and 3, Each pie wedge is placed in a cassette, embedded in paraffin, and sectioned radially. 4, The sections are placed on a glass slide for examination by the pathologist. Radial sectioning allows for examination of the centrifugal progression of the entire lesion, facilitating identification of the transition between lentigo maligna, atypical junctional hyperplasia, and normal histologic features (Reprinted with permission from Bub et al. [26])

describe the use of en face frozen section histology with a separate surgeon and pathologist [31], though its specific application to melanoma has not been reported and may be limited by the pathologist's ability to process multiple rounds of frozen section pathology for the surgeon in a day, especially in the setting of an inpatient OR.

Non-excisional modalities lack the ability to confirm histologic clearance but may be appropriate in limited circumstances. Although utilization of these alternatives remains infrequent, brief mention is merited. Radiation has been used with a degree of success for invasive lentigo maligna melanoma (4) [32–34] but is more commonly used as adjuvant therapy for desmoplastic melanoma (4) [35]. Cryotherapy is primarily thought of as an alternative for in situ disease, but one report does mention its use for invasive melanoma as well (4) [36].

Effectiveness of Treatments

The goal of excision is the complete removal of all cancerous tissue by achieving histologic tumor-free margins [16], to eliminate the chance of marginal persistence and subsequent clinical recurrence. Ultimately, the purpose is to eliminate ongoing risk of regional and distant metastases originating from unresected tumor. Permanent cure will never be guaranteed by any form of local treatment, since melanoma may have already

metastasized by the time of presentation, but ensuring the complete removal of the original tumor is the first and most important step to minimize poor outcomes. Some reports indicate patients who experience local recurrence (LR) go on to die from metastasis roughly 80–90% of the time (2b) [37, 38], although LR definitions often include in-transit and satellite metastases which are indicative of stage IIIB/C disease rather than true marginal recurrence. When a strict definition of local recurrence is employed which excludes satellite or in-transit metastases, the consequences of inadequate excision are less pronounced but still undesirable, with 33% recurring as a thicker melanoma and 25% of those with thicker recurrence dying after just under 3 years of follow-up in one study (2b) [39].

Wide excision using visual inspection to define the melanoma's margins with subsequent cross-sectional pathological margin assessment is the historical standard. For much of the twentieth century, 3–5-cm margin and even amputation was the standard of care, yet this more radical surgical concept has its roots in an autopsy finding of a single patient with lymphatic metastasis (5) [40]. The width of clinical margin recommended to bring about acceptable recurrence rates has decreased through the years, thanks to a number of randomized controlled trials (1b) [38, 41–52]. What is now termed "wide" local excision (1–2 cm) has been historically viewed as "narrow" margins. The NCCN and AAD guidelines are currently identical for invasive melanoma, recommending a 1-cm clinical margin for lesions with Breslow thickness </= 1.00 mm, 1–2-cm margin for lesions 1.01–2.00 mm thick, and 2-cm margin for lesions >2 mm thick. The key findings of the

Table 62.1 Rates of recurrence and overall survival in RCTs of primary cutaneous melanoma

Wide excision study	Inclusion/exclusion criteria	Breslow thickness (mm)	Surgical margin (cm)	No. of patients	Rate of local recurrence[a] (%)	Overall survival (%)
WHO	Exc: face, fingers, toes	≤2.0	1	305	LR at 12 years, 2.6	At 12 years, 87.2
			3	307	LR at 12 years, 1	At 12 years, 85.1

[a]Definitions of local recurrence, by study:

WHO: cutaneous or subcutaneous nodules that appeared along the scar or in an area of 1 cm or less in radius from the surgical scar

French: recurrence within 2 cm of the scar

Swedish I: recurrence in the scar or transplant

Intergroup: within 2 cm of the surgical scar, unless multiple in-transit lesions or metastases were present (then the recurrence was presumed to be in-transit or metastatic, respectively)

UK: within 2 cm of the scar or graft

Swedish II: recurrence in the scar or transplant

[b]MSS at 10 years was 70% for 2 cm arm and 77% for 4 cm arm

[c]Locoregional recurrence at 5 years was 37.1% in 1 cm arm and 31.0% in 3 cm arm, p = 0.05

trials supporting these recommendations are summarized and compared in Table 62.1. The range of 1–2 cm for 1.01–2.00-mm-thick melanoma has been interpreted by some to mean 2 cm is preferable given the lower local recurrence (LR) rate in the Intergroup trial versus the WHO trial (0.6% vs 4.5%) (5) [53], although conclusive evidence for 2 cm superiority cannot be assured by comparing separate RCTs with different LR definitions (Table 62.2). More recently, a 2-cm margin was retrospectively shown to have a significantly lower LR rate than 1 cm in this population (0.9% vs 3.6%, respectively) (2b) [54]. The 1 cm group was significantly skewed toward head and neck location, suggesting that the choice to reduce margin width is often based on anatomic constraints, and this choice may result in increased LR. Without examining 100% of the margin, a 1-cm margin may increase the risk of LR for this 1.01–2.00 mm category. A new RCT is ongoing and may help to differentiate the risk/benefit profile of 1-cm versus 2-cm margins in melanomas >1 mm deep, but the expected completion date is 2029 [55]. Although a recent meta-analysis attempted to define narrow margins as 1–2 cm and deemed the entire category unsafe when compared with wide margins (3–5 cm) (1b) [56], the study design and conclusions are flawed. Lumping 1-cm and 2-cm margin excisions together obscures whether the detrimental effect could be attributable to the 1 cm category alone. While 1 cm is often inadequate in thick melanomas without 100% margin control (2b) [22, 51, 57], a 2-cm margin is enough to excise nearly all melanomas regardless of thickness or location (2b) [58].

Deep margin boundary has not been subjected to RCT scrutiny and remains a topic of discussion among surgeons. Some advocate for inclusion of fascia, but preserving fascia has been compared and found to be safe even for thick melanomas (2b) [59]. Biologically, the possibility of in situ tumor extension down adnexal structures necessi-

Table 62.2 Advantages and disadvantages of excision techniques

	Advantages and disadvantages to the three key categories of surgery	
	Advantages	Disadvantages
MMS	Lowest marginal recurrence rate for all locations	Paucity of surgeons employing this method causes access difficulty
	Minimizes defect size	Immunostaining, if used, is technically demanding and usually requires specialized training
	May lead to simpler repair choice	Insurance coverage variable for truncal sites
	Low complication rate	
	Surgery nearly always completed in 1 day	
	Low complication rate	
	Patient goes home on surgery day knowing margin status	
SE	Lower marginal recurrence rate than WLE, due to rigorous peripheral margin assessment	Always requires two separate surgery days, possibly more, separated by at least 1–2 days
	Minimizes defect size	Higher complication rates reported with delayed closure
	May lead to simpler repair choice	Pathologist's experience and accuracy may not be known
		Requires coordination with a lab capable of rapidly producing difficult (square) or large numbers (radial) of slides
WLE	Surgery nearly always completed in 1 day	Patient must wait for margin status to be known
	Can be performed by any competent skin surgeon	Margin status subject to false-negative error due to inadequate margin sampling
		Pathologist's experience and accuracy may not be known
		Increased complication rate with larger margins
		NCCN margins not always possible due to anatomy
		Minimal evidence for head, neck, and acral sites and very high marginal recurrence in these sites

tates that the excision must fully remove them, but there exists no evidence to show that removing deep fat or fascia provides a benefit to the patient. In fact, recurrence rates of MMS performed on predominantly [24] or exclusively [22] head and neck melanomas have shown nearly identical low recurrence rates when excision is performed either to a level below adnexae [22] or down to fascia [24]. However, if the depth of the melanoma is unknown due to transection in the biopsy, inclusion of deep fat may be reasonable, especially in a WLE or SE specimen that will not be subjected to 100% margin assessment.

The narrow vs wide study arms of the key RCTs have not shown a difference in either local recurrence (between 2 and 3%) or overall survival, though the data is limited in that most excluded head, neck, and acral melanomas, which warrant further mention.Acral melanomas tend to recur more frequently after WLE or amputation, particularly when thicker than 1 mm, with one estimate of 6% (4) [60], though it may be even higher [61]. Head and neck melanomas recur at the margins between 9% and 13% of the time after WLE (1b-4) [42, 62, 63].

The concept of 100% margin control for cutaneous malignancies was pioneered by Dr. Frederic Mohs in the 1930s. The heart of its value lies in its ability to rely on a single physician serving simultaneously as surgeon and pathologist, 100% visualization of the entire three-dimensional surgical margin, and rapid frozen section pathology allowing, if needed, multiple stages of excision targeting residual tumor all in a single day. Since the first report of melanoma treated by Frederic Mohs (4) [64], a substantial body of literature has been generated describing its efficacy for both in situ and invasive disease. Marginal recurrence rates have been reported in a number of studies and generally range from 0% to 6% (2b-4) [21–24, 65, 66] with the most reliable estimates being between 0.2% and 0.7% [22, 24, 58]. Furthermore, all but one of these studies contained at least 80% head and neck melanomas [22–24, 65, 66], which currently only represent about 28% of cases overall (2c) [5] and are strongly associated with increased risk of local recurrence when WLE is performed [54].

Radiotherapy (RT) is rarely considered in treatment of primary melanomas, as melanoma is considered to be relatively radioresistant (4) [67]. Grenz rays or soft x-rays are most commonly used, and only thin invasive melanomas are treatable, since penetration is minimal beyond 1–2 mm. Radiotherapy has been used alone (4) [68] and in combination with surgery (4) [32, 68] for invasive melanoma, though it is more commonly reported as an option for in situ disease. Some studies combine in situ and invasive disease in their statistics (4) [33]. Series of only invasive melanomas are very small (<25 patients) (4) [32, 68, 69] and may include patients with as little as 1 month of follow-up [69], making it difficult to obtain reliable recurrence rates.

Desmoplastic melanomas are often deeply invasive and may recur locally more often than other subtypes, between 17% and 39% (4) [35, 70], but they are rare and more difficult to study. It is not clear whether this propensity for recurrence is due to marginal recurrence or local metastasis. Radiation has been reported as adjuvant therapy after WLE for desmoplastic melanoma (2b-4) [71, 72], but conclusions are difficult to draw due to small sample size. One retrospective cohort seemed to show improved local control in patients who received WLE and RT, though negative resection margin was even more important in preventing recurrence and no survival benefit was seen for irradiated patients [35]. The largest (277 patients) retrospective study showed improved local recurrence in patients who received RT after WLE when surgical margins were positive but no statistically significant benefit when margins were clear unless other high-risk features were present (2b) [73]. Since MMS evaluates 100% of the margin, RT after MMS would not be expected to provide any benefit, though recurrence rate in desmoplastic melanomas treated with MMS has not been defined in the literature.

Cryotherapy sought to exploit the sensitivity of melanocytes to cold thermal injury and had been considered in the past. Available evidence for invasive melanoma is limited to a single report of eight patients who had clinical resolution [36].

Comparative Effectiveness of Common Treatments

The melanoma patient's greatest concern is that the treatment minimizes the chance of relapse [56]. The necessity of wide margins beyond visible tumor to effect complete removal is a by-product of several limitations of traditional excision techniques. First, the margin of excision must be measured from the visible edge of the tumor that is often clinically poorly defined, particularly in sun-damaged skin and on the head and neck. Determination of the edges of any residual lesion after biopsy by visual inspection is inherently subjective, and subclinical, amelanotic extensions compromise the accuracy of tumor delineation between 33% and 62% of the time (2b) [74, 75]. Furthermore, cross-sectional histologic sections sample less than 1% of the true surgical margin [19]. The combination of frequent subclinical extension with subtotal histologic margin assessment will lead to higher recurrence rates for WLE than for excision techniques employing more meticulous histologic margin control; these rates rise with more narrow margins. Consequently, the WLE marginal recurrence rate lies between 2–3% for trunk and extremities and 9–13% for head and neck tumors, with acral tumors likely at least 6% and possibly higher.

Despite WLE's higher marginal recurrence rate, many authors still perpetuate the theory that undetected microsatellite metastases are removed by WLE in addition to the primary tumor, and that their removal provides a benefit to the patient. Although no prospectively controlled comparison exists for WLE vs MMS or staged excision, prospectively maintained databases after MMS treatment have shown that metastasis and long-term survival rates are equivalent or superior to WLE (2b) [21, 22, 58, 65]. Furthermore, WLE RCTs have consistently failed to show a metastasis or survival benefit from excising centimeters of normal skin beyond what NCCN currently recommends for WLE. These data suggest that even if microsatellites can be found in skin beyond the contiguous primary tumor, the theoretical inclusion of nearby metastases does not provide a meaningful, measurable recurrence or survival benefit to the patient. Furthermore, it is exceptionally unlikely to find microsatellites in thin melanomas. Microsatellites are detected in up to 37% in tumors >3 mm thick (2b) [76, 77] but are rare when Breslow depth is <3 mm and exceptionally unlikely under 1 mm (2b-4) [76–78].

WLE marginal recurrence rates do increase as margins are narrowed beyond NCCN guidelines, and the likely explanation is that the primary tumor is not completely removed. 1-cm margins for thick melanomas is inadequate to completely remove an acceptable percentage without 100% peripheral margin evaluation, particularly for 1.01–2-mm [54] and >2-mm melanomas [22, 51]. A logical extension of this data is that 2-cm margins should be advocated for WLE when the original biopsy is partial or when the melanoma is transected, since deeper melanoma cannot be excluded; alternatively, a form of margin-controlled excision may serve the patient better, as complete extirpation does not depend on a predetermined margin. Another notable concept is that of distance between tumor and margin pathologically. Although margin proximity is not universally reported to be a poor prognostic factor (4) [79], others have shown negative consequences such as nodal and distant recurrence associated with <8-mm pathologic margins (2b) [80]. Narrow margins seem to increase the likelihood of subclinical, undetected positive margins.

Both the surgeon and the patient usually desire the most effective therapy, and this is the most important aspect of margin-controlled excision versus its tissue-conserving nature. In addition to greater than 99% chance of complete removal, MMS alone provides additional and important benefits to the patient. MMS is performed in an outpatient setting using local anesthesia and therefore avoids the risks and cost associated with general anesthesia and often a hospital stay. The patient's tumor is completely removed in a single day in all but the rarest occasions, which avoids uncertainty and anxiety while waiting for pathology results. It also eliminates the need to return to repeat surgery in the case of positive margins. This benefit is magnified when compared to the other methods of staged excision, which require the patient to come back on separate days every time an additional stage is performed, as well as for reconstruction. In both MMS and staged exci-

sions, reconstruction is only performed once, whereas WLE is often reconstructed immediately while expecting clear margins, but again in cases with positive margins or clinical recurrence.

Individuals with head and neck melanomas are uniquely poised to benefit from both the tissue-conserving nature and highly reliable local control of margin-controlled excision. Confidence in a negative margin allows the surgeon to consider all available reconstructive techniques without fear of utilizing adjacent tissue containing residual melanoma. A further benefit is the potential for a smaller defect to close. A survey on head and neck melanomas showed patients were significantly more satisfied with primary closure and local flaps versus skin grafts, and smaller defects caused less emotional impairment (4) [81]. Eyelid and nose tumors had a greater emotional impact than other locations. Overall, the degree of appearance alteration was correlated with emotional impairment. Patient satisfaction should not take precedence over patient safety and the cure of melanoma, but given the ample evidence for safety with a smaller defect size and exceptionally low local recurrence with MMS and other forms of margin-controlled excision, these modalities may be preferable to WLE for head and neck melanomas.

Any type of narrow but 100% margin-controlled excision for acral melanoma (AM) has the potential to safely reduce disfigurement or amputation while preserving function, by avoiding the removal of normal skin needed to compensate for the incomplete margin control in WLE. Amputation rates for AM were 21% in one series [60] and reached 34% in another study (4) [82]. By contrast, amputation was never necessary in 20 invasive and 6 in situ primary melanomas treated with MMS in one report [21], neither was it required for the 3 invasive and 25 in situ lesions in another [24]. A recent study examining MMS exclusively on digital melanoma showed 8.2% local recurrence in 62 tumors (35 were invasive with 3 recurrences), which is higher than MMS studies for other locations but comparable to the AM WLE/amputation literature (2b) [83]. Only 2 patients out of the 57 originally referred for primary melanoma required amputation (3.5% amputation rate), which was performed due to recurrent deeply invasive disease. Five- and 10-year melanoma-specific survival rates for AM patients treated with MMS for invasive disease were 91.8% and 67.8%. Reconstruction options are profoundly affected by the size of the defect in this functionally critical area, though directly comparing WLE and MCE with respect to reconstruction is not possible from the current literature. For reconstruction in AM treated by WLE, free flaps were done for the majority of patients in the largest available series [60]. Primary digital melanomas treated with MMS were closed with full-thickness skin graft in more than 3/4 of the cases [83].

While no reports on invasive melanoma have focused exclusively on MMS for trunk and extremity locations, one series had a preponderance of these lesions and showed a lower recurrence rate than WLE [21], despite the lack of immunostaining to aid in melanocyte identification in this cohort. A newer study of in situ melanomas treated with MMS (using immunohistochemistry) showed a 0.5% local recurrence rate for trunk and extremity lesions (2b) [84]; this would be expected to apply to invasive disease, as the largest MMS study to date reported statistically equivalent rates of LR for in situ and invasive melanoma [58]. The increase in average surgical defect size for WLE over MMS on the trunk and proximal extremities may be less problematic than other sites, but other factors still deserve a place in the discussion. As noted above, marginal recurrence carries the risk of deeper invasion [39] and ongoing and increasing risk of metastasis; any increase in efficacy in complete removal of melanoma should be embraced. Given the expense of systemic therapies for melanoma when nodal/metastatic disease develops, vast cost savings might be realized by even a small decrement in metastases requiring systemic therapy, not to mention the potential value to the individual who would develop metastases from persistent melanoma.

Wide local excision without meticulous margin examination is still the most commonly performed surgical procedure for invasive melanoma, but the case for complete margin control and therefore more assured complete excision via Mohs surgery or staged excision is compelling.

Preoperative Evaluation

Biopsy is the first and most important step in the diagnosis and treatment of melanoma, as the decisions made for definitive treatment hinge on an adequate specimen. NCCN and AAD guidelines emphasize the need for complete removal whenever possible, whether it be by saucerization (deep shave), punch, or excisional biopsy [16, 18]. For dermatologists skilled in clinically evaluating pigmented lesions, deep-margin transection after saucerization technique is very rare (4) [85, 86]. Correctly estimating the depth of a melanocytic lesion before biopsy is important if a shave biopsy is chosen, to avoid deep-margin transection. Dermoscopy may be helpful in identifying areas of deeper invasion based on the presence of a blue-white veil, a consistent indicator of depth > 0.75 mm (4) [87]. In tumors that are too large for excisional biopsy, the deepest portion of the lesion should be sought for sampling; areas of ulceration or nodularity should be identified, and, again, dermoscopy may be a helpful adjunct, especially when a blue-white veil is present. During the office visit, a complete HPI and review of systems should be elicited, followed by a full skin exam to identify other concerning lesions (particularly skin metastases and synchronous melanoma), as well as palpation of the lymph node basin(s) draining the biopsy site. Clinically positive nodes identified prior to biopsy are important to document, as post-biopsy lymphadenopathy can be inflammatory in nature.

A great deal of prognostic information can be found in the biopsy report. Breslow depth is the single most important value to note, as it determines WLE margins and has the greatest prognostic impact [88]. Ulceration, and to a lesser extent mitotic rate, also foreshadows a poor prognosis and is factored into the most recent AJCC system (Table 62.2).

Prognostic information can be obtained through one or more ancillary tests. Genetic expression profile (GEP) is a newer technique that uses the genes expressed in a melanoma to identify those with a high risk for metastasis. High-risk lesions originally designated class 2 had 31% 5-year disease-free survival (DFS) versus low-risk class 1 lesions which had 97% DFS (1b) [89]. Since the original report, melanomas are now subdivided into classes 1A, 1B, 2A, and 2B with 5-year recurrence-free survival rates of 92%, 90%, 77%, and 48%, respectively.

Sentinel lymph node (SLN) biopsy can be done in conjunction with or after primary tumor removal for further staging information. NCCN guidelines recommend it be offered in melanomas thicker than 1 mm and recommend consideration when ulceration or mitoses ≥1 per mm^2 are found in those 0.76–1 mm in depth. However, some studies have shown that SLN biopsy has no effect on melanoma-specific or overall survival (1b) [90]. A full review of SLN and subsequent LND is beyond the scope of this chapter, but the primary effect of removing the at-risk nodal basin is the prevention of later recurrence in that nodal basin. Therapeutic benefits, such as reduced rates of distant metastasis and death, have not been confirmed. A potential indirect benefit of clarifying SLN status is the possibility of identifying those who may benefit from systemic therapy. Delineation of its use in early identification of those who may benefit from systemic therapy is under way but has not yet been completed. The use of this procedure as a requirement to obtain potentially beneficial treatments has been questioned (5) [91]. However, as GEP becomes more widely used and its data more refined, this test and other future less invasive tests also hold promise in accurately identifying high-risk melanomas which may benefit from systemic therapy, or as a screen for SLN biopsy. If metastases are suspected by history or exam, referral to the appropriate surgical or procedural service for tissue diagnosis is indicated and appropriate systemic therapy instituted by a medical oncologist. Clinical trial participation should be offered whenever appropriate.

Impact of Patient Preference

Patients who are given complete informed consent may have a variety of reasons for choosing among procedures for melanoma, but most can be summarized in a few categories. The single most distressing aspect of melanoma is the specter of recurrence and ultimately metastasis and

death [56]. Therefore, efficacy will commonly be a key factor in the decision. As described above, MMS has the lowest local recurrence rate of any procedure, and other forms of 100% margin-controlled excision (MCE) can be expected to provide enhanced therapeutic benefit as well.

Surgical risk and morbidity is the other major category most patients consider in choosing a treatment, and the difference between the surgical options varies by body site. Of the surgical options, MMS and other MCE techniques offer the potential for the smallest possible wound. However, delayed reconstruction in MCE is less convenient for the patient and can increase surgical complications such as infection and dehiscence, particularly when the repair is completed more than 1 day after initial excision (3b) [92]. WLE wounds are usually larger than Mohs defects as well as MCE when narrow margins are used as the starting point. Wider margins may require the surgeon to choose between compromising critical anatomic structures or excising smaller than recommended margins which will increase the risk of incomplete removal. Furthermore, the larger defects are more likely to require closure techniques that can involve hospitalization, incur higher cost, carry higher complication rates, and increase risk of disfigurement or dysfunction.

Beyond surgical complications, aesthetic and functional complications are equally worthy of consideration, particularly on head and neck, hands and feet, and where there are specific functional concerns that may be mitigated with more conservative excision. Appearance is a true function of the face, as it allows for recognition of one's identity. This facial function has been ranked by patients as more important than the sense of smell or facial expression (2b) [93]. Congruently, patients were significantly more satisfied with primary closure and local flaps versus skin grafts, and smaller defects caused less emotional impairment [81].

Convenience will play into many patients' decision, though not as importantly as efficacy and risk. Issues to consider include time away from a job or other responsibility, the potential for hospitalization, wound care time and supplies, and the potential for a friend or family member to be needed for transportation to and from the treatment facility. Many studies on radiotherapy use anywhere from 5 to 12 treatments, though up to 30 can be used, making it the most inconvenient option in terms of patient visits. WLE and MMS are typically accomplished in a single day as an outpatient surgery, and other forms of MCE require separate visits for excision and closure. Some WLEs are performed under general anesthesia and occasionally involve hospital stays.

Overall, when patients are offered a procedure that evaluates 100% of the surgical margin and provides the lowest recurrence rate with the smallest surgical wound which is closed on the same day, the authors observe that they usually elect Mohs surgery.

Typical Treatment Plan: Case Narrative

Mr. C is a 68-year-old male with a biopsy-proven 2.8 mm deep non-ulcerated lentigo maligna melanoma of the left medial cheek; the deep margin is negative but lateral margin is positive. He presented for a consult, and a discussion was undertaken to educate him about the various excisional procedures to remove the tumor in its entirety. A 2 cm margin was drawn around the 2.4 × 2.2 cm clinical tumor to show the recommended margins for WLE. The resulting 6.4 × 6.2 cm proposed excision involved part of his nasal ala and upper cutaneous lip. Local recurrence rates were disclosed at roughly 10% for WLE on the head and neck, and less than 1% for Mohs. Removal and reconstruction in a single operative session was discussed for WLE versus potentially multiple stages and repair later in the day for MMS. A delay of 5 days was anticipated for the pathology report after WLE, while the clearance of the tumor was expected to be pathologically confirmed that day with MMS. Due to its ability to achieve 100% margin evaluation with a smaller defect and be repaired on the same day, he chose Mohs surgery. He decided against a SLN biopsy but requested his biopsy specimen undergo GEP for further prognostication. He was educated on self-monitoring his skin for new or changing lesions, as well as periodic lymph node self-examination. He was instructed to return for

examination if a new or changing lesion was identified on his monthly self-exam; likewise, he will return for any new palpable changes in his lymph node exam. Rigorous sun protection was advised. There was no suspicion for nodal or metastatic disease discovered by history or exam. Surgery was scheduled for the next week.

On the day of surgery, visible tumor extent was marked, along with a 6-mm margin of normal-appearing tissue. Local anesthetic was infiltrated into the operative area, and the specimen was excised down to the level of the deep subcutaneous tissue and then inked for mapping. The area was bandaged, and he returned to the waiting room while H&E and MART-1 staining were performed on the frozen sections. One area of residual melanoma in situ was identified at the 12 o'clock position, and a subsequent 3-mm-wide margin of tissue was taken around the positive margin. This second stage was histologically negative using the same stains, and the patient was brought into the room for reconstruction. The defect measured 3.8 × 3.6 cm and primary closure was chosen, oriented along the nasofacial sulcus and melolabial fold. The patient was then bandaged and sent home with instructions for care. Acetaminophen and, if necessary, ibuprofen were recommended for pain control (1b) [94]. The wound was healing well at his 1-week wound check, and regular follow-up skin and node exam was scheduled for 3 months.

Staged excision with en face permanent sections would have been an appropriate third surgical option in this patient. A surgeon may provide staged excision as an option, obviating the need to interpret the pathology oneself if impractical or not preferred. Its virtue over WLE with immediate closure is that more complete histologic clearance is obtained, and a smaller wound is often achieved; however, it requires sending the patient home with an open surgical wound (except in the original description of the square technique, in which residual melanoma at the biopsy site would be allowed to remain until reconstruction). Furthermore, it requires at least one additional surgery date for reconstruction or more if margins prove to be positive. These issues may limit surgeons' willingness to adopt the technique and patients' acceptance of it. However, it should be considered when geography limits access to a Mohs surgeon trained to operate on melanoma.

Safety

Excisional surgery on the skin and subcutaneous tissue can be done with a high degree of safety, but the exact nature and incidence of complications depend heavily on the body site, the type of anesthesia, and the width and depth of the excision, as well as the planned repair. The excision margin RCTs focus on treatment results and many reported no information on complications or how they are affected by margin width. One useful finding from the Intergroup trial (trunk and proximal extremity lesions) was that 11% of defects required skin grafting when a 2-cm margin was removed [41]. Hospital stay was longer when skin grafts were used, and delayed ambulation was implicated in the extended stays. For those who had no LND, patients were hospitalized for an average of 3 days. Wound infections occurred in 5.4% and dehiscence in 4.6% in the 2- cm margin cohort. The UK trial (3 cm vs 1 cm, trunk and limbs excluding palms and soles) reported that 66% of patients in the 3 cm cohort had an inpatient procedure under general anesthesia vs 32% of those in the 1 cm cohort [50]. Complications were reported as a lump sum, with 13.9% vs 7.8% favoring 1-cm margins. The 2011 Swedish trial (trunk and extremity excluding hands and feet) reported primary closure was used in 69% of those with 2-cm margins, while split-thickness skin grafts were used in 12% and flaps in 4% [52]. A quality assurance study for melanoma found that primary closures and flaps were rarely complicated, while 5.9% of skin grafts had more than 20% area of failure, but surgical site was not described (2b) [95]. Grafts are the repair choice associated with the most morbidity in melanoma surgery, and body site affects their success; grafts on the lower limb have failure rates as high as 33% (4) [96], and negative influences include vascular disease, increased body mass index, and immunosuppressant use. All findings were favorable to the smaller margin of excision.

WLE complication data for other sites such as head, neck, and acral sites are less reliably assem-

bled from the melanoma literature, as few RCTs included these sites and none have reported site-specific complication rates. Retrospective studies are complicated by the possibility that some complications were managed by other physicians, or that they were not reported to any physician. A review of desmoplastic melanomas, 62% of which were head and neck, reported an overall 16% complication rate, which most commonly included infection or delayed healing, hematoma requiring evacuation and ligation, and microstomia requiring surgical correction [35]. Regarding repair type, patients with head and neck melanoma treated with NCCN margins will most commonly require a local flap [63]. WLE for acral melanoma necessitates amputation in over a fifth of cases [60], with thicker melanomas treated with amputation more often [82], and repairs are often highly complex with more than half requiring a free flap [60].

The literature describing MMS for melanoma primarily emphasizes efficacy, but many of the same types of complications would be expected regardless of the excisional type, such as infection, bleeding, and tissue distortion. Some WLE literature compares complication and repair statistics between different margin widths, and smaller defect size is universally associated with better outcomes and simpler repairs [41, 50, 52, 63]. With a mean final MMS margin of 7.2 mm in one large report containing both in situ and invasive disease [58], excisional trauma and repair complexity are unquestionably reduced. Digital melanomas treated with MMS had a markedly simpler repair and did not require amputation except in case of two patients with 5-mm-thick recurrent lesions [83]. Since MMS is performed as an outpatient surgery under local anesthesia, eliminating general anesthesia and hospitalization provides a benefit to the subset of patients who otherwise would be subject to these risks. One prospective MMS cohort showed a 2.6% overall complication rate, with bleeding being most common. A significant association was seen between complications and tumor size, postoperative defect size, older age, and choice of repair other than linear closure (2b) [97]. A British review of mostly basal cell carcinomas treated by MMS showed <1% overall complication rate and none were serious (2b) [98]. Further study of surgical complication rates in melanoma treated by MMS would be useful to aid in comparing to WLE, as melanoma defects are often deeper.

Staged excision (SE) techniques add an additional element to the milieu of issues affecting safety. Potentially more narrow tissue excision and therefore lower repair complexity, as well as outpatient setting compare favorably to WLE; however, delayed repair may raise the complication rate as discussed earlier. One series of 51 facial melanomas (9 of which were invasive) treated with SE had a 9.8% overall complication rate, which included partial loss of flap or graft tissue, as well as hypertrophic scars (4) [99]. No functional complications were found, which highlights the importance of tissue-sparing technique on the head and neck. Flaps were used in 44% and grafts in 36%. According to a large study on delayed reconstructions after MMS (primarily in non-melanoma skin cancer), the elapsed time between initial excision and repair correlates with complication risk, with 3 or more days being worse than 1–2 days [92].

Complications in radiotherapy for melanoma are 21% overall according to one study, with 8% being serious (osteoradionecrosis, nonhealing scalp wounds requiring surgical revision, and failure of skin graft) [35]. Less serious issues include hypothyroidism, delayed wound healing, edema, xerostomia, and keratoconjunctivitis sicca. Unlike surgical complications, many radiotherapy complications take months to years to develop, with the median time to development in this study being 19 months. Another report highlights that all patients experience an erosive reaction in the first weeks after treatment [32].

Postoperative Care and Follow-Up

Monitoring patients after melanoma treatment is a complex topic, and little evidence exists to confirm the validity of commonly used schedules. Many sets of guidelines have been presented by various groups, and though this has been succinctly reviewed [100], further research may lead to more uniformity and agreement in these guidelines (Table 62.3). Two categories of monitoring

Table 62.3 Summary of follow-up recommendations

NCCN and AAD guideline summary for following patients with melanoma		
Shared recommendations	NCCN-specific	AAD-specific
At least yearly follow-up (f/u) for life	Stage 0 f/u with physician yearly	Stage 0 f/u every 6-12 months for 1-2 years
3–12-month f/u interval based on clinical details and clinician judgment	Stage IA-IIA f/u every 6–12 months for 5 y	Stage IA-IIA f/u every 6-12 months for 2-5 years
Patients should examine skin and lymph nodes at regular interval	Stage IIB-IV f/u every 3–6 months for 2 y, then every 3–12 months for the next 3 y	Stage IIB-IV f/u every 3-6 for first 2 years, no more than 6 month interval between years 2-5
Asymptomatic stages 0–IIA need no blood work or imaging	Stage IIB-IV without evidence of disease: consider imaging every 3–12 months for 5 years	No baseline studies for asymptomatic stages 0-II
Nodal ultrasound may be considered in certain circumstances	CT chest/abdomen/pelvis with contrast and MRI brain with contrast, and/or PET/CT, are preferred for screening	Lab and imaging only recommended to evaluate signs and symptoms of metastasis

should be considered separately, patient-directed and physician-directed. Patients should be remembered as the most likely entity to detect a recurrence in thicker melanomas (4) [60, 101], and patient education is vital to ensuring the timely identification of disease. The authors routinely instruct patients to perform monthly full-body self-examinations and alert their dermatologist to any new or changing skin lesion. If they have invasive melanoma, they are instructed to examine the regional lymph node basin(s) on at least a monthly basis. Physician-directed surveillance should involve dermatologic history and physical (H&P). The role of imaging is currently not clearly defined [18], but appropriate imaging should be performed for investigating symptoms concerning for metastasis. Imaging asymptomatic patients is controversial and not clearly supported by current evidence. H&P should be performed at least annually for life for two key reasons: the risk for latent disease to manifest as a clinical metastasis never completely disappears, and a melanoma diagnosis identifies a patient as having a much higher risk (probably 8–10% [2b]) [102] of a second melanoma. More frequent visits may be reasonable for invasive melanoma within the first 5 years after diagnosis, since most recurrences occur within this range. Imaging in lower-risk melanoma patients is uniformly discouraged unless there is a specific finding identified on H&P, and imaging higher-risk but asymptomatic patients is controversial. Preferred modalities vary by site, but ultrasonography is the best imaging modality for lymph node staging and surveillance, and PET/CT excels for distant metastasis (2a) [103]. There is no specific blood test for detecting persistent or recurrent melanoma, though surrogate tests include S100β and LDH; neither are uniformly recommended for either staging or surveillance, and they do not offer a reliable opportunity to improve survival.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE).

