Preface to the Second Edition

Since the first edition of this text, much has changed. The methodologic quality of the literature in dermatologic surgery has continued to improve [1, 2]. Journals are encouraging, and authors are accepting, the importance of well-designed studies that are also written up in accordance with appropriate reporting guidelines, like those maintained by Equator [3].

For therapeutic and interventional studies, the importance of carefully selected outcome measures is increasingly apparent. As the Cochrane Collaboration and others have found, research waste can result when the results of small studies cannot be pooled because the outcome measures used are too disparate to reconcile [4, 5]. This problem may ultimately be rectified by the development of core outcome sets, or minimum groups of agreed-upon outcomes that would be employed by all investigators studying a particular disease or condition. In dermatologic surgery, the IMPROVED group is a US-based collaboration working on relevant core outcome sets for the treatment of skin cancers and cosmetic conditions.

High-quality patient-level data may also soon be forthcoming from the many qualified clinical data registries being created by professional specialty societies in the United States. While the presumptive primary incentive for such registries is to facilitate practitioners' ability to report required quality metrics to the federal government, the data collected will also be a fruitful resource for a range of clinical questions. Registries in dermatology, such as DataDerm at the American Academy of Dermatology, are currently "maturing" but within 5 years may be being mined by interested researchers. In dermatologic surgery, the American College of Mohs Surgery has initiated the MohsAIQ Registry, and the American Society for Dermatologic Surgery (ASDS) has planned a registry to track adverse events specifically.

Funds for clinical and comparative effectiveness research in dermatologic surgery are still sparse. A notable bright spot is the ASDS' new Brandt grant program, which specifically supports multicenter clinical research in dermatologic surgery. Investigators are learning to work across centers in ways that are cost- and time-efficient.

The first edition of *Evidence-Based Procedural Dermatology* was named after the ACGME-approved advanced fellowship in dermatologic surgery started in 2003. More recently, this fellowship has been modified to exclude most cosmetic procedures and has been renamed Micrographic Surgery and Cutaneous Oncology (MSDO). A new fellowship program, Cosmetic Dermatologic Surgery, has arisen under the auspices of ASDS to fill the

training gap in advanced cosmetic and laser procedures. Collectively, there are now about 100 fellowship positions in dermatologic surgery each year, with approximately 1 in 4 US dermatology residents choosing to obtain advanced dermatologic surgery training. Perhaps even more importantly, dermatologic surgery is permeating residency training in dermatology, with young dermatologists better trained in the surgical management of relevant conditions. The techniques pioneered by dermatologic surgeons have also entered other specialties, including plastic surgery, head and neck surgery, ophthalmology, vascular surgery, medical and surgical oncology, and many others. As a consequence, this text is more relevant than ever. The growing cadre of specialists in dermatologic surgery need current, authoritative, and comprehensive information that weighs the benefits and limitations of various treatment approaches for conditions of concern.

We have opted to stay with the moniker "Procedural Dermatology," which concisely conveys the breadth of our charge. But the second edition is much expanded from the first. More topics are addressed, and more outstanding chapter authors are included. I am deeply grateful to the many gifted, busy, and generous dermatologic surgeons who have written this book.

Designing Randomized Clinical Trials in Dermatologic Surgery

1

Murad Alam

Abstract

There are many ways to better understand how to diagnose and treat our patients. An unusually powerful tool is the randomized controlled trial (RCT). The first well-reported RCT assessed utility of streptomycin for the treatment of tuberculosis in 1948 (Williams, How to critically appraise a randomized controlled trial. In: Williams H, Bigby M, Herxheimer A, Naldi L, Rzany B, Dellavale R, Ran Y, Furue E (eds) Evidence-based dermatology, 3rd edn. Wiley, New York, pp 39–45, 2014). Although a relatively newcomer to the scientific toolbox, the blinded RCT is now widely acknowledged as the key building block that underpins high-level medical evidence.

There are many ways to better understand how to diagnose and treat our patients. An unusually powerful tool is the randomized controlled trial (RCT). The first well-reported RCT assessed utility of streptomycin for the treatment of tuberculosis in 1948 [1]. Although a relatively newcomer to the scientific toolbox, the blinded RCT is now widely acknowledged as the key building block that underpins high-level medical evidence.

Potential Benefits of a Blinded RCT [1]

Since performing a blinded RCT is time-consuming and costly, it is helpful to consider why undertaking this burden may be worth the trouble. The specific benefits include reduction of bias and elimination of unknown confounders. Since patients in such a trial are randomly assigned in a concealed manner to two or more groups, patients' characteristics are likely to be similar across groups. Selection bias is therefore avoided. Since outcome assessment is also blinded, we would also expect the absence of detection bias, meaning the outcome of interest is not likely to be observed and measured differently across groups.

The avoidance of unknown confounders is inherent to the randomization process and difficult to achieve in any other experimental design [2]. As an example, let us say we know patients of different ages and genders have different inherent susceptibilities to postoperative dehiscence, and we want to compare two different methods for prevention. We may choose to perform a prospec-

tive cohort study, with two groups matched for age and gender. But what if dehiscence rates are also directly correlated with BMI, which we have not considered or matched for? Now, if one preventive technique turns out to be superior, this may be due not to the intrinsic superiority of that technique but to the greater abundance of obese patients in the group receiving the other technique. When we randomize, we need not identify every potential confounder, which is generally impossible. Instead, the process of randomization helps ensure that the prevalence of every confounder is more or less equal in each group.

Elements of a Well-Designed RCT

Power, Sample Size, and Procedure Specification [3, 4]

Before beginning a study, it is crucial to consider, and then to write out in extreme detail, exactly what will be done, step by step. Recruitment, blinding and randomization, interventions, follow-ups, outcomes, and statistical analyses must all be prespecified. It may be helpful to consult with other content experts, as well as epidemiologists and experts in trial design. Study design errors are rectifiable at this stage, but less so later. Failure to prespecify and double-check study design elements before initiating the study may lead to inconsistent or changing study procedures, which impairs the quality of your data.

Also necessary at this time is a statistical analysis. Given the comparison you are trying to make, the primary outcome measure you are planning on using, and the expected difference across groups on this measure, a biostatistician will be able to tell you how many patients you will need to enroll. Depending on the power, or ability to detect a difference, you preselect for your study (typically 0.8 or 0.9 for dermatologic surgery studies), the statistician will be able to tell you the sample size that will likely be sufficient to detect a difference of a particular magnitude, if in fact such a difference exists. Simple power studies can be performed without a statistician's assistance; however, if in doubt as to the accuracy of your calculation, it is preferable to hire a professional who can detect mistakes earlier, thereby saving time and money later. It is possible that the sample size for certain studies may be prohibitive and impractical, and so you may choose not to conduct the study. Conversely, fewer patients than expected may be required, and this may free you and your staff to work on other projects.

Randomization and Blinding

These elements are well described elsewhere, and so we will review them briefly. First, the allocation to groups should be truly random. Alternating enrollment between group 1 and 2 is not random but in fact quite determined. A random number generator or table should be used, as just writing down numbers, say 1 s and 2 s, as they come to you has also been shown to be not random. Finally, the random allocation must be concealed from the investigator assigning patients to groups. Concealment may entail opaque envelopes (although these can sometimes be tampered with or backlit) with randomization information inside that you tear open right when you need to assign [1]. Or you may call another investigator at a different site who may tell you which group is next by clicking on a database link. The specific method should be thought out in advance, with different investigators instructed regarding their roles, so that errors and confusion about the steps required do not inadvertently lead to unblinding. Blinding is important because even a well-meaning unblinded investigator may preferentially assign sicker or needier patients to the intervention believed to be more effective or safer. Alternatively, an investigator with a stake in seeing the success of a particular treatment may allocate to that arm patients who are more likely to respond. Either of these cases would, of course, introduce selection bias. Even when blinding is maintained, by chance alone, randomization can be unsuccessful in creating two or more similar groupings. This is more common with smaller sample sizes, just as it is not uncommon to flip a fair coin and get three heads in a

row, but it is much less likely to have this happen consecutively 300 times. It is customary to include a table showing the salient demographic and other characteristics of the several groups to reassure the reader that randomization was successful.

Importantly, blinding remains important throughout the study, through to the point when results are being analyzed. For many dermatologic surgery studies, especially those assessing skin scar evolution or cosmetic interventions, the primary outcome measure may be visual assessment of outcomes. While live, in-room assessors may capture more information than those who perform delayed assessments based on standardized photographs, photographic assessments are easier to blind. Also, with photographic assessments, it is feasible to compare before and after outcomes, since pictures exist of both. Live assessments are not only notoriously difficult to blind; they are further impractical in that the same observer may not be available to observe each patient at every assessment visit. If there are two blinded rater assessments for each observation, the practical obstacles only grow in magnitude.

Similarity of Interventions and Sham Arms

For intervention trials, which are common in dermatologic surgery, what happens to patients in the two or more groups after assignment should be kept as similar as possible. Patients should be treated identically, except for the intervention(s) being compared across groups. As a counterexample, if those receiving surgery A are receiving care in an air-conditioned, sterile operating room at a flagship hospital and those receiving surgery B are treated in a hot, stuffy procedure room under clean rather than sterile conditions, the perceived better outcomes of surgery A may be attributable to the environment and not the procedure. Another benefit to maintaining similarity across groups is that this may allow the patient to remain blinded as to treatment allocation. This can be particularly helpful in avoiding bias if patient-reported outcomes are among the primary study outcomes. Sometimes, it will be impossible to keep the patient blinded. For instance, if one arm is a laser treatment and one is a cutting surgery, the patient will hear different sounds, feel different types of anesthesia, and ultimately see different types of scars or sequelae at the treatment sites. When possible, sham treatments may be of utility in preserving blinding. For example, if the study is comparing the use or avoidance of cautery during Mohs repairs, those not assigned to the cautery intervention may be kept blinded if the investigator cauterizes pigs' foot tissue at the appointed time, thus creating the sound and smell of cautery, while pressing down on the patient's surgery site. The illusion may be better maintained if all patients in the study have their eyes covered during the procedure. Note that sham treatment arms may not always be ethical, especially if they create substantial additional risk for patients not receiving a particular treatment. Institutional review boards should be asked to carefully vet any proposed sham procedures.

Dropouts and Intention-to-Treat

Studies involving human subjects will commonly have dropouts. After being consented, some patients may fail to come for their initial visit, others may not complete all their interventions, and yet others may miss follow-up visits. To avoid attrition bias, these dropouts should be noted and they should be included in the statistical analysis of the primary outcomes. This is so because while it is possible that dropouts are due to factors unrelated to the study, such as job relocation or unrelated illness, dropouts may also indicate study-related issues, such as adverse events, intraoperative pain, or delayed healing. Intention-to-treat (ITT) analyses take into account everyone who was initially randomized, regardless of whether they completed the study. So-called per protocol analyses just analyze those who completed all of the study procedures. Whenever possible, ITT analyses should be reported in addition to per protocol analyses. Reports of RCTs should also include a flow chart

that graphically illustrates the movement of patients through the study, including dropouts, which are specified by number, reason for exit, and time point of exit.