Findings	GRADE score: quality of evidence
When WLE based on visual inspection is used, NCCN guidelines should be followed	A
Treatment safety is first and foremost related to complete removal of melanoma	A
More thorough tissue exam leads to lower local recurrence	B
When 100% margin control is used, cure rates are less dependent on margin width	B
Treatment options differ enough that complete informed consent is needed	D

Self-Assessment Questions

1. Recommendations for 1- and 2-cm margins of excision for invasive melanoma are:
   (a) Based on multiple randomized controlled trials
   (b) Based on the Breslow's Thickness of the melanoma
   (c) Based on studies primarily of MM of the trunk and proximal extremities
   (d) Based on RCTs, including the head, neck, extremities, and trunk
   (e) A, B, and C

2. Which of the following techniques are based primarily on visual ID of the melanoma margin:
   (a) Wide local excision
   (b) Mohs micrographic surgery
   (c) Serial excision with curvilinear margins and en face histology sections
   (d) Serial excision with polygonal margins and en face sections (square technique)
   (e) Serial excision with radial sections

3. Components of informed consent include:
   (a) Review of treatment options
   (b) Review of risks
   (c) Review of benefits
   (d) Review of alternative treatments
   (e) All of the above

4. Which of the following is false?
   (a) Recurrence rates decrease with increasing margins, up to 2 cm
   (b) Excision of clinically inapparent satellite metastases likely leads to improved overall survival
   (c) Removing less than recommended margins in WLE results in increased recurrence
   (d) Wider margins of excision result in improved overall survival
   (e) NCCN guidelines for follow-up are based on low-level evidence

5. Which of the following is true?
   (a) LDH should be obtained as surveillance for metastasis in high-risk melanomas
   (b) Imaging plays an important role in discovering recurrence in asymptomatic patients
   (c) A patient with a thin melanoma has a higher risk of a future second primary melanoma than a recurrence from their first primary
   (d) Patients should not be relied upon to perform self-examination of their skin and lymph nodes
   (e) Yearly follow-up visits can be ended after 10 years, since recurrence is exceptionally rare beyond this time

Correct Answers

1. e: Recommendations are based on RCT evidence and vary depending on the Breslow's thickness, but most of the RCTs excluded head and neck locations. In addition, most excluded some or all of the hand/foot.
2. a: WLE is the only method that involves histologic processing that is not standardized and does not always rigorously study the margin. Successful extirpation of the tumor is therefore predicated on using a large clinical margin beyond the visible tumor, to account for subclinical spread and minimize the chance of tumor extending beyond the sparsely sampled margin.
3. e: Informed consent is vital to procedural medical practice yet is often hastily or incompletely performed. Physicians should make an effort to present the evidence for and against each option without injecting opinions to influence the patient's decision. Each patient has their own set of values and thought processes and must be allowed to choose their treatment based on an honest summary of their available options.
4. b: There is no evidence for the benefit of excision beyond removing the primary contiguous tumor; undetected satellite foci, if present, are indicative of metastatic behavior. No evidence suggests these are limited only to the NCCN margin distance from the primary tumor.
5. c: Second primary melanoma occurs in approximately 10% of melanoma patients, which is far higher than the risk of recurrence in thin melanoma. LDH (or any blood test) and imaging are not recommended in asymptomatic patients. Patients should be educated on self-examination of their skin and lymph nodes, as they frequently detect new primary melanomas and recurrences first. Yearly follow-up visits are recommended for life, as recurrence risk never drops to zero.

Prevention and Treatment of Procedure-Associated Infection

63

James V. Twede and Christian L. Baum

Abstract

Procedure-associated and surgical site infections (SSI) in dermatology are rare; however, it is prudent to understand their prevention and treatment. SSI has been variably defined, which may contribute to the broad range of results from studies aimed at quantifying the risk of SSI. The Centers for Disease Control and Prevention (CDC) defines an SSI as a wound that suppurates within 30 days of the procedure, even in the absence of a positive culture (Horan TC, Gaynes RP, Martone WJ, Jarvis WR, Emori TG. Am J Infect Control 20(5):271–4, 1992). The application of this definition is particularly challenging for dermatologic procedures since wounds may become colonized with organisms, such as *Staphylococcus aureus* (*S. aureus*), and suture granulomas may present with a sterile suppurative exudate within 30 days of the procedure. In this situation, good clinical judgment and the quantity of bacteria (>10^5) (Robson MC, Heggers JP. J Surg Oncol 2(4):379–83, 1970) in the wound can be helpful in differentiating colonization versus a true SSI.

Introduction

Procedure-associated and surgical site infections (SSI) in dermatology are rare; however, it is prudent to understand their prevention and treatment. SSI has been variably defined, which may contribute to the broad range of results from studies aimed at quantifying the risk of SSI. The Centers for Disease Control and Prevention (CDC) defines an SSI as a wound that suppurates within 30 days of the procedure, even in the absence of a positive culture [1]. The application of this definition is particularly challenging for dermatologic procedures since wounds may become colonized with organisms, such as *Staphylococcus aureus* (*S. aureus*), and suture granulomas may present with a sterile suppurative exudate within 30 days of the procedure. In this situation, good clinical judgment and the quantity of bacteria (>10^5) [2] in the wound can be helpful in differentiating colonization versus a true SSI.

Dermatologic surgery has historically low infection rates ranging from <1% to 4% [3] (2b) [4] (2b), with differing rates based on body site and the specific procedure performed [5] (2b). SSI can result in significant patient morbidity,

medical costs, lost time from work, flap or graft failure, and a poor cosmetic result. Most current approaches to assessment, prevention, and treatment of SSI are published in the general surgery and surgical subspecialty literature. However, over the past few decades, there has been a renewed focus in dermatology on SSI risk and mitigation. In fact, the bulk of the data related to dermatology procedure-associated infections is derived from excisional surgery and Mohs micrographic surgery (MMS). In an effort to evaluate surgical complications, the American College of Mohs Surgery has created a registry specifically analyzing complications related to MMS. SSI is one important item being assessed in the registry, which may be able to define practices that ameliorate or heighten the risk of SSI [6]. The purpose of this chapter is to systematically review the evidence related to the variables that influence procedure-associated and SSI in dermatology.

Risk Factors for Surgical Site Infection

Multiple variables such as wound quality and size, type of procedure performed, and patient demographics may influence SSI risk. Surgical sites with ulceration, purulence, and/or inflammation have a higher risk of postoperative wound infection due to an increased bacterial load and presence of pathogenic bacteria [7] (2b) [8]. Excision of cutaneous malignancies such as basal cell carcinoma (BCC) and squamous cell carcinoma (SCC) was identified in one report as independent risk factors for wound infection when compared to the excision of benign lesions such as atypical nevi [9] (2b). Another study demonstrated that individuals undergoing MMS for noninvasive malignant melanoma also had an increased risk of SSI compared to those who had a BCC treated with excision [10] (2b). These particular risk factors may have less to do with the actual tumor than the nature of the procedure. When the time for excision of benign and malignant tumors extended beyond 24 min, there was a significantly higher risk for infection compared to procedures that took less than 24 min [11] (2b). Likewise, this may be why MMS, with its longer duration and intermittent wound care, puts the surgical site at risk for infection compared to a standard elliptical excision [5] (2b). Lastly, the size of the surgical defect tends to be larger with malignant neoplasms than with benign neoplasms, which would increase the amount of time spent on excision and repair.

SSI rates differ significantly from one area of the body to another and the type of procedure performed. An analysis of 5,091 dermatologic procedures revealed rates of infection of 0.73% for curettage, 2.94% for skin flaps, 0.54% for elliptical excisions, 8.7% for skin grafts, and 8.57% for wedge excisions [5] (2b). A subanalysis of these procedures that determined the size of the wound also demonstrated implications for SSI with a 2.24% risk for wounds <11 mm and an 11.6% risk in wounds >11 mm when located below the knee ($p = 0.0001$). On the whole, sites below the knee had a 6.92% infection rate. The groin had a similar high rate of infection at 10%.

Studies assessing the experience of the surgeon and risk for SSI have shown mixed results. One study showed the overall risk for mild and severe infections performed by experienced surgeons was lower than procedures performed by less experienced surgeons (0.6% vs. 3.1%), a finding that may be the result of an experienced surgeon's ability to delicately handle tissue and the speed with which they are able to complete a surgical procedure [7] (2b). Another study evaluating surgical experience showed no difference in adverse events such as bleeding and impaired wound healing between experienced Mohs surgeons and those who had recently completed fellowship [12] (2b).

A patient's age has been shown to influence SSI risk. One study demonstrated infection risk in dermatologic surgery increased with every decade of life and ranged from 2.9% in patients aged less than 40 years to 13.6% in patients aged over 70 years [5] (2b). Another study showed that all patients with severe infections after primarily scalpel-based dermatologic surgery were over the age of 70 [7] (2b). A multicenter prospective cohort study evaluating adverse events

relating to MMS showed the mean age for SSI was 70.8 years [12] (2b). It is well known the aging process leads to a decline in the innate and adaptive immune system [13], and this may influence the increased rate of infection in the elderly.

Patient gender does not appear to influence SSI rate. One prospective study showed no difference in rates between men and women undergoing a variety of scalpel-based dermatologic procedures [5] (2b). To date, there are no data to suggest a link between BMI or ethnicity and dermatology procedure-related infections.

Severity and Duration of Infectious Complications

The vast majority of dermatology procedure-associated infections are not associated with long-term sequelae or mortality. A large multicenter prospective cohort study was performed to quantify adverse events associated with MMS [12] (2b). It showed an overall adverse event rate of 0.72% with SSI reported as the most common event at 61.1% of all complications. Infectious complications that resulted in hospitalization included one case for infection and partial necrosis and two others with cultures positive for methicillin-resistant *S. aureus* (MRSA). None of these patients showed any other temporally related vascular or pulmonary complications, and no deaths were reported.

A multicenter study was conducted analyzing minor and major complications associated with MMS over a 4-week period [14] (2b). Infection was the primary complication with a 0.9% incidence (16 of 1709 patients). There were no deaths during the treatment or in the postoperative period.

A study assessing the severity of infections in primarily scalpel-based dermatologic surgery showed an infection rate of 1.47% (75 out of 5,091 lesions) [5] (2b). Two of the individuals with infected lesions developed serious infections (cellulitis); the third required hospitalization, wound debridement, and intravenous antibiotics.

In another study, the safety of MMS in office-based and hospital-based settings was compared [15] (2c). A total of 3937 cases of MMS were performed with 2397 at an outpatient dermatology office and 1540 treated in a hospital setting. There were no significant differences in patient demographics, tumor types, and repairs. When evaluating the major complications of the two settings, there were no deaths, cardiac or pulmonary complications, deep wound infections, sepsis, or distant infections as a result of the cutaneous surgery.

Isolated, rare cases with severe adverse infectious complications have been reported following dermatologic surgery. A case of toxic shock syndrome occurred after minor dermatologic surgical excision that resulted in multiorgan failure [16]. In another instance, necrotizing fasciitis occurred after excision of malignant melanoma and eventuated into multiorgan failure and death [17].

Laboratory Evaluation

Laboratory values as predictors of SSI are not well defined, but some values may be helpful when stratifying a patient's SSI risk. In a prospective observational cohort study of elderly patients, undergoing a variety of general and orthopedic surgeries, lab values such as hemoglobin, hematocrit, CRP, glucose, AST, ALT, and creatinine showed no influence on SSI risk [18] (2b). Likewise, elderly patients undergoing orthopedic or general surgical procedures often show a blunted febrile response to SSI [19] (2c), making absence of fever an unreliable factor in determining presence or absence of infection.

Serum prealbumin levels as a predictor of complete wound healing has been demonstrated in a number of studies [20] [21] (2b). One particular study assessing skin graft placement in burn patients suggested that prealbumin levels may be a sensitive predictor of successful implantation [22] (3b). Complete graft healing was noted in 93.8% in those with normal prealbumin levels compared to 44.4% in those with low levels. Graft sites in those with normal prealbumin levels showed a preponderance of the less virulent *Pseudomonas aeruginosa* (*P. aeruginosa*) and a relative absence of the more virulent staph-

ylococcus and streptococcus organisms, which may be the reason for enhanced graft survival. One review in the dermatology literature suggested skin infection was one of the most common reasons for skin graft failure [23]. The above evidence suggests low prealbumin levels that may be seen in malnourished and/or elderly patients may be a risk factor for wound colonization with virulent bacterial microorganisms and potential skin graft failure. However, there is currently no data to directly associate prealbumin levels with dermatologic SSI risk.

Patient Behavioral and Medical Risk Factors

Anticoagulants

The use of anticoagulants has increased dramatically over recent decades, and the continuation of these medications for dermatologic surgery is the accepted standard of care [24] (2b). A prospective study evaluating the SSI rate of individuals taking warfarin or aspirin demonstrated a SSI rate of 1.85% and 1.1%, respectively, in patients undergoing a variety of excisional dermatologic procedures [5] (2b). These percentages are in line with the historical infection rate of <4% for dermatologic surgery, but the study had no control group for comparison. Another study examined the effects of antiplatelet and anticoagulant medications on complications related to dermatologic surgery showing a risk of infection of 1.3%, which is not different from the accepted SSI rates for dermatologic surgery [25] (2b). Ultimately, there is no evidence to suggest the use of anticoagulants increases the risk of dermatologic SSI.

Diabetes

The prevalence of diabetes has risen dramatically, and it is currently estimated that the prevalence among Americans is 12.1% [26]. A 5-year prospective observational study evaluating complications after cutaneous surgery in those with known diabetes showed a statistically significant greater risk for SSI in diabetics when compared to those without a history of diabetes (4.2% vs. 2.0%) [27] (2b). Of note, the study subjects were diagnosed with diabetes by a referring provider and the investigators did not quantify the severity of diabetes. There was also no analysis relating HbgA1c levels to rates or severity of SSI. An additional prospective study evaluating patients undergoing aesthetic body surgery demonstrated over double the infectious complications in diabetics compared to those without the condition [28] (2b). Abdominoplasty had the highest rate at 6.1% in diabetic patients versus 3.0% of controls.

Tobacco Use

It is well known that smoking leads to increased risks of myocardial infarction, stroke, deep vein thrombosis, and pneumonia in those undergoing major surgery [29] (2b). A review and meta-analysis assessing the clinical impact of smoking and smoking cessation on wound healing and infection in general surgery demonstrated smoking cessation intervention significantly reduced SSI [30] (1a). Smokers were shown to have a twofold increased risk for infection compared to nonsmokers. Another study from the general surgery literature demonstrated a SSI rate of 12% in smokers compared to 2% in individuals who had never smoked. Other studies have shown no statistical difference, but these randomized controlled trials (RCTs) may have been underpowered [31] (2b) [32], (1b).

Presently in the dermatologic literature, there are conflicting conclusions regarding the impact of smoking on SSI risk. A prospective study evaluating SSI risk between smokers and nonsmokers undergoing a variety of excisional dermatologic surgical procedures showed no statistical difference (2.1% vs. 1.9%) in the risk of SSI [33] (2b). Another study assessing wound complications after biopsies performed on an inpatient dermatology service showed a significant risk for infection in current smokers compared to nonsmokers [34] (4). However, the individuals biopsied suffered from a multitude of medical problems and

the overall infection rate for all biopsies was 27%, which far exceeds other quoted values in dermatologic surgery and therefore may not be applicable to a typical outpatient dermatologic surgery setting. Another study assessing risk factors and outcomes after MMS demonstrated a twofold increase in adverse surgical events (bleeding and wound dehiscence/necrosis) in former smokers compared to current smokers, but there was no association between these risk factors and SSI [12] (2b).

Preoperative Patient Interventions

Preoperative Patient Antisepsis

Numerous preoperative antiseptic interventions have been studied with the purpose of lowering SSI rates. Preoperative bathing or showering with chlorhexidine scrub has long been implemented as a way to reduce bacterial colonization prior to a variety of primarily general, orthopedic, and vascular surgical procedures. A fifth update of a Cochrane review evaluating this practice included seven different trials [35] (1a). It concluded that bathing with chlorhexidine compared to placebo did not significantly reduce SSI and that regular bar soap when compared to chlorhexidine showed no difference in SSI risk. However, one larger study in the review did show a statistically significant difference in favor of bathing with chlorhexidine versus no bathing.

One systemic review of patients undergoing minor skin excision surgery in the primary care setting evaluated the SSI risk for patients who showered or bathed within 48 h of surgery (early bathing) or waited for 48 h after surgery (delayed bathing) [36] (1a). There was no statistical difference in infection rate between the groups with 8.5% in the early bathing group and 8.8% in the delayed group.

There have been no RCTs assessing benzoyl peroxide gel as a topical agent to prevent SSI. However, one prospective study of 673 patients showed that preoperative use of 10% benzoyl peroxide gel may help to decrease SSI. The study compared the application of the gel to the centrofacial area for 7 days to no application prior to dermatologic excisional procedures. The results showed a statistically significant decrease in SSI rate in those using the gel (1.93%) compared to those who did not (3.24%) [37] (2b).

Bleach bathes have often been used in atopic dermatitis to reduce *S. aureus* colonization and may have relevance to those undergoing dermatologic procedures [38] (1b). A retrospective cohort study of children who underwent incision and drainage (I&D) for methicillin-resistant *S. aureus* (MRSA) abscesses, followed by a decolonization procedure with bleach baths and application of intranasal mupirocin ointment, found no statistical difference between individuals undergoing decolonization and those who did not in regard to need for repeat I&D or presence of repeat MRSA-positive cultures [39] (2b). No studies have been performed to date evaluating the use of bleach bathes and SSI risk.

The use of intranasal mupirocin has been advocated as a preventive measure due to its ability to decrease endogenous sources of *S. aureus* [40] (1b). *S. aureus* carriage of the anterior nares is present in 37% of the general population at any given moment [41]. The specific strain of *S. aureus* associated with SSI can be matched through molecular typing with an organism that colonizes a patient's nares 80–85% of the time [42] (1b).

A prospective randomized study evaluated preoperative screening for nasal bacterial colonization and its influence on SSI in patients undergoing MMS [40] (1b). Those with nasal cultures showing *S. aureus* carriage were randomized to receive no treatment or to undergo a decolonization protocol consisting of intranasal application of 2% mupirocin ointment and once daily full body wash with 4% chlorhexidine for 5 days. They reported an infection rate of 4% in carriers who underwent the decolonization protocol and an 11% rate in carriers who did not undergo decolonization. The relative risk of SSI in untreated carriers versus noncarriers was statistically significant. Despite these results, the authors admit that the cost of the decolonization procedure may be a limiting factor when implementing these measures.

A Cochrane review was performed to determine whether mupirocin nasal ointment would reduce *S. aureus* infection rates in individuals with identified *S. aureus* nasal carriage undergoing a variety of general, orthopedic, gynecological, and neurosurgical surgeries and dialysis [43] (1a). The review included nine RCTs and showed a significant reduction in *S. aureus*-associated infections in those who used intranasal mupirocin. When subgroup analysis was performed examining SSI caused by *S. aureus,* the effect disappeared, but the authors conclude this may have been the result of inadequate power.

Given the relatively high cost and inconvenience of intranasal mupirocin, alternative treatments have been sought to treat intranasal *S. aureus* colonization. A prospective, open-label, randomized trial of twice-daily application of intranasal 2% mupirocin ointment ($130 USD) for 5 days prior to surgery compared with two 30-s intranasal applications of povidone iodine (PI) 5% solution ($20 USD) within 2 h of surgical incision was conducted in patients undergoing arthroplasty or spinal fusion [44] (1b). In the intent-to-treat analysis, there was no statistical difference in the *S. aureus* deep SSI rate in the mupirocin group (0.6/100) compared to the PI group (0.1/100). Patient tolerability favored intranasal PI over mupirocin with 3.6% of patients in the PI group rating the experience as unpleasant compared to 38% of patients using mupirocin.

Attire

Much of the evidence for surgical attire is derived from the general surgery and other surgical subspecialty literature. Applying and customizing the available evidence on surgical attire may help to facilitate new and innovative methods in dermatologic surgery making for more efficient processes and improved patient outcomes.

Surgical Face Masks

Surgical face masks have been utilized for over 100 years and have become an intuitive standard amongst most surgical specialties [45]; however, their benefit on decreasing SSI rate is unclear.

A 2016 Cochrane review of three trials demonstrated no significant difference in infection rates between those wearing and those not wearing surgical face masks [46] (1a) for a variety of general, orthopedic, and gynecological surgical procedures.

Despite the lack of conclusive findings that surgical face masks decrease SSI rate, they may continue to serve the purpose of protecting the surgeon from macroscopic facial contamination [47]. A study from the vascular surgery literature showed that 45% of all cases showed blood or body fluid on the protective eye lens of the operator [48] (2b). Additionally, laparoscopic cases showed a 50% blood or body fluid splash on protective lenses, which presumably would have fewer bodily fluid splashes than open surgical cases.

Ultimately, there is no evidence that face masks influence SSI rate. Moreover, there are no well-designed studies demonstrating that face masks protect the surgeon from aerosolized or splash droplet-related infectious diseases. However, given the minor inconvenience, surgical face masks serve the purpose of promoting surgical and sterile discipline and protect the wearer from body fluid exposures.

Head and Feet Covers

Surgical head coverings presumably function to prevent hair fomite contamination of a surgical field. A study of 508 subjects in an emergency department setting evaluating infection rate for uncomplicated sutured wounds showed no difference in infection rates between one group wearing both a head cap and surgery mask and another group wearing no mask nor cap [49] (2b). A 2011 dermatology review of surgical attire concluded surgical head coverings were unlikely to make a difference in SSI risk [50] (2a).

The use of surgical gowns has shown conflicting results in regard to bacterial contamination and SSI, and their utility in dermatologic surgery is uncertain [50].

The use of dedicated footwear (theater shoes) has been advocated by some to minimize bacterial contamination of surgical floors. It is known that outdoor shoes harbor significantly more bacteria compared to theater shoes [51] (2b), but there are no studies to suggest that use of theater shoes decrease the risk for SSI.

The use of shoe covers to prevent bacterial contamination is controversial. One study found no difference in the bacterial contamination of a surgical floor when shoe covers were used and when they were not [52] (2b). At the same time, shoe covers are considered by some to be inconvenient while they also incur cost. Furthermore, their removal and replacement may increase the risk of bacterial contamination of the hands [53].

Jewelry and Nail Polish

The wearing of finger rings and use of nail polish have been implicated as factors that decrease the efficacy of surgical scrubs, subsequently leading to potential increase in bacterial counts and SSI. To date, there have been no RCTs investigating infectious complications comparing the wearing of finger rings and not wearing them [54] (2b). Furthermore, there have been no trials evaluating the impact of wearing nail polish versus no nail polish. Despite this lack of evidence, the advisory committee and the HIPAC/SHEA/APIC/IDSA Hand Hygiene Task Force continue to recommend that surgical team members remove rings, watches, and bracelets before surgical hand scrub and avoid the wear of artificial nails [55] (5).

Intraoperative Interventions

There are a number of dogmatic principles and some evidence-based practices to guide the dermatologic surgeon in the preoperative and intraoperative routine. The choice of surgical antisepsis, use of sterile vs. clean surgical gloves, employment of hair removal techniques, utilization of prophylactic antibiotics, choice of surgical instruments, and other intraoperative techniques are just a few items where evolving evidence has positively influenced dermatologic surgical behaviors and practices.

Surgical Drapes

Use of surgical drapes is a common method to avoid fomite contact outside of the surgical field. Interventions to augment surgical draping systems include iodine-impregnated and non-iodine-impregnated adhesive drape systems, as well as impermeable and permeable adhesive drapes. Systematic reviews on the superiority of one system over another show mixed conclusions [56] (1a). One prospective randomized trial in patients undergoing cardiac surgery showed a more rapid recolonization of bacteria in groups using adhesive drapes versus no drapes [57] (2b). Another prospective randomized study assessing drape permeability and its effect on SSI during breast reconstruction surgery showed a statistically significant higher SSI rate when reusable sterile woven drapes were used compared to disposable drapes [58] (1b). An additional study showed elevated bacterial counts in operative fields with permeable linen drapes (664 CFU/50 cm^2) compared to impermeable nonwoven drapes with self-adhesive edges (393 CFU/50 cm^2). A similar difference in CFU counts between the two draping systems was also noted in the wound itself (164 CFU/sample vs. 12 CFU/sample, respectively) [59] (2b).

Gloves

The use of sterile versus nonsterile gloves in dermatologic surgery has been investigated quite extensively. The first randomized prospective trial to compare the infection rates of wounds with clean versus sterile gloves was performed during the repair of simple lacerations in an emergency room setting [60] (1b). The study of 816 subjects showed no statistical difference in infection rates between sterile gloves (6.1%) versus clean, nonsterile gloves (4.4%). The first dermatologic study examining this topic was a retrospective chart

review of 1,810 consecutive patients performed in 2006 evaluating the tumor extirpation with MMS. The results showed no statistical difference in SSI rate between the use of sterile and clean nonsterile gloves [10] (2b). A 60-subject, prospective, patient-blinded, pilot study showed no difference in SSI rates when using clean, nonsterile gloves versus sterile gloves for reconstruction after MMS. The authors noted considerable financial benefit to the institution with estimates ranging from $17,580 to $23,440 in annual cost savings [61]. (2b). A prospective trial of 3,491 patients undergoing flap or graft reconstruction found a significantly higher rate of SSI when nonsterile gloves were used compared to sterile gloves (14.7% vs. 3.4%), but no difference was noted for simple excisions and closure (1.7% vs. 1.6%) [62] (2b). Lastly, a systemic review and meta-analysis of multiple high-quality studies to include multiple randomized clinical trials and prospective or retrospective comparison studies evaluating the use of sterile versus nonsterile gloves for MMS, laceration repair, and mucosal dental procedures showed no difference in SSI or other adverse events [63] (1a).

Surgical Site Scrub

The use of preoperative surgical site scrub is routinely performed to reduce transient and resident microorganisms prior to surgical intervention. The most common agents used in the United States are iodophors (mainly povidone-iodine (PI)) and chlorhexidine gluconate (CHG) (with and without alcohol).

A Cochrane review assessing the ability of topical antiseptics to prevent SSI applied immediately prior to incision in clean surgery was performed [64] (1a). Thirteen studies were included in the review containing 11 different comparisons between various antiseptics. The comparisons included iodine in alcohol and alcohol alone, and various products containing iodine versus products containing CHG. One study suggested that 0.5% CHG in methylated spirits led to a reduced risk of SSI compared with an alcohol-based PI solution. This particular study has gained traction in support of CHG as a preoperative surgical scrub in dermatologic surgery. All the other studies in the review showed no significant differences in SSI rates between the various antisepsis regimens.

One prospective randomized clinical trial compared 2% CHG and 70% isopropyl alcohol (ChloraPrep®, Cardinal Health) and 10% PI aqueous solution (Scrub Care Skin Prep Tray®, Cardinal Health) [65] (2b). The overall rate of surgical site infection (superficial, deep and organ space) was significantly lower in the CHG-alcohol group than in the PI group (9.5% vs. 16.1%, respectively).

Surgical Team Preoperative Scrub

Preoperative surgical scrub of the hands, fingernails, and forearms of the operative team is a well-established method to decrease SSI. A Cochrane review of the effects of surgical hand antisepsis on preventing SSI and diminishing number of bacterial CFU was performed [66] (1a). The review included fourteen RCTs: four trials with SSI as the primary outcome and ten trials assessing CFU quantities (not SSI rate). In the trials covering SSI risk, various antiseptic solutions were compared. The comparisons included basic hand hygiene (soap and water) and antiseptic alcohol rubs and aqueous scrubs. There was no firm evidence that any of these scrubs were superior to one another. For the trials covering CFU growth, some key findings included the evident superior ability of CHG to lower CFUs immediately after scrubbing, 2 h after initial scrub, and 2 h after subsequent scrub when compared to PI. Additionally, alcohol rubs with added ingredients may reduce CFUs when compared to aqueous scrubs.

There are a number of RCTs and reviews that have been conducted on preoperative surgical personnel scrub techniques. A systemic review of preoperative hand scrubbing protocols on skin integrity and SSI rates that included eight RCTs and two nonrandomized controlled studies (NRS) was performed [67] (1a). Of the trials reviewed,

two assessed SSI within 30 days of surgery. The first compared a traditional hand scrub of 7.5% PI or 4% CHG and water for 3–5 min prior to surgical procedures and a similar hand scrub technique prior to the first procedure followed by alcohol hand rub for subsequent procedures. The second study compared a 5-min hand scrub with 4% PI or 4% CHG and with an alcohol-based solution. The pooled analysis showed no statistical difference in SSI rate between the groups. Ultimately, alcohol rubs appear to be as effective as traditional scrub techniques, and they appear to have superior skin tolerability for operative personnel.

Hair Removal

Preoperative hair removal is commonly performed to increase surgical site visualization and decrease impairment of surgical technique. Various methods have been employed, but there is currently a lack of data to support the efficacy of this intervention and the degree to which each technique influences SSI risk. A Cochrane review of 14 trials assessing hair removal prior to surgery was performed in 2011 [68] (1a). The trials compared hair removal (shaving, clipping, or depilatory cream) with no hair removal as well as the use of depilatory cream and shaving, showing no statistical difference in SSI rates in any of the comparisons. Three trials found a greater SSI risk with shaving when compared to clipping, although the comparison was underpowered to detect a statistically significant difference. One trial compared individuals who either shaved or clipped their hair the day prior to surgery or the day of surgery. The trial found no statistically significant difference in SSI rate between the two groups. Another more recent meta-analysis showed similar findings with no difference in SSI rates between various hair removal methods [69] (1a). The authors of both studies conclude there is insufficient evidence to determine if one technique increases SSI risk over the other and if hair removal, in general, affects SSI rate. Given the available evidence, if it is necessary to remove hair, it seems prudent to gently clip hair with scissors or electric clippers rather than shave the area with a razor.

Electrocautery

It is well known that electrocautery creates necrosis and inflammation of treated skin. This alteration has been postulated as a cause of a suboptimal healing environment that potentially increases SSI. A study of the effect of electrocautery on MMS wound outcomes showed that excess use impaired wound healing (partial necrosis, dehiscence, or full necrosis), but an effect on SSI could not be concluded [12] (2b).

The use of electrocautery scalpel for skin incisions versus a cold scalpel has been assessed by a systematic review and meta-analysis of randomized controlled trials (RCTs). The study found no statistical difference in SSI between the two modalities. At the same time, the electrocautery scalpel was faster and patients experienced less postoperative pain [70] (1a).

A randomized, controlled, clinical pilot study in patients undergoing Caesarean sections evaluated the use of electrocautery for coagulation versus nonintervention and found similar rates of infection 7–10 days after the surgery (10% and 8.7%, respectively) [71] (1b). Of note, this study lacked statistical power to demonstrate significant statistical difference.

Surgical Instruments

In many clinical practices, when performing MMS, it is common to use one set of instruments for tumor extirpation and another set of sterile instruments for reconstruction. One prospective study of 338 subjects undergoing MMS used a single set of sterile instruments for both surgical phases and found an overall infection rate of 2.1%, which is in line with the reported average SSI rate for dermatologic surgery [72] (2b). Some limitations to the study included a lack of control group, and all skin grafts were treated

postoperatively with a 7-day course of antibiotics, which may have falsely decreased the true SSI incidence.

Wound Closure Materials

Antimicrobial sutures have been developed with the intent of inhibiting bacterial colonization and, ultimately, reducing SSI. A meta-analysis of patients undergoing primarily general, pediatric, vascular, and cardiac surgeries found that triclosan-coated polyglactin 910 sutures (Vicryl Plus) significantly reduced SSI when compared to regular polyglactin 910 sutures (Vicryl) [73] (1a). Other studies have failed to demonstrate a protective effect of these sutures after elective colorectal surgery and in head and neck reconstruction [74] (1a) [75] (2b).

Materials used for wound closure as well as closure technique and their effect on SSI have been evaluated by various surgical subspecialties with some implications for dermatologic surgery. A systemic review and meta-analysis of 13 studies comparing SSI incidence with staples versus sutures for skin closures after orthopedic surgery showed no significant difference in infection risk [76]. In contrast, another meta-analysis of RCTs that included primarily general, obstetric/gynecological, and head and neck operations (excluding orthopedic operations) found a statistically decreased risk of SSI with staple versus suture closure [77] (1a).

2-Octyl-cyanoacrylate is a commonly used adhesive for rapid, simple closure of surgical wounds. In a prospective randomized clinical trial comparing 2-octyl-cyanoacrylate to subcuticular suture closure for maxillofacial wounds, there was no significant difference in wound complications or patient satisfaction [78] (2b). The time for closure was also significantly less for 2-octyl-cyanoacrylate. Another cohort study of individuals undergoing spinal surgery was performed comparing 2-octyl-cyanoacrylate versus staples for wound closure, which demonstrated a statistically significant decreased risk of SSI in the 2-octyl-cyanoacrylate group [79] (2b). The authors also conclude that use of 2-octyl-cyanoacrylate is more cost effective and requires less time to perform.

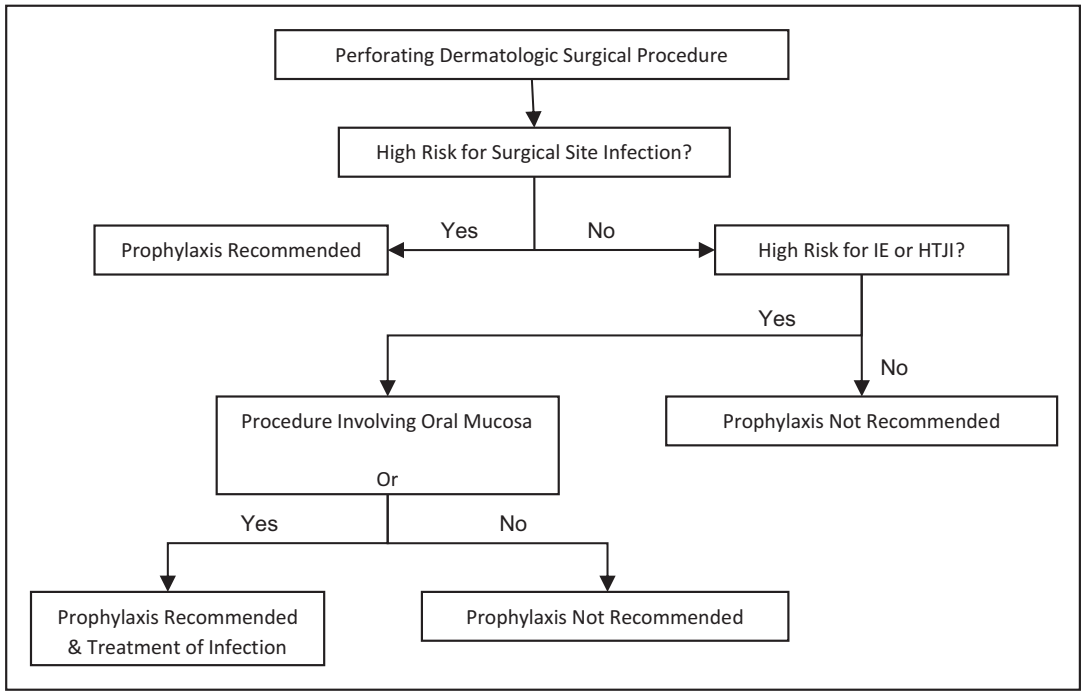
The use of simple interrupted and running epidermal closure are both commonly performed in dermatologic surgery. A Cochrane review that included five RCTs assessing the benefits and harms of continuous running suture versus single interrupted suture closure in nonobstetric surgery found no statistical difference in SSI between the two techniques, but a lower risk of dehiscence was noted with running subcuticular sutures [80] (1a).

Prophylactic Antibiotics

Antibiotic prophylaxis in dermatologic surgery remains controversial, and our current understanding relies primarily upon expert consensus and extrapolation of data from other specialties due to the lack of RCTs in dermatologic procedures. The incidence of bacteremia in immunocompetent individuals undergoing dermatologic surgery on non-infected skin is <1% [81] (2b). The 2008 dermatologic surgery antibiotic prophylaxis advisory statement provides direction on the indications for prophylactic antibiotic use and reflects guidelines given by the American Heart Association, the American Dental Association, and the American Academy of Orthopaedic Surgeons [82] (5). These recommendations are based on preventing hematogenous total joint infection (HTJI), infective endocarditis (IE), and SSI prevention of specific high-risk sites and/or procedures (Table 63.1.). The algorithm has recently undergone a small update from the original 2008 statement within the Mayo Clinic dermatologic surgery division to remove levofloxacin as an alternative treatment for prophylaxis for surgery done on the lower extremity. The change was made after the US Food and Drug Administration (FDA) increased warnings in 2016 regarding permanent adverse events related to the use of fluoroquinolone antibiotics.

Performing dermatologic surgery without the use of prophylactic antibiotics has the benefit of decreasing healthcare costs, avoiding the emergence multidrug-resistant bacterial clones, and eliminates the possibility of allergic drug reac-

Table 63.1 Recommendations for antibiotic prophylaxis in dermatologic surgery



IE = Infective Endocarditis, HTJI = Hematogenous Total Joint Infection

***IE* infective endocarditis, *HTJI* hematogenous total joint infection**

tions. One study evaluating 1,000 patients with 1,204 lesions demonstrated an infection rate of 0.91%, using only clean surgical technique (without oral antibiotic use) for all steps of MMS including wound reconstruction [83] (2b). There were no infections with skin grafts, wedges of the lips or ears, or wounds healing by second intent. Primary closure showed an infection rate of 0.78%, and for skin flaps, which have been known to be at an elevated risk for infection, the rate was 2.67%.

One RCT was performed evaluating the effect of preoperative oral antibiotics versus topical decolonization measures in patients with positive nasal cultures for *S. aureus* undergoing MMS [84] (1b). Patients were separated into two groups: swab negative (no *S. aureus*) and swab positive (presence of *S. aureus*). They were subsequently randomized into two cohorts: one receiving topical nasal mupirocin and 4% CHG body wash to be used for 5 days preoperatively and the other receiving 2 g of cephalexin 30–60 min prior to surgery and 1 g 6 hours after surgery. The results showed a disproportionate infection rate in cases receiving oral antibiotics compared to the topical regimen (9% versus 0%, respectively), and the study was prematurely terminated based on ethical grounds.

The optimal application of prophylactic antibiotics in dermatologic procedures is influenced by multiple factors and is an opportunity for well-designed, prospective research. The current guidelines (with a few minor modifications) set out by the 2008 advisory statement aim to mitigate HTJI, IE, and SSI of specific high-risk sites. There is some evidence suggesting that antibiotic prophylaxis for some high-risk indications and procedures, such as site (lower extremity) and type of closure (skin graft, skin flap and wedge closure), may not be always necessary [83] (2b). The evidence also suggests that topical mupirocin may be preferable to oral cephalexin for preoperative decolonization in patients with *S. aureus* nasal carriage.

Finding ways to mitigate the risk of SSI in patients undergoing cutaneous surgery is of paramount importance. Preoperative antibiotics have important value, but their use also exposes the patient to potential health consequences to include multidrug-resistant bacteria, drug reactions, and disruption to the patient's gut microbiome [85] (2a). To illustrate this point over 140,000 annual visits to the emergency room in the United States are attributable to adverse effects from antibiotics [86] (2c). The strong emergence of MRSA can be partially attributable to antibiotic overuse, with estimated costs to the US healthcare system ranging from $478 million to 2.2 billion dollars every year [87] (2c). Moreover, the dreaded complication of *Clostridium difficile* colitis, commonly caused by clindamycin and second- and third-generation cephalosporins, is on the rise [88] (2c). These circumstances highlight the need for judicious and responsible application of antibiotics in dermatologic surgery.

Intraincisional Antibiotics

Huether and colleagues described a unique approach to reduce SSI by using intraincisional clindamycin mixed with an injectable lidocaine-based anesthetic preparation [89] (1b). They performed a prospective, blinded, placebo-controlled study of 1030 subjects undergoing MMS comparing an anesthetic solution containing clindamycin to standard local anesthetic. The results showed a statistically significant reduction in SSI rate with the clindamycin containing solution (0.2%) compared to standard local anesthetic (2.5%). There were no allergic reactions in either group. Four patients experienced nausea in the clindamycin group, and no diarrhea occurred in either group. The same authors performed another study using intraincisional nafcillin [90] (1b), but given the high rate of stated penicillin allergy, injectable clindamycin was found to be a more suitable alternative with similar reduction in SSI rate. The authors conclude that intraincisional antibiotics decrease systemic exposure to the medication, provide immediate delivery to the surgical site, and are relatively less expensive compared to oral antibiotics.

Enhanced Infection Control Practices

Despite the already published low infection and complication rates of MMS, one study performed showed heightened infection control practices could lower the rate even further [91] (2b). This study demonstrated an infection rate of 2.5% using a standard sterile surgical tray setup and chloroxylenol 3% surgical patient prep. When the infection control practices were introduced, this rate dropped to 0.9%. The interventions included adding surgical caps and hair containment, use of sterile towels, limitations on jewelry, use of sterile gloves during Mohs stages, changes to patient antiseptic and surgeon hand rubs, and use of surgical gowns. The cost of these measures equaled $10.76 per case and in a practice performing approximately 1,000 cases a year added up to a cost of $10,760. Based on the percent reduction in SSI, this would cost the practice $672.50 to prevent one infection. The authors make the point, in their particular situation, that these measures may be cost effective when considering the physician time in managing the infection and the associated costs of wound cultures and antibiotics. A follow-up on analysis to this study was performed by one of the coauthors showing infection-control costs could be reduced by eliminating sterile gloves during Mohs stages and sterile gowns and half-sheet drapes during reconstruction [92] (2b). These changes did not demonstrate a significant change in the SSI but reduced the infection control cost from $678.75 to a more cost-effective $136.67 per infection.

Managing Postoperative Wound Infections

There are a number of general principles regarding the use of wound care and therapeutic antibiotics when dealing with postoperative wound

infections. Most interventions are based on dogmatic principles from other surgical specialties with minimal evidence from RCTs.

Topical Antibiotics

The use of topical ointments after dermatologic procedures is a common, highly accepted practice. A systematic review and meta-analysis of topical antibiotics used in dermatologic surgery of four different trials did not show a statistically significant difference in postoperative surgical wounds between topical antibiotics and topical petrolatum/paraffin with the ultimate conclusion that topical antibiotics should not be used as prophylaxis in dermatologic surgery [93] (1a). There is also a lower risk of contact dermatitis when using white petrolatum compared to bacitracin [94] (2b).

An RCT compared the SSI rate of no ointment, paraffin ointment, and mupirocin ointment to sutured wounds prior to application of wound dressings [95] (1b). The respective infection rates between the groups (1.4%, 1.6%, and 2.3%) were not statistically different. Moreover, there was no variation in postoperative pain, wound perception, or patient satisfaction with either intervention.

Topical application of acetic acid has long been advocated as a way to reduce *P. aeruginosa* colonization on superficial burn wounds [96]. The efficacy of 1% acetic acid compared to normal saline on the treatment of burn and other chronic wounds infected with *P. aeruginosa* was determined, showing the use of acetic acid eliminated *P. aeruginosa* on average 7 days faster than the saline group [97] (1b). There was no evidence to show that this sped up the wound healing or improved patient comfort.

Wounds on the ear are commonly encountered in dermatologic surgery, and second intent wound healing is frequently utilized. The uses of topical or oral antibiotics are often advocated given the elevated risk of inflammatory chondritis and suppurative chondritis with a variety of organisms, most prominently *P. aeruginosa* [4] (2b). A prospective study of 142 patients undergoing MMS was performed comparing wounds treated with gentamicin ointment or petrolatum ointment showing no statistical difference in the prevention of postoperative auricular suppurative chondritis [98] (2b). The study was not powered statistically to show a difference in inflammatory chondritis, but there were a disproportionate number of patients affected in the gentamicin group compared to petrolatum (11.90% versus 3.33%, respectively). This study suggests that gentamicin ointment shows no benefit for ear wounds healing by second intent and may potentially increase the risk of inflammatory chondritis. Gentamicin may also be a source of allergic contact dermatitis [99], which could further compromise wound healing.

Systemic Antibiotics

Empiric treatment of dermatologic SSI should be based on clinical suspicion and community sensitivity patterns. Microorganisms causing cutaneous abscesses are often related to more virulent strains of MRSA [100] (2a). Microorganisms related to dermatologic SSI, on the other hand, are often derived from endogenous strains of bacteria [42] (1b), which may or may not originate from virulent strains of *S. aureus*. Therefore, the recommendations for abscesses cannot be completely applied to the treatment of all dermatologic surgical wounds. For treatment of an SSI in communities with low risk for MRSA, empiric treatment for methicillin-sensitive *S. aureus* (MSSA) with a first-generation cephalosporin such as cefadroxil or cephalexin is reasonable. When MRSA is the likely etiology, guidelines have been established by the CDC and Infectious Diseases Society of America (IDSA) for antibiotic treatment of cutaneous abscesses [101] (1a), which include clindamycin, tetracycline (doxycycline, minocycline), and trimethoprim-sulfamethoxazole (TMP-SMX). Empiric use of these antibiotic choices would be the same for dermatologic SSI in cases with high suspicion for MRSA. Linezolid can be considered if the above antibiotics fail and the CDC recom-

mends it be administered in conjunction with infectious disease consultation. For simple abscesses, the IDSA recommends treatment with incision and drainage alone (without antibiotics). Many uncomplicated wound infections on the trunk or extremities that develop after dermatologic surgery fall into this category and will respond to drainage and removal of sutures alone. Conversely, concomitant antibiotic therapy and incision and drainage should be considered in patients with wounds of the head and neck and those with associated comorbidities to include extremes of age and immunosuppression [101] (1a).

The duration of antibiotic treatment after SSI has been debated. A randomized noninferiority trial was performed assessing the duration of treatment with TMP-SMX after surgical drainage of uncomplicated skin abscesses in pediatric patients [102] (2b). The patients were randomized to either 3- or 10-day courses. Among the individuals with positive cultures, 87% grew *S. aureus* (55% MRSA). Patients receiving 3-day courses showed a 10.7% higher recurrence rate when compared to 10-day courses if the patient was infected with MRSA. There was no difference between the groups when the patients were infected with MSSA. When other potential confounders were resolved, there was almost a sixfold greater risk of recurrent infection in the 3-day group when compared to 10-day group. The authors suggest the option of giving patients a 3-day supply of TMP-SMX (to limit longer term exposure to antibiotics) for all patients and adding an additional 7-day supply if their cultures grow MRSA. This is a reasonable option but may be logistically difficult to coordinate.

Initial choice of empiric antibiotic therapy after SSI is often made based on physician preference and local sensitivities. A randomized, double-blind, superiority trial at five US emergency departments was conducted evaluating clindamycin versus TMP-SMX for uncomplicated wound infections primarily caused by MRSA or MSSA [103] (1b). Both antibiotics had similar cure rates for the infections; however, there was a significantly lower rate of recurrence in the clindamycin group when compared to TMX-SMP at 7–14 days (1.5% vs. 6.6%) and 6–8 weeks (2.0% vs. 7.1%).

Excellent clinical judgment, antibiotic stewardship, and adherence to prescribing guidelines for dermatologic SSI are imperative to avoid the emergence of multidrug-resistant bacterial clones and patient complications. The temptation to prescribe empiric postoperative antibiotics for noninfected wounds without evidence-based SSI risk factors should be resisted and is not a sustainable practice.

Wound Packing

Packing of wounds is a common practice in many surgical fields, but there is currently no evidence to support its benefit over second intent healing without packing. A Cochrane review on the use of wound cavity packing after perianal abscess drainage was performed. The review concluded there is insufficient evidence this practice decreased healing time, pain, development of fistulae, or recurrence of abscesses [104] (1a). Furthermore, packing and repacking of a wound may lead to excess cost and time expenditures and potentially increase patient discomfort. Given the limited depth and size of most dermatologic surgical defects, the utility of wound packing is uncertain.

Postoperative Care

Wound Dressings

Application of wound dressings is a dogmatic part of the postoperative phase of surgical site care. A Cochrane review that included 11 studies evaluated the use of antiseptic and topical antibiotics for wounds healing by second intention [105] (1a). The review concluded that no high-quality RCT has adequately answered the question, but there was some low- and moderate-quality evidence that a few interventions relevant to dermatologic surgery may provide some benefit. These include the following: (1) sucralfate cream increased wound healing after hemorrhoidectomy when compared to petrolatum [106] (2b), (2) honey-soaked gauze decreased healing times after abscess excision compared to stan-

dard gauze [107] (2b), and (3) Dermacyn (a superoxidized disinfectant solution) increased postoperative wound healing in diabetic foot ulcers when compared to iodine [108] (2b). These options may be considered in wounds healing by second intent or as post-treatment skin care after resurfacing procedures.

A systemic review and meta-analysis that included 20 RCTs evaluating the impact of various dressings on the infection rate of surgical wounds closed by a primary repair found no clear evidence that any particular dressing offered a clear advantage over others in regard to SSI incidence [109] (1a). Similarly, another systemic review and meta-analysis found no difference in SSI between various dressing types and also showed no increased risk of infection in exposed surgical wounds [110] (1a). Despite these findings, properties such as containment of odor and/or exudate as well as autolytic ability and patient comfort offered by the various wound dressings may still offer advantages in the postoperative phase of wound healing.

The current guidelines given by the CDC recommend that postoperative surgical wounds be covered for 24–48 h after surgery [111] (5). A review was performed evaluating early (<48 h) versus delayed (>48 h) dressing removal after primary closure of clean and contaminated surgical wounds [112] (1a). The review concluded there was no difference in serious adverse events, to include SSI, between the two dressing removal times.

Negative-pressure wound therapy (NPWT) has been advocated as an intervention for nonhealing pressure ulcers and other chronic wounds. A Cochrane review found no rigorous RCT evidence that NPWT offers any benefit over standard wound care in the treatment of pressure ulcers [113] (1b).

Special Situations

Laser Resurfacing

Laser resurfacing and other resurfacing procedures are common in the United States, but there is currently no set standard for patients regarding antiviral, antibiotic, and antifungal prophylaxis.

Of the three methods of prophylaxis, the use of antibiotics is most in question. One retrospective study of 133 patients comparing the use of a variety of prophylactic antibiotic regimens to no prophylaxis in individuals undergoing CO_2 laser resurfacing showed an infection rate of 24% versus 0%, respectively [114] (2b). Surprisingly, the group with the highest infection rate was exposed to the longest courses of antibiotics, which consisted of intraoperative cephalexin and postoperative azithromycin for 5 days.

Another retrospective study analyzed infection rates in 395 patients undergoing laser resurfacing for facial rhytides [115] (2b). The study found an overall infection rate of 4.3% with over half of patients demonstrating microorganisms similar to what is commonly found on burn patients, which included *P. aeruginosa*, *S. aureus,* and *Staphylococcus epidermidis.* All study patients were given oral preoperative antibiotics, and interestingly, when in addition to the standard antibiotic regimen (250 mg/d of azithromycin for 7 days), the application of an occlusive dressing and the use of topical prophylaxis (intranasal mupirocin and gentamicin sulfate otic solution) were employed, the infection rate increased seven-fold from 1.35% to 9.82%.

One study compared prophylactic ciprofloxacin and mupirocin antibiotic regimens to no prophylaxis [116] (2b). Those receiving ciprofloxacin had a post-treatment bacterial infection rate of 4.3% compared to 8.2% in those without prophylaxis. The study also demonstrated only those using intranasal mupirocin went on to develop *S. aureus* infections. Despite some evidence that prophylactic ciprofloxacin may decrease post-treatment infections, its routine use should not be uniformly recommended given the knowledge of potential serious adverse effects.

The use of antifungal prophylaxis has been advocated by some in patients undergoing full-face laser resurfacing (FFLR) procedures. One study showed that fluconazole significantly increased re-epithelialization and decreased healing time after facial resurfacing [117] (2b). Another study compared oral ketoconazole and fluconazole prophylaxis to no prophylaxis demonstrating zero yeast infections in the prophylaxis group and 6/356 patients (1.7%) developing

yeast infections in those without prophylaxis [116] (2b). Given the demonstrated low risk of yeast infections in those undergoing FFLR, the use of antifungals for the prevention of yeast infections may not be necessary, and, even though there is accelerated healing with fluconazole, it is uncertain if use of the medication has any long-term cosmetic consequences.

Reactivation of herpes simplex virus-1 (HSV-1) can be a devastating complication for individuals undergoing FFLR and prophylactic use of antiviral medications has been strongly encouraged. One study evaluating antiviral prophylaxis with famciclovir 125 mg–250 mg twice daily starting 1–2 days prior to laser resurfacing and continued for 5 days afterward compared to no prophylaxis showed a reactivation rate of 1.1% and 9.4%, respectively [118] (2b). Another study assessing valacyclovir 10- or 14-day regimens showed no difference HSV-1 reactivation in either group [119] (2b). Another randomized study showed no difference in reactivation in patients given valacyclovir either the day before or the day of the resurfacing procedure [120] (1b). Another prospective study evaluated the difference in HSV reactivation between using famciclovir 250 mg and 500 mg twice daily prior to FFLR [121] (2b). They noted a higher incidence of reactivation in those with a clinical history of herpes labialis (33.3%) compared to those without a clinical history (5%). The authors emphasize the importance of eliciting a clinical history of herpes labialis in those undergoing resurfacing procedures and recommend a prophylactic dose of 500 mg twice daily in those with a strong history and 250 mg twice daily in those without a history of herpes labialis.

In conclusion, many questions remain regarding the optimal prophylaxis regimen for those undergoing FFLR. The use of antiviral prophylaxis is a low-risk and accepted technique and should be highly considered for all patients. The evidence suggests the use of prophylactic antibiotics may increase risk for infection by selecting out and tipping the balance away normal skin flora toward organisms more resistant to antibiotics [114] (2b). Antifungal prophylaxis should not be routinely recommended given the already low risk for fungal infection with resurfacing procedures. Ultimately, responsible use of antimicrobial medications, employment of meticulous technique, thorough wound care, and close patient observation should be the focus of the laser surgeon.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE).

Summary of the prevention and treatment of procedural-related infections
Risk factors for surgical wound infection
Surgical sites with ulceration, purulence, and/or inflammation have a higher risk of SSI (B)
Surgical sites of the groin and below the knee have higher infection rates compared to other areas (B)
Skin flaps, skin grafts, wedge excisions of the ear and lip, wounds >11 mm in size, and procedures >24 min are at increased risk for wound infection (B)
Surgical site infection rates increase with every decade of life after the age of 40 and severe infections are more common over the age of 70 (B)
Laboratory values, patient behavioral factors, and medical risk factors
Warfarin and other antiplatelet and anticoagulant medications have no impact on wound infection rates (A)
Diabetics have an increased risk of surgical site infection (A)
Evidence suggests smoking is associated with an increased risk of SSI (B)
Preoperative interventions
Preoperative body wash with chlorhexidine and bathing with bar soap are associated with equivalent SSI (A)
Benzoyl peroxide 10% gel applied to the centrofacial area may decrease SSI if used around the surgical site 7 days prior to surgery (C)
The use of preoperative intranasal mupirocin in patients with *S. aureus* nasal carriage decreases postoperative infection rate (A)
Intranasal mupirocin is superior to oral cephalexin when decolonizing patients with intranasal *S. aureus* prior to surgery (B)

Summary of the prevention and treatment of procedural-related infections
Surgical attire
Face masks do not influence SSI rate (A)
Surgical head coverings, gowns, dedicated theater shoes, and shoe covers do not influence SSI risk (B)
Wearing of finger rings and nail polish increases wound infection risk (D)
Intraoperative interventions
Adhesive drapes increase the rate of bacterial recolonization of surgical fields compared to no drapes (B)
Reusable woven drapes have a higher wound infection rate compared to disposable draping systems (B)
Use of impermeable drapes results in lower bacterial counts in the surgical field than permeable linen drapes (B)
Clean, nonsterile gloves may be used for laceration repair and tumor extirpation of Mohs surgery, including reconstruction, with no difference in infection rate (A)
Chlorhexidine isopropyl alcohol solution is superior to povidone iodine scrub in reducing SSI rates (B)
Chlorhexidine 0.5% in methylated spirits has a reduced risk of SSI compared with an alcohol-based povidone iodine solution (B)
Preoperative surgical personnel scrub with traditional chlorhexidine and povidone iodine shows similar abilities in reducing infection rates (A)
Chlorhexidine surgical scrub demonstrates residual activity to lower bacterial CFU beyond the time of application (A)
Alcohol-based rubs are as effective as traditional povidone iodine and chlorhexidine aqueous hand scrubs in preventing surgical site infection (A)
There is no evidence that hair removal decreases SSI (A)
If hair removal is necessary, it is prudent to clip the hair with scissors or an electric razor (A)
There is currently no evidence to suggest that the use of electrocautery increases SSI rate (C)
Use of a single set of instruments for tumor extirpation with Mohs micrographic surgery and reconstruction does not increase the overall infection rate (B)
Use of triclosan-coated polyglactin 910 sutures reduces SSI compared to regular polyglactin 910 sutures (B)
Staple skin closure has a lower SSI risk when compared to a sutured wound closure (B)
2-Octyl-cyanoacrylate has a decreased risk of surgical site infection compared to staple closure (B)
Subcuticular skin closure and interrupted suture closure have similar surgical site infection risks (A)
Prophylactic antibiotics should be given when there is a risk of hematogenous joint infection or infective endocarditis (A)
Skin grafts, wedges of the lips or ears, and skin flaps have a low infection rate and may not require prophylactic antibiotics (B)
Intraincisional administration of clindamycin or nafcillin mixed with an anesthetic solution decreases surgical site infection risk (B)
Postoperative interventions
White petrolatum ointment is recommended over topical antibiotics for clean and clean contaminated wounds
Early bathing (<48 h) and delayed bathing (>48 h) after minor skin surgery have no effect on SSI (A)
The use of ointment on sutured wounds shows no reduction in wound infection compared to no ointment (B)
The use of gentamicin ointment for ear wounds does not decrease SSI and may increase the risk of inflammatory chondritis and allergic contact dermatitis (B)
Packing of surgical wound abscesses does not reduce rate of recurrence or decrease healing time (C)
Short 3-day courses of antibiotics are preferable over longer 10-day courses unless the wound is infected with MRSA (B)
There is no clear evidence that one wound dressing is superior to another in reducing infection rates (A)
There is no difference in infection rates for early (<48 h) versus delayed (>48 h) dressing removal (A)
Negative-pressure wound therapy offers no benefit over standard wound care in the treatment of chronic wounds (B)
Antiviral prophylaxis should be given to all patients undergoing ablative fractionated facial laser resurfacing (A)
Prophylactic systemic and/or topical antibiotics may increase the risk for infection in patients undergoing laser resurfacing procedures(B)

Self-Assessment Questions

1. Which one of the following preoperative interventions has been shown to decrease surgical site infection (SSI)?
   (a) Surgical face mask
   (b) Waiting to bathe 48 h after surgery
   (c) Intranasal mupirocin
   (d) Bleach baths

2. Which intervention has been shown to prevent postoperative wound infections?
   (a) Iodoform packing strip for deep wounds allowed to heal by second intent
   (b) Intraoperative injectable mixed lidocaine and clindamycin solution.
   (c) Dedicated operating room footwear
   (d) Gentamicin ointment for wounds on the ear with exposed cartilage

3. What statement best explains the current recommendations for prophylaxis prior to full-face laser resurfacing?
   (a) Treatment with prophylactic antibiotics, antiviral agents, and antifungal agents are recommended for the majority of patients
   (b) Postoperative intranasal mupirocin, gentamicin otic solution, and an occlusive dressing decrease post-treatment infection risk
   (c) Ciprofloxacin is the antibiotic of choice for prophylaxis
   (d) Prophylactic antibiotics should be discouraged

4. What statement best explains the current recommendations for hair removal prior to dermatologic surgery?
   (a) Shave the area with a razor the day of surgery
   (b) Use a depilatory cream the day before surgery
   (c) Clip the area with scissors or an electric razor just prior to surgery
   (d) Hair removal should never be attempted prior to surgery

5. A patient is undergoing preoperative workup for Mohs surgery. What factor is true in regard to surgical site infection risk?
   (a) Surgical site infection risk increases with every decade of life
   (b) Men are at a statistically higher risk for wound infection compared to women
   (c) Use of warfarin has been shown to increase dermatologic surgery infection risk
   (d) Skin flaps and elliptical excisions have approximately equivalent infection rates
   (e) Duration of surgery has shown no impact on surgical site infection rate

Answers

1. c: Intranasal mupirocin. The use of intranasal mupirocin in patients with *S. aureus* nasal carriage decreases postoperative infection rate and is superior to oral cephalexin when decolonizing patients with intranasal *S. aureus* prior to surgery.
2. b: Intraoperative injectable lidocaine and clindamycin solution. Intraoperative clindamycin anesthetic solution has been shown to significantly reduce the surgical site infection rate with minimal side effects and low cost
3. d: Prophylactic antibiotics should be discouraged. Prophylactic antibiotics have shown no benefit in reducing postprocedure infection risk, and in many instances, they increase the risk of bacterial infection. Likewise, their use carries the risk of antibiotic resistance and allergic reactions. The use of antiviral prophylaxis is a low-risk and accepted technique and should be highly considered for all patients undergoing resurfacing procedures.
4. c: Clip the area with scissors or an electric razor just prior to surgery. There is currently insufficient evidence to determine if one technique of hair removal is superior to another. Hair removal should be done only if it hinders proper surgical technique or surgical field visualization. It is generally accepted that hair should be gently clipped hair with scissors or electric clippers rather than shave the area with a razor.
5. a: Surgical site infection risk increases with every decade of life. Surgical site infection rate increases with every decade of life after the age of 40, and severe infections after dermatologic surgery were more common over the age of 70. This increase may be related to the decline in the innate and adaptive immune systems seen with age.

64 Prevention and Treatment of Bleeding Complications in Dermatologic Surgery

Bryan Sofen and Isaac Neuhaus

Abstract

In general, the rate of complications in dermatologic surgery is extremely low. A single-center prospective analysis of 1343 cases of Mohs micrographic surgery (MMS) reported an overall complication rate of 1.6% (22/1,343 cases), including wound infection, postoperative hemorrhage, hematoma, wound dehiscence, and flap or graft necrosis (Cook JL, Perone JB. Arch Dermatol 139(2):143–52, 2003) [4]. A recent multicenter, prospective study of 23 centers revealed an even lower complication rate of 0.72% (149/20,821 cases) (Alam M, Ibrahim O, Nodzenski M, Strasswimmer JM, Jiang SI, Cohen JL, et al. JAMA Dermatol 149(12):1378–85, 2013) [2a]. This chapter reviews the available evidence regarding the prevention of bleeding complications of cutaneous surgery. Information regarding treatment options after the bleeding has occurred is discussed elsewhere. Although much of the data will be generated from the collective dermatologic experience with Mohs micrographic surgery, the conclusions drawn will be applicable to standard excisional surgery, as well as other common procedures of the dermatologist and dermatologic surgeon. Not only is perioperative bleeding the most common complication associated with cutaneous surgery, but it is also the subject for which the most robust evidence exists. The decision as to whether or not to discontinue anti-coagulation is important as it is estimated that 35–38% of patients undergoing cutaneous surgery are taking an antithrombotic agent (Callahan S, Goldsberry A, Kim G, Yoo S. Dermatol Surg 38(9):1417–26, 2012) [3a]. It is additionally important to note that complications involving dehiscence, necrosis, poor wound healing, and infection often occur after difficulties with hemostasis.

Introduction

In general, the rate of complications in dermatologic surgery is extremely low. A single-center prospective analysis of 1343 cases of Mohs micrographic surgery (MMS) reported an overall complication rate of 1.6% (22/1,343 cases), including wound infection, postoperative

hemorrhage, hematoma, wound dehiscence, and flap or graft necrosis [1] [4]. A recent multicenter, prospective study of 23 centers revealed an even lower complication rate of 0.72% (149/20,821 cases) [2] [2a]. This chapter reviews the available evidence regarding the prevention of bleeding complications of cutaneous surgery. Information regarding treatment options after the bleeding has occurred is discussed elsewhere. Although much of the data will be generated from the collective dermatologic experience with Mohs micrographic surgery, the conclusions drawn will be applicable to standard excisional surgery as well as other common procedures of the dermatologist and dermatologic surgeon. Not only is perioperative bleeding the most common complication associated with cutaneous surgery, but it is also the subject for which the most robust evidence exists. The decision as to whether or not to discontinue anticoagulation is important as it is estimated that 35–38% of patients undergoing cutaneous surgery are taking an antithrombotic agent [3] [3a]. It is additionally important to note that complications involving dehiscence, necrosis, poor wound healing, and infection often occur after difficulties with hemostasis.

Consensus Documents

A review of the websites of the American Academy of Dermatology (AAD), the American Society for Dermatologic Surgery (ASDS), the American College of Mohs Surgery (ACMS), and the Association of Professors of Dermatology (APD) reveals no published consensus documents regarding complications in dermatologic surgery. Similarly there are no relevant documents published by Cochrane.

Bleeding

The first step in the prevention of bleeding complications occurs through preoperative assessment of an individual patient's risk. A complete and directed preoperative history is the first step in assessing potential risk for bleeding in a patient undergoing a dermatologic surgery procedure. Common medical problems such as hypertension and anxiety can contribute significantly to bleeding, especially intraoperatively, and every effort should be made to adequately manage these medical problems in the pre- and perioperative periods. History taking should also include medical conditions that can contribute to altered platelet function and coagulation. This includes, but is not limited to, liver disease, renal dysfunction, and both hematologic and solid malignancies. For example, one paper reported a case of disseminated intravascular coagulation and persistent postoperative bleeding in a patient with metastatic prostate cancer unmasked by Mohs micrographic surgery for a relatively small basal cell carcinoma on the forehead [4] [5]. In another case, persistent postoperative bleeding unmasked an extremely rare form of acquired autoimmune hemophilia A, with autoantibodies targeting factor VIII [5] [4]. Poor nutritional status must also be considered a risk factor for excessive bleeding. This is especially relevant in the elderly population, the most common group of patients undergoing surgery for cutaneous malignancy. Many mild forms of bleeding disorders go undiagnosed, so clinicians should specifically assess for any prior history of significant bleeding during low-risk surgical procedures (i.e., dental extractions), episodes of epistaxis, menorrhagia, or extensive bruising. Though a patient's description of prior operative bleeding is often very subjective, a previous history of excessive bleeding in this setting may indicate an inherited bleeding disorder such as hemophilia or von Willebrand disease, the most common hereditary bleeding disorder. Peterson and Joseph have provided an excellent review on inherited bleeding disorders in dermatologic surgery patients [6] [5], as have Bunick and Aasi [7] [3a]. Both reviews emphasize the importance of working in conjunction with an experienced hematologist when dealing with this patient population.

Much more common than inherited bleeding disorders are acquired abnormalities in coagulation or platelet function secondary to medications and ingested products. It is well known that ethanol consumption contributes to bleeding via

decreased vasoconstriction and impaired platelet and coagulation function [8] [5]. Though this effect is difficult to quantify, patients who routinely consume alcoholic beverages may be advised to abstain for several days before and after cutaneous surgery. Alternative medicines and therapies may also effect bleeding, and the use of such modalities has dramatically increased in recent years. A 2007 National Health Interview Survey found that four out of ten adults had used some form of complementary alternative medicine during the past years [9] [4]. Another report found that 22% of presurgical patients take various herbs and 51% consume vitamin supplements [10] [5]. Looking at MMS patients specifically, Collins and Dufresne reported in a 2002 study that 49% of MMS patients were actively taking dietary supplements [11] [4]. Vitamins and herbal supplements are also often overlooked in the preoperative history. Patients frequently do not readily reveal their alternative medications to their physicians, and physicians frequently do not specifically ask patients. One report found that over 35% of patients on alternative therapies did not inform their doctor during the medical history [12] [3b]. In the report by Collins and Dufresne, of those patients taking dietary supplements, 65% neglected to report them on preoperative questionnaires [11] [4]. Similar results are seen in the anesthesiology literature, with one study showing that 89% of patients consuming herbal plant products did not consider them to be a medication and that 91% would not have told an anesthesiologist about them on routine interview [13] [5]. Dinehart and Henry published an excellent comprehensive review on dietary supplements and altered bleeding and coagulation [14] [1]. They report that many dietary supplements can alter coagulation and platelet function, with many effects on platelets being irreversible. Therefore, the recommendation is for patients to stay off all vitamins and supplements for 7–10 days prior to surgery. The exceptions are vitamin E and ginkgo, which can be discontinued several days prior to surgery [14] [4]. Nonetheless, for the sake of simplicity, the authors typically advise patients to discontinue all of their supplements and herbals for the full 7–10 days.