Appropriate Outcome Measurement

Most RCTs will have primary and secondary outcome measures. Outcome measures should be (1) relevant for the purpose of the study, (2) sufficient but not excessive in number, (3) adequate to capture the patient experience, and (4) inclusive of relevant core outcome measures for the disease or condition studied.

A relevant outcome measure is one that is able to answer the question raised by the RCT. For instance, if a study is comparing infection risk associated with surgery on the ear versus surgery on the lip, a bacterial culture may be a relevant outcome measure. Purulent drainage may also be a relevant feature but overall skin-related quality of life or precise assessment of the resulting scar using a validated scar scale would not be. A fine, well-developed outcome measure can still be entirely inappropriate for a particular study.

While there is a natural tendency to include as many outcome measures as are relevant and feasible, this is not a good practice. At the 5% significance level, there is small risk that a single outcome measure will show a difference across groups by chance alone. However, if five, or a dozen, or more outcomes are evaluated, the chance that at least one will be a false positive is quite substantial. In general, it is best to select a small group of highly relevant outcome measures.

In recent years, there has been increasing interest in understanding the patient experience during medical procedures. We have moved away from a paternalistic model, in which the physician decided what outcomes were most important, to one that asks patients what they prefer and how satisfied they are. It is highly advisable that RCTs now include at least one "patient-reported outcome." Validated scales are available, for instance, FACE-Q for skin cancer [5].

Another concern currently receiving attention is that results of RCTs on similar topics are often difficult to pool due to differences in the outcomes studied [6]. "Core outcome sets" (COS) are minimum groups' outcomes that based on expert and patient consensus should be used in all studies of particular conditions or diseases. Core outcome measures, or specific measures recommended for assessing each of the outcomes in a COS, are also available in some cases. Notably, a core outcome set is a minimum list of outcomes, and it is entirely proper and even expected that individual investigators will choose to assess additional outcomes.

The COMET group [7] maintains a database of currently available core outcome sets, as well as sets in development. The CSG-COUSIN group [8], affiliated with the Cochrane Collaboration, is specifically focused on skin-related COS. The IMPROVED group [9–12], based in the USA, is taking the international lead in developing COS for dermatologic surgery. Investigators in dermatologic surgery planning an RCT should consider consulting these research groups prior to finalizing their outcome measures.

Primacy of Preplanned Analyses

When an RCT is complete, the results are analyzed. As stated before, an ITT analysis should be provided when feasible, even if a per protocol analysis is also performed and reported. It is important that all analyses prespecified in the methods section be executed as planned. Omitting some analyses or changing the way in which others are done is strongly discouraged, as it can be perceived as evidence of cherry-picking or only showing the analyses that prove your point. On the other hand, doing additional analyses after you have completed preplanned analyses *is* allowed. If you choose to perform additional analyses, these should be labeled as ad hoc or unplanned analyses to avoid confusing the reader. Similarly, after you review your planned analyses, you may perceive an unexpected subgroup difference that you then choose to test statistically. Again, you should note that this was an unplanned subgroup analysis. Consider limiting the number of subgroup anal-

yses to those that are most interesting or reasonable. Performing too many comparisons will inevitably increase the risk of false-positive findings.

Complete Reporting of Results

It is important to report all the variables that were planned to be collected and all the analyses planned to be performed. Data tables should be complete, showing everything found, not just the outcomes considered interesting or those that supported the experimental thesis. It is appropriate to focus on the most relevant findings in the discussion section, but the results section should neither be unencumbered by excess editorial commentary nor overly abbreviated or truncated. Complete and clear reporting of all outcomes reassures the reader that there is no selective reporting bias.

Sometimes studies will be negative. In dermatologic surgery, failure to detect a difference may frequently be attributable to a small sample size rather than true absence of difference. RCTs in the field typically enroll a few dozen patients, with this number perhaps sufficient to reveal large differences but not small differences. While negative results may be disheartening for the principal investigator, it is still important to publish or otherwise disseminate the findings. Otherwise, publication bias, or the selective reporting of more positive studies than negative studies, can create a falsely optimistic perception of the effectiveness of an intervention. By reporting small negative studies and employing core outcome sets, investigators can facilitate pooling of their results with other similar studies to provide a more complete picture.

For RCTs, most high-impact journals will require written reports to conform to the CONSORT guidelines [13, 14]. The CONSORT checklist is a brief expression of these rules. Following the checklist ensures that the recommended types of information are included in each of the major subsections of the paper. If the writer wants further instruction on adhering to these reporting rules, there is a long elaboration document that describes each checklist item in detail and offers examples and rationales.

Role of RCTs in Dermatologic Surgery

Dermatologic surgery is responsible for many of the RCTs in dermatology [15, 16]. Every 5 years during the past decade the number of RCTs reported in the journal *Dermatologic Surgery* has doubled. From 2005 to 2010, more than 130 such trials have been published. Also, over a similar period, the reporting of these RCTs improved consistently, with ever greater adherence to the CONSORT reporting criteria [15, 16].

Many of the RCTs in dermatologic surgery are comparative effectiveness studies of surgical and procedural treatments. This is to be expected, because dermatologic surgery is a field that emphasizes therapeutics. Trials have been performed on both surgical interventions to treat skin cancer and other lesions and cosmetic and laser interventions to improve appearance and the visible signs of aging. It is perhaps surprising that so many RCTS have been performed in a procedural field, as the procedural arena has generally been viewed as less hospitable for such investigations. Contributing factors may include the low risk associated with most dermatologic surgeries, as well as the abundance of alternative procedural interventions for many dermatologic indications.

Practical Considerations Regarding RCTs in Dermatologic Surgery

Steps in Study Design, Personnel Management, Subject Recruitment, and Data Collection and Analysis

Randomized control trials are resource intensive. Before embarking on one, it is useful to contemplate how all the necessary elements will be assembled. Once a preliminary clinical question has been suggested for exploration via an RCT, a complete literature search performed by a skilled investigator is typically needed. The output of

this search will more precisely delineate the practice or research gap, with this in turn helping to narrow or redirect the research question. A rough draft of a proposed study plan, including patient selection, methods, analyses, and expected results, is then prepared. Biostatistical consultation and advice from a methodologist or clinical trials design expert may be helpful at this point. Sample size can be assessed and methodological oversights can be corrected before proceeding. Post-intervention follow-ups should be sufficient in number to provide long-term outcomes data but not so many as to unnecessarily deplete clinical resources. Similarly, if a series of interventions are required, as is common in cosmetic studies, these should be sufficient to achieve a measurable result, but not so many that they are prohibitively expensive in terms of equipment, supplies, and staff time. If it is desirable and possible, a sham treatment arm should be considered. Sufficient research personnel should be dedicated to the study, and their roles should be specified: these may include two or more data collectors; at least one investigator responsible for delivering the intervention; several personnel responsible for the randomization sequence and allocation; a senior research associate or staffer to oversee data collection and compliance, possibly an IRB consultant; and one or more biostatisticians, in addition to the principal investigator. A finalized study protocol will then be used to construct an IRB protocol submission. Specialized staff, possibly borrowed from a research core or hired on an hourly or per task basis, may assist with the generation of the IRB protocol, as well as requested revisions. A recruitment plan may be included in the IRB, especially if external advertising and promotion is needed.

After IRB approval is obtained, and before patient enrollment can begin, randomization sequences are prepared and secured. All necessary personnel, including clinical staff, data collection staff, and other research assistants, are apprised of their roles. For complex studies, a detailed standard operating procedure can be developed to ensure that patients receive interventions systematically, with preservation of blinding. A few mock patients may also be enrolled and treated so that the process is well understood by the staff, with any minor discrepancies corrected at this point. If certain process details are uncertain as they were overlooked in the research and IRB protocols, relevant procedures can now be codified to fill these gaps. Before the first patient is enrolled, the study must also be posted on clinicaltrials.gov. For investigators working in research institutions, this may mean working through an intermediary at the institution.

Once data collection commences, at least two primary data collectors are needed to ensure that data loss does not occur due to absence or unavailability. In addition, the investigator(s) or other individual(s) delivering the intervention are usually different and also need to be present. Space and equipment may need to be reserved. Scheduling, even for a study with relatively few subjects, may be a formidable task, as several treatment and follow-up visits may be required for each, and patients may frequently no-show or request rescheduling.

When patients are enrolled, randomized, and treated, their data will need to be carefully recorded. A senior research staffer may routinely review the paperwork submitted by the primary data collectors to confirm data integrity and compliance with IRB reporting requirements. After the first several patients, the research team may reconvene to correct any process problems. Should serious obstacles arise, the study may need to be suspended, modified, and resubmitted to IRB for approval prior to resumption.

Particularly resource-intensive studies may have a preplanned interim analysis, with a stopping rule. Since dermatologic surgery studies are usually extremely safe, a data safety monitoring board is seldom required. Interim analyses may instead be useful for seeing if the expected results have been obtained, which may presage early termination of the study. During the process of the interim analysis, a biostatistician may need to be unblinded but the remaining members of the team should remain blinded, if possible.

Once the study is completed and data collection is over, data tables are prepared for review. If some of the data were on paper and not previously entered into a database, data entry into

appropriate software will precede preparation of data tables. Looking at the data carefully allows the principal investigator to ensure that the data is valid and without error. Planned analyses are then performed by the biostatistician. Based on the outcome of these, additional ad hoc or subgroup analyses may be added. The report of the RCT is then written. This will generally be reviewed by multiple investigators prior to submission for publication.

Resource Allocation and Costs

In summary, performing a high-quality RCT does require resources. Even a small trial requires a significant number of staff with diverse responsibilities, although not all of them need to devote more than a fraction of their time to the endeavor. If the intervention is partly standard of care, and being delivered in standard clinic space, additional clinical staff and space may not be required, but if not, then they may. IRB approval can slow down the process. Recruitment rate can also be a limiting factor. Even with rapid recruitment and an efficient IRB, such as a non-institutional one, the timeline from inception to writeup for a longitudinal RCT in which treatments are delivered and long-term outcomes assessed will seldom be less than 1 year and often closer to 2.

Direct costs of the RCT will include at the very least: IRB submission fees; payment, either hourly or per project, to the biostatistician and methodologist; and the salary fractions of research staff on the study. Equipment or supplies required may also need to be bought, or they may be donated. Another cost may be reduction in efficiency of the clinical enterprise when research procedures are interjected into standard clinic days.