While most patients can easily discontinue their alternative therapies or alcohol consumption in the perioperative period, discontinuation of nonsteroidal anti-inflammatory drugs (NSAIDs) or anticoagulant and antiplatelet medications such as warfarin and aspirin is a much more complex issue that continues to be debated among dermatologic and other surgeons. A large percentage of patients are on NSAIDs for musculoskeletal aches and pains as well as other chronic inflammatory conditions. A significant proportion of the US population takes aspirin for primary prevention of cardiac and cerebrovascular events, with primary prevention being defined as treatment aimed at preventing vascular events in patients who currently have no evidence of vascular disease. Furthermore, a variety of anticoagulants and blood-thinning agents are currently utilized in patients as secondary prevention for thromboembolic events. Secondary preventative efforts focus on identifying and treating those with established disease or those at very high risk for developing thromboembolic disease. Common indications for secondary prevention include patients with artificial heart valves or valvular heart disease, history of stroke or myocardial infarction, atrial fibrillation, underlying coagulopathies, and a history of pulmonary embolism and/or deep venous thrombosis (DVT) [15] [5].

Table 64.1 summarizes the currently utilized antiplatelet and antithrombotic agents, with brief explanations of their mechanisms of action [15] [5]. It is important to note that the various anticoagulants act at different levels in the process of coagulation and are therefore theoretically predicted to result in problems at different times in the perioperative period. Antiplatelet agents such as aspirin interfere with primary hemostasis: platelet aggregation and activation at the site of blood vessel injury. These agents are therefore predicted to cause more difficulty in the initiation of hemostasis intraoperatively. This is distinct from that which might be expected from warfarin, which interferes with secondary hemostasis, the enzymatic activity of coagulation factors that leads to the formation of a fibrin clot. These agents might therefore be expected to cause more

Table 64.1 Blood-thinning agents and their mechanisms of action

Class	Subclass/mechanism	Chemical (brand) name
Antiplatelet	Block formation of thromboxane A2 via inhibition of cyclooxygenase	Aspirin
		Ticlopidine hydrochloride (Ticlid)
	Inhibitors of ADP-induced activation of platelets	Clopidogrel (Plavix)
	Glycoprotein IIb/IIIa inhibitors (block platelet adhesion)	Abciximab (Reopro)
		Eptifibatide (Integrilin)
		Tirofiban hydrochloride (Aggrastat)
Antithrombin	Unfractionated heparin (binds antithrombin III and rapidly inactivates coagulation enzymes)	Heparin
		Hirudin (Refludan)
	Direct thrombin inhibitors	Agatroban (Novastan)
		Dabigatran (Pradaxa)
	Low molecular weight heparins (similar mechanism to unfractionated heparin)	Enoxaparin sodium (Lovenox)
	Factor Xa Inhibitor	Rivaroxaban (Xarelto)
		Apixiban (Eliquis)
	Coumarins (antagonists of vitamin K which decrease vitamin K dependent clotting factors II, VII, IX, X, and protein C and S)	Warfarin (Coumadin)
Thrombolytic	Plasminogen activators (activate plasminogen and hence cause fibrinolysis)	Streptokinase (Streptase)
		Alteplase (tPA)

Adapted from Alam and Goldberg [44]

problems postoperatively since they handicap the terminal portion of the coagulation process. Similar to warfarin, newer antithrombotic agents also interfere with secondary hemostasis by blocking other components of the coagulation cascade such as factor Xa (rivaroxaban [Xarelto®, Janssen], apixaban [Eliquis®, Bristol-Myers Squibb]), or thrombin itself (dabigatran [Pradaxa®, Boehringer Ingelheim]).

The decision of whether or not to discontinue anticoagulant therapy in patients with significant thromboembolic risk has been subject to significant study and debate in dermatologic surgery and other fields. The deliberations center around balancing the possible increased risk of bleeding and hemorrhage with the low, but potentially life-threatening, risk of a thrombotic event if anticoagulant therapy is temporarily discontinued. The vast majority of published literature involves the use of warfarin and aspirin. The effects of perioperative discontinuation of other blood-thinning agents are not well studied, with few studies examining the effects of clopidogrel or the new direct thrombin and factor Xa inhibitors.

In order to provide guidelines regarding anticoagulant use in dermatologic surgery, several factors need to be taken into consideration:

- What is the overall rate of hemorrhagic complications in dermatologic surgery?
- Is the risk of hemorrhagic complications in patients taking blood-thinning agents higher than this overall risk?
- Does temporary perioperative discontinuation of blood-thinning agents significantly decrease the risk of hemorrhagic complications?
- Are there objectively measurable adverse operative effects of warfarin and aspirin?
- What is the risk of thromboembolic events following temporary perioperative discontinuation of blood-thinning agents?
- What is the relative magnitude of bleeding vs. thrombotic complications?

As previously mentioned, there is a very low baseline risk of hemorrhagic complications in dermatologic surgery. One prospective study investigating immediate and delayed dermatologic surgery complications demonstrated an overall complication rate of 1.64%. Many of these complications (postoperative hemorrhage, hematoma formation, flap or graft necrosis, wound dehiscence, and infection) were either directly or indirectly related to problems with hemostasis [16] [4]. In this series, none of the

patients required hospitalization or the assistance of another specialist. This demonstrated 1.64% rate of complications is comparable to two additional reports estimating 2% rates of significant hemorrhage or hematoma in control patients undergoing dermatologic surgical procedures in the absence of blood-thinning agents [17, 18] [3]. A recent multicenter, prospective study of 23 centers revealed an even lower overall complication rate of 0.72% (149/20,821 cases), of which 22 (15.4% of all complications) were related to bleeding [2]. The majority of the complications were mild, with only four serious adverse events noted (0.02% of all procedures). While there are no randomized controlled studies on the subject, the question of continuing or discontinuing anticoagulants lends itself to a study design where rates of hemorrhagic complications are compared between patients who underwent surgery on anticoagulants and those who underwent surgery without. While the study of this kind cannot control for the possible contribution of the underlying indication for anticoagulation to a patient's risk of bleeding, the data are relatively consistent across studies and therefore lend themselves to making confident recommendations. Numerous studies have compared the rate of hemorrhagic complications in patients on vs. off of blood-thinning agents. A review of these published reports reveals the near-unanimous conclusion that there is no increased risk of severe hemorrhagic complications in anticoagulated patients. Furthermore, the literature suggests that perioperative discontinuation of anticoagulants does not significantly decrease the risk of bleeding complications [19] [4]. Several of these studies even focused specifically on Mohs surgical procedures, during which difficulties with hemostasis would have been expected to be tested by increased defect size, extensive undermining, and relatively more complex repair methods. Sufficient data exist to support that blood-thinning agents may be safely continued in dermatologic surgery without exposing the patient to a significant increase in risk for bleeding complications (see Table 64.2).

Billingsley and Maloney published one large prospective study regarding anticoagulant use in dermatologic surgery [17] [2b]. The authors reported no significant increase in severe adverse events in MMS patients on blood-thinning agents (12 patients on warfarin and 97 on either aspirin or NSAID) compared with controls. There was also no significant difference between these groups in the complexity of repair performed. Thirty-three percent of the aspirin/NSAID group and 8% in the warfarin group underwent flaps or grafts, compared with 34% in the control group. The only statistically significant finding noted was that 5/12 (42%) of warfarin patients had "excessive intra-operative bleeding," defined as excessive if the time required to achieve hemostasis during closure was greater than 3 min [17].

Another larger prospective study by Bordeaux and Maloney looked at the complication rates following dermatologic surgery in a cohort of 1911 patients [20] [2b]. The overall rate of hemorrhagic complications was 0.89% (18/1911 cases). Of those, 11 cases had persistent bleeding perioperatively and 2 postoperatively, and 5 developed hematomas. All were sufficiently mild to be handled in an office setting without hospitalization. The authors found a statistically significant increased risk of bleeding with patients taking warfarin ($P < 0.0001$) and to a lesser degree clopidogrel ($P = 0.03$). Patients on both clopidogrel and warfarin were 40 times more likely to have a hemorrhagic complication. Of note, in this study aspirin, anatomic location and closure type did not increase bleeding risk.

In the multicenter study by Alam and colleagues, of the few (22/202,821 cases) occurrences of hemorrhagic complications, all but one patient was on some form of anticoagulation [2]. Regarding the specific agent, 22.7% were taking clopidogrel, 18.0% warfarin, 9.1% aspirin plus warfarin, 4.6% aspirin plus clopidogrel, and 4.6% other anticoagulants. Most bleeding did occur in patients receiving anticoagulants, but the majority of the complications were mild and all were easily controlled. While the majority of bleeding complications in this study were in patients on some form of anticoagulation, this difference was not seen in other studies. Liu et al. looked at 423 MMS procedures in 383 anticoagulated patients and found no significant difference

Table 64.2 Summary of studies examining the incidence of dermatologic surgical complications in patients on blood thinners

Drug and study	No. of patients	Controlled study	Increased severe complications[a]	Evidence level

[a]Excessive bleeding (>1 h despite pressure), hematoma, flap/graft necrosis, wound dehiscence, or infection

in the relative risk of bleeding complications between groups where the pre-existing anticoagulation was either stopped or continued during surgery [21] [2b].

Otley et al. published another large retrospective study of warfarin, aspirin, and NSAID use in cutaneous surgery patients [18] [2a]. In this study, the incidence of severe complications was reported for 653 patients undergoing MMS and excisional surgical procedures. Severe complications were defined as significant intraoperative or postoperative hemorrhage, wound bleeding greater than 1 h and not stopped with pressure, acute hematoma, necrosis of flap or graft, or dehiscence greater than 2 mm. Of the 26 patients who continued warfarin, only 1 experienced a severe complication, compared with the control group of 101 patients in whom warfarin was held, where there was also only one severe event. Similarly, four severe events were reported in the 286 patients continuing aspirin or NSAID compared to three out of the 240 patients who discontinued these medications perioperatively. On the basis of these results, the authors concluded that continuation of warfarin or platelet inhibitors is associated with a very low risk of severe complications and that the rate of complications is not statistically significantly increased compared to patients in whom the same medications are discontinued. It is worth noting that only 54 (8%) of the 653 patients underwent flap or graft repairs, with 2 out of the 5 severe events in patients on warfarin or blood thinners occurring in these more complex repairs [18].

Other smaller prospective studies have also supported the safe use of blood-thinning agents in cutaneous surgical procedures. Alcalay and Alkalay reported no significant adverse events in 68 consecutive patients undergoing Mohs micrographic surgery while on warfarin, including those with therapeutic INR [22, 23] [4]. Another retrospective review by Ah-Weng et al. looked at 68 patients on warfarin who underwent a variety of dermatologic procedures and found no

instances of hemorrhagic complications or necrosis, even at a maximum INR of 3.5 [24] [4]. Similarly, Lam et al. found no difference in adverse events in a small group of dermatologic surgery patients continuing warfarin therapy during the procedure as compared to those patients who had their warfarin stopped and were treated with perioperative heparin [25] [4]. In contrast, Syed et al. published a prospective study of 47 patients on warfarin undergoing cutaneous surgery, noting significantly more minor bleeding in patients on warfarin compared with controls [26] [4]. In this report, nine patients experienced minor bleeding, but there were no major adverse events. Of those cases of minor bleeding, three had an intraoperative international normalized ratio of 3.5 or greater. Of note, only 5 out of 47 patients had intraoperative INRs of 3.5 or greater, with 60% of those experiencing the minor bleeding episodes [26]. A more recent study has prospectively addressed the potential correlation between INR values and bleeding complications in patients undergoing excisional surgery while anticoagulated on warfarin. While very few patients were noted to have INR values greater than 3, no correlation was found between increased INR value and intraoperative or postoperative bleeding [27] [3]. One can conclude that perioperative INRs may only serve to identify the small subset of patients with supratherapeutic values who may be at particular risk for bleeding complications, postoperative, or otherwise. Shalom and Wong reported a statistically increased incidence of intraoperative suture ligation for hemostasis in 41 patients on aspirin compared with 212 controls undergoing excisions of cutaneous and subcutaneous lesions [28] [5]. However, the authors did not find any increased risk of significant bleeding events in those patients taking aspirin. Barlett et al. reported no increased incidence of minor, severe, or overall bleeding complications in 52 patients undergoing minor dermatologic surgery while on aspirin compared with 119 patients who were not taking aspirin [29] [3]. Only one group has published data suggesting significantly increased major bleeding complications in patients undergoing minor cutaneous surgery while on warfarin [30] [4]. Of 21 patients on warfarin, 5 (24%) experienced a major bleeding complication, which was defined as persistent bleeding, wound hematoma, loss of skin graft, or wound infection. This number was significantly higher than that in the 37 patients on aspirin and the 44 controls. This study did not report on INR values or monitoring in the warfarin-treated patients. No significant difference between the aspirin and control groups with regard to bleeding complications was observed [30].

A recent meta-analysis increases the power of many of the aforementioned small studies [31] [1]. Somewhat surprisingly, there was a statistically significant sixfold increased risk of bleeding complications for patients taking warfarin vs. controls (12.3% vs. 2.1%, respectively). A similar but much less robust trend was observed for patients taking aspirin; however, this distinction failed to meet statistical significance. The reliability of this meta-analysis is somewhat compromised by virtue of summing data from several small heterogeneous studies. It is also important to note that additional medical comorbidities were not controlled for in any of the aforementioned anticoagulation studies. It is likely true that anticoagulated patients tend to be older and have greater number and severity of medical problems. If the risk of bleeding complications is somewhat higher in anticoagulated patients, the question of acceptable risk persists. As pointed out by Alcalay, the observed complications have never been reported as life-threatening, while there are numerous reported cases of life-threatening complications potentially attributable to the discontinuation of anticoagulants perioperatively [22] [5].

While multiple studies in the dermatologic surgery literature have addressed NSAID, aspirin, and warfarin use, there are few published reports addressing bleeding complications in patient on clopidogrel (Plavix®, Bristol-Myers Squibb), and fewer still of the newest anticoagulants, dabigatran (Pradaxa®, Boehringer Ingelheim), rivaroxaban (Xarelto®, Janssen), and apixaban {Eliquis®, Bristol-Myers Squibb). Clopidogrel is a selective inhibitor of platelet adhesion to fibrinogen and aggregation via inhibition of ADP-induced platelet activation. Its use

continues to increase as a component of secondary prevention among cardiac and cerebrovascular patients, and it is often used in combination with aspirin, as they have synergistic antiplatelet effects. In a study by Cook-Norris et al., patients taking clopidogrel monotherapy were 28 times more likely to have severe bleeding complications after Mohs micrographic surgery than controls on no anticoagulation and 6 times more likely than patient on aspirin monotherapy [32] [3b]. In contrast, in a prospective study by Kramer et al. comparing anticoagulant use, there was no significant difference in complication rate in 32 patients on clopidogrel monotherapy or clopidogrel vs aspirin as compared to 2329 other patients taking no anticoagulants, aspirin monotherapy, or warfarin monotherapy [33] [3b]. Reports from the nondermatologic picture further suggest an increased risk of perioperative bleeding with clopidogrel. A 2006 prospective study from the pulmonology literature found that clopidogrel significantly increased the bleeding risk in patients undergoing transbronchial biopsy, with the effect exacerbated by concomitant aspirin use [34] [3]. A paper from the cardiology literature also found that combination therapy with clopidogrel and aspirin led to an increased perioperative bleeding risk, in this case comparable to that of warfarin [35] [2a]. The multicenter study by Alam and colleagues did not show much increased risk of the aspirin-clopidogrel combination, but the numbers of such patients were too low to draw concrete conclusions [2]. As this agent continues to be utilized in more patients, studies regarding its effects on dermatologic surgery complications will be beneficial.

There are a number of newer antithrombotic agents that have been developed and approved in the past several years targeting other portions of the coagulation cascade, including direct thrombin inhibitors such as dabigatran (Pradaxa®, Boehringer Ingelheim), direct factor Xa inhibitors such as rivaroxaban (Xarelto®, Janssen), apixaban {Eliquis®, Bristol-Myers Squibb), and several others in various stages of development. Even more agents targeting these and other components of the coagulation cascade are currently in development. These new oral anticoagulants are increasingly used as they have more predictable pharmacokinetics, do not require routine monitoring, and have fewer severe life-threatening hemorrhagic complications as compared to warfarin [36] [2b]. Despite their widespread popularity amongst cardiologists, these drugs often remain prohibitively expensive for many patients. An antidote to dabigatran has been approved for patients with life-threatening perioperative bleeding, but antidotes to the factor Xa inhibitors rivaroxaban and apixaban are still in development. Unlike with warfarin, the lack of effective reversal agents to these drugs has caused considerable debate for recommended practice with more invasive surgical procedures, but with dermatologic surgery, the risk of severe bleeding is much less. With these new agents, there is only one study of bleeding rates in cutaneous surgery and two case reports of complications during cutaneous surgery with dabigatran. There are no reports of bleeding complications during cutaneous surgery with rivaroxaban or apixaban. Chang and colleagues retrospectively looked at surgical outcomes for patients on these newer agents undergoing Mohs micrographic surgery and found a hemorrhagic complication (mild, intermittent postoperative bleeding that resolved after 3 days) in only one of 27 patients on dabigatran [36] [2b]. Of four patients taking rivaroxaban, there were no bleeding complications. Regarding the case reports, one described an elderly patient on dabigatran who developed a subarachnoid hemorrhage following dermabrasion for scar revision [37] [4] and another who developed a hematoma following a melanoma excision [38] [5]. The half-life of these drugs is relatively short (dabigatran 13–18 h, rivaroxaban 7–13 h, apixaban ~12 h) [39] [2a], suggesting that cessation 2–3 days prior would eliminate most hemorrhage risk. However, initial data is in line with past studies of other antithrombotics (e.g., aspirin, warfarin, and clopidogrel) demonstrating that continued use during cutaneous surgery is safe. Moreover, these newer agents are currently used predominantly for secondary vs. primary prevention, i.e., in patients with established cardiac disease and increased risk of a devastating event with cessation. Further studies are necessary to

draw more definitive conclusions regarding these new agents, but at this time, we recommend continuing the use of these medications during surgery.

An increasingly relevant subject for which there is little published has to do with patients on multiple anticoagulants. Patients are increasingly put on multiple anticoagulants as a number of studies demonstrate the efficacy of combination therapy [20]. There are many frequent combinations of both prescription and nonprescription agents that may or may not act synergistically in terms of enhancing the risk of bleeding, especially when there are agents interfering with both primary and secondary hemostasis as described above. This subject is difficult to study since the number of patients on any particular combination is much less than the total number of dermatologic surgery patients on any one particular agent. Nonetheless, one report attempted to address the subject retrospectively through a chart review [40] [5]. There were no significant bleeding complications in 227 patients undergoing Mohs surgery on one anticoagulant (ASA, warfarin, clopidogrel, dipyridamole/ASA, vitamin E, or fish oil). There were three cases of significant bleeding in a total of 58 patients on 2 or more blood thinning agents. While the authors did show statistical significance for these findings, they are somewhat limited by the very low number of adverse events. Furthermore, none of the patients exhibited any significant morbidity associated with their bleeding complications. This is consistent with the absence in the literature of any life-threatening or lethal bleeding complications after cutaneous surgery. The subject deserves more study with larger numbers to better quantify the increased risk potentially associated with multiple agents. Regardless, it seems difficult to justify modifying a patient's multiple anticoagulant regimen on the basis of this study alone.

Despite the belief by many surgeons that they can predict anticoagulant or blood thinner status intraoperatively, one study of dermatologic surgeons demonstrated that physicians at all levels of training were equally unable to assess blood thinner status based on visual inspection of intraoperative oozing [41] [5]. This is similar to findings reported in coronary artery bypass patients, in which surgeons' impressions of aspirin status were unreliable [42] [2].

There have been several documented reports of serious thromboembolic events occurring in patients who discontinued warfarin or aspirin therapy for dermatologic surgery. Kovich reported data from a survey of 504 members of the American College of Mohs Micrographic Surgery and Cutaneous Oncology, and 168 respondents reported 46 patients who experienced thrombotic events [43] [4]. These were all serious events and included 24 strokes, 3 cerebral emboli, 5 myocardial infarctions, 8 transient ischemic attacks, 3 deep venous thromboses, 2 pulmonary emboli, 1 retinal artery occlusion leading to blindness, and 3 deaths were reported. Of the 46 patients who experienced thrombotic events, 54% had an event when warfarin was held, 39% occurred when aspirin was held, and 4% of events happened when both medications were held. Alam and Goldberg presented two additional cases and reviewed the above data, calculating an estimated thrombotic risk of one event per ~12,800 operations, and suggested that at least one event would occur per career in half of all dermatologic surgeons [44] [3a]. A meta-analysis of 50,000 patients demonstrated a three-fold higher risk of cardiac events associated with preoperative cessation of aspirin [45] [2a]. A systematic review of published cases from the dental literature found that in 542 cases of preoperative discontinuation of warfarin, there were 5 thrombotic complications, 4 of which were fatal [46] [3a]. There are other documented case reports in the dermatologic surgery literature of stroke, pulmonary embolus, and clotted prosthetic valve occurring in patients in whom anticoagulation or antiplatelet medications were discontinued perioperatively [44, 47] [5].

Anticoagulation is often critical given the profound morbidity and mortality of thromboembolic events. The risk of ischemic stroke increases 1.5-fold for every 10 years of age increase, with estimated incidence of 14 per 1000 person-years for people aged 75 to <85 years and 29 per 1000 person-years for people 85 years and older [48] [2a]. A review in the *New England Journal of*

Medicine highlights the potential gravity of thromboembolic complications. A patient who experiences a recurrent episode of venous thromboembolism has a 6% mortality risk and 2% risk for serious permanent disability [49] [1]. Arterial thromboembolism morbidity and mortality rates are higher, with 20% of events being fatal and 40% resulting in serious permanent disability. The risk of these grave complications varies somewhat depending upon the circumstance and indication for anticoagulation. Patients with older mechanical cardiac valves or a mechanical mitral valve are at higher risk than those with newer or aortic mechanical valves. Patients with DVT are at much greater risk if the DVT was diagnosed within 1 month of the perioperative period. In addition, patients with stable, lone atrial fibrillation who have no history of stroke or other risk factors for stroke are at much lower risk than those atrial fibrillation patients who do have such a history [50] [5].

For two of the common indications for warfarin or the newer anticoagulants, (atrial fibrillation and artificial heart valve replacement), the estimated risks of thromboembolism are 1–20% per year and 8–22% per year, respectively [50] [4]. For the third most common indication, DVT, the estimated clotting risk is 1% per day for patients who have had a DVT within 1 month, and 0.2% and 0.04% for patients with DVTs within 2–3 months and over 3 months, respectively. Using these numbers, the estimated 2-day risk of a thrombotic event in a patient taken off warfarin for a dermatologic procedure is 0.01–0.3% in the setting of atrial fibrillation and 0.08–0.4% for a patient with an artificial heart valve replacement. For DVT patients, the 2-day risk is 4–6% in those less than 1 month after a DVT, 0.8–1.2% in those 2–3 months after DVT, and 0.16–0.24% in those more than 3 months after DVT [50].

The majority of studies support the continued use of existing anticoagulation during dermatologic surgery, but providers do have variable practices. A 2005 ACMS survey of Mohs surgeons found that 87% discontinue prophylactic aspirin, 37% medically necessary aspirin, 44% discontinue warfarin, 77% discontinue NSAIDs, and 77% discontinue Vitamin E [51] [2c]. These numbers are down from an earlier 2002 survey of Mohs surgeons reporting that rather than 44%, fully 80% of surgeons discontinued warfarin preoperatively, marking a notable shift in the paradigm of anticoagulant use during cutaneous surgery [52] [3b]. With continued, mounting evidence to support the continuation of anticoagulation, those numbers are likely even lower today.

These data lend themselves to the clinical recommendations summarized below with their accompanying evidence levels. The literature overall supports the continuation of anticoagulants given the ease of managing the potential minimally increased risk of bleeding given that thrombotic complications are potentially devastating and life-threatening. While it is generally clear that patients should be maintained on anticoagulants for secondary prevention, some cases inevitably merit further discussion. It is important to remember that these guidelines have not necessarily been adopted by other surgical fields who often extrapolate data from more invasive surgeries in considering the risk of continuing an anticoagulant during surgery. Therefore, communication with our colleagues in the other surgical disciplines is critical if, for example, the dermatologic surgeon anticipates referral to a plastic or head and neck surgeon for repair of a Mohs surgery defect in an anticoagulated patient. Our consulting colleagues may wish to hold anticoagulants for large defects, defects involving the scalp or eyelids, or any reconstruction that is expected to require extensive and/or deep undermining. Though the data in the dermatologic surgery literature is quite clear, and even other specialty groups such as the American College of Chest Physicians have recommended continuing anticoagulation for minor dermatologic procedures [53] [3a], it is important to remember that the decision to withhold anticoagulants preoperatively depends upon numerous clinical factors and assessment of risk must be conducted on a case-by-case basis. This decision depends not only upon a critical appraisal of the relevant literature but also on the clinical acumen of the surgeon performing the procedure. Furthermore, while it seems common to consult with a patient's cardiologist or primary care physician regarding

perioperative anticoagulants, the value of this practice is limited by these physicians' lack of familiarity with the above reviewed literature and dermatologic surgery procedures in general.

Cutaneous surgery is performed commonly on patients taking medically necessary blood-thinning medications such as warfarin and aspirin. Available data suggest that the risk of severe hemorrhagic complications is not increased if these medications are continued. Importantly, brief perioperative discontinuation does NOT lower this already minimal hemorrhagic risk. Life-threatening thromboembolic complications have been related temporally to perioperative discontinuation of both warfarin and aspirin. In general, the risks of stopping anticoagulants far outweigh the risks of continuing them for most dermatologic surgery procedures. As the use of these agents increases, the onus is on the dermatologic surgeon to help prevent bleeding complications through careful preoperative assessment, meticulous intraoperative hemostasis, effective use of pressure dressings, and excellent postoperative care and follow-up.

Observations and Recommendations

Findings	GRADE score: quality of evidence
Recommendations regarding perioperative use of blood-thinning agents	
All vitamin supplements and herbal medications should be discontinued 7–10 days preoperatively and resumed 1 week following surgery. For practical purposes, and since many supplements and over-the-counter vitamins can affect bleeding, we do not distinguish between various agents with regard to recommending patient discontinuation	C
Nonsteroidal anti-inflammatory medications (NSAIDs) should be stopped 3 days prior to surgery, with recommended resumption 1 week following the procedure. Because of their reversible effect on platelet aggregation via cyclooxygenase inhibition and the relatively short drug half-life, 3 days of preoperative discontinuation is sufficient for resumption of platelet function, and we find that most patients can tolerate being off NSAIDs for that period of time	B
Primary preventative aspirin, which irreversibly inhibits platelet function, should be discontinued 10–14 days prior to surgery and restarted 1 week after the procedure	B
Medically necessary warfarin and aspirin should be continued, with an INR value recommended within at least 1 week of surgery. Care must be taken to assess the preoperative history whether or not the warfarin doses and INR measurements are stable. In addition, a careful medication history assessing for new medication additions that may affect warfarin levels is crucial	A
We currently recommend that patients continue clopidogrel in the perioperative period, although further studies regarding this medication and complications are warranted	B
Regarding current use of thrombin inhibitors dabigatran, rivaroxaban, and apixaban, we currently recommend that medically necessary use should be continued, but further studies are needed	B

Self-Assessment Questions

1. Which of the following conditions assessed in a preoperative evaluation of past medical history does not contribute to altered platelet function and coagulation?
   a. Liver disease
   b. Renal dysfunction
   c. Hematologic and solid malignancies
   d. Hypertension
   e. All of the above can promote bleeding

2. What is the consensus recommendation for stopping over-the-counter supplements prior to surgery?
   a. Stop supplements 1–3 days prior
   b. Stop supplements 7–10 days prior
   c. Stop supplements 2 weeks prior
   d. Stop supplements 4 weeks prior
   e. It is not necessary to stop supplements prior to surgery

3. Which of the following complications is least likely to be related to complications with hemostasis?
   a. Wound infection
   b. Wound dehiscence
   c. Flap or graft necrosis
   d. Hematoma
   e. All of the above can be related to bleeding complications

4. Based on consensus guidelines, it is necessary to stop which of the following antithrombotic agents before surgery?
   a. Warfarin
   b. Aspirin
   c. Clopidogrel
   d. Dabigatran
   e. Rivaroxaban
   f. None of the above

5. Circle all correct answers: For which class of anticlotting medications is there a known reversal agent?
   a. Thrombin inhibitors (dabigatran [Pradaxa])
   b. Factor Xa inhibitors (rivaroxaban [Xarelto], apixaban [Eliquis])
   c. Inhibition of vitamin K-dependent clotting factors (warfarin [Coumadin])
   d. Platelet inhibitors [aspirin, clopidogrel [Plavix])
   e. All of the above have known reversal agents

Correct Answers

1. e: All of the above can promote bleeding. Explanation: All of the above answers can contribute to dysfunction of coagulation. Hypertension increases systemic pressure and thus increases bleeding from vessels cut during a procedure, while hepatic and renal disease can lead to an abnormality of normal levels of clotting factors. Malignancies as well can stress the system and lead to an excess of factors that inhibit normal clotting.
2. b: Stop supplements 7–10 days prior. Explanation: Common anticoagulant supplements such as vitamin E and Gingko have shorter half-lives and could be stopped only 3 days prior to surgery without causing much problem. However, many other supplements are less well studied, and to be safe, consensus practice suggests 7–10 days of discontinuation.
3. e: All of the above can be related to bleeding complications. Explanation: Without proper hemostasis, bleeding complications can lead to hematoma and possible wound breakdown and dehiscence. A resolving clot can also serve as a nidus for infection in that scenario.
4. f: None of the above. Explanation: Consensus guidelines have shown through a multitude of studies that it is not necessary to stop any antithrombotic agents prior to dermatologic surgery. The risk of thrombotic events (myocardial infarction or cerebrovascular accident) is of much greater concern than bleeding in cutaneous surgery, as the bleeding is typically controlled with relative ease. It is recommended for those on warfarin to have a stable INR, but studies have shown that even with an elevated INR, bleeding during cutaneous surgery is minimal. The majority of providers discontinue use of prophylactic aspirin in patients with no history of cardiovascular disease prior to surgery, but this has not been shown to be necessary in the literature.
5. a and c: Explanation: Vitamin K or prothrombin complex concentrate are known reversals for inhibitors of vitamin K-dependent clotting factors (warfarin [Coumadin]), with IV administration working in less than 24 h. There is also a new reversal agent for the direct thrombin inhibitor dabigatran [Pradaxa]. There are no known reversal agents for the platelet inhibitors aspirin and clopidogrel [Plavix] or factor Xa inhibitors rivaroxaban [Xarelto] or apixaban [Eliquis]. Particularly for the newer factor Xa inhibitors, the lack of an antidote has led to concerns over an inability to stop surgically induced bleeding in a life-threatening situation. No such situations have been reported during dermatologic surgery thus far in the literature.

Prevention and Treatment of Perioperative Pain and Anxiety

65

Kristina Navrazhina, Cerrene N. Giordano, and Kira Minkis

Abstract

A rise in skin cancer incidence alongside the increasing popularity of dermatologic procedures necessitates continued advances in dermatologic surgery. Unlike other types of surgeries, the majority of patients are conscious during dermatologic surgery, and thus it is critical for physicians and the medical team to minimize pain and anxiety levels associated with the procedure. Perioperative anxiety can lead to elevated blood pressure, syncope, and increased risk of intraoperative and postoperative bleeding (2b, 3a) (Ravitskiy et al, J Am Acad Dermatol 64:310–322, 2011; Kreicher and Bordeaux, JAMA Facial Plast Surg, 2016). Importantly, a negative surgical experience may hinder the patient from seeking dermatologic care in the future. This chapter assesses the current evidence regarding prevention and treatment of perioperative pain and anxiety.

Keywords

Perioperative anxiety · Perioperative pain
Anxiolytics · Analgesia · Topical anesthetics
Infiltrative anesthetics · Regional nerve blocks · Pain management

Introduction

A rise in skin cancer incidence alongside the increasing popularity of dermatologic procedures necessitates continued advances in dermatologic surgery. Unlike other types of surgeries, the majority of patients are conscious during dermatologic surgery, and thus it is critical for physicians and the medical team to minimize pain and anxiety levels associated with the procedure. Perioperative anxiety can lead to elevated blood pressure, syncope, and increased risk of intraoperative and postoperative bleeding (2b, 3a) [1, 2]. Importantly, a negative surgical experience may hinder the patient from seeking further dermatologic care in the future. This chapter assesses the current evidence regarding prevention and treatment of perioperative pain and anxiety.

Preoperative Pain and Anxiety Management

Administration of Preoperative Anxiolytics

The diagnosis of skin cancer and the subsequent surgical treatment can be a daunting and overwhelming experience for patients. A thorough preoperative evaluation is necessary to establish an understanding of the patient's anxiety level. Anxiety directly impacts cardiovascular physiology and can lead to syncope and increased risk of bleeding (2b) [1]. These adverse effects may hinder patients from seeking future surgical treatment for cutaneous malignancies. Preoperative anxiolytics can mitigate anxiety and decrease pain perception, ultimately resulting in a more positive surgical experience.