That being said, many dermatologic surgeons have sufficient staff to easily perform RCTs. Post-residency fellows, whether assigned to micrographic surgery and dermatologic oncology or cosmetic dermatologic surgery, may benefit from the research experience and are required to complete at least one research project during their year-long tenure. Clinical nurses and mid-level providers may enjoy participating in research in addition to the regular clinical duties. In Mohs services, histotechs may have downtime at the end of the day when they may be able to help, and these staff are generally very precise and detail-oriented, and as such, possibly well-equipped to review study paperwork. IRB approval is often easy for those in private practice, with high-quality external IRBs requiring as little as a week to approve low-risk studies. Finally, if a biostatistician or methodologist is not available, the dermatologic surgeon may consider reaching out to a colleague more experienced in the conduct of clinical trials for advice or to review a research protocol.

Closing Thoughts

Many, if not most, important questions in the field of dermatologic surgery remain unanswered. Those questions that have been addressed usually have not been definitively settled and await more data and higher-quality investigations. At the other end of the spectrum, dermatologic surgeons work in resource-rich environments where they can easily perform modest-sized RCTs without much direct expense. Indeed, they are already doing so, in large numbers. Moreover, RCTs can productively engage clinical staff, and at least some may find such work interesting. RCTs are particularly exciting for the principal investigator, who in a relatively brief period can develop a question, test it, find an answer, and communicate this to the world. The answer may change practice or it may not. But it will clear up a small mystery, in at least a small way, and thereby be a voyage of discovery for those on board and a valuable addition to our collective scientific know-how.

2 Outcomes Assessment in Dermatologic Surgery

Murad Alam

Abstract

Whether performing a randomized controlled trial, a cohort study, or a case-control study, it is essential to select the outcomes to be measured (Dupuy et al, Outcome measures. In: Williams H, Bigby M, Herxheimer A, Naldi L, Rzany B, Dellavale R, Ran Y, Furue E (eds) Evidence-based dermatology, 3rd edn. Wiley, New York, pp 71–74, 2014; Alam et al, Rationalizing outcome measures in dermatologic surgery. Curr Derm Rep 4(3):140–146. doi:10.1007/s13671-015-0106-5, 2015; Alam, Evidence based procedural dermatology. In: Maibach HI, Gorouhi F (eds) Evidence based dermatology, 2nd edn. PMPH-USA, Shelton, pp 539–545, 2012). Deciding on appropriate outcomes requires consideration of the purpose of the study, the types of outcomes available, the number of outcomes that may be appropriate, outcomes that are commonly measured, and outcomes that convey patients' perceptions. Closely related to the task of outcomes selection is choosing specific outcome measures to represent these outcomes. For example, if scar appearance is a selected outcome, a particular validated scar scale may be the corresponding outcome measure.

Keywords

Outcome · Measures · Study · Skin · Core · Set

Whether performing a randomized controlled trial, a cohort study, or a case-control study, it is essential to select the outcomes to be measured [1–3]. Deciding on appropriate outcomes requires consideration of the purpose of the study, the types of outcomes available, the number of outcomes that may be appropriate, outcomes that are commonly measured, and outcomes that convey patients' perceptions. Closely related to the task of outcomes selection is choosing specific outcome measures to represent these outcomes. For example, if scar appearance is a selected outcome, a particular validated scar scale may be the corresponding outcome measure.

Selecting Outcomes Appropriate for the Clinical Question

Outcomes and outcome measures should be selected so that the underlying clinical question posed by the study can be answered. A study to measure recurrence rates of skin cancer may reasonably use a live clinical assessment by an expert dermatologist or diagnosis based on skin biopsy, but a measure of skin elasticity or color may be less appropriate, even if these features are accurately and precisely assessed.

Types of Outcomes

As there are different types of outcomes, outcome selection requires not just selecting the best individual outcome(s) but also deciding the categories from which to select. Outcomes can be classified by degree of objectivity, from highly objective, like linear distance, to highly subjective, like global assessment of appearance. Intermediate between these may be normed, validated scales for measuring specific parameters, like color or scar. Another way entails dividing outcome measures based on the type of mechanism used to collect the relevant data. In this formulation, outcomes may be measured by devices or machines; text instruments, like normed or validated questionnaires; or unaided humans. Outcomes that are measured by people, like scales and blinded assessments, can be further subdivided into those that are reported by neutral or blinded raters, those by physicians or investigators, and those by patients or participants. Indeed, these outcomes can otherwise be identical, with their valence impacted by who is doing the measuring. Outcomes can also be rated on the degree to which they conform to underlying theories of pathophysiologic mechanism of action. As an example, if an electronic pulse is said to induce apoptosis in basal cell carcinomas, and this apoptosis is said to manifest as increase in skin erythema, then a precise measure of skin erythema may be said to be an appropriate measure of the rate of apoptosis as well as the effectiveness of the electronic pulse. The problem with relying on a story regarding a proposed mechanism of action is that the story, however convincing, may soon be shown to be wrong, or at least incomplete. Yet another classification scheme considers the extent to which an outcome is insensitive to factors other than those it is expected to measure. If the goal is to measure the degree of collagen remodeling induced by an ablative laser 2 months after treatment, a computed photographic measure of cheek volume may be a poor measure since it may be altered not only by collagen thickening but also by residual post-treatment edema, which may be marked even months after such a procedure. Microscopic evaluation of a tissue biopsy may be better for specifically gauging the degree of collagen growth.

Characteristics of a Robust Outcome Measure

Regardless of type, outcome measures should meet three criteria. They should be accurate, precise, and sensitive to change. Accuracy means that they should truthfully measure the underlying construct. So a temperature measuring device should display the actual temperature, as verified by a reference device measuring temperature. Precision refers to how finely the construct being measured can be distinguished. In the case of a temperature gauge, one that measures to within 0.01 ° is less precise than another which measures to within 0.001 °. Sensitivity to change means that the outcome measure should change in response to changes in the relevant stimulus. If the day becomes cooler, the mercury in the thermometer should fall. Measures that are more sensitive to change may be better able to reveal minor differences over the course of a study. If a hair removal laser removes 5% of total hair per unit surface area per procedure, this may be detectable by a 10-gradation hairometer that provides integral values from 0 (no hair) to 10 (maximum hair), but not by a 3-gradation hairometer (1 = no hair, 2 = some hair, and 3 = maximum hair).

Limitations of Objective and Precise Outcome Measures

The choice of outcome measure is not always obvious. While it may seem like an objective, machine-generated statistic that is highly precise and incredibly sensitive to change would be optimal in most cases, this is not always so. An objective measure need not be accurate and despite the sleek, brushed aluminum case in which it is housed may not reflect with fidelity the real underlying construct it purports to represent. To be convincing, any such measure must be validated against a gold standard. One real-life

example that was not thus validated was a device for measuring fine textural change of facial skin introduced a few years ago. With much fanfare, eager acolytes predicted that this would be the optimal way to quantify the minor but definite degree of skin smoothening induced by some topical cosmeceuticals. In fact, it was not clear what the pretty color pictures the device produced were measuring and if these computed images accurately showed smoothness. Furthermore, the high levels of precision and sensitivity to change were punitively extreme. Indeed, washing the face, sweating a little, or just running a hand over the cheek in a sigh would completely change the character of the output.

Instances When Subjective Outcomes Measures Are Preferred

Even when objective measures are not intrinsically flawed, they may not be the most appropriate outcomes to include. In some cases, subjective outcomes and measures may be said to be philosophically superior and better able to measure what is observed. The clearest case is when grading the aesthetic appearance of facial skin. Since patients receive treatment to reduce facial acne scars or diminish the visible signs of aging in order to look better to themselves, family, friends, and colleagues, the best way to measure the success of such procedures is through visual examination by a perceptive human observer. If the patient looks improved to several such observers, then this is sufficient. Even if a highly accurate and precise electron microscope could detect numerous residual flaws, this is not interesting to the patient, whose friends cannot resolve such tiny features.

The Utility of Complex Outcome Measures

Another consideration is the complexity associated with a particular outcome measure. Some validated scales are extremely complex, with many parts and subparts, and may also require time-consuming internal computations. Study participants and data collectors may become exhausted during the measurement process. Unless the quality of these outcome measures is far superior to that of simpler measures, the more complex measures may be more resource intensive than they are worth.

Core Outcome Sets: What They Are and Why They Are Important [4–10]

In recent years, it has become apparent that heterogeneity in outcomes and outcome measures for studies of the same disease or condition lead to research waste. Since the combined results of many similar studies, or meta-analyses, are believed to be more reliable than the results of any single study, it is unfortunate when such studies report different outcomes, and thereby preclude pooling of their data. The leadership of the Cochrane Collaboration has expressed concern that this problem undermines the usefulness of Cochrane systematic reviews, which may defer specific conclusions and instead plead "insufficient evidence." The solution appears to be development of so-called core outcome sets or minimal groups of outcomes that are intended for use in all studies pertaining to a particular disease or condition. Individual investigators can use more than the core set of outcomes, ideally adding the core set to whatever other outcomes they wish to consider.

Core Outcome Sets: How They Are Developed and by Whom

The development of core outcome sets is a laborious process based on literature review and stakeholder consensus. A long list of outcomes is first produced from a literature search and data extraction. Then this is subjected to refinement and lumping by a steering committee. Several rounds of Delphi process are then used to identify the most important outcomes and those with the greatest degree of consensus. Stakeholders involved in the process may include physicians,

other health-care workers, patients, caregivers, support group representatives, researchers, industry representatives, regulators, methodologists, and others. Since the goal is to produce a set of outcomes that are of universal utility, stakeholders are drawn from many countries and diverse environments. The output of the Delphi process is subject to further refinement and lumping. A face-to-face consensus meeting is then convened to approve a small group of outcomes for the core set. Subsequent similar processes, including Delphi consensus, may be used to identify the best outcome measure for each outcome in the core set. The lead international consortium championing core outcome sets and advancing research methodology for developing these is COMET (Core Outcome Measures in Effectiveness Trials), based in the UK and in existence since 2010 [11]. COMET hosts meetings and also maintains a database of core outcome sets in development. CSG-COUSIN [12], based in Germany, is the core outcome set initiative of the Cochrane Skin Group and focuses on outcome measures relevant to dermatology. The IMPROVED (Measurement of Priority Outcome Variables in Dermatologic Surgery) group [13], based in the USA, is taking the lead in development of core outcome sets relevant to dermatologic surgery [5–7].

Patient-Reported Outcomes

Another new trend in outcome selection is the frequent inclusion of at least one patient-reported outcome in clinical trials. Investigators, government regulators and scientists, and private payers have conceded the obsolescence of the paternalistic model in which only physicians decide what should be measured and what is important for patients. It has become clear that patients' estimation of procedure effectiveness, safety, comfort, downtime, cost, overall satisfaction, and other parameters may differ from that of physicians. As those experiencing treatments, patients are obviously uniquely qualified to assess their impact. In fact, sometimes, patients may notice procedure-related effects that physicians have not even thought to measure. Validated, well-designed patient-reported outcome measures now exist for skin cancer treatment as well as facial rejuvenation.