An optimal anxiolytic for dermatologic surgery would have a rapid onset, a short half-life, and a large safety margin, thereby enabling appropriate outpatient administration [1]. Benzodiazepines provide anxiolytic, hypnotic, and anterograde amnestic effects that are dose dependent (2b, 4) [1, 3]. Midazolam, which is a short-acting benzodiazepine, has an elimination half-life of 1.5–3 hours and can be administered intravenously, intramuscularly, or orally [1]. The most common side effects include nausea, coughing, vomiting, and hiccoughing, with rarer adverse effects including cardiac arrhythmias and allergic reactions (2b, 5) [1, 4]. Several studies have examined the role of preoperative oral midazolam in patients undergoing dermatologic surgery. Otley and colleagues analyzed a cohort of pediatric patients who received oral midazolam prior to dermatologic procedures. The authors concluded that oral midazolam is a safe and effective anxiolytic and that the provided anxiolysis, in combination with local anesthetics, was sufficient without intravenous sedation or general anesthesia [3].

A randomized double-blind placebo-controlled study led by Ravitskiy and colleagues examined the efficacy of single-dose oral midazolam in anxiolysis during Mohs surgery [1]. Patients were randomized to receive either preoperative 5 cc of 2 mg/mL of midazolam, or color and texture matched placebo. A subset of the patients chose to receive midazolam in a prospective manner. The authors used a ten-point visual analog scale (VAS) to assess anxiety levels 60 minutes following administration of midazolam or placebo. Additionally, adverse effects associated with each study arm were evaluated. Patients in the randomized arm that received midazolam showed a tenfold mean decrease from baseline anxiety at 60 minutes compared to the control cohort. Patients that received midazolam prospectively were more than three times less anxious than at baseline. The decreased anxiety in these patients was accompanied by decreased alertness at 60 and 120 minutes. Midazolam was associated with a statistically lower systolic and diastolic blood pressure at 60 minutes. There was only one self-limited minor respiratory event in the cohort of patients who received midazolam. The group of patients choosing to receive midazolam prospectively had almost threefold higher levels of anxiety at baseline than patients who were willing to be randomized, suggesting that there is a subpopulation of patients who may particularly benefit from receiving an anxiolytic [1].

Although limited in sample size, both studies promote the utility of oral midazolam as an effective anxiolytic in patients undergoing dermatologic surgery. This can be of particular utility in the subpopulation of patients with higher baseline anxiety levels. While there is currently a dearth of reports examining the efficacy of other benzodiazepines in anxiolysis prior to cutaneous surgery, other randomized controlled studies showed the efficacy of several benzodiazepines including clonazepam, diazepam, alfentanil, and midazolam in patients undergoing same-day non-cutaneous surgeries (2b) [5–7].

Paradoxical reactions to benzodiazepines, characterized by increased talkativeness, restlessness, excessive movement, excitement, agitation, and aggressive behavior, have been documented in <1% of patients (5) [8]. Pediatric and the elderly populations are at a higher risk for paradoxical reactions to benzodiazepines [8]. Although these paradoxical reactions are exceedingly rare, physicians using benzodiazepines

should remain cognizant of these potential effects and be prepared to either cease benzodiazepine use or counter the effects in serious cases with the benzodiazepine antagonist flumazenil.

Preoperative Education

With the majority of dermatologic surgeries taking place in outpatient facilities, it is essential that patients are comfortable taking on a key role in their own postoperative care at home. Preoperative education allows physicians to adequately prepare patients regarding postoperative wound care, expected level of pain, both pharmacological and non-pharmacological pain control, and any relevant management regarding their postoperative recovery. Adequate understanding of the surgical procedure as well as postoperative care may decrease anxiety levels in patients undergoing dermatologic surgery.

While there are no studies specifically addressing the benefit of preoperative education on anxiety and pain levels of patients undergoing dermatologic surgery, O'Donnell and colleagues implemented a quality improvement project to assess the value of preoperative pain management education on the reported pain levels in patients undergoing same-day laparoscopic cholecystectomy. During the preoperative visit, subjects in the intervention group received written and verbal education on postoperative pain management, including proper use of medications, potential side effects and their management, non-pharmacological ways to subdue pain, and the overall importance of timely pain management (3b) [9]. Patients who received detailed preoperative education about pain management reported less severe pain during the first 24 hours postoperatively. This clinically significant result suggests that preoperative education can decrease the severity of pain that patients experience after their operation and thus allow patients to return to regular activities sooner [9].

Sobanko and colleagues conducted a clinical trial of 53 patients randomized to receive same-day consultation versus 51 patients randomized to receive both same-day consultation and preoperative phone call 1 week prior to Mohs surgery. Interestingly, there were no statistical differences in anxiety levels or overall satisfaction with the surgery between patients who received a phone call and those who did not (2b) [10]. Sharon and colleagues retrospectively surveyed 97 patients who underwent Mohs surgery regarding whether patients preferred separate or same-day preoperative consultation. While having a separate-day consultation may decrease anxiety levels by allowing patients to have more time to establish a relationship with the dermatologic surgeon, become better informed regarding the procedure, and allow the surgeon to better understand the patient's concerns, attending a separate appointment may present both a financial and a time burden on the patients and delay the time to removal of the neoplasm. In the cohort of patients studied by Sharon et al., 67% of the patients preferred same-day preoperative consultation. When analysis was accounted for other covariates, the authors showed that higher education level was associated with predilection for same-day consultation. Furthermore, the authors suggest that patients with a more difficult surgical history may benefit from advanced preoperative consultation (3b) [11].

Studies by O'Donnell, Sobanko, Sharon, and colleagues highlight a clear role of preoperative education on pain and anxiety levels of patients undergoing same-day surgery [9–11]. While same-day preoperative education may be sufficient, physicians must balance patient preference with urgency for the procedure.

Intraoperative Pain Management

Perioperative pain remains a leading concern for patients. When disregarded or inappropriately managed, pain may lead to decreased patient satisfaction and an increase in postoperative complications including inferior wound healing, insomnia, substance abuse, cardiovascular sequelae, transition to chronic pain, and other psychological disorders (5) [12]. However, even patients who report continuous pain maintain a higher overall satisfaction when the staff

attempted to appropriately manage their pain (4) [13]. Dermatologic surgery is unique in its outpatient basis and complete patient consciousness throughout the duration of the operation. Therefore, intraoperative pain control is imperative for the comfort of the patient and the safety of the procedure.

Postoperative pain in dermatology has been widely studied (3b) [14, 15]; however, the literature remains sparse on intraoperative pain assessment and control. In one recent study by Connolly et al., 270 patients undergoing Mohs micrographic surgery were queried on their pain level (on a scale of 1–10) between each layer (3b) [16]. Participants reported pain during 32.8% of procedures, with a majority of patients demonstrating a mild degree of pain with an average score of 3.7 out of 10. Younger patients, those requiring three or more layers, periorbital and nose anatomic locations, more complicated tissue rearrangement repairs, and total elapsed time of at least 6.6 hours, were all associated with a higher likelihood of pain intraoperatively. Interestingly, the authors concluded that patients were less likely to report pain unless prompted by the staff, suggesting that intraoperative pain may be more prevalent than previously reported.

The most efficient approach at reducing pain due to dermatologic surgery is through adequate anesthesia prior to procedure initiation. A majority of dermatologic surgeries are conducted with the use of local anesthesia due to the reduced recovery time, decreased cost, and improved safety relative to procedures performed under general anesthesia or intravenous sedation (3b) [17]. However, while this modality is ultimately safer in practice, this requires the patient to remain awake through the duration of the procedure, which may increase the possibility for pain and/or anxiety intraoperatively. In addition, the process of anesthetizing a patient, while successfully eliminating intraoperative pain, may in turn evoke pain and anxiety itself (5) [18]. There are many described procedural, behavioral, and communication techniques, as well as anesthetic additives, which can ease the process and reduce patient-perceived pain.

Procedural Techniques

Patient expectation, needle phobia, and suboptimal injection technique may all lead to patient intraoperative anxiety and discomfort (5) [19]. The perception of pain associated with local anesthetic injection occurs in a two-part phenomenon. The first sensation is related to the physical insertion of the needle tip, leading to a rapid, sharp pain (5) [20]. Infiltration and rapid tissue expansion cause both chemical and physical stimulation of tissue nociceptors responsible for the second more prolonged and intense portion (3b) [21]. Various injection techniques have been studied with the goal of optimizing anesthesia and easing the burden for both the patient and surgeon.

One of the simplest and most important basic techniques involves proper patient positioning to establish patient and provider comfort. Ergonomics is an applied science concerned with designing and arranging a space to improve the efficiency and safety of human-environment interactions and is becoming an increasing focus in medicine to maintain provider health and longevity. One study surveyed members of the American College of Mohs Surgery and suggested that 90% of surgeons reported some types of musculoskeletal symptoms or injuries, including neck (65%), lower back (63%), upper back (53%), and shoulder (61%) pain (3b) [22]. Even more concerning evidence exists that musculoskeletal pain occurs early in the careers of Mohs surgeons, with 69% of young surgeons reporting musculoskeletal ailments within their first 5 years of training. Similar evidence exists in the dental literature as well, with 90.2% of dental practitioners surveyed reporting musculoskeletal pains, with shoulder pain and lower back pain significantly related to years of experience (3b) [23]. This is likely due to the improper positioning, frequent reaching, and repetitive bending during procedures. Proper positioning can ensure provider comfort and minimize surgeon error from accidental slips as well as allow patient stability and reduction in unexpected movements. Bhatia et al. suggest frequent breaks to

stretch, core strength training, and early posture improvement to combat these issues early on in training (5) [24]. Data from other fields suggests that ergonomic interventions may improve and prevent musculoskeletal disorders (3b–4) [25, 26]. Additionally, workers who receive training in ergonomics in addition to workspace redesign have fewer symptoms compared to those who receive training only without available supportive equipment (2b–3a) [27, 28]. Formal studies are indicated in the field of dermatology and dermatologic surgery in order to validate interventions that promote and improve ergonomics for our specialty.

Smaller needle sizes, particularly 32 gauge, may reduce pain perception upon needle entry (1b) [29]. This has shown benefit for cosmetic procedures; however, it may be extrapolated to anesthetic injections as well. In addition, needles should be frequently replaced to reduce injection-associated pain [29] and where possible, injection through a large pore or follicle has been demonstrated to minimize discomfort with anesthesia as well as cosmetic injections (2b) [20, 30]. Anecdotal evidence exists for additional techniques such as pinching or stretching the skin through the duration of injection and slow infiltration with initial depot aimed below the dermal-subcutaneous junction with slow advancement into the dermis, where a majority of nerve fibers are located (3a–5) [20, 21, 31]. Injection at a 90-degree angle can minimize the number of transected nerve fibers as well [20], and anterograde injection in a fanlike manner may minimize the number of needlepoint injections while maintaining the anesthetic wheal before the needle tip to avoid further needle-related pain (3a) [31].

Local external cooling has shown benefits in reducing postoperative pain and edema, and attempts have been made to capitalize on this evidence perioperatively (1b–2b) [21, 32–37]. Some suggest that cooling can substitute for the injection of local anesthetics with minor cutaneous procedures [21]. However, more practical uses involve the application of cryoanalgesia to lessen the pain of injectable anesthesia, not to replace it. A randomized trial examined the effect of ice application on pain reduction prior to anesthetic infiltration for eyelid surgery (2b) [38]. The authors concluded that the ice application prior to anesthesia reduced the level of perceived pain by 24.6%. The method of cryoanalgesia has also been examined in a split-hand study for botulinum toxin injections for palmar hyperhidrosis, comparing ice packs to dichlorotetrafluoroethane spray for 5 seconds prior to injection (3b) [39]. Authors concluded that 36 out of 40 patients reported at least a mild decrease in intensity of pain associated with the dichlorotetrafluoroethane spray compared to the ice packs. This has also previously been demonstrated (2b–5) [40–44].

In one small prospective split-arm study, 60 healthy volunteers were treated with lidocaine and epinephrine buffered with sodium bicarbonate in one arm and injection of an unbuffered solution after ice application for 2 minutes to the other arm [21]. Subjects rated the pain immediately after each injection, and while investigators found a trend toward improved anesthesia with the buffered solution (60% of subjects reporting less pain compared to the ice application), there was no significant difference noted between the two methods, suggesting that cryoanalgesia shows equivalent benefit. A number of theories have been postulated in an attempt to explain the mechanism behind skin cooling and pain reduction. Postulates range from vasoconstriction and reduced tissue metabolism in lessening inflammatory mediators and edema to local cooling directly retarding pain signal or neuromuscular transmission, with the activation of A-delta fibers and inhibitory pain pathways (4, 5) [21, 45, 46]. Additionally, the "counterirritant" theory has been postulated, where a temperature stimulus overrides a painful stimulus in the same region, thereby reducing the perceived painful sensation [39]. However, caution must be taken as prolonged application of ice or cooling may in turn cause a burning discomfort. While duration of ice application has been studied (3b) [38, 47, 48], randomized trials are necessary to determine the most appropriate time threshold for ice application.

Behavioral/Communication Techniques (Table 65.1)

Physical distraction methods such as vibration, slight pinching of the skin, and tapping alternate body areas are fairly common, also utilizing the concept of counterirritation or the "gate control" theory where the activation of dermal mechanoreceptors leads to the stimulation of large-diameter A-beta fibers, thereby "closing the gate" and reducing spinal cord transmission of signals produced by pain fibers (5) [20, 31, 49]. Various vibration stimulation devices have been reported in small series to decrease injection-related pain, when applied at or near the injection site (3b–4) [50, 51]. In one small survey-based, split-faced study, 86% of individuals reported mild to no pain with coordinated use of vibration with dermal filler injections, compared to only 12% of those without vibration (4) [52].

Pain interpretation is subjective and individualized; therefore, behavioral interventions are often successful in minimizing pain and anxiety. Distraction or "talkesthesia" is a simple and popular modality that involves talking with the patient about their occupation, hobbies, family, etc. to focus their mind elsewhere during a painful procedure [20]. Often a calming voice, an unhurried attitude, and an anticipatory warning prior to the injection can significantly reduce pain and anxiety [20]. In addition, a soothing and relaxed atmosphere through guided imagery and/or listening to music can be beneficial for the patient and physician (2a–2b) [53–55], each showing benefits in anxiety reduction intraoperatively (1a–1b) [56, 57]. Interestingly, in one randomized study by Alam et al., patients undergoing cutaneous excisions were not significantly impacted by short-contact imagery or music; however, surgeon anxiety was significantly lower when compared to the control group (1b) [58]. Presumably, patient distraction of any method allows the surgeon the freedom to focus on the technical aspects of the procedure, while minimizing the peripheral struggle of limiting patient awareness of the intraoperative proceedings such as cautery, sounds of instruments, etc. In general, music or guided imagery is a favorable technique with growing popularity given its low cost, efficiency, and relative ease of application in daily practice.

More limited evidence exists for the use of hypnosis or meditation (3b–5) [53, 59–61] or additional distraction techniques such as breathing modalities (3b) [62] or physical visual barriers, particularly in the pediatric literature (5) [63].

Table 65.1 Techniques for minimizing pain on injection

Type	Technique	Clinical considerations	Quality of evidence
Procedural	Proper positioning and ergonomic equipment [22, 24]	Patient and provider comfort	C
	Smaller gauge needle with frequent replacement [29, 31]	32 gauge > 30 gauge	B
	Injection through a pore/follicular orifice [30]		C
	Slow, deeper infiltration, injection at 90-degree angle [29, 31]	Fewer nerve fibers transected	D
	Local external cooling—ice, dichlorotetrafluoroethane spray [38–39]		C
	Warming the solution [31, 69–70]		C
Behavioral	Vibration, pinching, tapping, stretching skin [31, 50–51]	Counterirritation theory	C
	"Talkesthesia," music, guided imagery [56, 58]	Distraction	B
	Hypnosis, meditation [53, 59–61]		D
Anesthetic additives	Bicarbonate [64, 67]	Generally 9 or 10:1 mixture	B
	Epinephrine [20, 31]	Vasoconstriction. 1:200,000 adequate	B
	Hyaluronidase [71]	Enhanced diffusion	D

Anesthetic Additives

Additions to injectable anesthetics such as bicarbonate, epinephrine, and hyaluronidase can enhance efficacy and/or improve patient comfort during procedures. The pH of the solution, duration of action of the anesthetic agent, diffusion capabilities, and temperature can all impact the anesthetic effect and degree of patient comfort.

Lidocaine solutions are often acidic, which contributes to pain upon initial infiltration. Commercial preparations of lidocaine generally have a pH of around 6.6–7.0 with the addition of epinephrine decreasing the pH further closer to 3.5–4.6 in order to promote epinephrine stability (1a–3b) [20, 64, 65]. Epinephrine is often added for its vasoconstrictive property. The vasoconstriction provides multiple benefits including minimization of bleeding at the operative site and minimizing systemic absorption. A dual effect is achieved, reducing the potential for systemic toxicity while simultaneously concentrating the anesthetic agent at the target nerves. The addition of epinephrine prolongs the duration of anesthesia by a factor of at least 2 (5) [66]. However, epinephrine increases the acidity of the solution thereby increasing pain with infiltration [20].

To counteract the acidity, bicarbonate is commonly added to increase the pH of the solution, thereby reducing the pain with product infiltration. In a recent Cochrane review, pain associated with the infiltration of a buffered lidocaine solution was significantly less than the pain of unbuffered lidocaine [64]. As expected, the difference in magnitude of the decrease in pain intensity was greater when the solution contained epinephrine, given the lower pH of the unbuffered epinephrine-containing solution compared to plain lidocaine (1a–3b) [64, 67]. Additionally, patient preference results were homogeneous across multiple studies within the meta-analysis with patients universally preferring buffered solutions [64]. A study by Al Shahwan *et al.* noted no significant difference when comparing bicarbonate-buffered lidocaine with preoperative cooling for 2 minutes with ice [21]. While no significant difference existed between the two methods, 60% of subjects reported more pain after the skin cooling compared to the buffered method.

Additional methods have been attempted to reduce the pain of anesthetic infiltration. One small prospective, double-blind study evaluated the difference between a buffered, premixed 1% lidocaine with epinephrine solution and 1% lidocaine freshly mixed with epinephrine on the day of the procedure, both commonly used methods in dermatology offices to reduce anesthetic-associated pain (2b) [68]. Subjects received an intradermal injection of each solution and rated the pain of each injection immediately after using a visual analog scale. While 65% of subjects reported less pain with the buffered solution, results did not achieve statistical significance. Additionally, warming the solution to 98.6–130 °F, particularly when combined with buffering, has been shown to reduce injection-related discomfort (1b–5) [31, 69, 70]. Hyaluronidase is another potential anesthetic additive that promotes diffusion of the anesthetic through digestion of the extracellular matrix. While hyaluronidase has no known properties to reduce pain directly, it has been shown to enhance analgesic efficacy over a larger surface area with a mixture of lidocaine and hyaluronidase when compared to lidocaine alone, requiring lower volumes of anesthetic solution to achieve proper local anesthesia (2b) [71]. No increase in onset or duration was observed [71].

Topical Anesthesia (Table 65.2)

Topical anesthetic agents encompass a wide variety of non-invasive, painless products, which are commonly used prior to minimally invasive cosmetic procedures, such as soft tissue augmentation and laser procedures (2a–3b) [72–77]. They have also shown success with use prior to injections in order to minimize the pain associated with needle stick or venipuncture (1b) [78]. Topical lidocaine and Eutectic Mixture of Local Anesthetics (EMLA, Astra Pharmaceuticals, Westborough, MA) are the two most widely studied and commonly used topical agents in dermatology. Lidocaine is available in many

Table 65.2 Topical anesthetics for cutaneous surfaces

Anesthetic	Onset	Duration	Clinical considerations
EMLA cream (2.5% lidocaine and 2.5% prilocaine hydrochloride)	60–120 minutes [132–133]	3 hours	Applied under occlusion for a recommended minimum of 1 hour, risk of methemoglobinemia [133]
Ela-Max Cream (4% liposomal lidocaine)	Not Defined [133]	Not defined	Over-the-counter. Multiple formulations available, including spray, patches, ointment, and jelly [133]

formulations including cream, viscous solution, jelly, ointment, spray, and patches [77]. Due to its unique liposomal delivery system to enhance penetration through the stratum corneum, lidocaine 4% cream (LMX-4, Ferndale Laboratories, Ferndale, MI, USA) has the advantage of ease of application without occlusion, more rapid onset compared to EMLA, and availability without a prescription [78]. EMLA consists of a eutectic mixture of 2.5% lidocaine and 2.5% prilocaine hydrochloride and is applied to intact skin, under occlusion, for a minimum of 1 hour to facilitate absorption through the stratum corneum.

In one small, randomized pediatric study, a 30-minutes application of 4% liposomal lidocaine without occlusion was shown to be equally as effective as a 60-minute application of EMLA with occlusion prior to venipuncture in children [78]. Further studies exist documenting the success in pain reduction associated with topical anesthetic use prior to minor invasive procedures such as venipuncture or intravenous catheterization (2b) [79–82]. An additional study in children compared the use of an EMLA patch versus placebo prior to local anesthetic infiltration followed immediately by a skin biopsy (1b) [83]. The authors concluded that the EMLA patch did significantly reduce the degree of pain associated with the local anesthetic injection according to verbal pain scores, as assessed by both the patients and physicians. As venipuncture and intravenous catheterization are not synonymous with dermatologic cutaneous procedures, more studies in the dermatologic setting are warranted to truly determine product efficacy.

Additional formulations for topical therapy continue to arise. Friedman *et al*. assessed the efficacy of four commonly used topical agents (EMLA, 4% liposomal lidocaine, tetracaine gel, and Betacaine-LA ointment) with the use of a Q-switched Nd:YAG laser [75]. EMLA and liposomal lidocaine 4% emerged superior and the authors concluded that all four agents achieved adequate anesthesia 90 minutes after initial application. One systematic review concluded that topical tetracaine, liposome-encapsulated tetracaine, and liposome-encapsulated lidocaine are all equally as efficacious as EMLA [74]. This same systematic review compared topical formulations with infiltrated anesthetic during minor superficial instrumentation such as venipuncture, cannulation, or lumbar puncture. While results were largely mixed, some studies demonstrated non-inferiority or superior results with topical formulations over infiltrative anesthesia. While this data may be extrapolated to advocate the use of topical agents prior to local anesthetic injection, the additional time delay due to the necessary incubation time makes consistent use of this technique impractical for the average busy dermatology practice. However, use should be considered prior to certain pre-planned dermatologic procedures, including treatment of anxious patients and children.

New Longer-Acting Agents (Table 65.3)

The ideal local anesthetic would be nontoxic, relatively painless to inject, have a rapid onset, and a lengthy duration of action, providing adequate intraoperative pain relief throughout the duration of the procedure without the need for frequent injections. Lidocaine is the mainstay for achieving local anesthesia in dermatologic surgery due to its rapid onset and moderate duration. However, for a lengthy, multi-hour procedure such as Mohs micrographic surgery, multiple series of injections are often required to maintain adequate anesthesia through the duration of the multi-step procedure. To combat this issue, some

Table 65.3 Local infiltrative anesthetics

Class	Anesthetic	Onset (minutes)	Duration (hours) with epinephrine	Duration (hours) without epinephrine	Clinical considerations
Amide	Bupivacaine [84]	2–10	2–4	4–6	High concentrations in blood may cause re-entrant arrhythmias that are refractory to treatment; increased cardiac toxicity in pregnant patients [86]
	Etidocaine [84]	3–5	3.3	4–6	High concentration in blood can lead to cardio-toxicity
	Levobupivacaine [86, 88]	2–10	2–4	4–6	
	Lidocaine [101]	<1	0.5–2	1–6.6	Most commonly used local anesthetic in dermatology. Pregnancy category B
	Mepivacaine [101]	3–20	0.5–2	1–6.6	
	Ropivacaine [88–91, 101]	1–15	2–6	Not defined	Safer and longer-acting than bupivacaine
Ester	Procaine [101]	5	0.25–0.5	0.5–1.5	
	Tetracaine [101]	7	2–4	2–8	Longest acting of the ester anesthetics

surgeons are supplementing with a longer-acting agent to ease the burden of multiple injections between layers.

One commonly used agent is bupivacaine. Bupivacaine is a slower-acting agent, with a 2–10 minutes onset; however, it has one of the longest durations of action, lasting 120–240 minutes without epinephrine. Due to the longer duration of action, bupivacaine is commonly used in lengthy surgical procedures. In one randomized, double-blind trial comparing local infiltration of intradermal etidocaine 1%, bupivacaine 0.5%, and lidocaine 2%, each with and without epinephrine, it was concluded that adrenalized bupivacaine lasted 27% longer than lidocaine and 45% longer than etidocaine (1b) [84]. However, it was more painful to inject when compared to lidocaine. Some practitioners will use lidocaine and bupivacaine concurrently to combine the more rapid onset of lidocaine with the longer duration of bupivacaine. One small study investigated intradermal injections of 0.25% bupivacaine, 1% lidocaine, 0.125% bupivacaine mixed with 0.5% lidocaine, and 0.25% bupivacaine mixed with 1% lidocaine, with all solutions also containing epinephrine, although the concentrations of epinephrine differed with each solution (2b) [85]. The authors concluded that there was no statistical difference in time to onset for all four solutions. The mean duration of effect was longer in the bupivacaine groups compared to plain lidocaine, with the longest mean duration noted in the 0.125% bupivacaine with 0.5% lidocaine group which was statistically significant compared to plain lidocaine but not to the other groups. Concentrations of epinephrine differed based on the commercially available formulations and may have played a role in the observed clinical durations. The risk of bupivacaine causing cardiac and neurologic toxicity remains a concern (2b) [86]. However, adverse event data is lacking in the dermatologic literature for local cutaneous procedures suggesting that these toxicities should not preclude its use if staying well below the maximum suggested dosage (5) [87].

Ropivacaine and levobupivacaine are two newer amide anesthetics that have a similar duration of action to bupivacaine with fewer cardiotoxic and central nervous system effects and less pain on injection when compared to lidocaine with epinephrine (2b) [86, 88]. In one prospective randomized study comparing lidocaine 2% to ropivacaine 0.75% for digital nerve blocks, ropivacaine had a longer time to onset for pain control (4.5 minutes) but a longer duration of action (21.5 hours) with less patient requirement for analgesics during the first 24 hours postoperatively (2b) [89]. There have been various reports citing the vasoconstrictive properties of ropivacaine (2b–3b) [88, 90, 91]. While clinical

cutaneous blanching was observed, free blood flow was established with removal of the tourniquet, and no harmful effects were observed in the ropivacaine group suggesting comparable safety profiles to lidocaine even with digital blocks. Moffitt *et al.* compared intradermal injections of four different concentrations of ropivacaine (1, 2, 5, and 7.5 mg/mL) and lidocaine 2% with epinephrine 1:80,000 [88]. Pain of ropivacaine increased with increasing strength, and lidocaine with epinephrine was significantly more painful than 7.5 mg/mL of ropivacaine. Ropivacaine had a fairly rapid onset and long duration of action, with the 7.5 mg/mL concentration having the most rapid onset (51 s) and longest duration of action (773 minutes) compared to the lower concentrations. Compared to prilocaine 1% with epinephrine 1:100,000 for upper blepharoplasties, ropivacaine with epinephrine resulted in significantly less intraoperative bleeding and postoperative edema in a split-faced study (2b) [92]. Additionally, plastic surgery groups have compared the use of ropivacaine 0.375% and levobupivacaine 0.25% for acute postoperative pain relief after septorhinoplasty and found similar postoperative analgesic effects between the two agents [86]. Evidence for the use of levobupivacaine in local cutaneous procedures is lacking and more data is needed.

Regional Nerve Blocks (Table 65.4)

Some of the pain associated with local infiltrative anesthetics involves the volume used and degree of tissue distention during infiltration. Regional nerve blocks involve the anesthesia of small selective nerves for the regional elimination of pain. Nerve blocks hold the advantage of utilizing less total volume of medication, thereby minimizing significant tissue distortion and limiting toxicity, while ultimately causing less patient discomfort (4) [93]. However, they are more challenging to administer and require a thorough knowledge of locoregional anatomy in order to be effective. Regional nerve blocks have an excellent safety profile, with one retrospective study of 135 patients with 816 nerve blocks undergoing a laser procedure demonstrating complications in 1.1% of patients, including vasovagal syncope, swelling, and transient neuropraxia (4) [94]. Most evidence surrounding nerve block anesthesia in dermatology is for facial laser procedures or botulinum toxin injection for hyperhidrosis of the palm. One study found significantly lower pain scores in patents receiving peripheral nerve blocks for facial laser treatments compared to topical anesthesia (3b) [95]. In addition, patients undergoing fairly aggressive treatment with a fractional ablative carbon dioxide laser for rhinophyma tolerated the procedure well with regional paranasal nerve blocks (4) [96]. Multiple clinicians have discovered the advantage of nerve blocks prior to acral injections for hyperhidrosis, (2b–4) [97, 98] with one study showing superiority of nerve blocks to cutaneous cooling (2b) [99] and another showing comparable anesthetic results and high safety profile for peripheral nerve blocks compared to Bier's block (intravenous regional anesthesia) (2b) [100]. Nerve blocks have also demonstrated clinical benefit in more sensitive anatomic locations such as the digits, eyelids, nose, and lips with the added benefit of minimized tissue distortion during cutaneous procedures, which aids with improving reconstruction results, postoperative edema, and ecchymosis (1a, 5) [101].

Management of Postoperative Pain and Anxiety

The pathophysiology of acute postoperative pain is multifactorial, involving the stimulation of nociceptive fibers by direct surgical manipulation, postoperative inflammatory pathways that result in downstream modulation of afferent and cortical networks, and previously established psychosocial and neurologic factors that influence cortical pain modulation (5) [12]. Previous studies have demonstrated that failure to properly manage acute postsurgical pain increases the rate of complications including bleeding, poor wound healing, insomnia, chronic pain, substance abuse, and various psychological disorders [12]. Thus, understanding the nature of pain experienced by patients undergoing

Table 65.4 Regional nerve blocks

Nerve block	Clinical indication	Nerve involved	Technique	Area anesthetized
Supratrochlear/ Supraorbital	Laser resurfacing or other laser procedures, local surgery [93, 95]	Supratrochlear, supraorbital	Supratrochlear at medial eyebrow and nasal root junction Supraorbital foramen in midpupillary line at orbital rim	Supratrochlear-medial brow, central forehead/ frontal scalp Supraorbital- middle/ lateral brow and lateral forehead/frontal scalp
Infraorbital		Infraorbital	Percutaneous or mucosal approach Infraorbital foramen in midpupillary line Mucobuccal fold over the second premolar	Lower eyelid, medial cheek, nasal ala, upper cutaneous lip [101]
Mental		Mental	Percutaneous or mucosal approach Foramen midway between the upper and lower edges of the mandible in a direct line with the second bicuspid Gingival-buccal fold at the base of the first bicuspid and directed parallel to the bicuspid in the direction of the foramen [135]	Soft tissues of lower lip and chin
Regional paranasal	Mohs surgery, rhinophyma correction, rhinoplasty [96]	Dorsal nasal branches	Where the nasal bone meets cartilage about 0.6–1.0 cm lateral to midline	Dorsal/lateral nose and tip
Digital	Local surgery, nail procedures	Digital nerves (fingers or toes)	Lateral finger/toe on each side Interweb injections generally less painful. Single volar subcutaneous block is another option [134]	Digit distal to area of anesthesia
Wrist	Hyperhidrosis botulinum toxin injections, local acral surgery [97–98]	Median and/or ulnar nerves	Median insertion between the palmaris longus and flexor carpi radialis at the most proximal wrist crease Ulnar—same level, between the ulnar artery (pulse) and the flexor carpi ulnaris tendon	Median—majority of palm, digits 2–3, and partial anesthesia of digits 1 and radial side of 4 Ulnar—hypothenar eminence, digits 5, and ulnar side of 4

dermatologic surgery and the proper treatment of such postoperative pain is critical in the successful management of postsurgical patients.

Predicting Postoperative Pain

Patients undergoing dermatologic surgery typically experience mild to moderate postoperative pain (4) [14, 102]. Several studies have examined how preoperative and perioperative factors influence postoperative pain levels following Mohs surgery (2B, 4) [14, 15, 103]. The highest pain levels occur on the day of surgery, being most prominent 4 hours postoperatively, and decrease with each successive postoperative day. There has been no reported significant difference between pain levels in the morning and in the evening [15, 103].

Several studies have demonstrated that younger patients have higher levels of postsurgical pain [14, 15]. Firoz *et al.* prospectively analyzed the relationship between postoperative pain levels and

surgical and patient characteristics of 433 patients undergoing Mohs surgery [15]. The authors reported that patients younger than 66 years (the mean age of the cohort) had significantly higher pain levels than patients older than 66 years. There were no statistical differences in pain levels between men and women. Conversely, a study by Merritt and colleagues entailing 1550 patients undergoing Mohs surgery showed women had significantly higher levels of postoperative pain [100]. Multiple studies have shown that patients undergoing Mohs surgery for more than one lesion at a time report higher pain levels than those with only one lesion treated [14, 15, 102].

Although there is clear evidence that having multiple same-day lesions removed and being younger correlate with higher postoperative pain, the significance of location, lesion size, and modality of repair requires further elucidation. While Firoz and colleagues did not find significant differences in postoperative pain levels when separating lesion locations by head and neck versus trunk and extremities [15], several studies associated scalp lesions [14]; lip, nose, and ear lesions [103]; and genital lesions [102] with higher postoperative pain levels among patients. There is no clear consensus regarding the type of closure and mean pain scores. Firoz *et al.* showed that full-thickness skin grafts and flaps (rotation, advancement, transposition, and island pedicle) correlated with the highest pain scores on the day of the surgery, followed by linear closures and secondary intention healing [15]. However, Limthongkul and colleagues did not find any statistical differences in pain scores among patients who underwent different closure techniques in their cohort [14].

These conflicting reports suggest that there are additional factors responsible for pain levels following Mohs surgery other than repair type and lesion site. Studies of non-dermatologic procedures report that obesity, depression, history of hyperalgesia, opioid, and anxiolytic use may be associated with higher postsurgical pain [12]. While it is difficult to predict which patients are more likely to experience pain, surgeons should discuss the spectrum of postoperative pain patients may experience in order to establish appropriate expectations and create a proper management plan.

Postoperative Pain Management

There is no universally accepted treatment for postsurgical pain following dermatologic surgery [12]. As such, balancing successful postoperative analgesia with potential side effects of pain medications is a challenging but crucial step for any dermatologic surgeon. Successful pain management can not only increase patient's comfort and overall satisfaction of the surgery but ensure the surgical experience will not hinder the patient from seeking further dermatologic care.