Selecting a Suite of Outcomes

As explained in the preceding paragraph, selection of appropriate outcomes for a clinical study is a complex process. However, selection of outcomes need not be an either/or process. Outcome selection can be inclusive, with several outcomes all measured in a single study. An investigator may start with a condition-specific core outcome set, which may include some objective measures, and perhaps also a validated independent rater questionnaire or photographic assessment, as well as a patient-reported outcome measure. To this, the investigator may add one or more other outcome measures that he or she deems inadequately covered by the core set and specifically relevant to the particular clinical trial at hand.

When to Measure Outcomes

Once outcomes are selected, it must be decided when to measure them. A clinical trial in dermatologic surgery may have several treatment visits followed by several follow-ups. Some outcomes, such as standardized photographs, may be obtained at every visit, and others, like patient-reported satisfaction, may only be elicited a few times, perhaps just at the last visit. Measuring outcomes more often can be helpful in providing a clearer understanding of the impact of an intervention, including the length of post-procedure recovery time, time to maximum benefit, and the duration of persistence of benefit. But many measurements can also fatigue patients and data collectors, resulting in more patient dropouts, excess resource utilization within the research team, and possibly less accurate data. For many aesthetic studies, the most convincing results are long-term outcomes, after edema and erythema have resolved. On the other hand, asking patients to come back more than 6–12 months after treatment is unlikely to be fruitful. Keep in mind that adding two more follow-up visits to a study involving 50

patients means at least another 100 h of data collection, and possibly much more, if patients cancel and need to be rescheduled. Data collection in clinical trials is also often not contiguous, as patients come when they can and when they wish to, so 100 h of data collection may in fact be spread over many weeks, with some wasted time between visits.

Preplanning Outcomes

Outcome selection should occur before enrollment in a clinical trial commences. The methods section of the study protocol and IRB protocol should detail the outcomes that have been chosen, and when they are to be measured, as well as how and by whom. While multiple outcomes and outcome measures might be included, the total number should be judicious. Assessing very many outcomes is not only resource intensive but also increases the risk that at least one of these outcomes shows a difference by chance alone. The 5% significance level is reasonably protective if only one or a few comparisons are performed, but if numerous outcomes are assessed, the likelihood of a false positive arises.

Reporting of Outcomes

The results section of the report of a clinical trial, cohort study, or other clinical studies should present all of the outcomes that were mentioned in the methods section. If these are too numerous or cumbersome to discuss in the text, they may be displayed in tables or figures. Although some outcomes may be relatively more interesting or supportive of the experimental hypothesis, selective results reporting must be avoided, as it can bias the results.

Closing Thoughts

Determining the appropriate outcomes and outcome measures for a study is of primary importance. Haphazard outcome selection can result in research waste, as the data may not be useful or interpretable. There are different types of outcome measures, and a suite of such, including patient-reported outcomes, may be used for a particular study. Inclusion of a core outcome set, if available, can help aggregate the results of a given study with those of other studies of the same disease, condition, or intervention. Outcomes should be measured as often as needed, but not so often as to unnecessarily deplete resources. Reporting of preplanned outcomes should be complete, so that readers can draw their own conclusions.

Level of Evidence and Strength of Recommendation

3

Murad Alam

Abstract

The purpose of this book is to convey the evidence (Guyatt et al, JAMA 274(22): 1800–1804, 1995; Guyatt et al, JAMA 284(10): 1290–1296, 2000) in support of procedural dermatology therapies for specific indications. After sifting the data, chapter authors provide their assessment in words and numerical ratings. Specifically, findings based on evidence are accompanied by the level of this evidence in parentheses immediately following. At the conclusion of each chapter, a table is provided that lists findings and recommendations, with numbers to represent the associated levels of evidence and strengths of recommendation.

The purpose of this book is to convey the evidence [1, 2] in support of procedural dermatology therapies for specific indications. After sifting the data, chapter authors provide their assessment in words and numerical ratings. Specifically, findings based on evidence are accompanied by the level of this evidence in parentheses immediately following. At the conclusion of each chapter, a table is provided that lists findings and recommendations, with numbers to represent the associated levels of evidence and strengths of recommendation.

Level of Evidence

Level of evidence is a hierarchical measure. At the top are meta-analyses of randomized control trials (RCTs) and individual RCTs, and expert opinion is far lower in the order. The hierarchy is not intended to denigrate the importance of findings supported by lower levels of evidence. Instead, the purpose of the hierarchy is to show the limits of the data. In some situations, RCTs may be impractical and lower levels of evidence may be all that is achievable or at least sufficient to justify therapeutic decisions.

Since the popularization of measures of level of evidence, many specific formulations have emerged [1–3]. Largely similar, these differ mostly in detail and nuance. We have chosen to use the 2009 Oxford scheme [4], shown below. We feel this is intuitive and easy to use, while also being sufficiently granular in its discriminations (Table 3.1).

Table 3.1 Evaluating level of evidence for individual studies: Oxford Centre for evidence-based medicine 2009 levels of evidence

Level	Therapy/ prevention, etiology/Harm	Prognosis	Diagnosis	Differential diagnosis/symptom prevalence study	Economic and decision analyses
1a	SR (with homogeneity) of RCTs	SR (with homogeneity) of inception cohort studies; CDR validated in different populations	SR (with homogeneity) of Level 1 diagnostic studies; CDR with 1b studies from different clinical centers	SR (with homogeneity) of prospective cohort studies	SR (with homogeneity) of Level 1 economic studies
1b	Individual RCT (with narrow confidence Interval)	Individual inception cohort study with >80% follow-up; CDR validated in a single population	Validating cohort study with good reference standards or CDR tested within one clinical center	Prospective cohort study with good follow-up	Analysis based on clinically sensible costs or alternatives; systematic review(s) of the evidence; and including multi-way sensitivity analyses
1c	All or none	All or none case series	Absolute SpPins and SnNouts	All or none case series	Absolute better-value or worse-value analyses
2a	SR (with homogeneity) of cohort studies	SR (with homogeneity) of either retrospective cohort studies or untreated control groups in RCTs	SR (with homogeneity) of Level >2 diagnostic studies	SR (with homogeneity) of 2b and better studies	SR (with homogeneity) of Level > 2 economic studies
2b	Individual cohort study (including low-quality RCT, e.g., < 80% follow-up)	Retrospective cohort study or follow-up of untreated control patients in an RCT; derivation of CDR or validated on split sample only	Exploratory cohort study with good reference standards; CDR after derivation, or validated only on split sample or databases	Retrospective cohort study or poor follow-up	Analysis based on clinically sensible costs or alternatives; limited review(s) of the evidence or single studies; and including multi-way sensitivity analyses
2c	"Outcomes" research, ecological studies	"Outcomes" research		Ecological studies	Audit or outcomes research
3a	SR (with homogeneity) of case-control studies		SR (with homogeneity) of 3b and better studies	SR (with homogeneity) of 3b and better studies	SR (with homogeneity) of 3b and better studies
3b	Individual case-control study		Non-consecutive study or without consistently applied reference standards	Non-consecutive cohort study or very limited population	Analysis based on limited alternatives or costs and poor-quality estimates of data but including sensitivity analyses incorporating clinically sensible variations
4	Case series (and poor-quality cohort and case-control studies)	Case series (and poor-quality prognostic cohort studies)	Case-control study, poor or non-independent reference standard	Case series or superseded reference standards	Analysis with no sensitivity analysis

Table 3.1 (continued)

Level	Therapy/ prevention, etiology/Harm	Prognosis	Diagnosis	Differential diagnosis/symptom prevalence study	Economic and decision analyses
5	Expert opinion without explicit critical appraisal or based on physiology, bench research, or "first principles"	Expert opinion without explicit critical appraisal or based on physiology, bench research, or "first principles"	Expert opinion without explicit critical appraisal or based on physiology, bench research, or "first principles"	Expert opinion without explicit critical appraisal or based on physiology, bench research, or "first principles"	Expert opinion without explicit critical appraisal, based on economic theory or "first principles"

Produced by Bob Phillips, Chris Ball, Dave Sackett, Doug Badenoch, Sharon Straus, Brian Haynes, and Martin Dawes since November 1998. Updated by Jeremy Howick in March 2009
SR systematic review, *RCT* randomized clinical trial, *CDR* clinical decision rule, i.e. an algorithm or scoring system that leads to a prognostic estimation or a diagnostic category, *SpPin* a diagnostic finding whose Specificity is so high that a Positive result rules-in the diagnosis, *SnNout* a diagnostic finding whose Sensitivity is so high that a Negative result rules-out the diagnosis

Strength of Recommendation

Level of evidence attaches to any specific finding, which may or may not be prescriptive. Some findings, however, are not merely observations and may naturally lead to clinical recommendations. For such findings, it is helpful to assess how strongly the evidence supports the recommendation. Strength of recommendation is thus a way to practically interpret clinically relevant findings. We have selected the Grading of Recommendations Assessment, Development and Evaluation (GRADE) scheme [5], below, for rating the strength of each recommendation proposed by our authors. We feel this system aligns well with our level of evidence ratings, is simple, and also takes into account the expected value of future research (Table 3.2).

Table 3.2 Assigning quality of evidence for each recommendation: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Code	Quality of evidence	Definition
A	High	Further research is very unlikely to change our confidence in the estimate of effect Several high-quality studies with consistent results In special cases: one large, high-quality multi-center trial
B	Moderate	Further research is likely to have an important impact on our confidence in the estimate of effect and may change the estimate One high-quality study Several studies with some limitations
C	Low	Further research is very likely to have an important impact on our confidence in the estimate of effect and is likely to change the estimate One or more studies with severe limitations
D	Very Low	Any estimate of effect is very uncertain Expert opinion No direct research evidence One or more studies with very severe limitations

Patient-Specific Factors and Clinical Decision-Making

Level of evidence and strength of recommendation are not the only factors that determine whether or not a therapy is appropriate for a patient. If there is high-level evidence that a treatment works, we still need to understand how much benefit can be expected [1]. In some cases, the degree of benefit may be very small and the associated costs may be

large, and so the treatment may fail to be widely adopted. The circumstances of the clinical problem, and the particular patient, may further impact whether the treatment is appropriate. The complexity of individual treatment decisions is beyond the scope of a rating scheme.

Additional Readings

There are many excellent sources on the methodology of evidence-based medicine. The journal *JAMA*, under the guidance of Guyatt and colleagues, has published a series of articles to educate the reader. Many of these have been compiled into a single-volume user's guide [6]. Dermatologists will also benefit from Hywel Williams' Evidence-Based Dermatology, now in its third edition [7]. This includes a part entitled "The Critical Appraisal Toolbox," edited by Michael Bigby, which is readable, succinct, and authoritative.

Mohs Surgery

4

Arif Aslam and Sumaira Z. Aasi

Abstract

In the early 1940s, Dr. Frederic Mohs first published a technique for the removal of skin cancers utilizing in vivo tissue fixation by the application of a zinc chloride paste directly to the skin, followed by excision and specimen mounting for histologic evaluation the next day. The procedure was based on the principles that cutaneous malignancies grow in a contiguous manner from a central origin and complete removal is necessary and sufficient for local tumor control. Since that time, the practice of Mohs micrographic surgery (MMS) has evolved into the fresh tissue technique with frozen sections. This procedure omits fixation of the tissue in situ prior to excision and rapidly processes the tissue after excision using an embedding medium and a cryostat to freeze and section the specimen prior to histologic staining. MMS is divided into two phases: surgery and pathology.

Indications for Mohs Surgery

National Comprehensive Cancer Network

The National Comprehensive Cancer Network (NCCN), a global alliance of cancer specialists, maintains that the goal of primary treatment of skin cancer is cure along with maximal maintenance of function and cosmetic outcome. MMS is indicated for low-risk basal cell carcinoma (BCC) after positive margins are found on excision with postoperative margin assessment and for all high-risk BCCs in those suitable for surgery. Similarly, for low-risk squamous cell carcinoma (SCC), MMS is indicated if margins are positive after excision, but another option is excision with complete circumferential peripheral and deep margin assessment (CCPDMA) with permanent or frozen sections (2b) [1, 2].

High-risk cutaneous SCCs are those tumors which exhibit clinical or histological features that have been associated with increased risk for aggressive tumor behavior. However, there is no consensus on which features define high-risk cutaneous SCC. The following risk factors which may be the most significant drivers of poor outcomes in SCC include clinical tumor diameter 2 cm or greater, depth of invasion >6 mm or beyond the subcutaneous fat, poor differentiation, perineural invasion, location on the ear, and immunosuppression (2a) [3–5].

AAD/ACMS/ASDSA/ASMS 2012 Appropriate Use Criteria for Mohs Micrographic Surgery: A Report of the American Academy of Dermatology, American College of Mohs Surgery, American Society for Dermatologic Surgery Association, and the American Society for Mohs Surgery

Historically, determining which skin cancers are appropriate for MMS has been challenging, given the lack of consensus on the treatment guidelines for the use of MMS. However, this need was addressed in September 2012, when appropriate use criteria (AUC) for MMS were released by a collaboration of the American Academy of Dermatology, American College of Mohs Surgery, American Society for Mohs Surgery, and American Society for Dermatologic Surgery. It evaluated 270 scenarios for which MMS is frequently considered and specified criteria for appropriate use based on available published data, clinical practice experience, and expert judgment (5) [6, 7]. The criteria incorporate a number of factors including location (high-, medium-, or low-risk sites), cancer subtype, size, recurrence, and immunocompromised status (Fig. 4.1).

Effectiveness of Mohs Surgery

Basal Cell Carcinoma and Squamous Cell Carcinoma

A randomized controlled trial of 612 facial BCCs treated with either MMS or standard excision (SE) was the first of its kind to demonstrate the advantage of MMS surgery in avoiding large defects and obtaining better cosmetic outcomes for primary aggressive and all recurrent facial BCCs (1b) [8]. The same group reported their 5-year follow-up data to show that MMS is preferred over surgical excision for the treatment of facial recurrent BCC, on the basis of significantly fewer recurrences after MMS than after surgical excision. However, they concluded that because there was no significant difference in recurrence of primary BCC between treatment groups, treatment with surgical excision is probably sufficient in most cases of primary BCC [9]. Their 10-year data showed fewer recurrences occurred after treatment of high-risk facial BCC with MMS compared to treatment with SE. The proportion of recurrences occurring more than 5 years post-treatment was especially high for primary BCCs, stressing the need for long-term follow-up in patients with high-risk facial primary BCC [10].

A randomized comparison of MMS and standard excision for small nodular BCCs was the first trial demonstrating MMS as a tissue-sparing

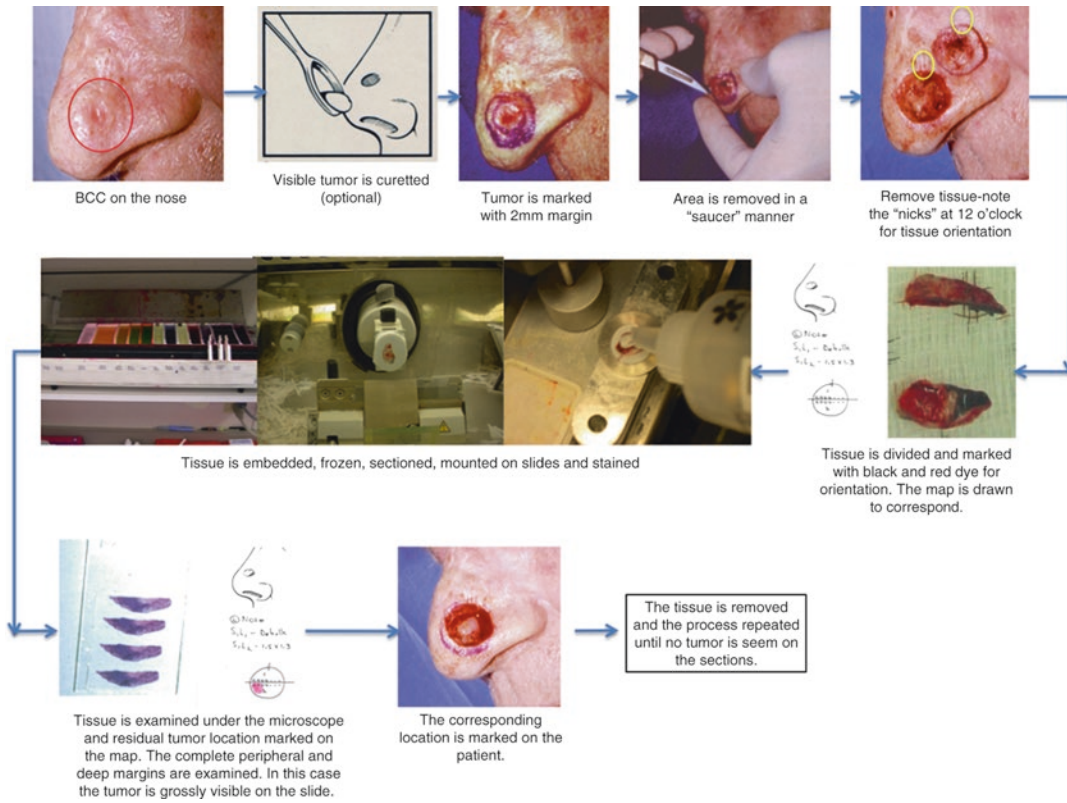

Fig. 4.1 Schematic of Mohs micrographic surgery

treatment, with the median area of the surgical defects in the MMS group being 116.6 mm^2, versus 187.7 mm^2 in the standard surgery group (1b) [11].

A retrospective European study that reviewed 350 cases of head and neck primary and recurrent BCCs treated with MMS with a median follow-up period of 7 years found 3.4% for primary BCC and 4.9% for recurrent BCC; these were similar to the recurrence rates reported in the literature (4) [12].

Although there are no randomized controlled trials comparing MMS and conventional surgery for the treatment of SCC, there is significant evidence supporting its efficacy.

A systematic review of observational studies which assessed outcomes from MMS in a total of 1572 patients with cutaneous SCC found a pooled average local recurrence rate of 3.0% (2a) [13].

In a retrospective study in which 215 patients with 260 high-risk tumors (defined as a site on the ear or lip, or temple in elderly men; size >2 cm; rapid growth >1 cm; perineural involvement; or occurring in the setting of immunosuppression) were treated with MMS, the recurrence rate after almost 4 years was only 1% (2b) [14].

An Australian case series that included 381 patients with primary (n = 229) or recurrent (n = 152) cutaneous SCC followed up for 5 years after MMS found recurrence rates of 3% and 6%, respectively (4) [15].

Melanoma In Situ (MIS) and Melanoma

A long-term outcome study of 882 cases of melanoma in situ (MIS) on the trunk and proximal extremities treated with MMS showed 83% were treated with a 6 mm margin and margins of 9 mm were required to excise 97% of MIS. Only one recurrence occurred in this cohort (2b) [16].

A retrospective review of 662 patients with MIS treated with either (MMS) or wide local exicision (WLE) found no significant differences in the recurrence rate, overall survival, or melanoma-specific survival of patients with MIS treated with MMS compared with WLE (3b) [17].

A retrospective cohort study that evaluated 2114 melanomas in 1982 patients excised using MMS and MART-1 immunostain showed lower local recurrence rates and equivalent or higher Kaplan-Meier survival rates than conventional wide local excision (3b) [18].

A retrospective chart review of 343 head and neck MIS cases treated with MMS found 65% were cleared with a 5 mm margin, but to achieve a 97% cure rate, 15 mm was necessary. This study confirms that MIS on the head and neck can spread significantly beyond the clinical margin and demonstrates the importance of confirming clearance histologically before closure procedures (4) [19].

A Dutch study of 100 lentigo maligna (LM) after micrographically controlled staged surgical excision found four patients with recurrence after a mean follow-up of 60 months (4) [20].

It is widely accepted that MMS for digital melanoma is digit sparing. A retrospective review of 62 digital melanomas over 35 years, of which 57 (91.9%) were primary and 5 (8.1%) were recurrent on enrollment, was performed. Melanocytic antigen recognized by cytotoxic T lymphocytes (MART-1) from melanoma patients and human melanoma black-45 (HMB-45) immunostains were used in 34 (54.8%) and 14 (22.6%) cases, respectively. Five (8.2%) tumors recurred locally during the course of the study, none of which occurred with MART-1 use. Three (60.0%) local recurrences were salvaged with additional MMS. Local recurrence-free survival rates for primary melanomas at 5 and 10 years were 91.8% and 82.6%, respectively. Overall, 55 (96.5%) patients with primary digital melanomas avoided amputation. Five- and 10-year melanoma-specific survival rates for all patients were 95.0% and 81.2%, respectively (4) [21].

Dermatofibrosarcoma Protuberans

A systematic review of the efficacy of dermatofibrosarcoma protuberans (DFSP) treated with MMS found a weak recommendation is given in favor of MMS or similar surgical techniques with meticulous histologic evaluation of all margins as the first-line therapy for DFSP, particularly in recurrence-prone regions. Attention should be given to longer than a 5-year follow-up period. High-quality trials with sufficient follow-up periods should be encouraged (2a) [22].

A retrospective case series review from the Mayo clinic between 1955 and 2012, the largest study from a single institution comparing MMS and WLE for the treatment of DFSP, showed recurrence-free survival rates were higher for MMS with smaller mean postoperative defect size (3a) [23].

A large series of DFSP treated with MMS found the mean minimum margin of 1.34 cm was required to achieve complete clearance for the 74 tumors analyzed. The mean percentages of skin spared using MMS rather than conventional surgery with 2 and 3 cm margins were 49.4% and 67.9%, respectively, confirming MMS can achieve tumor clearance with smaller margins and greater preservation of healthy tissue than conventional surgery (4) [24].