Evidence for Pain Management with NSAIDs and Acetaminophen (Table 65.5)

Nonsteroidal anti-inflammatory drugs (NSAIDs) reduce pain and inflammation by selective or nonselective inhibition of the pro-inflammatory enzyme cyclooxygenase (COX), which facilitates the metabolism of phospholipid-derived arachidonic acid into prostaglandins in response to tissue injury. Non-selective NSAIDs inhibit both COX-1 and COX-2, while selective NSAIDs are specific for COX-2. It is hypothesized that inhibition of COX-2 is responsible for decreased pain and inflammation, while inhibition of COX-1 may impair renal perfusion as well as lead to gastric perforation [12]. The benefit of NSAIDs in postoperative care can be attributed not only to pain control but also to decrease in postoperative opioid consumption (2B; 5) [104–106].

While the effect of NSAIDs in postoperative pain management, specifically in dermatologic surgery, has not been well studied, previous trials examined the efficacy of ibuprofen versus acetaminophen with codeine in mitigating postoperative pain in patients undergoing cosmetic facial surgery. Chen *et al.* performed a prospective, double-blind randomized trial where patients received either 400 mg of oral ibuprofen or 600/60 mg of acetaminophen/codeine four times a day through the third postoperative day [107]. There were no significant differences in pain levels or the amount of bruising or hematomas between two groups; however, the group

Table 65.5 Non-opioid management for postoperative pain following dermatologic surgery

Chemical class	Drug	Half-life (hours)	Recommended oral dose	Maximum oral dose per 24 hours	Clinical considerations
P-Aminophenol derivative	Acetaminophen [103, 107, 112, 137]	1–4	650–1000 mg every 4–6 hours	3000 mg	Higher doses may lead to hepatic toxicity and renal damage; avoid in chronic alcohol consumers and known liver disease
Salicylate	Aspirin [108, 136–137]	0.3	325–1000 mg every 4 hours	4000 mg	Long-term usage may lead to gastric ulcers and bleeding
Cox-2 selective NSAID	Celecoxib [136, 137]	11	50–100 mg every 12 hours	400 mg	Special consideration in the elderly population as peak plasma concentrations can be up to 40% higher than in younger population
Propionic acid class of NSAIDs	Ibuprofen [107, 136, 137]	2–4	200–800 mg every 4–6 hours	2400 mg	Elderly (>60 years), smokers, patients with previous history of peptic ulcers, patients receiving corticosteroids or anticoagulants, or patients with renal, cardiac, or liver disease may be at a higher risk for GI side effects and renal failure
Acetic Acid class of NSAIDs	Ketorolac [104, 106, 136–137]	5–6	10 mg every 4–6 hours	40 mg	Treatment should be limited to 5 days; dose should be reduced by 50% in patients over 65 years
Anticonvulsant	Gabapentin [114, 137]	5–7	100–300 mg every 24 hours	3600 mg	May lead to dizziness, drowsiness, peripheral edema
	Pregabalin [123, 137]	6–11.5	25–75 mg every 12 hours	600 mg	

receiving ibuprofen had significantly less side effects [107].

Given that NSAIDs inhibit platelet aggregation, thus potentially prolonging bleeding time, there is a concern that postoperative NSAID use may lead to bleeding complications including dehiscence, hematoma formation, or cutaneous hemorrhage. In a series of case studies, Lawrence *et al.* showed that intraoperative bleeding complications during dermatologic surgery only occurred in patients who are taking aspirin and have prolonged bleeding times, suggesting that patients who have normal bleeding times may continue NSAIDs prior to surgery (4) [108]. Similarly, in their cohort of patients, Chen and colleagues did not find evidence of ibuprofen increasing bruising or rates of hematoma compared to non-NSAIDs [107].

For certain patients, acetaminophen may be more advantageous than NSAIDs as it does not impede platelet function and is safer to use in patients with a previous history of peptic ulcers. Firoz and colleagues prospectively evaluated 433 patients undergoing Mohs surgery with the Wong-Baker pain scale [15]. Patients recorded their perceived pain levels up to postoperative day 4. Only 52% of 433 patient cohort took any medications on the day of the surgery, with the majority of patients managing their pain with 500 mg of acetaminophen. 7.1% of patients took narcotic medications on the day of surgery, with a steadily decreasing usage seen on each successive postoperative day. Postoperative defect size was not a significant predictor of the medication type preferentially used by patients. Thus acetaminophen is an effective analgesic following cutaneous surgery. Additionally, considering albeit limited studies, that ibuprofen is as effective at managing postoperative pain as acetaminophen and codeine, with fewer side effects and without increased rates of bruising or hematoma, eligible patients may receive ibuprofen for pain control rather than prescribed narcotics for treatment of postoperative pain.

Pain Management with Narcotics

Opioids are reserved for patients with moderate to severe pain. Oral opioids, such as codeine, oxycodone, and hydrocodone, may be used alone or can be prescribed in combination with acetaminophen or NSAIDs. Opioid analgesia is often limited by the adverse side effects including vomiting, constipation, nausea, pruritus, and more rarely respiratory depression. Special attention must be given while prescribing narcotic medications to the geriatric population, who make up a significant portion of patients undergoing dermatologic surgery for malignancies. As such, choosing opiates as the analgesic of choice in postoperative pain control must be weighed against their adverse effects.

In a retrospective review of 233 charts, Harris and colleagues showed that 82 patients (35% of the cohort) received postoperative opioid prescription following dermatologic surgery (4) [109]. A different study by Harris and colleagues showed that 86% of patients who filled a prescription for opioids had left over pills (49 out of 57 patients). Additionally, 26 of these 49 patients reported that they considered the possibility of not discarding the excess medication (4) [110]. As such, there may be a tendency for dermatologic surgeons to over-prescribe opioids following dermatologic surgery. Since opioids carry a high side effect profile and previous studies have shown that acetaminophen and NSAIDs provide satisfactory analgesia following dermatologic surgery, acetaminophen and NSAIDs should be recommended as first-line analgesics and opioids should only be prescribed if pain control with non-opioids is insufficient.

Evidence for Pain Management with Dual Therapy

Multimodal analgesia can be an effective treatment for postoperative pain due to combining differing mechanisms of the multiple drugs. A Cochrane review analyzed three trials that compared the postoperative efficacy of ibuprofen 400 mg plus 5 mg oxycodone versus placebo (603 subjects), 400 mg ibuprofen plus 5 mg oxycodone versus 400 mg ibuprofen monotherapy (717 subjects), and 400 mg ibuprofen plus 5 mg oxycodone versus 5 mg oxycodone monotherapy (471 subjects). The authors concluded that combining 400 mg ibuprofen with 5 mg oxycodone produced longer pain relief than oxycodone alone but not ibuprofen alone (1A) [111]. A meta-analysis conducted by Ong and colleagues examined the multimodal therapy of NSAIDs with acetaminophen for postoperative pain management. Of the 21 human trials analyzed, the multimodal combination of acetaminophen and NSAIDs was more effective than paracetamol or NSAIDs alone in 85% and 64% of the studies, respectively (1A) [112]. In a systematic review of 60 trials, Maund *et al.* showed that when paracetamol, NSAIDs, and COX2 inhibitors were added to patient-controlled analgesia morphine, all produce a postoperative morphine-sparing effect, with a mean cumulative reduction of morphine usage of 6.34–10.92 mg compared to placebo (1A) [113].

A randomized, double-blind study led by Sniezek and colleagues examined the efficacy of analgesia between 1000 mg acetaminophen monotherapy, 1000 mg acetaminophen plus 400 mg ibuprofen, and 325 mg acetaminophen plus 30 mg codeine in 210 patients undergoing Mohs surgery for solitary head and neck skin cancers [103]. Patients received a mandatory dose immediately following surgery and additional doses every 4 hours as needed. Postoperative pain levels were analyzed at postoperative hours 0, 2, 4, 8, and 12 using a 100-mm visual analog scale. The group randomized to receive acetaminophen and ibuprofen had the smallest change in pain scores from baseline at 2, 4, 8, and 12 hours postoperatively. There were no statistical differences in pain levels among patients in the three cohorts who underwent surgery for lesions larger than $10cm^2$ [2]. Interestingly, although both acetaminophen plus ibuprofen and acetaminophen plus codeine groups provided adequate analgesia, the former cohort reported no adverse side effects, while the latter cohort reported increased bleeding episodes, which is contrary to the commonly held belief that postoperative NSAID use causes

an increase in bleeding complications [103]. Importantly, this study highlights that the use of non-opioid analgesics for small dermatologic defects may be superior to the use of opioids.

Given the high efficacy and minimal complication rate of acetaminophen and ibuprofen, patients should be offered this combination as the first-line analgesic regimen for Mohs surgery. In cases where patients are more likely to experience higher levels of postoperative pain, such as those patients undergoing multiple procedures in a day, or procedures in sensitive regions, such as the scalp or lips, this subset of patients may be offered narcotic medications. However, they should be prescribed a limited number of pills to minimize dependency, as well as to improve interval follow-up rates for refractory pain.

Evidence for Pain Management with Gabapentin/Pregabalin

Gabapentin, a structural analog of γ-aminobutyric acid, is an FDA-approved anticonvulsant for the treatment of seizures and post-herpetic neuralgia (5) [114]. While the exact mechanism of gabapentin-mediated neuropathic pain mitigation is unclear, one plausible explanation entails nerve injury leading to redistribution of calcium and sodium channels, causing neurons to fire spontaneously or at higher frequencies (5) [113–115]. It has been suggested that gabapentin may employ its antihyperalgesic effects by counteracting the hyperexcitability of these pathological channels (5) [115].

Gabapentin possesses a relatively benign side-effect profile, the most common adverse effects being dizziness and somnolence [116]. However, cases of gabapentin-induced ataxia, myoclonus, diplopia, nausea, rhinitis, and Stevens-Johnson syndrome have been reported (5) [116, 117]. The antinociceptive properties combined with a relatively mild side effect profile make gabapentin an attractive candidate for managing postoperative pain. A Cochrane meta-analysis analyzing double-blind trials comparing a single dose of preoperative gabapentin versus placebo in patients undergoing either dental or orthopedic surgeries demonstrated that gabapentin is superior in controlling acute postoperative pain. However, the number needed to treat is inferior to routinely prescribed analgesics (1A) [116].

Gabapentin's role in the postoperative pain management of dermatologic surgeries has not been explored in detail. One case report illustrated the efficacy of gabapentin in a 52-year-old woman who presented with diffuse left cheek pain radiating to the neck and ear following a face-lift procedure. The pain, while refractory to previously administered analgesic medications, responded to a 2-week course of 300 mg gabapentin administered three times daily (5) [118]. Gustorff and colleagues examined the efficacy of gabapentin compared to opioid remifentanil following UVB-induced inflammatory hyperalgesia (2b) [119]. In a double-blind, placebo-controlled study, a patch of skin on 16 healthy volunteers was irradiated with UVB light prior to treatment with either placebo, oral gabapentin, IV remifentanil, or a combination of IV remifentanil and gabapentin. Hyperalgesia in these spots was measured via heat pain perception threshold and heat pain tolerance threshold. Gabapentin did not affect these thresholds, suggesting that gabapentin may not be an effective analgesic for hyperalgesia due to inflammatory skin conditions. Taken together, this evidence suggests that while gabapentin may be a potential avenue for treatment of neuropathic pain, it does not play a role in inflammatory cutaneous conditions where there is no nerve injury [116].

Pregabalin has a similar mechanism of action to gabapentin but with faster oral absorption (5) [120]. In a prospective, randomized, placebo-controlled, double-blind trial involving 52 patients, Wei and colleagues examined the efficacy of 150 mg pregabalin administered 15–60 minutes prior to eyelid surgery compared to placebo (3b) [121]. Subjects were given postoperative acetaminophen for pain control and were asked to evaluate their pain levels using a visual analog scale at time intervals up to 48 hours postoperatively. Throughout the evaluation, patients who were randomized to receive pregabalin reported a 5.5-point lower pain score on average (in a scale of 0–100) compared to

those receiving placebo. Additionally, subjects that received preoperative pregabalin required less postoperative acetaminophen for pain control [121]. However, in a similar randomized study entailing 110 women undergoing same-day cosmetic surgery, Chaparro *et al.* found no statistical difference in the postoperative opioid or anti-inflammatory requirements between those receiving either 75 mg of oral pregabalin every 12 hours for 5 days prior to surgery or placebo (2b) [122]. A systemic review analysis involving 55 studies which assessed the analgesic efficacy of various doses of perioperative pregabalin showed that pregabalin was associated with opioid sparing 24 hours following surgery (1a) [123].

Both gabapentin and pregabalin are potentially effective options to control neuropathic pain following cutaneous surgery. However, further research is warranted to identify whether gabapentin and pregabalin could control non-neuropathic pain following cutaneous surgery and whether the abovementioned studies can therefore be extrapolated to dermatologic surgery.

The excellent safety profile and often expedient postoperative recovery after dermatologic surgery often preclude a detailed discussion about pain control as many patients require minimal to no postoperative pain management. However, patients should be aware of the sequela of postoperative healing, including bruising, swelling, and proper management of pain should they encounter it. Acetaminophen and ibuprofen are a common and efficient treatment for pain in minor dermatologic procedures [15, 103]. However, in a subset of patients who are more likely to encounter more severe pain, they may be offered narcotic pain medication [103]. The side effects of narcotics should be disclosed to the patient, such as constipation and nausea, as these may negatively influence the patient's adherence to the medication—leading to inadequate pain control. Additionally, dermatologic surgeons should remain cognizant of potential for abuse of prescribed narcotics, especially in the setting of the high volume of dermatologic surgeries performed. Therefore, for all the abovementioned reasons, non-opioid alternatives should be considered as first-line analgesics in patients undergoing cutaneous surgery.

Current Evidence on Postsurgical Wound Care

A moist wound environment increases the healing rate of cutaneous lesions by preventing cellular dehydration and subsequent cell death, fostering growth factor release by viable cells, and promoting angiogenesis, ultimately reducing pain during healing and improving cosmetic results (5) [124, 125]. While many dermatologic surgeons achieve this by advising patients to apply topical emollients for 1–2 weeks following surgery, there is no universally accepted standard of care regarding wound care following cutaneous surgery (4) [126].

The risk of infection after dermatologic surgery is low, with previous studies reporting infection rates of 2.45% in Mohs surgery and 2.13% following excisions (2c) [127]. Despite these low infection rates, a previous study demonstrated that dermatologists were more likely to prescribe topical prophylactic antibiotics (6.5%) compared to non-dermatologists (3.5%) (4) [128]. A randomized, double-blind, prospective trial of 922 patients undergoing dermatologic surgery showed that postoperative use of white petrolatum carried the same infection rate as bacitracin but with a lower risk of allergic contact dermatitis (2b) [129]. Campbell and colleagues prospectively randomized patients undergoing auricular Mohs surgery to receive either gentamicin ointment or petrolatum postoperatively. The authors showed that there was no statistical difference in the rates of infection among both cohorts. However, 11.9% of patients using gentamicin, and only 3.33% of patients using petrolatum, developed inflammatory chondritis (2b) [128]. This data suggests that prophylactic topical antibiotics are not necessary following Mohs surgery. Indiscriminate use of such treatment may not only cause dermatitis but can ultimately lead to bacterial resistance.

A 2013 survey of practicing Mohs surgeons reported that petroleum jelly (53.1%) was the most common topical emollient applied immediately post-surgery, followed by Aquaphor (19.4%) and bacitracin (8.2%) [126], with topical antimicrobial treatment being used by 17.7% [124]. For postoperative wound care at home,

the majority of surveyed surgeons recommended petroleum jelly (69.4%), Aquaphor (38.4%), and bacitracin (10.0%). It is important to note that petroleum jelly has a low risk of allergic dermatitis, while Aquaphor, which contains lanolin, may cause a positive reaction in a subset of patch-tested individuals [124]. The successful trend of dermatologic surgeons educating patients regarding the use of topical emollients, rather than antimicrobial agents, may ultimately lead to lower rates of antibiotic resistance and allergic dermatitis.

Postoperative Cold Analgesia

The use of ice packs to reduce pain and swelling is a common household practice. Cooling causes vasoconstriction, thus decreasing blood flow and resulting in reduced tissue metabolism and oxygen consumption, inflammation, and muscle spasms of the treated region (5) [130]. However, the evidence behind the use of ice packs following dermatologic surgery is limited.

Previous studies demonstrate that cold-pack application immediately following surgery reduces postoperative pain levels. Koc *et al.* enrolled 40 patients undergoing inguinal hernia repair in a double-blind, randomized study (4) 131]. Either ice or room temperature water in a plastic bag was applied postoperatively over the incision for 20 minutes, and pain levels were assessed using a VAS scale. There was a decrease in pain levels associated with postoperative ice treatment. Pool *et al.* enrolled 38 subjects undergoing bilateral upper blepharoplasty to study the effect of local ice-pack application on postoperative pain (4) [131]. One eyelid per patient was randomized to receive an ice pack for 30 minutes immediately after surgery, 15–20 minutes upon returning home, and three times for 15–20 minutes on the first postoperative day. The authors used a VAS to assess pain levels at 1 hour and 1 day postoperatively. While the pain levels did not differ between each eyelid on the day of surgery, there were significantly lower pain levels in cooled eyelids on the first postoperative day. However, while statistically significant, the reported pain-level differences were not found to be clinically relevant, nor did ice-pack application reduce hematoma, erythema, or edema between the two groups. Based on these findings, the authors concluded that postoperative cooling following blepharoplasty should not be recommended.

While some studies suggest cold-pack application may potentially decrease postoperative pain, further research is needed to validate the clinical utility of this affordable and simple way to reduce pain following dermatologic surgery.

Conclusions

Management of perioperative and anxiety levels is critical in dermatologic surgery. Preoperative education plays a critical role not only in ensuring the patient's understanding of the procedure and post-procedural care but also in helping the physician assess the patient's baseline anxiety level. Studies show that same-day preoperative education is sufficient to counsel patients regarding their care. Current evidence supports the utility of preoperative oral benzodiazepines to ease patients' anxiety throughout the surgery, particularly in a subset of patients that have a higher baseline anxiety level. Multiple perioperative measures may be utilized to reduce pain and anxiety of conscious surgery and local anesthesia administration. These range from perioperative music and intraoperative distraction techniques to various methods of limiting pain associated with anesthesia including buffered solutions of local anesthesia, warmed solutions, and longer-acting local agents. Dermatologic surgery has an excellent safety profile, often associated with minimal postoperative pain. Nontheless, it is important to prospectively address patient concerns regarding potential for postoperative pain, and establish a clear plan between the medical team and the patient. Multiple studies support the efficacy and favorable side effect profile of ibuprofen and acetaminophen in postoperative pain reduction; thus, prescription of narcotics should be reserved for a subset of patients with increased risk factors for higher

postoperative pain. Finally, larger-scale and controlled trials are needed specifically in dermatologic surgery in dermatologic surgery to further validate optimal peri- and postoperative pain control to allow dermatologic surgeons to continue to provide excellent, evidence-based care for our patients.

Observations and Recommendations

Evidence-Based Summary for Management of Perioperative Pain and Anxiety

Level of Evidence	Conclusions
B	Oral midazolam reduces perioperative anxiety during dermatologic surgery
C	While there is a clear role of preoperative education in management of pain and anxiety, same-day preoperative education may be sufficient in dermatologic surgery
C	Smaller-gauge needles with frequent replacement, and needle insertion into a pore/follicular opening, can minimize injection pain
B	Sodium bicarbonate is often added to local anesthetic mixtures to increase the pH of the solution and reduce pain with product infiltration
B	The use of longer-acting agents such as bupivacaine, ropivacaine, or levobupivacaine is recommended in lengthy, multi-step procedures
C	Regional nerve blocks are useful in anesthetizing large areas (i.e., full face), and anatomically sensitive areas (i.e., eyelid, nose, lip), to minimize tissue distortion and limit toxicity
C	Patients undergoing same-day surgery for multiple lesions as well as younger patients may have higher postoperative pain levels
C	Postoperative use of topical petrolatum carries the same rate of infection as postoperative use of topical bacitracin
B	Individual or multimodal use of acetaminophen and ibuprofen may be sufficient in management of postoperative pain following dermatologic surgery and can be used as first line in place of opioids

Self-Assessment Questions

1. Based on current evidence, what is the recommended topical ointment following dermatologic surgery for most anatomic locations?
   (a) Gentamicin ointment
   (b) White petrolatum
   (c) Bacitracin ointment
   (d) Aquaphor

2. Which of the following local infiltrative anesthetics has the longest duration of action?
   (a) Ropivacaine
   (b) Bupivacaine
   (c) Tetracaine
   (d) Lidocaine

3. Which of the following statements regarding postoperative pain is correct?
   (a) Older patients typically have higher levels of postoperative pain
   (b) Men in general experience higher pain levels then women
   (c) Having multiple lesions removed on the same day correlates with higher postoperative pain
   (d) Patients should expect the highest pain levels on the second postoperative day

4. Based on current evidence, which of the following benzodiazepines has shown promise in the treatment of preoperative anxiety in patients undergoing dermatologic surgery?
   (a) Oral midazolam
   (b) IV diazepam
   (c) Oxazepam
   (d) IV midazolam

5. Which of the following anesthetic additives has the strongest evidence to support its use in reducing pain on infiltration?
   (a) Epinephrine
   (b) Hyaluronidase
   (c) Sterile saline
   (d) Bicarbonate

Answers

1. b: White petrolatum. Evidence suggests that wounds receiving white petrolatum had the same infection rates when compared to wounds treated with bacitracin or topical gentamicin. White petrolatum had the same infection rate when compared to bacitracin or topical gentamicin. Additionally, petrolatum had a lower risk of allergic contact dermatitis and inflammatory auricular chondritis compared to the antibiotic ointments.
2. a: Ropivacaine. Ropivacaine has been shown to last an average of 2–6 hours without epinephrine, with studies demonstrating a duration of 21.5 hours when used in a nerve block and 12.9 hours when combined with epinephrine.
3. c: Having multiple lesions removed on the same day correlates with higher postoperative pain. Younger patients and those undergoing same-day multiple site surgeries tend to have higher levels of pain. The highest pain is generally within the first 24 postoperative hours.
4. a: Oral midazolam. An optimal anxiolytic for dermatologic surgery would have a rapid onset, a short half-life, and a large safety margin, thereby enabling appropriate administration in an outpatient setting. Several studies have examined the role of preoperative oral midazolam in patients undergoing dermatologic surgery. The authors concluded that oral midazolam is a safe and effective anxiolytic and that the provided anxiolysis, in combination with local anesthetics, was sufficient without intravenous sedation or general anesthesia.
5. d: Bicarbonate. To counteract the acidity of lidocaine, bicarbonate is commonly added to increase the pH of the solution, thereby reducing the pain with product infiltration. In a recent Cochrane review, pain associated with the infiltration of a buffered lidocaine solution was significantly less than the pain of unbuffered lidocaine. Additionally, patient preference results were homogeneous across multiple studies within the meta-analysis with patients universally preferring buffered solutions.

Prevention of Undesirable Outcomes

66

Nicholas Golda, Brandon Brown, Alison Basak, Kathryn Potter, and Nita Kohli

Abstract

When performing reconstructions in cutaneous surgery, there are several potential pitfalls that can lead to suboptimal outcomes. The most common of these issues include wound edge necrosis, trapdoor deformities, flap or graft necrosis, nasal valving, and free margin distortion. In this chapter, the causes of these issues are explored, and evidence-based techniques for minimizing or preventing inferior outcomes related to these factors as well as techniques that can be used to address these outcomes should they arise are discussed.

Wound Edge Necrosis

Epidemiology

The incidence of skin edge necrosis has not been described, though, anecdotally, this is a more or less common occurrence in dermatologic surgery depending on patient and technique factors existent in different surgeons' offices.

Severity and Duration

Wound edge necrosis can result in a more obvious scar where wound edges have been brought together. While the cosmetic impact of this may be important to some patients, it may be less so to others. The furrowing along the wound edge that can be present in the setting of resolved wound edge necrosis is typically permanent though some improvement may be noted during the first 6–12 months postoperatively during which time collagen remodeling and wound maturation occur.

Preoperative Evaluation

As most known causes of wound edge necrosis are technique-dependent, there are no significant preoperative factors to consider in an effort to

prevent this complication. One of the most significant patient factors associated with wound edge necrosis is smoking. A meta-analysis of several cohort studies including thousands of patients found a significantly increased risk of wound necrosis, healing delay, dehiscence, and infection in smokers when compared with nonsmokers. With respect to smoking cessation, a meta-analysis of studies of complications following elective general surgical and orthopedic procedures showed a significantly lower rate of overall complications, wound healing complications, and infections in patients on smoking cessation programs with the benefit increasing with every week of smoking cessation up to 6 weeks (2a) [1]. A prospective study focusing on skin surgery, however, showed no significant difference between smokers and nonsmokers with respect to infection, bleeding, wound dehiscence, and total complication rate. A significant difference was, however, found with respect to scar contour distortion with smokers having a greater risk of this result. This may be attributable to wound edge necrosis, but that attribution is not certain with the information collected in the study (3b) [2].

Effect of Wound Edge Necrosis on Patients

Scars, especially on the head and neck, can change physical appearance and negatively impact psychosocial functioning (2a) [3]. For some patients, their satisfaction with skin cancer treatment correlates significantly with the final aesthetic outcome of their surgery. The impact of flap and graft necrosis on patients has not been studied specifically, but common sense dictates that this complication is likely to distress patients about the future cosmesis and functionality of their repair. Infection, multiple office visits, and supplementary surgeries may be additional worries. For most patients, knowing that their surgeon takes their concerns seriously and stands behind their work goes a long way toward assuaging their worries. Most patients can be reassured that they will heal without the need for further significant intervention. If further interventions are needed, then a repeat surgical procedure should not be feared. If either the surgeon or the patient is uncomfortable revisiting the surgical site, referral of the patient to a colleague for support may be warranted. It may also help to preemptively counsel patients about how their underlying conditions can influence outcomes prior to initiating the repair process. This is true of all of the succeeding sections with the addition of some functional implications associated with nasal valve dysfunction and free margin violation.

Preventive Interventions

There are many widely accepted beliefs among surgeons regarding the techniques that can be used to reduce or eliminate wound edge necrosis. Although some data from rigorous evidence exists, the majority of the dogma regarding wound edge necrosis arises from collective experiential wisdom of experts in the field. In general, the best practices and techniques that avoid flap necrosis should apply for the prevention of wound edge necrosis as well, and this section will deal only with evidence related to wound edge necrosis specifically and a literature search focused on wound edge necrosis as a search term.

Proper suturing technique is often mentioned as a means of avoiding wound edge necrosis. Recommendations that can be found without citations in texts and that are taught in many training programs often center around placing sutures in a manner meant to avoid interference with blood flow to the wound edges. Suturing techniques that may impede blood flow to the wound edge include the placement of too many sutures in a wound and placement of sutures too close to one another, both of these being very subjective as to what constitutes too much or too close (5). Sutures placed too tightly can also contribute to wound edge necrosis. Extreme cases of sutures being placed too tightly can be readily identified by tissue bulging between each suture bite. Less readily identifiable cases of overly tight suturing occur when suture technique and suture materials do not allow for the increased

tension caused by post-procedural tissue edema. The suturing pattern can also increase the risk of wound edge necrosis by wound edge ischemia with the use of horizontal mattress, vertical mattress, or running locked sutures (5). One technique that has been shown in studies to reduce wound edge necrosis is proper wound edge or epidermal apposition [4, 5]. A microscopic study of the healing process in sutured wounds in rats, pigs, and humans showed that imperfect apposition of the epidermal edges caused increased dermal necrosis from the overhanging margin as the regenerating epidermis follows the most superficial plane that supports its growth and effectively planes through the overhanging dermis and epidermis. The dermis that is lost is replaced by a scar, and the greater the failure of approximation, the greater the amount and width of scar that is formed (2c) [4].

Handling of tissue is another potential cause of wound edge necrosis. We know from studies of traumatic wounds that tissue that has been subjected to crush injury tends to undergo necrosis [6]. (D) Further, it is widely held that delicate tissue handling, such as with skin hooks or gently with the teeth of tissue forceps, can avoid crush injury to the wound edge and is recommended both during the process of undermining and hemostasis and during suturing or any other scenario where the edges of a wound are to be handled with instruments (5). Further, during the suturing process, multiple attempted passes of a needle through the same region of the wound edge causes tissue trauma that may result in wound edge necrosis (5). Undermining in a superficial plane may possibly predispose to wound edge necrosis due to interruption of blood supply to the skin from deeper perforating vessels that traverse the subdermal fat (5).

A small internally controlled study on piglets compared wound tension forces on sutured wounds closed with and without undermining and/or the use of a skin stretching device for 30 min. The study showed a statistically significant reduction in wound closure tension when the stretching device was used without undermining compared with undermining without the use of the stretching device ($p < 0.001$). This study also showed deep and shallow wound necrosis in 8 out of 15 cases where undermining was employed, while only 1 out of 15 cases that closed with the skin stretching device without undermining showed superficial necrosis. No statistical analysis was done on the significance of this difference, but if significant, this decrease could be due to less vascular interruption by the elimination of undermining or decreased wound tension through use of the skin stretching device (2b) [7].

Another widely held principle of proper wound closure is that wounds under tension will exhibit a greater degree of wound edge necrosis and dehiscence than wounds under little or no tension. This concept is based at least in part on Poiseuille's law, which states that the flow rate through a vessel is proportional to the radius of that vessel to the fourth power. As a vessel is stretched under tension, the lumen shrinks, and according to this concept even small reductions in the radius of a vessel can dramatically reduce the flow of blood to the edges of a wound. One study has demonstrated that there is a measurable inverse relationship between tension and blood flow with necrosis becoming significantly more likely when experimental skin flaps are put under 250 g or more of tension (5) [8].

Electrocautery used injudiciously around wound edges has also been implicated in wound edge necrosis (3b) [5]. This can occur by two key mechanisms: direct injury of the wound edge tissue by contact with the electrosurgical electrode or burning of the wound edge by contact with boiling liquid due to insufficient removal of blood from the operative field during hemostasis.

Other factors that may contribute to wound necrosis were presented in a secondary analysis of data from a multicenter prospective RCT assessing tissue closure techniques, which found that in addition to the factors mentioned previously, extremity location of the wound and wound width resulted in poorer cosmetic appearance of wounds on both univariate and multivariate analysis when applying a validated ordinal scale for wound cosmesis. Interestingly, the development of wound infection and the use of

buried sutures showed statistically insignificant effects on wound cosmesis (2b) [5].

Several topically applied agents have been shown to reduce random-pattern skin flap necrosis, such as topical nifedipine, topical trolamine salicylate, topical nitroglycerin, and others (4) [9]. With respect to flap edge necrosis specifically, topically applied 60% dimethylsulfoxide (DMSO) postoperatively and for the week following breast reconstruction with flap closures showed significantly less flap edge necrosis by weight than untreated flaps (23.48 vs. 126.27 micrograms, $p = 0.03$) with shorter hospital stays postoperatively as well (9.6 vs. 11.8 days, $p = 0.02$). This study on breast reconstruction may, however, not be generalizable to facial reconstruction with random-pattern flaps (2b) [10].

Corrective Interventions

There is no published evidence of treatments for poor or marginal scarring following wound edge necrosis other than what is traditionally done for suboptimal scarring. These interventions include but are not limited to dermabrasion, subcision, pulsed dye laser, fractional resurfacing, and excision of the scar with reclosure.

Flap and Graft Necrosis

Epidemiology

Flap and graft necrosis constitutes an uncommon but potentially devastating outcome following dermatologic surgery. Rates of necrosis have not specifically been assessed in large prospective trials, but rough incidence data in the United States can be extracted from studies looking at complication rates in cutaneous surgery. In a multicenter prospective cohort study of 20,281 Mohs micrographic surgery (MMS) cases, the rate of reported partial and complete necrosis was only 0.14% (1b) [11]. In single-center studies, the necrosis rates have been somewhat higher. A cohort of 1911 MMS patients found flap and graft necrosis rates as 1.7% and 8.6%, respectively (1b) [12]. A prospective single-year study of 578 combined flaps and grafts found some degree of necrosis in 1.9% of cases (1b) [13]. When reviewing 422 cheek reconstructions, investigators found that 1% of the flaps had distal necrosis (2b) [14]. Retrospective analysis of 1334 nasal reconstructions after MMS found that 13 (roughly 1%) experienced partial flap necrosis (2b) [15]. In a study of 171 bilobed transposition flaps, Moy et al. (2b) [16] reported a 7% incidence of partial necrosis.

Any comorbidities, substance use habits, or wound conditions that impair wound healing can increase a patient's risk for necrosis. Diabetes [16–18], older age (4, 5) [17–19], alcohol consumption [20], (5) immunosuppression (5) [21], malnutrition (5) [22], hypercoagulable states [21], (5) and obesity [23, 24] (4) can all retard wound healing (5) [25, 26]. The most important patient factor, however, is tobacco exposure. Cigarette smokers undergoing facelifts had over 12 times the relative risk of superficial necrosis compared with nonsmokers [27] (2b) and experienced greater degrees of tissue ischemia in skin flap surgery (2b, 2b, 5) [28–30]. Goldminz et al. [29] (2b) showed a striking dose-response effect between the packs per day smoked and the development of necrosis in flaps and full-thickness skin grafts (FTSGs). In the study of 1334 nasal reconstructions mentioned earlier, 75% of patients with skin graft death were active smokers (2b) [15].

Wound conditions that increase risk for necrosis include high tension closures, inadequate vascular supply, crush injury, hematoma, seroma, and infection [31, 32].

Severity and Duration

No human studies have examined the severity and duration of flap and graft necrosis. Clinical experience has shown that the seriousness and resolution will greatly depend on the degree of underlying ischemic insult. With epidermal ischemia, patients experience superficial sunburn-like sloughing that resolves within a week or so.

For partial-thickness skin necrosis, the dead tissue may take a couple of weeks to work loose prior to revealing residual intact dermis underneath that then completes healing via re-epithelialization originating from follicular appendages and wound edges. Full-thickness necrosis will take even longer to declare itself and require complete healing by second intent from the wound edges. This may take several weeks depending on the defect size and may result in the greatest severity of cosmetic or functional impairment. Fortunately, severe adverse events appear to be extremely rare. Hospitalization or death as a result of failed dermatologic reconstructions is not reported in the literature as part of the larger case series looking at MMS complications (1b, 1b, 1b, 2b, 2b, 2b) [11–16].

Preventive Evaluation

Specific evidence-based preoperative protocols for evaluating patients in whom a flap or graft is being considered do not exist. A review of medical comorbidities and substance use is important so that patients can be educated on treating their other health conditions that could compromise healing and stopping tobacco and alcohol use in the perioperative period. There is a dose-response effect between packs per day smoked and development of necrosis (2b) [29]. In heavy smokers who are unable or unwilling to limit their tobacco use, avoiding random-pattern flaps and skin grafts may be preferred, if possible.

Scanning laser devices exist for evaluation of adequate cutaneous blood flow (5, 2b) [33, 34] for use in research purposes but are of limited utility in measuring the critical blood flow thresholds that would predict flap survival [35], (5) especially in an outpatient, real-world setting. Intraoperative clues to future random-pattern flap necrosis include pallor, cool temperature, and delayed capillary refill (5) [36]. If in doubt about the distal viability of a flap, the blood can be manually exsanguinated from the tip toward the pedicle base using a cotton dental roll. The tip can then be pricked with a pin; if there is adequate vascularity, the vessels should have been refilled and bright red droplets of blood should be visible (4, 5) [30, 37].

Preventive Interventions

An understanding of the pathophysiology of necrosis is important for mitigating the damage as much as possible. Skin flap failure causes can be divided into extrinsic (infection, shear forces, trauma) and intrinsic (inadequate blood flow, tension) (5) [38]. After flap elevation, vascular flow diminishes, especially to the distal end of the flap. The recipient bed site must have an adequate blood supply to revascularize the flap or graft (5) [33, 39]. Neural increases in sympathetic flow can result in vasoconstriction (5) [30, 40]. Animal skin studies suggest that random-pattern flaps get roughly 50% of their blood supply from their pedicle and the other half, especially distally, by behaving like a graft and sustaining themselves from their recipient bed (5) [41]. Irreversible ischemia, when it happens, occurs approximately 12–15 h following a procedure (5) [42–44].

Exacting surgical technique is paramount in preventing necrosis (C). Techniques that may improve outcomes include designing flaps so that the pedicle can support the distal-most tissue, removing standing cones in a way that does not jeopardize the pedicle, placing tacking sutures parallel rather than perpendicular to underlying feeding blood vessels to avoid a tourniquet effect [45], (5) avoiding excessive cautery [11] (1b) and undermining sufficiently to maximally reduce wound closure tension (5) [45, 46]. Expanding hematomas should be evacuated acutely and hemostasis achieved (5) [42].

For full-thickness skin grafts, defatting the graft and achieving hemostasis of the recipient bed can improve outcomes (5) [47]. Adipose tissue is poorly vascularized and not a good medium for new vessel growth between the graft and wound bed (3a) [48]. Exposed bone, cartilage, and tendon without their associated connective tissue sheaths cannot be relied upon to support the metabolic needs of grafts (D) (5) [32, 33]. Most studies and surgeons support the use of some version of a bolstering apparatus in order to

encourage apposition between the graft and recipient bed (C) (all 5) [20, 32, 49–52]. A few surgeons have successfully used basting sutures instead (5, 2b, 5) [47, 53, 54].

There is evidence to suggest that cessation of smoking improves wound healing and decreases necrosis (level B). Measurements of forearm circulation in smokers versus nonsmokers showed that smoking is associated with cutaneous microvascular dysfunction and that the severity of impairment is related to the duration and intensity of exposure to smoking (2b) [55]. The outcome following flap necrosis was three times worse in former smokers when compared to nonsmokers (2b) [29]. Facelift patients who had stopped smoking for at least 1 year before surgery had a complication rate similar to that of never-smokers (2b) [56].

A systematic review of nicotine replacement therapy (NRT), while acknowledging the need for large randomized trials, found no increased risk in complication rates in patients using NRT and suggested that this can be considered in heavy smokers who may not otherwise be able to tolerate perioperative smoking cessation (C) [57]. In very high-risk patients, surgical delay of the flap may be advisable (level B) (2b, 5, 5) [15, 30, 43]. A prospective trial of immediate versus delayed FTSGs of the nasal tip and ala overlying denuded cartilage showed improved graft survival in the cohort where grafting was delayed by 12–14 days and allowed for the formation of granulation tissue [58]. (2b) Others have replicated these results (5, 5, 2b) [47, 59, 60]. Although specific data regarding alcohol's impact on necrosis is not available, it increases hemorrhage and infection susceptibility (5, 2b) [61, 62]. Many dermatologic surgeons recommend alcohol cessation for a short period following reconstruction [30, 63] (5) and a Cochrane review [64] (1a) supports this general recommendation (C).

A variety of studies, primarily in rat and pig animal models, have attempted to explore the impact of vasodilatory medications on flap survival (5) [9, 65, 66]. Most of these have not been replicated in humans. An exception is topical nitroglycerin, which has been examined in humans with mixed results (1b, 4, 1b, 4) [67–69]. In neonates it was found to decrease skin necrosis after neurosurgical procedures [70] (4), and in women undergoing radical breast cancer resection, it was thought to prevent flap necrosis after a single application (1b) [69]. However, after being applied to 88 skin flaps and grafts as a single immediate postoperative application in dermatology skin cancer patients, topical nitroglycerin 2% ointment failed to show any survival benefit when compared with controls (1b) [67]. Daily application as slow-release pads in a different study also did not offer greater flap survival than in controls [68]. At this stage, more information is needed to understand the potential role of nitroglycerin and other topical agents in ischemic reconstructions and a firm recommendation cannot be made.

Hyperbaric oxygen therapy (HBOT) has also been used for tenuous flaps and grafts. A Cochrane review noted that HBOT might improve outcomes of skin grafting in burn patients but evidence is limited and does not robustly support its use, especially with respect to generalizability to skin grafts and flaps in other patient populations (2a) [71]. Negative pressure wound therapy (NPWT) may also be of benefit in minimizing skin graft necrosis. A Cochrane review included data from three trials involving skin grafts and concluded that NPWT may decrease graft loss, but given that all trials had a high or unclear risk of bias, more data is needed before NPWT can be routinely recommended (1a) [72].

Leeches can be used to improve tissue circulation after reconstruction and help save skin grafts, although they were not useful in flap-tip necrosis when applied after tissue death was clinically evident (5, 3a, 4) [73–75]. Early recognition of venous congestion and application of leeches within 3 h enhanced flap survival (4) [75]. The most dangerous complication of medical leech therapy is infection with *Aeromonas hydrophila*, a bacterium found in the leech gut that can be transmitted to the patient and cause sepsis; this complication is preventable with antibiotic prophylaxis. Hematocrit also needs to be monitored. Arterial insufficiency is a contraindication to use [75].

For composite grafts, there is sparse evidence to support the use of cooling postoperatively to

enhance graft take (5, 3a, 4) [76–78]. As a method to decrease tissue metabolic demand and thereby enhance survival, cooling was investigated in a case-control report of 14 patients with trauma reconstructions (4) [78]. Ice-water and aluminum foil compresses were applied for 3 days postoperatively to composite grafts. The survival rate of these grafts was 87.5% compared to 23.5% in 21 control cases with routine postoperative care. A similar technique using ice applied for 2 weeks in 12 nasal composite grafts in irradiated or scarred skin showed complete take in 10 of the 12 grafts (4) [79].

Corrective Interventions

Early detection of impending necrosis is paramount in limiting damage (5) [43]. A successful flap is usually light pink in color, although healthy grafts may often be red, dark blue, or purple in the early postoperative phase, and this is not a cause for concern; the color will return to flesh tone within a week or so. A black flap or graft signifies tissue death. If a flap becomes pale during reconstruction, the surgeon should analyze whether this is due to excessive tension, vasoconstrictive epinephrine, or a poorly designed or positioned flap. If the cause is not readily correctible at that time, then the prudent course of action is to return the flap to its original bed. The flap can then be delayed for 2–3 weeks and then used to repair the defect, at which point in time it is usually able to be self-sustaining (5) [59, 80].

Once necrosis has occurred, it is usually managed conservatively in the acute period with moist dressings using petrolatum ointment and minimal debriding, unless infected (5) [45, 81]. Infarcted grafts and flaps are left in place to act as biologic dressings under which healing will progress and then slough off naturally. Wounds then finish healing by secondary intent. The end result is often superior to that initially expected, and if patients are supported through the process, most do well. Only if essential tissue building blocks need to be salvaged for future repair should these be recovered as soon as possible by being returned to their donor bed. Once the area heals, a second revision procedure can be planned if needed.

A review of scar treatments is beyond the scope of this chapter, but for minor adjustments, dermabrasion [58], (1b) PDL, and ablative lasers can be used to improve cosmetic appearance. In those cases where an unacceptable cosmetic outcome results, revision surgery can be methodically planned and scheduled. Corrections for the initial cause of necrosis should be made when planning the second surgery so that history does not repeat itself.

Fortunately, necrosis in dermatologic surgery is not common and there has not been a strong impetus for large, comparative trials as the patient population for such a study does not exist.

Appropriate Schedule for Monitoring

Maintaining close and frequent follow-up reassures the patient that the surgeon is committed to helping them realize the best possible outcome (5) [81]. The specific follow-up schedule will depend on the practice setting and what is practical for the patient. More patient reassurance is typically required initially, and then visits can be spaced out as the wound progresses through the acute phase and remodeling begins. Evaluations for revisions are typically performed at least 6 months or longer after the initial surgery in order to allow for wound maturation, edema resolution, and better tissue handling once deficiencies are identified [82].

Pincushioning (Trapdoor Deformity)

Epidemiology

Pincushioning, or the trapdoor effect, is the upward movement of tissue within the confines of surrounding depressed scar. Mustarde described this unwanted surgical complication in 1966 [83]. Despite being a frequent topic in surgical texts and a relatively well-known complication of

transposition flaps, there is a paucity of rigorous data regarding the prevention and correction of this complication. While it is often referenced in regard to correcting defects on the nose, pincushioning can result after the repair of any semicircular wound in a U, C, or V shape [83]. This deformity appears commonly around 3 weeks after surgery but can appear up to 6 months post-procedure.

As Mohs micrographic surgery numbers increase annually, it can be extrapolated that the number of repairs by transposition flaps is also increasing and so is the risk of pincushion defects. At the Gainesville Veterans Administration Hospital, a retrospective analysis was performed on 13 patients who underwent nasolabial flaps after surgical extirpation of tumors by Mohs micrographic surgery. The mean age of these men was 63 years and follow-up mean was 8 months. Out of the 13 patients reported in the study, 6 required subsequent revision of their flap for trapdoor deformity (4) [84]. Although one small retrospective case series of adult men is certainly not indicative of the general population, one can postulate that pincushioning is a common adverse event after transposition flaps.

Preoperative Evaluation

In the preoperative period, the surgeon can start to consider which closure option will be best for the patient. After tumor extirpation, the surgeon will discuss closure options with their patient. Generally, the surgeon should discuss pincushioning as a possible risk during scar formation with any reconstruction having a U, C or V shape, particularly, when a transposition flap is used for wound closure.

Preventive Interventions

Several factors have been suggested in the past for the cause of trapdoor deformity including lymphatic and venous obstruction, bevel-shaped flap, excess fatty tissue under flap, scar hypertrophy, and wound contracture (5) [85]. However, currently the prevailing view among many surgeons in various disciplines seems to be that the most effective way to decrease the risk of trapdoor deformity is by minimizing recipient site wound contraction. There are several factors the surgeon needs to consider when planning a flap. Many texts state that geometric linear flap design is less prone to developing trapdoor deformities due to the theoretical dispersion of contractile forces away from the center of the flap, but to our knowledge this hasn't been confirmed with a controlled trial (5). Another consideration is the concept of contact inhibition, which has been explored in animal models. It has been demonstrated that coverage with full-thickness skin grafts and split-thickness skin grafts decreases myofibroblast concentration and function and ultimately wound contraction in rats (5) [86]. It has also been demonstrated that placement of a flap that occupies the full three-dimensional space of the defect induces apoptosis of granulation tissue fibroblasts and decreases wound contraction (5) [87]. If the base of the flap does not come into contact with the wound bed, then the inhibition of wound contracture that happens with appropriately sized flaps does not take place. The most discussed method of prevention of trapdoor deformities is wide local tissue undermining of the recipient site (5) [88–90]. Kaufman and colleagues demonstrated that wide undermining decreased the risk of pincushion effect in wounds on guinea pigs (5) [91]. In the absence of wide recipient site undermining, all of the wound contractile forces are directed inward, toward the center of the recipient site, and as the recipient site decreases in size due to wound contraction, the body of the flap is forced in an outward direction. With wide recipient site undermining, there are opposing contractile forces into the surrounding tissue as the sheetlike scar develops and the effect of centripetal wound contraction decreases (5) [92].

Corrective Interventions

Corrective interventions for the trapdoor effect include intralesional steroid injections, Z-plasties along the surgical wound, massage, and debulking.

One approach, if the wound is well approximated and the edges blend well with the surrounding skin, is injection of intralesional kenalog (ILK) into the subcutaneous tissue beneath the flap where the contracted scarring has occurred (5) [90]. By combining Z-plasties along the scar line as well as wide undermining, longitudinal and horizontal forces of contracture are corrected. The goal of correction is to re-direct the contractile forces tangentially away from the wound instead of into it.

Koranda and Webster treated 22 patients with trapdoor deformity with either intralesional Kenalog (ILK), Z-plasties along the scar line, or Z-plasties with wide undermining. Fifteen of the patients were treated with ILK 20 mg/mL once, and then if not improved, 40 mg/mL on repeat treatment 3–4 weeks later. Out of those patients, three improved to a satisfactory scar. Eight patients were treated with multiple Z-plasties along the scar line; each of the arms of the incisions was 8–10 mm in length and angles were between 45° and 60°. Of the eight patients treated with Z-plasty alone, five had complete resolution of the trapdoor defect. Six patients were treated with both Z-plasties and wide undermining, and all six patients had complete resolution of the trapdoor defect (4) [83].

Nasal Valve Dysfunction

Nasal valve dysfunction is a potential complication of dermatologic surgery involving the nasal ala. The term "nasal valve" was first described by Mink in 1903 and was defined as the angle between the cartilaginous septum and the caudal end of the upper lateral cartilages. It has been proposed that the valve maintains an evolutionary protective function, that of preventing large volumes of unhumidified and unheated air into the lower respiratory tract (5) [93]. That definition has evolved to separate the nasal valve into internal and external components. Much of the literature involving nasal valve dysfunction has been published by otolaryngologists who are interested in preventing internal nasal valve dysfunction which is most often associated with rhinoplasty or nasal trauma [94]. In contrast to the internal nasal valve, the external nasal valve is often disrupted after Mohs micrographic surgery, although the inner nasal valve can also be narrowed after surgery due to post-surgery scarring.

The external (outer) nasal valve is formed by the columella, nasal floor, and caudal border of the lower lateral cartilage. The lateral crus supports the anterior half of the ala, while the shape of the posterior half of the ala is supported by thick dermis and fibrous tissue [95]. The nasal valve structure is the point of maximal nasal flow resistance during inspiration. The external nasal valve allows the ala to remain patent during inspiration but is a collapsible flow-limiting segment should the nasal airflow reach critical transmural pressure. If the nasal valve structure is not intact, the negative pressure created during inspiration will result in collapse of the ala. The loss of patency of the ala is explained by Bernoulli's principle which states that as the velocity of flow increases, the pressure decreases. Nasal resistance is inversely proportional to the fourth power of the radius of the nasal passage according to Poiseuille's law and therefore small changes in the size of the nasal valve can have large effects on resistance [95].

Epidemiology

Mohs micrographic surgery that involves the nasal ala and defects that come within 1 mm of the alar groove are at risk of nasal valve dysfunction after surgery. It is important to recognize this risk because appropriate initial repair to avoid dysfunction is preferred over needing to correct valve dysfunction after surgery. Robinson and Burget report that 27% of patients at risk of nasal valve dysfunction due to proximity of the defects to the nasal ala developed symptomatic nasal valve dysfunction (4) [96]. Reynoulds and Gourdin also validated this finding in their own retrospective study in which 21% of their patients who had at-risk surgery developed nasal stuffiness on the operated side (4) [97]. Other risk factors for external nasal valve collapse include compression from a bulky flap or hematoma and nasal-tip ptosis [98, 99].

Severity and Duration

The primary symptom of nasal valve dysfunction post-surgery is a sense of nasal congestion although prolonged dysfunction can result in difficulty breathing while supine (4) [94]. Subjective assessment my include the nasal obstruction symptom evaluation (NOSE) which was validated by Stewart (2b) [100]. This questionnaire is frequently used to evaluate the degree to which nasal obstruction is affecting quality of life. It evaluates nasal congestion, nasal blockage, trouble breathing through the nose, trouble sleeping, and inability to get enough air through the nose during exercise. Another tool that has been used is the sino-nasal outcome test (SNOT 22) (5) [101], although it has not been as well validated. Objectively, the Cottle and the modified Cottle maneuver can further evaluate degree of obstruction. In the Cottle maneuver, one nare is closed and the patient inspires. Lateral pressure is applied to the open nare side, and the patient is asked if there is improvement. The modified Cottle maneuver is similar; the difference being lateral pressure is applied to the open nare with a swab rather than the lateral pressure on the cheek. As the symptoms of nasal obstruction are bothersome to the patient, so too is the cosmetic outcome of the constant collapse of the ala.

Preoperative Evaluation

It would be reasonable for the surgeon to evaluate a patient for external and internal valve dysfunction prior to starting surgery on the nasal ala. Although evaluation would not change the final outcome, the repair could aim to correct previous dysfunction while also avoiding further difficulty. This can be done objectively by use of the Cottle or modified Cottle maneuvers; indeed, Fung et al. demonstrated that this method is effective at predicting those with collapse prior to surgery (4) [98].

Effect of Nasal Valving on Patients

Nasal valve dysfunction can contribute to both cosmetic and respiratory concerns for patients. As discussed earlier, suboptimal scarring can have a negative impact on the patient's psychosocial functioning [3]. There is the additional concern of inspiratory deficits that can make respiration suboptimal [100].

Preventative Interventions

Prevention of external nasal valve dysfunction is preferable to addressing it as a postoperative complication. Burget and Menick have published descriptions of various techniques for cartilage grafting to correct the alar rim [102]. Ratner and Skouge published a simplified technique in 1997 describing the use of free cartilage grafts to restore the alar rim during repair of a Mohs defect. They state that the length of the cartilage graft should be the length of the defect plus 4–5 mm. The defect is undermined medially and laterally to create pockets in which the graft is placed. Lastly, the cartilage is sutured in place. At the time of their publication, they had completed the free cartilage graft on 20 patients with reportedly good outcomes (5) [103].

A retrospective analysis of 13 patients in 2009 showed that free cartilage grafts followed by secondary intention healing can provide another method for closure when the defect is between 10 and 20 mm. All of the patients treated with free cartilage graft and secondary intention healing with defects less than 20 mm and average follow-up of 17 months assessed their results as either good or satisfactory. Two patients did develop hypertrophic scarring, and one patient developed alar notching (4) [104].

Cartilage grafting is common to prevent nasal valve collapse but several other methods have also been published with good results. Wang and colleagues describe a lateral suspension suture technique that is a modification of the suspension technique frequently published in the otolaryngology literature. A suture enters the nasal tissue at the point of greatest depression and then is tied to the periosteum of the maxilla 2 cm laterally. They state that in over 100 patients they treated with this technique, none of them experienced collapse or infection (4) [105].

Another study looked at the use of titanium mesh rather than a cartilage graft to correct the alar rim. The authors retrospectively reviewed 11 patients who were repaired with titanium mesh with a mean follow-up time of 59.63 years, and none of the patients had infection, extrusion, or nasal valve collapse (4) [106]. Another report from Great Britain involving five patients who were repaired with titanium mesh also showed that patients had good outcomes with no complications (4) [107]. Mucosal defects that lead to scarring can also result in nasal valve incompetence and should be repaired.

External pressure from flaps can also result in closure of the nasal valve. Reynolds and Gourdin report two patients that received thicker paramedian forehead flaps who subsequently required thinning of the flaps because of valve collapse (4) [97].

Corrective Interventions

Repair of nasal valve dysfunction is more difficult than prevention. In a systematic review written in 2009, Spielmann and colleagues discuss seven studies which addressed external nasal valve collapse [108]. On further review of these articles, it should be noted that patients frequently do not undergo one single procedure during correction. Instead, multiple techniques including spreader grafts, alar batten grafts, auricular cartilage grafts, and columellar struts are employed. In the first study, 20 patients were treated with rhinolift procedure, and the outcome measured was subjective nasal patency. Out of the 20 patients treated, 10 were treated with rhinolift alone, while the others also had modifications in their upper lateral cartilage. All but one of the patients stated that they had subjective improvement in nasal patency (4) [109].

A Lateral crural spanning graft was used to treat 11 patients diagnosed with external valve dysfunction by positive Cottle test and all patients noted improvement of nasal symptoms. This technique is particularly helpful when the ala has been repaired but still remains too medial in position (4) [110].

Alar batten grafting can be placed through an external or endonasal approach. A small pocket is created in the ala and the auricular cartilage is inserted into this pocket. When the patient is also undergoing septoplasty, septal cartilage can be utilized as published by Millman and colleagues. This procedure was performed on 21 patients, and all patients were pleased with the aesthetic result as well as improvement in airway patency (4) [111].

There was one prospective randomized trial comparing cartilage lateral crural strut grafting vs. cephalic crural turn-in flap for correction of external nasal valve dysfunction. Clinical endpoints included VAS, NOSE, and SNOT22 as subjective data and also included objective data including minimum cross-sectional area (MCA), nasal peak inspiratory flow (NPIF), and nasal airway resistance (NAR). Both procedures worked well, and there was significant improvement relative to baseline reports with regard to the VAS, NOSE, and SNOT22 scores, despite the only objective improvement being the NPIF. There was a difference between the two groups favoring the lateral crural strut group in the NAR and total MCA; however, all subjective outcomes were statistically insignificant (1b) [112].

Apart from cartilage grafting, suspension sutures can also be used to prevent or treat nasal valve collapse. As discussed in preventative interventions, during Mohs surgery, the deeper tissues are exposed; therefore, the procedure is different from a corrective procedure. Twelve men treated with nasal suspension sutures all noted immediate improvement in nasal symptoms after surgery but there is question if the improvement will continue over time (4) [113].

Nasal valve dysfunction represents a very real complication that can adversely affect patients' lives. The literature regarding the prevention and treatment of this adverse outcome is not robust and for the most part represents retrospective case series. However, there are some validated tools that can be used to evaluate the severity of the dysfunction and determine if treatments have been effective. The most important point is that nasal valve dysfunction can be averted if the surgeon is cognizant of risk factors including size of defect and proximity to alar rim. Cartilage grafting has a reasonably good track record of bolstering the structural

integrity of the nasal valve. Prevention of this adverse outcome is important and should be utilized in at-risk patients, often in conjunction with other reconstructive options.

Free Margin Violation

Epidemiology

Free margin violation has many consequences that must to be considered. Even small deviations of these structures can be aesthetically catastrophic. While this violation can include any of the free margins of the face including the eyelids, nasal ala, and lips, herein we will focus primarily on the eyelids and lips. Both the lips and eyes play a critical role in facial expression and both verbal and nonverbal communication. Perhaps the most important consideration is that violation of these free margins can have significant functional implications and can lead to other symptoms. With regard to ectropion, it can lead to a variety of subsequent ophthalmologic concerns including xerophthalmia, epiphora, exposure keratopathy, and ultimately blindness [114]. Significant free margin deviation of the lips can lead to deficits in phonation and feeding/drinking; however, the degree of deviation required to cause a functional deficit is much higher in the lips than the eyelid [115]. Despite being known as a possible consequence of surgery of the central face, the incidence of ectropion and eclabium following Mohs micrographic surgery has not been specifically published to our knowledge. There were no reported cases of ectropion in a large prospective cohort study examining complications following Mohs surgery (1b) [11]. The prevalence of ectropion was examined in an Australian cross-sectional study evaluating patients aged 49–97. Ectropion was seen in 3.9% of respondents and when correlated to a history of tumor removal revealed an odds ratio of 1.8 (4) [116]. We are not aware of any specific literature regarding the incidence or etiologies of eclabium; however, in our experience, eclabium is typically caused by trauma or a surgical procedures (5).

Severity and Duration

Ectropion or eclabium, when present, is typically persistent and requires surgical intervention for resolution. Severity is variable as there is inherent variability of the degree of free margin distortion. Severe cases, while disfiguring, can also cause functional issues such as corneal ulceration in the case of ectropion and with significant distortion of the lip difficulty with speaking, eating, and drinking.

Preoperative Evaluation

As with all patients with cutaneous malignancies, tumor extirpation with concomitant conservation of surrounding tissue is vital. It is, perhaps, more important when performing procedures adjacent to free margins because even small changes in surgical defect size can sway which reconstructive options are available. There are some additional considerations when performing periorbital procedures. Older patients with increased lid laxity are at higher risk for developing ectropion (4) [116], including ectropion that may not be associated with surgical procedures. There are some additional assessment tools for evaluating lid laxity which include examination for scleral show, evaluation of lid resilience, and evaluation of lid position with maximal tension. Typically, the corneoscleral junction is inferior to the superior margin of the lower eyelid. If white sclera is visible above the lower eyelid, there is concern for excess lower lid laxity. The “snap-back” test is performed by pinching the lower eyelid between the thumb and index finger and retracting the lower lid from the globe. The test is positive if there is a delay in return to the surface of the globe or if the lid only returns after blinking (5) [117]. Laxity can be determined with maximal tension on the lower lid by having the patient look upward with simultaneously opening the mouth. It is prudent to evaluate and document any pre-existing ectropion or eclabium so as to help maintain appropriate patient expectations.

Additionally, there may be potential to incorporate a corrective component into the reconstructive option that is chosen.

Effect of Free Margin movement on Patients

What is most troublesome to patients is contingent on the severity of the free margin distortion and includes both function and form. The primary goal for the eyelid is to maintain its critical functions which include maintaining vision, protection of the globe, and maintenance of the lacrimal system. A secondary goal of reconstruction is restoring form and allowing for a maximally normal aesthetic appearance. Ectropion can lead to disruption of that function and can range from increase in dry-eye symptoms [118] and suboptimal cosmesis in mild cases to exposure keratopathy and vision loss in severe cases [119].

Preventive Interventions

Most the literature regarding iatrogenic ectropion involves blepharoplasty procedures rather than tumor removal. Of the data regarding ectropion and tumor extirpation, there is primarily a combination of retrospective cohorts, anecdotal/expert opinions, and cases involving reconstructive challenges. The underlying theme, which is applicable to any free margin including the lips, is to prevent any centrifugal tension vectors. This includes overt tension due to the closure and subsequent pull due to wound contraction. In small defects that are amenable to linear repair, the orientation should be with the long axis perpendicular to the lid margin or otherwise ensuring that the tension vectors course lateral to the lateral canthus (5) [90]. This prevents vertical tension vectors from pulling on the lid during wound closure by placing tension as horizontally as possible. There is potential for a less optimal cosmetic result, as this typically forces the closures against the relaxed skin tension lines, but helps satisfy the primary goal which is maintenance of function (5) [120]. This can be overcome by utilizing an S-plasty or O-Z repair. For smaller reconstructions involving the eyelid margin, an inverted pentagonal wedge closure is relatively simple and achieves both good aesthetic and functional results (5) [121].

Full-thickness skin grafts are an option available. A retrospective study following tumor excision and repair of the lower eyelid [122] reported a rate of ectropion of 14.2%. Interestingly 14.7% of all cases demonstrated positive margins after excision, which speaks to the importance of histologic margin control. Of the cases that developed ectropion, 25% (4 out of 12) were cases where the tumor had been incompletely excised (4). Another retrospective study with 100 patients showed only 4% of patients undergoing full-thickness skin grafts for periorbital defects developed ectropion (4) [123]. Neither of these studies discussed the nuisances of their grafting procedures, including if the grafts were oversized for the defect. Some advocate that grafts and flaps near or on the eyelids be oversized to compensate for wound contraction and to push upward on the lower lid (5) [121]. For large defects near free margins with involvement of cosmetically similiar adjacent tissue, Burrow's grafts offer a solution (5) [124]. This technique is not ideal for deep defects or those that require structural reconstruction [120].

Local flaps are frequently used for reconstruction of moderate-to-large defects of the lower lid and cheek. One such option is the cheek rotation or cervicofacial rotation flap (Mustarde). As patients age, increased laxity of the eyelid and reduced muscle tone combined with the vertical tension that a heavy flap can impose on the lower lid can lead to lid distraction and frank ectropion. A useful technique to help prevent this is the use of periosteal tacking sutures medially on the nasal bone and orbit or laterally on the orbital rim, which can prevent pull on the lower lid by suspending the weight of a flap in the infraorbital region to rigid support (4) [125, 126]. Inferiorly based cheek rotation flaps have been shown to be an effective method for closure with good aesthetic results and no incidence of ectropion in a case series of 20 patients (4) [127]. A retrospective study of 23 V-Y flaps

compared with 11 cervicofacial flaps found no difference in ectropion rate between the groups (3b) [128]. The authors emphasized the importance of careful preoperative assessment of lower lid laxity. If lower lid laxity is found, adding a lateral canthopexy or canthoplasty to the reconstruction is recommended.

Comparable to avoiding ectropion, avoidance of eclabium requires repairs to be oriented with the long axis perpendicular to the lip margin in the case of primary closures (5). This prevents vertical tension vectors from pulling on the lip during wound closure. Flaps on the lips are typically executed in a manner to replace surface area of the lip that is lost during tumor extirpation as this makes distortion of the lip less likely (5). Cosmetic subunits should be defined with gentian violet prior to infiltration of anesthesia, which can distort anatomic structures and prevent accurate realignment of important landmarks like the white roll upon reconstruction. For defects of the mucosa or vermillion that do not extend deeper than the superficial orbicularis oris, granulation should be strongly considered. Even relatively large defects, up to 2.5 cm, can be left to heal via second intent with excellent aesthetic and functional results (4) [115]. Although eclabium tends to be a focus for discussion of perioral free margin violation, it is important to recognize that inward projection of the lip can also be an issue. While it is less likely than eclabium to cause functional impairment, it can be cosmetically distracting and distressing to patients. Even simple primary closures can cause inward push of the lip (5) [129].

Grafts used for deep defects on the philtrum may have a higher risk of eclabium than flaps [130]. Island pedicle flaps are an option for defects of the philtrum between 50% and 150% the width and less than 50% the height of the philtrum. This allows advancement of an adequate amount of tissue to limit upward pull on the lip. This flap rebuilds the philtrum and vermilion border, minimizes distortion, and preserves cosmesis and function of the central upper lip. In a small case series of four patients with tumors of the philtrum cleared by Mohs surgery, reconstruction with island pedicle flaps achieved excellent cosmetic results with minimal deformation (4) [130].

Corrective Interventions

As discussed earlier, FTSG offers an option for treating ectropion. In a retrospective study, 76% of patients who underwent FTSG for ectropion had complete resolution. Of those, 83% underwent a concomitant procedure, with a lateral tarsal strip being the most common (4) [131]. There are several case series discussing various methods of correcting iatrogenic cicatricial ectropion. In a series of 19 patients treated with lateral tarsal strip and vertical vector cheek lift, 84% had resolution while 16% required a second procedure (4) [132]. A case series of 17 patients with cicatricial ectropion from periorbital burns reported full resolution of ectropion, patient satisfaction with final scar, and no major complications, with a vertical V-Y advancement technique (4) [133]. V-Y advancement flaps have also been reported in texts. However, given that the V-Y advancement flap is dependent on mobility derived from the subcutis and that the orbicularis oris inserts into the dermis, it should be used judiciously on the lip. In mild cases in which a revision surgery is not possible, digital massage for cicatricial ectropion following lid surgery may help loosen the scar (5) [134]. Revision by Z-plasty can be used to treat ectropion or eclabium. The traditional Z-plasty and modified "sliding Z-plasty" can improve vertical lip reconstruction and avoid or correct various lip deformities that arise during or from lip reconstruction (4) [135, 136].