A retrospective case review of 76 cases of DFSP treated with MMS with a mean follow-up of 50 months found recurrence rate of 1.5%, advocating MMS as the treatment of choice for DFSP in all locations (4) [25].

Other Tumors

Extra-mammary Paget's disease (EMPD) The meta-analysis of three observational studies found the treatment of EMPD with MMS resulted in significantly lower recurrence rates than wide local excision and that the current evidence supports the efficacy of MMS in the treatment of EMPD (2a) [26].

Eccrine porocarcinoma (EPC) A retrospective chart review of nine patients with EPC treated by MMS at the Mayo Clinic from 1995 to 2013 with a mean follow-up of 3.3 years showed no recurrence, metastases, or disease-related mortality (4) [27].

Hidradenocarcinoma (HAC) A retrospective review of ten patients in the largest reported

series from the Mayo Clinic of HAC treated with MMS with long-term follow-up showed no recurrences, with mean MMS stages of 1.5 (4) [28].

Sebaceous carcinoma A retrospective case series review of 37 patients with 45 sebaceous carcinoma treated with MMS in a single center reported no local recurrences, metastases, or disease-specific deaths over an average follow-up period of 3.6 years (4) [29].

Preoperative Evaluation

The most appropriate type of biopsy (shave vs. punch) to ensure accurate diagnosis before MMS is debated [30], along with the consequences of biopsy choice on the MMS procedure [31, 32]. A retrospective review of 873 cases found in 23 of 873 patients, the diagnosis changed following examination of the MMS debulk specimen of which 10 of the 23 patients had a diagnostic biopsy prior to referral for MMS, whereas 13 had no diagnostic biopsy performed (4) [33].

A prospective randomized controlled study of pretreatment with Imiquimod 5% cream before MMS showed it significantly reduced the tumor size in primary nodular BCC and reduced the surgical defect size (1b) [34]. Conversely a randomized double-blind vehicle-controlled study of preoperative Imiquimod 5% cream before MMS for nasal nodular BCCs did not reveal any differences in the number of Mohs stages, defect sizes, or costs between the two groups, but the sample size was small (2b) [35].

Several studies have examined the safety of the novel anticoagulants dabigatran, apixaban, and rivaroxaban during MMS [36, 37]. A retrospective chart analysis of 27 patients taking dabigatran and 4 patients taking rivaroxaban during MMS showed no severe hemorrhagic complications during surgery, supporting the strategy of continuing these important medications (4) [38].

An open-label clinical trial of preoperative Vismodegib for 3 months before Mohs surgery for high-risk BCCs showed when taken for 3 months, it appeared to reduce postoperative surgical defect (4) [39], but the authors question whether this made a significant difference in postoperative repair types or sizes.

Best Techniques and Performance

There are great variations in technique among Mohs surgeons regarding tumor debulking, the removal of layers, and the marking of specimens. The common elements for all Mohs procedures include a clinical delineation of tumor margins, removal of the clinical tumor with 1–3 mm margins with a disc or saucer shape, marking of the tumor bed to allow correlation of the surgical site with the excised specimen, and mapping of the specimen. During mapping, the tissue is cut into appropriate pieces and the edges are dyed with different colored inks to identify individual margins. The colors are coded to the corresponding edges on the tissue map. In the pathology phase of the procedure, the tissue is embedded in an appropriate medium in a manner that places the skin edge and the deep/central portion of the specimen in the same plane. The embedded tissue is frozen and sectioned on a cryostat in 2–6 mm sections. Once sections are mounted, they are stained with either hematoxylin or eosin or toluidine blue (T-blue) based on the tumor type and the preference of the surgeon. The sectioning and staining process takes 15–45 min depending on variables such as tissue size, lab volume, and histotechnician technique. After slide preparation, the surgeon examines the slides for the presence of tumor. With the Mohs procedure, the physician can examine the complete deep and peripheral margins of the tissue for the presence of residual tumor. Positive tumor is marked in the appropriate area on the map that is taken back to the bedside where the surgery phase resumes. Using the shape of the defect, the markings made in the wound edges, and the manner in which these correspond to the customized Mohs map created by the surgeon, the area of residual tumor is delineated along with an appropriate margin(s). The excisional and mapping process is repeated until histologically clear, deep, and peripheral margins are verified. Reconstruction of the surgical defect may follow clearance of the tumor with the

Mohs procedure, or the wound may be allowed to heal by second intention (Fig. 4.1).

Although hematoxylin and eosin (H&E) staining for Mohs frozen sections is universal, the utility of metachromatic staining of Mohs sections with toluidine blue (T-blue) has been established in the literature and by the experience of the Mohs surgeons who use it routinely. Toluidine blue highlights the metachromasia associated with BCC tumor stroma, and although retraction artifact is seen with both stains, the magenta staining of acid mucopolysaccharides (MPS) at the periphery of tumor lobules is characteristic of BCC and provides a strong visual clue to the possible presence of tumor [40]. The additional value provided by T-blue lies in its ability to highlight more subtle cords and nests associated with infiltrative neoplasms such as infiltrative BCC, infiltrative SCC, and microcystic adnexal carcinoma [41]. In these tumors, the stromal change can enhance the identification of sparse clusters or cords of cells.

A comparison study of microphthalmia transcription factor (MITF) and melan-A immunohistochemistry during MMS for LM-type MIS and LMM found that although both MITF and melan-A facilitate the identification of tumor during MMS for MMIS and LMM, the apparent melanocyte density on tumor-free chronically sun-damaged skin appears higher with melan-A, but MITF provides a crisp outline of melanocyte nuclei and is a useful alternative stain to melan-A for MMS of melanoma (5) [42].

A prospective cohort study which examined predictors of patient satisfaction with Mohs surgery found higher short- and long-term satisfaction with Mohs surgery is predicted by better preoperative skin-related quality of life and by more intraoperative Mohs stages. The effect of postoperative variables wanes over time, suggesting that factors influencing satisfaction can vary depending on the time frame when satisfaction is measured (2b) [43].

A randomized controlled trial comparing acetaminophen, acetaminophen and ibuprofen, and acetaminophen and codeine for postoperative pain relief after Mohs surgery and reconstruction found the combination of acetaminophen and ibuprofen is superior to acetaminophen alone or acetaminophen and codeine in controlling postoperative pain after MMS and cutaneous reconstruction (2b) [44].

A randomized prospective study on the use of oral midazolam for perioperative anxiolysis during MMS found it is safe and efficacious in perioperative anxiolysis for healthy patients undergoing outpatient MMS and it offers the benefits of amnesia, reduced alertness, and reduced blood pressure with no clinically significant adverse effects (2b) [45].

A cross-sectional study of practice patterns of early and mid-career surgeons found similarities to remove tumors with similar numbers of stages regardless of their experience, case volume, or geographic location, with the number of stages varying with anatomic location and tumor type (2c) [46].

Safety

MMS is safe, with a very low rate of adverse events, an exceedingly low rate of serious adverse events, and an undetectable mortality rate. Common complications include infections, followed by impaired wound healing and bleeding.

A multicenter prospective cohort study of 23 centers for MMS sought to evaluate intraoperative and postoperative minor and serious adverse events. Among 20,821 MMS procedures, 149 adverse events (0.72%), including 4 serious events (0.02%), and no deaths were reported. The common adverse events reported were infections (61.1%), dehiscence and partial or full necrosis (20.1%), and bleeding and hematoma (15.4%). Most bleeding and wound-healing complications occurred in patients receiving anticoagulation therapy. Use of some antiseptics and antibiotics and sterile gloves during MMS were associated with modest reduction of risk for adverse events. Bleeding and wound-healing issues are often associated with preexisting anticoagulation therapy, which is nonetheless managed safely during MMS. The authors were not certain whether the small effects seen with the use of sterile gloves and antiseptics and antibiotics are clinically significant and whether wide-scale practice changes would be cost-effective given the small risk reductions (2b) [47].

A randomized controlled trial of oral antibiotics versus topical decolonization to prevent surgical site infections (SSI) after MMS showed that in patients with demonstrable carriage of *S. aureus*, topical decolonization resulted in fewer SSI than in patients receiving perioperative oral antibiotics and recommended that antibiotics should be reserved for clinically suspected and swab-proven infections rather than being prescribed empirically (2b) [48].

A multicenter prospective cohort study evaluating the rate of major and minor complications as well as postoperative pain associated with the treatment of skin cancer using Mohs surgery in 1550 patients with 1792 tumors found no major complications occurred during Mohs surgery or reconstruction. A total of 44 (2.6%) minor primary postoperative complications occurred during the study (2b) [49].

A prospective study to evaluate the rate of wound infections in 338 patients undergoing MMS using a single set of instruments found an overall infection rate of 2.1% (7/332). Graft closures had an SSI rate of 3.1% (2/64), and flap closures had an SSI rate of 1.9% (5/268), suggesting savings without harming patients and maintenance of SSI rates within an acceptable range (2c) [50].

Comparison of the prevalence of surgical site infections with the use of sterile gloves (SG) and nonsterile gloves (NSG) during resection and reconstruction during Mohs surgery found the prevalence of infection was 0.50% in the SG group and 0.49% in the NSG group with 3.5 times cost savings (3b) [51].

The findings from a prospective study from nine centers by the UK Mohs and patient safety collaboration group concluded that patients tolerate tumor extirpation and subsequent reconstruction under local anesthesia well, with high levels of patient satisfaction (4) [52].

A prospective study evaluating pain during MMS found postoperative pain after MMS was associated with only mild to moderate pain on the day of surgery and the first postoperative day. Most pain was effectively managed using oral acetaminophen, with a minority of patients requiring prescription analgesics. Surgery on the scalp was significantly more painful than on other sites. Patients can be reassured that MMS and reconstruction are well-tolerated and associated with only mild to moderate discomfort postoperatively (4) [53].

A retrospective study of 214 patients over the age of 90 revealed no deaths within 1 month and median survival of 36.9 months post MMS, concluding this growing section of the population may safely undergo MMS (4) [54].

A prospective study of wound infections in MMS using clean surgical technique in the absence of prophylactic antibiotics found an exceedingly low rate of 0.91% SSIs, underscoring the overall safety of MMS and its performance in the outpatient setting without the use of antibiotic prophylaxis or sterile technique (4) [55].

A recent comprehensive evidence-based review addressing practice gaps in cutaneous surgery sought to address the following key areas: cost effectiveness, anticoagulation, local anesthetic and its administration, patient anxiety, postoperative pain, and topical agents after surgery (4) [56]. It demonstrated that large surgical resections can be done effectively and safely; medically necessary anticoagulant and/or antiplatelet medication should be continued during cutaneous surgery; music and anxiolytic medications are safe and effective ways to prevent patient anxiety; and postoperative opioids and topical antibiotics cause harm to patients and should be avoided.

Postoperative Care and Follow-Up

Patients with a history of NMSC often develop new keratinocyte tumors (KC), but information is limited on the frequency and timing of these subsequent tumors, yet this information is crucial to guide follow-up care. A systematic review and meta-analysis of the risk of subsequent cutaneous malignancy in patients with prior keratinocyte carcinoma found that for BCC patients, the pooled proportion for a subsequent BCC, SCC, or melanoma was, respectively, 29.2%, 4.3%, and 0.5%, and the pooled proportion of a subsequent SCC, BCC, or melanoma in SCC patients was, respectively, 13.3%, 15.9%, and 0.5% (1a) [57]. For

those with a prior melanoma, pooled proportions for a subsequent melanoma, BCC, or SCC were, respectively, 3.8%, 2.8%, and 1.0% (1a) [58].

Alternative Procedures and Modifications

There are no systematic reviews on the effectiveness of MMS in the treatment of NMSC compared with other treatment modalities. A previous systematic review to compare the effectiveness, cost, and complications of MMS and surgical excision in the treatment of periorbital BCCs yielded no reliable conclusions as no studies were found to meet the review's inclusion criteria (2a) [59].

A prospective cohort study of 1174 patients with 1488 tumors of which 24.3% ($n = 361$) were treated with destruction with electrodessication/curettage, 38.3% ($n = 571$) with excision, and 37.4% ($n = 556$) with histologically guided serial excision (Mohs surgery) found the unadjusted recurrence rates did not differ after treatments, 4.9% after destruction, 3.5% after excision, and 2.1% after Mohs surgery, and no difference was seen after adjustment for risk factors. In tumors treated only with excision or Mohs surgery, the hazard of recurrence was not significantly different, even after adjustment for propensity for treatment with Mohs surgery. This data indicates that common treatments for NMSCs were at least 95% effective, and further studies are needed to guide therapeutic choices for different clinical subgroups (2b) [60].

An observational prospective cohort study sought to compare recurrence rates after different treatments in those judged appropriate for MMS found recurrence was less common after MMS than after other treatments, but the absolute difference in recurrence rates was small (3b) [61].

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: quality of Evidence
Indications for Mohs surgery	
All high-risk BCCs	B
Recurrent or incompletely excised low-risk BCCs	B
High-risk cutaneous SCCs are those tumors which exhibit clinical or histological features that have been associated with increased risk for aggressive tumor behavior	B
Is the treatment of choice for periorbital BCCs	B
Effectiveness of Mohs surgery	
Creates smaller defects with better cosmetic outcomes for primary aggressive and all recurrent facial BCCs	A
Is tissue sparing for small nodular BCCs	A
Is associated with a lower recurrence rate for cutaneous SCCs especially those that are high risk	B
Mohs for melanoma using MART-1 immunostaining showed lower local recurrence rates than conventional wide local excision	C
Is the treatment of choice for DFSP	D
Is associated with lower recurrence rates for extra-mammary Paget's disease, eccrine porocarcinoma, hidradenocarcinoma, and sebaceous carcinoma	D
Appropriate preoperative evaluation before Mohs surgery	
Imiquimod before Mohs surgery does not affect the outcome	D
Novel anticoagulant use during Mohs surgery is not associated with severe hemorrhagic complications	D
Safety of Mohs surgery	
Is a safe outpatient-based procedure very rarely associated with severe adverse events or major complications	D

Self-Assessment Questions

1. MMS is recommended for all of the following tumors except
   (a) Radio recurrent basal cell carcinoma on the cheek
   (b) Squamous cell carcinoma of the nose in an organ transplant recipient
   (c) Well-defined nodular basal cell carcinoma on the forearm
   (d) Infiltrative basal cell carcinoma in the post auricular groove
2. MMS for high-risk facial basal cell carcinomas is associated with all of the following except
   (a) Smaller postoperative defects
   (b) Lower risk of postoperative infection
   (c) Better cosmetic outcomes
   (d) Lower risk of recurrence
3. The reported average local recurrence rate for cutaneous squamous cell carcinoma treated with MMS is
   (a) Less than 1%
   (b) Less than 5%
   (c) Between 5% and10%
   (d) Between 10% and 15%
4. The reported recurrence rates after MMS for dermatofibrosarcoma protuberans are
   (a) Less than 2%
   (b) Less than 0.5%
   (c) More than 10%
   (d) Between 5% and 10%
5. Which of the following stains is most commonly used for MMS of melanoma?
   (a) S100
   (b) Mel-5
   (c) MART-1
   (d) HMB-45

Correct Answers

1. c: All the above are indications for MMS except (c). For a primary nodular well-defined BCC measuring less than 1 cm in a healthy adult, excision with a predetermined margin should be considered as the initial management of choice**.**
2. b: All of the above are true except (b). While MMS is a safe, well-tolerated outpatient-based procedure with few risks, there is no evidence supporting the statement it is associated with a lower risk of postoperative infection versus conventional surgery.
3. b: There is significant data to support the statement (b). Several large observational and retrospective studies with up to 5 years of follow-up data report the recurrence rate for primary cutaneous SCC to be less than 5%.
4. a: The largest retrospective case review to date, of 76 patients with DFSP treated with MMS and a mean follow-up of 50 months, found recurrence rate of 1.5% advocating MMS as the treatment of choice for DFSP in all locations. There are no randomized controlled trials comparing Mohs surgery versus conventional surgery, but the evidence for it is robust.
5. c: Several stains have been used to identify melanocytes when evaluating melanoma with MMS, including S-100, human melanoma black-45 (HMB-45), Mel-5, and MART-1 (melanoma antigen recognized by T-cell 1 staining) also known as melan-A.

There are many studies supporting MART-1 as an effective and useful immunostain in the identification of residual tumor in Mohs margins, demonstrating superior sensitivity and specificity compared to other immunostains. Melan-A or MART-1 staining is the most effective single stain used in the evaluation of melanomas with epidermal and dermal components excluding desmoplastic and spindle cell melanoma types.

Advancement Flaps

5

Michael C. Cameron and Mariah R. Brown

Abstract

Local tissue flaps are single-stage procedures that take advantage of adjacent tissue reservoirs for tissue replacement in order to reconstruct cutaneous surgery defects. In dermatologic surgery, local flaps are commonly performed after removal of benign or malignant skin lesions, particularly surgical defects created by Mohs micrographic surgery to treat skin cancer. Other indications include scar revision, correction of congenital abnormalities, and reconstruction after trauma. Advancement flaps are local flaps that utilize the linear movement of incised tissue in a single direction for closure of a tissue defect. Advancement flaps can be used to close a variety of defects in different anatomic sites but are most commonly used in dermatologic surgery for surgical defects on the head and neck. This chapter will review the existing evidence for various advancement flaps and its various for different indications in the field of procedural dermatology.

Introduction and Indications for Advancement Flaps

Dermatologic surgeons commonly use tissue flaps to reconstruct cutaneous surgical defects that require more complex repairs. Flap closures are divided into local tissue flaps, interpolated or pedicled flaps, and microvascular free tissue transfer. Local tissue flaps are single-stage procedures that take advantage of adjacent tissue reservoirs for tissue replacement. The purpose of a local tissue flap is to achieve a greater degree of tissue movement or to provide a more favorable cosmetic and/or functional outcome than can be achieved by primary closure alone.

Tissue flaps have deep historical roots, but they rose to prominence in the first half of the twentieth century as physicians sought to repair the facial injuries caused by the First and Second World Wars (5) [1]. Advancements in anesthesia, antiseptics, and surgical technique since this time have made local tissue flaps increasingly safe and straightforward to execute. Local tissue flaps are performed by a variety of surgical specialties, including plastic surgery, otolaryngology, ophthalmology, and general surgery. In dermatologic surgery, local flaps are commonly performed after removal of benign or malignant skin lesions, particularly surgical defects created by Mohs micrographic surgery to treat skin cancer. Other indications for local tissue flaps include scar revision, correction of congenital abnormalities, and

reconstruction after trauma. Dermatologists perform the majority of local tissue flaps in the United States (1b) [2]. Dermatologic surgeons almost exclusively perform these flaps under local anesthesia, and data indicates a low rate of complications (1b) [3].

One of the local tissue flaps frequently used in cutaneous reconstruction is the advancement flap and its variants. Advancement flaps utilize the linear movement of incised tissue in a single direction for closure of a tissue defect. In practical execution, many advancement flaps also have some component of rotation. The tissue movement of an advancement flap is generated by multiple factors, including movement of the flap toward the defect (primary movement), stretching of the flap skin itself, movement of the defect skin toward the flap (secondary movement), and reduced flap travel distance created by the excision of standing cones (Burow's triangles) or by the excision of a crescent. Advancement flaps can be used to close a variety of defects in different anatomic sites, but are most commonly used in dermatologic surgery for surgical defects on the head and neck.

Effectiveness of Advancement Flaps

Advancement flaps can provide tissue replacement for surgical defects and place incision lines in more favorable locations. However, because of their linear movement, advancement flaps cannot redirect tension vectors. As a local tissue flap, advancement flaps have the advantage of recruiting skin tissue of similar texture, thickness, and color. There will be variability in the final outcome of an advancement flap based on the anatomic location and size of the surgical defect, patient factors, and individual surgical technique. The ideal advancement flap will provide optimal functional and cosmetic outcomes at the surgical site, without compromising function or cosmesis at the flap donor site. The majority of evidence regarding advancement flap reconstruction exists in retrospective or case series format without comparison groups (Oxford Centre for Evidence-Based Medicine 2009 Level 4).

Preoperative Evaluation

Preoperative evaluation should include a thorough past medical history and a list of current medications. There are no standard lab or imaging tests required for preoperative evaluation of patients undergoing advancement flaps. As with other invasive dermatologic procedures, labwork may be necessary in certain patient populations to rule out clotting abnormalities, thrombocytopenia, and kidney or liver dysfunction that may worsen intraoperative bleeding. While there are no consensus on critical values, many dermatologic surgeons consider a platelet level below 50,000 platelets/mm^3 and an International Normalized Ratio (INR) level of greater than 3.5 within 1 week of surgery to be relative contraindications to dermatologic surgery (5) [4]. Current literature recommends continuing therapeutic anticoagulation or antiplatelet agents prior to dermatologic surgery, as the risk of thromboembolic events outweighs the risk of bleeding complications (4) [5]. Flap closure has been shown to be associated with an increased risk of bleeding complications after dermatologic surgery (1b) [6]. As a result, dermatologic surgeons may choose in some cases to avoid flap closures in patients with other bleeding risk factors, such as concomitant use of warfarin and clopidegrel [6].