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
Wound edge necrosis	
Smoking cessation 4–6 weeks prior to a planned procedure (A)	A
Avoiding suturing techniques that may predispose to wound edge necrosis such as sutures placed too tightly, too close to one another, horizontal mattress, or running locked sutures	D
Reducing trauma to the wound edge by crush injury, multiple needle passes through the same area of tissue, or any other cause	D
Preventing electrocautery or electrocoagulation-induced thermal damage to the wound edges either from direct contact or from contact with boiling blood	C
Minimizing wound tension can all reduce the chance of wound edge necrosis	C
Topical agents may have an effect on lessening flap necrosis and wound edge necrosis, but further study is required to make evidence-based recommendations on these	N/A
Flap and graft necrosis	
Good intraoperative planning and technique is paramount to preventing necrosis	C
Watchful waiting is the main management strategy with flap and graft necrosis	C
Smoking cessation is the most helpful patient factor in limiting risk of necrosis	B
Delayed flap and graft reconstructions may be useful in those patients clinically at high risk for necrosis	B
Trapdoor deformity	
As with all flap designs it should be appropriately designed and meticulously executed	C
Wide recipient site undermining should be performed	C
Ensure that flap base makes contact with wound bed	D
Intralesional steroids can be used to correct modest trapdoor deformities	C
Z-plasties can be utilized in correcting this deformity	C
Incision and thinning of flap is an available option to correct moderate-to-severe trapdoor deformities	C
Nasal valve dysfunction	
Defects in close approximation to the alar rim with significant disruption of the integrity of the ala can result in nasal valve dysfunction	C
Nasal cartilage grafting used appropriately can help prevent nasal valve dysfunction in surgical defects of the ala	B
Lateral crural spanning grafts and ala batten grafting can all be used to correct nasal valve dysfunction	C
Free margin violation	
Free margin violations can be avoided with careful reconstructive planning and meticulous surgical technique	B
Free margin violations can lead to severe functional impairment	A
Creating smaller defects within cosmetic subunits can decrease the likelihood of free margin distortion	D
A variety of techniques are reconstructive options that will minimize the risk of free margin violation including primary closures without centrifugal tension, grafting, and local flaps with judicious use of suspension sutures	B
Scar lengthening and tension re-directing techniques including Z-plasty and V-Y advancement flaps are alternatives for correcting free margin violations	B

Self-Assessment Questions

1. A 57-year-old female presents to clinic in follow-up following Mohs surgery 6 months ago for a 1.3 cm basal cell carcinoma (BCC) of the cheek repaired with a primary linear-layered closure. She is concerned about how indented and noticeable the linear scar is. Her social history is significant for smoking one pack per day for 20 years and drinking 8–12 drinks per week. She works in a local meat-packing plant. During Mohs surgery and her repair, the tissue was handled with skin hooks alone, and use of electrocoagulation was focal and minimal. Which of the following likely played the most significant role in producing the scarring of concern to the patient?
   (a) High wound closure tension
   (b) Alcohol intake
   (c) Preoperative trauma
   (d) Smoking
   (e) Thermal damage
   (f) Crush injury

2. An 80-year-old diabetic female undergoes Mohs excision of a large basal cell carcinoma on her nasal tip. A two-stage reconstruction is undertaken with a paramedian forehead flap. After 3 days, a 3rmm area at the tip becomes black, and a clear line of demarcation develops between necrotic and viable tissue. Which of the following would be the best management options for the patient?
   (a) Aggressive debridement of obviously necrotic tissue followed by moist wound care with Vaseline and daily bandage changes
   (b) Return as soon as possible to take down the flap and let the entire wound heal with granulation
   (c) Postpone the pedicle division and inset for 6 weeks to give the necrosis time to declare itself and allow the rest of the flap to survive
   (d) Apply leeches to the necrotic area until it improves

3. A 54-year-old female underwent Mohs surgery for a basal cell carcinoma on the left nasal supratip/nasal sidewall with a final defect size of 1.1 cm. After a clear discussion of risks, benefits, and alternatives of a variety of reconstructive options, the patient and surgeon elect to perform a bilobed transposition flap. Which of the following is an effective way to minimize development of a trapdoor deformity?
   (a) Wide undermining of the recipient site
   (b) Extensively thinning the flap to help ensure it will not push up with wound remodeling
   (c) Ensuring the flap is inset without undermining with recipient site
   (d) Use of a rhombic flap

4. A 67-year-old male underwent Mohs for a squamous cell carcinoma of the left alar groove and alar rim. A tumor-free plane was achieved after two layers, leaving a final surgical defect of 1.2 cm that has encroached on the alar rim. What steps can be used to help prevent postoperative nasal valve dysfunction?
   (a) Second intention healing
   (b) Closing the defect with a bilobed flap and addressing any nasal valve dysfunction after it occurs
   (c) Use of a full-thickness skin graft to close the surgical defect
   (d) Use of a cartilage strut to maintain structural integrity of the nasal valve

5. A 32-year-old female, with a diagnosis of a rather large BCC of the left malar cheek (2.5 × 1.7 cm), is treated with Mohs. After three layers a tumor-free plane is achieved and a cheek rotation flap (Mustarde) is chosen for closure. Which of the following will help prevent postoperative cicatricial ectropion?
   (a) Wide recipient undermining
   (b) Ensuring adequate removal of the inferior tricone
   (c) Utilizing a backcut to help maximize flap mobility
   (d) Use of a periosteal suspension suture at the lateral canthus

Correct Answers

1. d: Smoking. Of the options listed, only the patient's history of smoking is a concern for causing wound edge necrosis. High closure tension, trauma, thermal damage by electrocautery, or superheated blood and crush injury are all potential causes of wound edge necrosis, but these factors are less likely given the information presented in the clinical vignette.
2. c: Postpone the pedicle division and inset for 6 weeks to give the necrosis time to declare itself and allow the rest of the flap to survive. Much of the flap may still be viable underneath the visible necrosis. Allowing the tissue time to heal and declare itself gives the body the chance to make the most of the repair that has already been done. If the tissue becomes infected, it must be debrided but there is no urgency to revising the surgery. Intervening too soon may result in unnecessary procedures and ineffectual attempts to mimic what the body's normal physiology would have done better.
3. a: Wide undermining of the recipient site. Wide undermining is thought to be the most effective way to help prevent trapdoor deformity by cancelling out the inward contractile forces with outward contractile forces. Thinning the flap not only threatens flap viability by sacrificing vascular supply, but it also prevents the contact inhibition that happens with appropriate flap/wound bed contact. Choice c is wrong as discussed earlier. Choice d is wrong because you have already chosen a bilobed flap.
4. d: Use of a cartilage strut to maintain structural integrity of the nasal valve. Choice a is incorrect in an unbelievable number of ways. It is almost universally preferable to prevent complications than treat them, excluding choice b. Choice c is virtually guaranteed not to provide the structural integrity to maintain function of the nasal valve. The correct answer is choice d.
5. d: Use of a periosteal suspension suture at the lateral canthus. Choice a and b should be done in most adjacent-tissue transfer closures unless there are mitigating circumstances. Choice c will help improve mobility but will not prevent downward pull on the lower eyelid.

Prevention and Management of Patient Dissatisfaction After Primary Cosmetic Procedures

Wayne Joseph Overman and Abigail Waldman

Abstract

Noninvasive cosmetic dermatologic procedures are generally safe and well tolerated when used by well-trained physicians; however, undesirable outcomes and adverse reactions are possible. This chapter focuses on both common and rare adverse outcomes of dermatologic cosmetic procedures with a focus on the most common procedures performed: Botulinum toxin injections, filler injections, and laser treatments. We will review the available evidence, the epidemiology of these adverse events, patient selection, prevention methods, and management.

Keywords

Cosmetics · Adverse reactions · Complications · Botulinum toxin · Filler · Laser

Millions of noninvasive cosmetic dermatologic procedures are performed each year. Although shown to be generally safe and well tolerated when used by well-trained physicians, undesirable outcomes and adverse reactions are possible and a reality of practice. This chapter focuses on both common and rare adverse outcomes of dermatologic cosmetic procedures with a focus on the most common procedures performed: Botulinum toxin injections, filler injections, and laser treatments. We will review the available evidence, the epidemiology of these adverse events, patient selection, prevention methods, and management to ensure good outcomes and patient satisfaction in your practice.

Common Adverse Outcomes

All Cosmetic Procedures

Some of the most common side effects are shared by filler injection, laser treatment, and to a lesser extent botulinum toxin injections. These include *pain* (incidence 5.2–90% filler) [1–3] (1b, 1b, 1b), *swelling* (12–91% filler) [1, 4] (2b) (68–82% non-ablative fractionated laser) [5, 6] (2b, 2c), *bruising* (10–62% filler) [7] (2a) [1] (0.01% fractionated non-ablative laser) [8] (2b), *redness* (12–90% filler) [2] (1–12.5% non-ablative laser, 100% ablative lasers) [8], and *itching* (23.9–38.5% filler) [2, 3] (36.6% laser) [6]. There are few known risk factors for many of these outcomes. Bruising may be more common in patients on blood thinners and elderly patients [9] (2a). Redness is seen more in patients with a history of "sensitive skin" or rosacea [10] (2a) or

when laser resurfacing is non-fractionated or laser pulses are stacked or multiple passes performed.

Filler

Nodules/lumps (5–80% filler) are a common side effect of fillers, particularly in highly mobile areas such as the perioral area. Nodules are most common with polylactic acid fillers (PLLA) and are thought to occur in 5–40% of those cases. Nodules may be more apparent in patients with darker skin or elderly patients with thin skin [2].

Laser

For ablative and non-ablative fractionated and non-fractionated laser resurfacing, common side effects include *crusting* (80% incidence with fractionated ablative resurfacing) [11] (4), *acne and milia* (14–80% ablative resurfacing, 2–19% non-ablative) [5, 6, 8, 12–14] (2a, 4, 4), and *contact dermatitis* (10–65% ablative resurfacing) [6, 15, 16] (4, 2b). Using ablative resurfacing is strongly associated with increased risk of acne and milia. Patients with history of acne [12] are predisposed to develop this outcome.

Pigment change may be noted in various laser types, and the incidence ranges from rare (1%) to common (32%) depending on the treatment type and patient risk factors [8, 17–21] (2b, 4, 2a, 4). The highest-risk patients for pigment change are those of darker skin types (Fitzpatrick IV–VI), those with preexisting pigmentary disorders, those on photosensitizing medications, or patients with a recent tan or photodamage. Using high-energy laser settings predisposes to this risk factor.

Botulinum toxin

Common events in the injection of botulinum toxin include *headache* (1–20%) [22, 23] (2a, 4).

Patients should be dutifully informed of these common effects prior to the procedure so that expectations are managed and so that the patient can appropriately plan their schedule. While bruising and swelling may not be severe and may be expected outcomes of the procedure, they can be embarrassing for patients (especially those who are trying to hide their treatment), and they may want to avoid treatment prior to a social event.

Rare Adverse Events

All Cosmetic Procedures

Infection is a rare complication of both lasers and filler injection. HSV and mycobacterial infections are thought to occur at an incidence of 0.04–0.2% of filler injections [24] (2b). The incidence is higher with laser treatments and can mostly be attributed to reactivation of HSV (0.2–8% HSV reaction) 0.1–4.5% bacterial infection [16, 25, 26] (1b, 2b). In the treatment with filler, risk factors include use of CaHA and prior local trauma or dental procedures. A prior history of HSV predisposes patients for reactivation during either laser or filler treatment.

Filler

Rare but serious side effects of filler injection include *granulomas and other delayed-type hypersensitivity reactions* (0.01–1%) [27–29], (2a, 2a, 4), *immediate-type hypersensitivity reactions* (0.02–0.8%) [30] (2b), *necrosis* (0.0001–0.05%) [31] (2a), and *blindness* (98 reported cases) [32] (2a).

Laser

Scarring is rarely seen with laser treatment (0.01% of cases) [33] (4) and is seen most commonly after treatment of thin skin such as the eyelid or neck area. *Lidocaine toxicity* due to topical numbing agents prior to procedure has only been reported in a few case reports (0.002% incidence) [34] (4).

Botulinum toxin

Rare events associated with Botulinum toxin injection include *eyebrow ptosis* (3–5.4%) [35–37] (2A, 2A, 1B); *eyelid ptosis* (0.12% incidence) [38] (2A); *diplopia*, *smile asymmetry*, *or other perioral complications*; and *dysphagia* (incidence not available). Eyebrow ptosis is a potential complication for patients who use the

frontalis muscle to lift excess upper eyelid skin. Perioral asymmetry and weakness is not more common in musicians or singers, but this complication may be more life affecting, and caution should be used when injecting Botulinum toxin periorally in this population.

Table 67.1 provides a list of both common and rare adverse events associated with com-

Table 67.1 Incidence of adverse outcomes and patient demographics

Undesirable outcome	Incidence	Quality of evidence	Patient risk factors	Quality of evidence	Resolution	Quality of evidence

mon dermatologic cosmetic procedures, patient risk factors for developing these outcomes, and the expected resolution.

Severity and Duration

All Cosmetic Procedures

Dermatologic cosmetic procedures are typically very safe. Even when undesired outcomes occur, they tend to be mild and remitting. Events that typically appear immediately or soon after the procedure include bruising, swelling, itching, pain, and redness. These side effects are typically mild and easily tolerated. Bruising is thought to spontaneously completely resolve within 2 weeks and typically resolves prior to 7 days [39, 40] (2A, 1B). Swelling, itching, pain, and redness dissipate within hours to weeks; however, permanent telangiectasias can form at the injection site [31], and redness can be persistent up to 5 months with ablative resurfacing.

Fillers

Serious adverse outcomes from fillers are very rare (thought to occur 0.001–0.0001% of cases) [31] but can lead to serious consequences. These adverse events include immediate- and delayed-type hypersensitivity, infection, necrosis, and other cerebrovascular occlusions that can lead to blindness or stroke. These rare events culminate in death in only one case reported in the literature, which was associated with autologous fat injections into the glabella [41] (4). Delayed-type hypersensitivity reactions typically appear on average 14.6 ± 5.27 months after injection, and of these, granulomatous-type reactions are most common (34.2%) [42] (2b). Immediate-type hypersensitivity resolves quickly after receiving appropriate care. Infections can present as recurrent herpetic lesions [43] (2a). Bacterial or atypical mycobacterial infections have also been reported and resolve with appropriate antimicrobials. Necrosis heals with no sequela within 1 month in the majority of cases (65–86%) [44, 45] (2a, 4). Permanent scarring occurs in 7–30% of cases, and often those were moderate scarring requiring resurfacing [44, 45]. When occlusion of the optic artery occurs, vision impairment is severe and results in permanent blindness in 50% of cases [31]. In 17% of cases, the patients had complete recovery of vision [31]. Stroke is rarely reported, and only one case of death is available in the literature. Table 67.1 lists resolution time for each adverse event associated with filler (Table 67.1).

Lasers

Crusting after laser treatment typically resolves within 2–7 days [6]; acne and milia resolve in 5–7 days. Pigmentary changes due to laser treatment may persist for months to years or may be permanent.

Botulinum toxin

Poor outcomes from Botulinum toxin are typically temporary since Botulinum toxin will lose effect after 3 months. Eyelid ptosis can be improved, or the course can be shortened to 2–4 weeks by using apraclonidine eyedrops 2–3 times daily until resolved [46] (1b). Diplopia can be improved over the course of 7–10 weeks with ophthalmic management, including eye patches [47] (2a).

Preoperative Evaluation

At this time, there are no labs, imaging, or anatomic tests available to aid in determining the likely incidence or severity of an undesirable outcome after a cosmetic procedure. The physical exam and history may be most useful in preventing adverse event and patient dissatisfaction [9, 22, 48] (2a). The best cosmetic outcomes will be achieved with a clear understanding of the patient's cosmetic goals. These goals and expectations must be consistent with realistic treatment options. Expectations can and should be managed by discussing the available treatments, the cost, anesthesia if applicable, potential risks and complications, and recuperation time. Depending on the offered treatment, a comprehensive history should be performed including

increased risk of bleeding, allergies, past cosmetic procedures/surgeries, recent sun exposure, pigmentary conditions, history of acne, medications (including topical regimes such as retinoids, glycolic acid, etc.), profession (e.g., musician/singer), and a history of herpes labialis or recent history of other infections [8–10, 17–20, 24, 31, 49] (4, 4, 2a, 4, 2b). Active cold sores or infection may be a reason to delay treatment [48]. Antiviral prophylaxis such as valacyclovir 500 mg before treatment and again 12 h after treatment may be considered in patients with recurrent cold sores [16, 25] (2b). Past medical history should include current pregnancies, active autoimmune disease, and history of neurologic condition such as multiple sclerosis [48, 50] (2a). Patients should be encouraged to avoid salicylate and anti-inflammatory drugs and herbs, including gingko biloba, garlic, ginseng, St. John's Wort, fish oil, and vitamin E for 7–10 days before treatment [9, 51] (2a). Some authors argue that prior trauma or surgery can increase the chance for necrosis since the normal anatomy has been altered [52]. Trauma or dental work may also increase the chance of infection, but this is based on anecdotal evidence. Pregnancy and breastfeeding are contraindications to treatment with elective cosmetic procedures because safety has not been established. Routine touch-ups may be performed to decrease the chance of asymmetry or lumps and to be alert to any early signs of infection, necrosis, or other adverse events [9]. Relative contraindications for Botulinum toxin include preexisting neuromuscular conditions of the neuromuscular junction, peripheral motor neuropathies, and skin conditions at the site of injection (e.g., contact dermatitis) and in patients with prior history of lower eyelid surgery which may predispose to ectropion when injected periocular [50]. Medications that are contraindicated in Botulinum toxin injections include aminoglycosides, cholinesterase inhibitors, succinylcholine, curare-like depolarizing blockers, magnesium sulfate, quinidine, calcium channel blockers, lincosamides, and polymyxin [50].

Troublesome to Patients

While physicians may have particular concerns (e.g., necrosis), patients may have other concerns. In particular, privacy and discretion may be critical to patients. Many patients do not want relatives to be aware that they are undergoing cosmetic procedures; therefore, contact with patients must be discrete. Consensus panels recommended that patients be asked for permission to contact them after their initial visit [9]. Common and self-remitting side effects such as bruising may be more bothersome to patients than to the physician for the same reason. Patients may not wish to have questions regarding the procedure and may have social events. A well-informed patient prior to the procedure will help to set expectations of the recovery and allow him or her to plan accordingly. Even if an outcome is expected or will self-resolve, it may be reasonable to offer treatment to help shorten the course and improve patient satisfaction (e.g., using PDL to treat post-procedure bruising). Other patient concerns are not well categorized, and our knowledge of patient-reported outcomes after filler may improve with the expansion of patient-centered research.

Prevention

All Cosmetic Procedures

There are several methods that may be used to help prevent or alleviate *pain* associated with cosmetic procedures. These methods include mixing lidocaine with hyaluronic acid or other fillers [53] (1b), nerve blocks or local lidocaine [35] topical numbing [54, 55] (1b, 2a), topical cooling [56] (1b), and using thinner fillers and appropriate needles [57] (2a). Using the smallest possible needles has been shown to decrease injection pain with Botulinum toxin [58] (1b). *Bruising and swelling* can be prevented by applying cold compresses [56, 58, 59] discontinuing nonessential blood thinning medications prior to procedure [39] using long pulse-dura-

tion PDL, arnica taken 3 times a day for 4 days immediately postoperatively, and vitamin K [40, 60–63] (1b, 2a, 2b). HSV *infection* can be prevented by giving prophylactic antivirals (e.g., 400 mg BID acyclovir) prior to filler or laser procedures in patients with a past history of cold sores [8, 16]. In patients with a past history of bacterial infection, it may be reasonable to give prophylactic topical or systemic antibiotics prior to full thickness resurfacing [16].

Filler

Nodules can be avoided by decreasing the speed and volume of injection [9] and to take extra precaution in areas that move around the mouth for PLLA and caHA, or cheeks and hands for PLLA [64] (2a). (For poly-l-lactic acid, increasing product dilution, mixing vigorously prior to injection, and using a large bore needle can help to prevent nodule formation) [64]. *Granulomas* can be prevented by avoiding infraorbital injection of PLA [65] (4) as well as avoiding large injection volumes or repeated injections [27]. Silicone and PLA are associated with increased risk of nodules and delayed-type hypersensitivity, and extra precaution should be used [42].

With the use of small needles, cannulas [66–68] (2b, 4, 2b), microdroplet technique, or small increment injections [69–74] (2b, 2a, 2a, 2a, 2a, 2b), proper knowledge of the facial anatomy and injection plane [48, 52, 75, 76] (2a, 2b) can help prevent *necrosis and other vascular complications*. It is controversial whether aspirating prior to injection is beneficial in helping to prevent necrosis, since the viscosity of the fillers may prevent an accurate flash [70, 72]. There is theoretical support for mixing filler with epinephrine to cause vasoconstriction and thus decrease the size of any arterial targets; however, the data is insufficient to recommend this at this time [70] (2a). Necrosis is most common on the nose (33% of cases) and the nasolabial fold (31.2%), so special precaution should be taken in these areas [31]. *Blindness* or other ocular changes are associated with injection into the glabella in 38.8–50% of cases [31, 32]. Ocular changes are most commonly associated with autologous fat injections in 47.9% of cases, and autologous fat injections resulted in the most severe adverse events [32].

Laser

Crusting experienced after laser treatment can be minimized by discontinuing retinoids prior to procedure [10]. Patients should avoid sun exposure for 2 weeks prior to laser treatment to avoid *hyperpigmentation* [8, 49]. For darker-skinned patients, the use of higher fluencies and lower-density settings with longer treatment intervals can reduce the chance of dyspigmentation [49, 77] (1b). Patients with a prior history of *milia/acneiform eruption* after laser should be treated with prophylactic low-dose doxycycline [8]. To avoid *scarring* with lasers, it is important to avoid treatment on those with prior surgery that may have moved neck skin onto the face and to decrease energy or density on thin skin (e.g., eyelids, neck) [33] (4).

Botulinum toxin

Headache after Botulinum toxin injections is thought to be due to tapping against periosteum, and so avoiding this may help to prevent this adverse effect [22]. "The Spock" can be prevented by injecting the medial frontalis with balanced injection of the lateral frontalis [12] (2a). *Eyelid ptosis* can be prevented by avoiding massaging Botulinum toxin in corrugators [12] reconstituting Botulinum toxin with smaller amounts of diluents to decrease local toxin diffusion [50] as well as injecting 1 cm above the orbital rim and medial to midpupillary line [37]. *Eyebrow ptosis* can be prevented by first assessing frontalis compensation by pressing finger above brow and ask patient to open eyelid, which will demonstrate any subtle lid ptosis [78] (2a). *Diplopia* can be avoided by injecting outside the bony orbital margin to prevent diffusion to extraocular muscles [79–81] (2a, 2a, 2a). *Asymmetric smile and unwanted perioral changes* can be avoided by staying 1 cm above the zygomatic notch when treating crow's feet [81] and per-

forming conservative treatment of the orbicularis oris [12]. *Dysphagia and voice changes* can be prevented by avoiding deep injection in the neck and using less than 10 units of ONA per platysmal band, 50 units per session [28, 82] (2a).

Table 67.2 lists all methods for preventing complications and undesired effects of fillers, as well as the expected effect of the intervention (Table 67.2).

Correction Procedures

All Cosmetic Procedures

For *pain* after fillers, laser, and Botulinum toxin, ice compresses are a tried and true remedy [83] (2c). Icing after the fillers has also been shown to reduce the incidence of *bruising* by 88% [59]. For severe cases of pain and *swelling* after fillers or laser, pulse prednisone may be utilized [6] (2c). For redness and bruising after cosmetic procedures, PDL or IPL 2–5 days after the procedure can be used to minimize these adverse events [12, 84] (1b). Treatment with arnica [40, 85] (3a) and vitamin K [61, 62] has shown to help minimize bruising. *Itching* after procedures can be corrected with antihistamines or mild topical steroids [86] (2a).

Fillers

Lumps and nodules after filler can be treated in several ways. For hyaluronic acid fillers, injecting hyaluronidase can be effective [45, 54]; however, extrusion with a 26-g needle or 11

Table 67.2 Methods for preventing complications and undesired effects of fillers

Filler	Methods to prevent complications	Quality of evidence for methods to prevent complications
Pain	Lidocaine in HA	B
	Nerve blocks	B
	Topical numbing	B
	Topical cooling/ice	B
	Small needles (Botulinum toxin)	B
Swelling		
Redness		
Bruising	Cold compresses (reduces bruising 88%)	B
	PDL with long pulse duration	B
Itching		
Lumps	Decrease speed of injection	B
	Increase product dilution	B
	Large bore needle	B
Rare		
Granulomas	Avoid infraorbital injection of PLA	D
	Avoid large or repeated injections	B
Necrosis/vascular compromise	Use of cannula	C
	Proper knowledge of facial anatomy	D
	Microdroplet technique/small increment injections	B
	Inject in correct plane	B
	Mixing filler with epi to vasoconstrict	B
	Aspirate	B
	Use extreme caution injecting patient who has had local surgery that could alter the anatomy	B
Blindness		
Infection	ppx antivirals (e.g., acyclovir 400 mg BID) for patients with past history	B
	ppx oral or topical antibiotics for patients with past history of infection or full thickness resurfacing	B

Table 67.2 (continued)

Filler	Methods to prevent complications	Quality of evidence for methods to prevent complications
Immediate-type hypersensitivity reactions		
Lasers		
Crusting	Pretreatment cessation of topical retinoids	B
Hyperpigmentation	Avoid sun exposure for 2 weeks prior to laser treatment	B
	Darker skin-- > use higher fluencies and lower-density settings, longer treatment intervals	B
Hypopigmentation		
Milia	Doxycycline low dose for patients with prior eruptions	B
Scarring	Take history about neck lifts (which can pull neck skin onto the face)	C
	Decrease energy or density on thin skin (eyelids, upper neck, lower neck)	C
Botulinum toxin		
Headache	Avoid going deep and tapping the periosteum	B
Spock	Injection into medial frontalis without balance of lateral frontalis	B
Eyelid ptosis	Avoid massaging Botulinum toxin in corrugators	B
	Injections should be 1 cm above orbital rim and medial to mid-pupillary line	B
	Reconstituting Botulinum toxin with smaller amounts of diluents to decrease local toxin diffusion	B
Eyebrow ptosis		
	Assess frontalis compensation by pressing finger above brow and ask patient to open eyelid. Will demonstrate any subtle lid ptosis	B
Diplopia	Injections should be outside the bony orbital margin to prevent diffusion to extraocular muscles	B
Asymmetric smile, cheek flattening, perioral changes	Stay 1 cm above zygomaticus notch when treating crow's feet	B
	Conservative treatment of orbicularis oris	B
Dysphagia, voice change	Avoid deep injection in the neck	B
	Use less than 10 units of ONA per platysmal and/or 50 units per session, thin necks-- > no more than 3 bands per session	B

blade may be required for persistent lesions, and this method has been shown to be superior by patient-reported outcomes [87, 88] (2c, 2a). Granulomas should be worked up for infectious causes, and empiric antibiotics may be considered [89] (2a). If there is no improvement, granulomatous reactions should be biopsied with tissue culture [89] and can be treated with hyaluronidase 20–60 units/ml of filler for granulomas [45, 90] (2a). Corticosteroid injections (Kenalog 2.5–5 mg/cc every 3–4 weeks per granuloma) with or without 5-FU can be effective [53, 89, 91] (4) as well as prednisone or other systemic steroids [92, 93] (2a, 4). Oral antibiotics and COX2 inhibitors minimize granuloma swelling. For immediate hypersensitivity reactions, prednisone or other systemic steroids should be administered [93, 94] (4). Bacterial and other infections should be cultured and treated with appropriate antimicrobial. For caseating granulomas, it is important to consider atypical mycobacteria such as *M. marinum* or *M. fortuitum* that may be identified with polymerase chain reaction [42, 95] (2a).

Immediate-type hypersensitivity reactions should be treated immediately with prednisone or

other systemic steroids in addition to antihistamines [93, 94].

For necrosis due to hyaluronic acid fillers, injection with hyaluronidase as soon as possible is recommended [45, 90]. Topical nitroglycerine has been advocated, but its efficacy is controversial [96, 97] (2a, 2a). Low-dose aspirin and hyperbaric oxygen have also been proposed [97, 98] (1b). For ulceration secondary to necrosis, topical EGF or stem cells [99] (4) and PRP [100] (4) have shown some promise. Blindness or vision changes can be permanent if intervention does not occur within 90 min. Prompt consultation with ophthalmology should occur for any eye pain or vision changes, and the patient should be brought directly to the ophthalmologist [70, 101] (4). Based on ophthalmology recommendations, imaging may be considered, or reduction of intraocular pressure can be considered using ocular massage, intravenous mannitol, or Diamox based on the urgency of the situation [70]. Hypothetically, retrobulbar injection of 300–600 units of hyaluronic acid can be issued for HA fillers, but this has not been tried in practice and is not recommended at this time [102] (5). Unfortunately, despite intervention, patients rarely regain vision, and it's a modest improvement if any [70, 103] (2b).

Laser

Crusting due to laser may be managed with cool soaks and emollients [10]. Milia may be extracted [8]. Hyperpigmentation secondary to lasers can be treated with glycolic acid peels, hydroquinone, azelaic acid, or ascorbic, glycolic, or retinoic acid [8, 16]. Hypopigmentation can be at least partially corrected with fractionated 1550 nm erbium-doped laser, 308 nm excimer laser, topical bimatoprost and tretinoin, or pimecrolimus [104–106] (4, 4, 2b). Scarring due to laser treatments can be partially corrected using topical steroids, intralesional and antiproliferative drugs, vascular and non-ablative laser [33].

Botulinum toxin

Severe headache secondary to Botulinum toxin injection can be treated with analgesics or short course of steroids [23]. "The Spock" can be corrected by having the patient return in 2 weeks for 1–2 units of ONA or INA or 2.5–5 units of ABO in lateral frontalis [107] (2a). For asymmetric smile after Botulinum toxin, one can treat the contralateral depressor labii inferioris.

For eyelid ptosis, apraclonidine 0.5% drops should be administered 2–3 times/day until resolution occurs [46]. An injection of 0.5–1unit of Botulinum toxin can be placed in the medial and lateral tarsus [79] (2a). For diplopia, the patient should be referred for ophthalmologic consultation, and correction can be accelerated with an eye patch or prismatic lenses [47]. If dysphagia or voice change should occur after Botulinum toxin injection of the neck, the patient should be monitored for airway compromise [28, 38].

Observations and Recommendations

Lists of the observations and recommendations we can support using the available evidence are available in Tables 67.1 and 67.2. The highest level of evidence supporting each recommendation is provided.

Self-Assessment Questions

1. All of the following are effective methods for preventing necrosis or vascular compromise during filler injection except
   (a) Use a large bore needle for injection.
   (b) Proper knowledge of facial anatomy and injecting in the correct plane.
   (c) Aspirate prior to injection.
   (d) Microdroplet technique (small incremental injections).
   (e) Use of cannula.
   (f) Mix filler with epinephrine for vasoconstrictive effects.

2. Treatment of bruising with a pulsed dye laser is most effective in what time period after the bruising occurs?
   (a) Immediately
   (b) 14–21 days after
   (c) 5–7 days
   (d) 2–5 days
   (e) 1–2 days after

3. All the following are methods to avoid eyelid ptosis during Botulinum toxin injection except:
   (a) Avoid massaging Botulinum toxin in corrugators.
   (b) Injections should be 1 cm above the orbital rim.
   (c) Injections should be medial of the mid-pupillary line.
   (d) Dilute reconstitution of product.
   (e) Concentrated reconstitution of product.

4. Which of the following can decrease the risk of post-procedure bruising?
   (a) Vitamin K
   (b) NSAIDs and aspirin
   (c) Vitamin E
   (d) Arnica
   (e) Both arnica and vitamin K

5. What is the most appropriate management if blindness or other ocular complications are suspected after filler injection?
   (a) Careful monitoring
   (b) Prompt consultation with ophthalmology for any vision change or eye pain
   (c) Injection of 300–1500 IU of hyaluronidase into the filler injection site
   (d) Warm compresses and vigorous massage to the affected eye
   (e) Corticosteroids

Correct Answers

1. a: Using a large bore needle may increase the likelihood of injecting into a blood vessel. Small bore needles or cannulas with slow and incremental injections may decrease the likelihood of vascular compromise. Injecting in the correct plane, aspirating prior to injection, and mixing with epinephrine may help to prevent necrosis.
2. d: Although it may not always be ideal, the most effective time to treat post-procedure bruising with PDL is 2–5 days after the bruising has occurred.
3. d: Dilute reconstitution of botulinum toxin A is not recommended when injecting into the corrugators as dilute product is more likely to diffuse and risks weakening the levator palpebrae superioris and resulting eyelid ptosis. Methods used to avoid injecting near the levator palpebrae superioris muscle (including avoiding massage, injecting 1 cm above orbital rim and medial to the midpupillary line, and concentrated product) may help prevent eyelid ptosis.
4. e: Both arnica and vitamin K have been shown to decrease the risk of post-procedure bruising. The other options are blood thinners and may increase the risk of posttreatment bruising. If not medically indicated, these can be discontinued prior to treatment in order to reduce risk.
5. b: Blindness or other ocular complications are a rare but serious complication of filler injection. If pain or vision loss is noted, immediate consultation should be placed to ophthalmology since these changes can be permanent within 90 min. Other reasonable treatments after consultation may include imaging and methods to reduce intraocular pressure. Careful monitoring is not suggested since the vision changes can become permanent if not addressed immediately. Although retrobulbar injection of hyaluronidase may theoretically prove effective, there is no indication for filler site injection of hyaluronidase. Warm compresses and massage may be used when impending necrosis is suspected but is not useful for ocular complications.

Correction to: Rosacea

Shlomit Halachmi

Correction to: Chapter 58 in: M. Alam (ed.), Evidence-Based Procedural Dermatology, https://doi.org/10.1007/978-3-030-02023-1_58

In Chapter 58, the affiliation of the chapter author was incorrect.
The affiliation is now corrected and updated.

The updated online version of this chapter can be found at: https://doi.org/10.1007/978-3-030-02023-1_58

Correction to: Repairs of the Nose

Mark E. Burnett and John A. Zitelli

Correction to:
Chapter 32 in: M. Alam (ed.), *Evidence-Based Procedural Dermatology*,
https://doi.org/10.1007/978-3-030-02023-1_32

The book was inadvertently published with an incorrect figure 32.13 which is now replaced with the below correct figure.

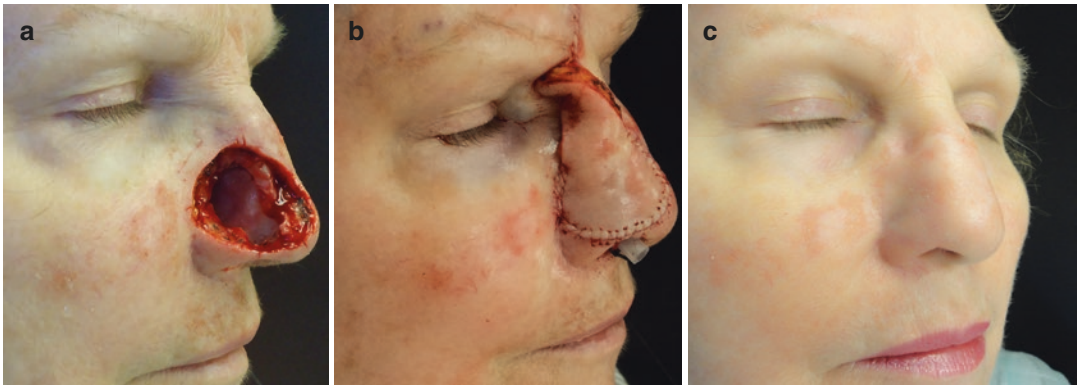

Fig. 32.13 (**a**) Full-thickness loss of the ala, ipsilateral vestibular lining, and lateral half of nasal tip. (**b**) Repair with a fold-under paramidline forehead flap and cartilage strut. (**c**) Result after second-stage inset of flap