Best Techniques and Performance

In its purest sense, an advancement flap can be visualized as a primary closure with one or both standing cones displaced to a more favorable anatomic location (Fig. 5.1). However, there

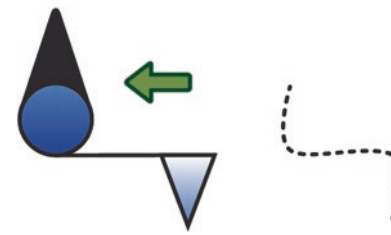

Fig. 5.1 The most basic version of an advancement flap, with linear tissue movement similar to a primary closure and displacement of the standing cones into a more favorable anatomic location. (Diagram by Anne Nichols)

are multiple variations of the advancement flap, including a single rectangular flap (U-plasty), a double rectangular flap (H-plasty), a single triangular flap (O-to-L), and a double triangular flap (O-to-T). Named variants of advancement flaps exist, but all of these variants rely on the same linear geometric principles, with specific modifications dictated by the cosmetic or functional requirements of that anatomic location. A specific type of advancement flap, the V-to-Y advancement flap (previously designated an island pedicle flap), relies on severing the entire cutaneous attachment around the flap and maintaining blood supply through a deep subcutaneous or muscular pedicle. Due to the severing of the entire cutaneous flap attachment, a V-to-Y advancement flap does not typically require the removal of redundant tissue or the extensive undermining of other advancement flaps (Table 5.1).

Advancement Flaps for Reconstruction of the Ear

The use of advancement flaps for surgical defect reconstruction of the ear is limited to case series studies (Table 5.2). *Postauricular cutaneous advancement flaps*, a type of U-plasty advancement flap, have been shown to yield excellent cosmetic results for defects of the helix (4) [7, 8]. The *chondrocutaneous advancement* or *Antia-Buch flap* is another option for reconstruction of helical defects (4) [9] The surgeon has the

Table 5.1 Advancement flap variants

Flap variants	Description
Classic or Burow's advancement flap	Can be visualized as a primary closure with displacement of one or both standing cones Size of standing cones can be varied as needed; standing cone adjacent to defect will most commonly be largest Anatomic variants include: dorsal nasal advancement flap or east-west flap
U-plasty	Rectangular in shape Prone to tip necrosis Standing cone removal reduces the length of flap travel, but can create suboptimal scar lines Variants include: postauricular advancement flap, Rintala flap
H-plasty	Bilateral U-plasty advancement flaps 2 flaps may be sized differently Similar limitations as a U-plasty
O-to-L	Also described as 'A-to-L' or 'L-plasty' Horizontal line is extended along/beyond the base of defect and mobilized on excision of the standing cone at opposing defect edge Large pedicle more favorable to flap survival
O-to-T	Also described as 'A to T' or 'T-plasty' Bilateral O-to-L advancement flaps Often recruits more laxity than a single flap
V-to-Y	Formerly described as an 'island pedicle flap.' This designation is now reserved for V-to-Y flaps that contain a named axial vessel. Random pattern flap with complete incision of cutaneous borders of the flap and maintenance of a vascular pedicle based on the underlying subcutis and/or muscle Minimum of one-third of the flap surface should remain attached to pedicle Reduced need for undermining decreases risk of hematomas/seromas Rarely needs excision of redundant tissue Incision lines often fall outside of cosmetically favorable location
Crescenteric	Variant of an L-plasty Tissue redundancy is removed in crescent shape to increase flap length rather than as a standing cone to decrease the length of the flap recipient side Useful in areas where defects border anatomical regions with a curved border (i.e., nasal ala)
Double O-to-Z	Also described as a 'Burow's triangle flap' Useful for repair of 2 defects of similar size that are in close proximity Two O-to-L flaps, where each defect serves as the Burow's triangle for the other

Table 5.2 Summary of studies of advancement flap for ear surgical defect reconstruction

Reference	Flap variant	Defect location	Sample size	Main findings
Goldberg et al. [7]	Postauricular advancement	Helix	12	Excellent cosmetic results; superficial necrosis in 1 patient
Field [8]	Postauricular advancement	Helix	5	Highly acceptable cosmetic results
Varas-Meis et al. [10] and Fangman et al. [11]	Chondrocutaneous (Antia-Buch)	Helix	2	Excellent aesthetic result with preservation of landmarks/auricle height
Ramsey et al. [12]	Chondrocutaneous (Antia-Buch)	Helix	47	No ischemic necrosis; transient hematomas in 2
Schipper et al. [13]	Modified chondrocutaneous (Antia-Buch)	Helix	1	Good cosmesis; minimal reduction in ear height; preservation of anatomic landmarks
Butler [14]	Modified chondrocutaneous (Antia-Buch)	Helix, scapha, antihelix	2	Minimal alteration of ear contour; slight reduction of vertical height
Zilinsky et al. [15]	Ear-lobe advancement	Helix	13	No complications; cosmesis excellent (76.9%), good (15.4%), fair (7.7%) Axial flap based on cadaver studies
Humphrey et al. [16]	Postauricular V-Y advancement	Helix, scapha, antihelix	2	Excellent cosmetic results
Fader and Johnson [19]	Flip-flop flap	Concha, external auditory canal, antihelix, antitragus	13	Excellent cosmetic results; 11 tumors; two graft donor sites
Patterson et al. [17]	Flip-flop flap	Conchal bowl	41	Cartilage graft donor site two minor postauricular wound dehiscences

option of advancing the superior, inferior, or both helical segments in order to restore helical contour (4) [10–14]. Taking advantage of the increased mobility of a full-thickness helical incision, the *earlobe-based advancement flap* can be used to reconstruct similar helical defects (4) [15]. Based on cadaver studies, this flap is felt to be an axial flap, unlike the majority of advancement flaps [15]. V-to-Y advancement flaps can also be used to reconstruct surgical defects on the ear, in particular as a mechanism to recruit tissue from the postauricular region to repair anterior auricular defects. The *revolving door flap*, also called the *flip-flop flap* or *retroauricular island flap*, can be used to reconstruct the conchal bowl or antihelix of the ear. This flap uses an island of postauricular skin on a subcutaneous pedicle that is then passed through a full-thickness cartilage incision to the anterior ear (4) [16–19]. The flap can also be modified to be tunneled beneath a skin bridge or folded on itself for more versatile applications (4) [20].

Advancement Flaps for Reconstruction of the Nose

The use of advancement flaps for surgical reconstruction of nasal and perinasal defects is similarly limited to case series studies (Table 5.3). Given the risk of free margin distortion, flaps that redirect tissue vectors or use remote tissue donor sites are more commonly used on the nose than advancement flaps.

The *dorsal nasal advancement flap* or *east-west flap* can be used for defects of the nasal supratip off the midline (4) [21–23]. This flap takes advantage of a large superior standing cone along the nasal dorsum or sidewall and a small inferior standing cone along the columella,

Table 5.3 Summary of studies of advancement flap for nasal/perinasal surgical defect reconstruction

Reference	Flap variant	Defect location	Sample size	Main findings
Lambert et al. [21]	Modified dorsal nasal horizontal advancement	Off-midline nasal tip	30	Good to outstanding results; no complications
Love et al. [33]	Columellar advancement	Small, shallow midline nasal tip	2	Excellent cosmesis in all
Zeikus et al. [30]	One-stage simple advancement	Small partial thickness lateral nasal tip or nasal ala	>10	Excellent cosmesis in all; no immediate or long-term nasal valve obstructions or breathing difficulties
Onishi et al. [31]	Rintala and modified Rintala	Middle or distal 1/3 of nasal dorsum	15	Stable blood supply and favorable outcomes with suitable contour in all cases
Rybka [34]	Nasalis-based myocutaneous island	Nasal tip (unilateral for size <1.25 cm, bilateral for size $1.25 < x < 2$ cm)	47	Excellent cosmetic outcomes with no postoperative complications
Constantine [35]	Nasalis-based myocutaneous island	Nasal supratip	24	100% flap survival; excellent cosmetic results
Wee et al. [36]	Nasalis-based myocutaneous island	Nasal tip	19	100% flap survival; no revisions required
Asgari and Odland [41]	Nasalis-based myocutaneous island	Small deep nasal ala	8	Seven of eight with excellent conventional/functional outcome; one with full-thickness vascular necrosis of flap
Willey et al. [38]	Single-sling nasalis myocutaneous island	Nasal tip	61	High aesthetic and functional goals achieved in all patients; complications included hemorrhage ($n = 1$), infection ($n = 2$), and alar notching ($n = 1$)
Krathen et al. [40]	Single-sling nasalis myocutaneous island	Nasal ala	2	Excellent cosmetic results
Husain et al. [24]	Modified perialar crescentic advancement (PACA)	Lower nasal sidewall and mid/lower dorsum	44	Excellent aesthetic/functional results in all cases; six treated with intralesional corticosteroid at postoperative week 3 to improve flap contour.
Borchard et al. [28]	Modified perialar crescentic advancement (PACA)	Lateral nasal sidewall	25	Good cosmetic outcome in all; minor complications restricted to ecchymosis
Zeikus et al. [29]	Dog ear island pedicle	Large nasal ala/sidewall	5	Excellent cosmetic/functional outcomes

but risks nasal tip depression if used for too inferior or too large of a surgical defect. For surgical defects involving perialar skin, the *perialar crescentic advancement flap (PACA)* is a well-established repair option (4) [24–28]. This flap is a variant of an O-to-L advancement that uses a crescent to extend the flap length, rather than removing a Burow's triangle to shorten the donor site length. For defects spanning the alar groove to involve the nasal sidewall and ala, the PACA flap can be modified to use the superior standing cone as a V-to-Y advancement flap to close the alar portion of the defect, referred to as a *dog ear island pedicle flap* (4) [29]. An O-to-L- or O-to-T-type advancement flap has been described for defects of the lateral nasal tip or nasal ala (4) [30], although this flap carries a risk of alar distortion.

For defects of the nasal dorsum, use of the *Rintala* and *Peng* (modified Rintala flap) advancement flaps has been described (4) [31, 32]. The Rintala flap is a superiorly based U-plasty, with the flap pedicle based on the glabella and standing cones removed medially along the alar grooves or at the forehead. The Peng flap adds a component of rotation by removing a central standing cone to create two flap tips that rotate and advance into the defect. Both the Rintala and Peng flap carry the risk of nasal tip elevation. A U-plasty-type flap can also be used to advance tissue superiorly for reconstruction of the nasal tip using a *columellar advancement flap* (4) [33].

V-to-Y advancement flaps, also called *nasalis-based myocutaneous island flaps*, have been used for the reconstruction of nasal defects, most commonly on the nasal tip and supratip (4) [34–36]. This flap is based on the highly vascular nasalis muscle, which can be developed as either a unilateral or bilateral muscular sling to provide flap vascularity (4) [37–39]. The flap limits free margin distortion in studies, but mobilizing the nasalis muscle can be technically difficult. V-to-Y advancement flaps have also been successfully described for alar defects but have some limitations in practice. Superiorly based flaps risk blunting the alar groove (4) [40], while laterally based flaps have more limited tissue mobility and vascularity (4) [41].

Advancement Flaps for Reconstruction of the Perioral Region

Although one randomized controlled trial exists, literature on reconstruction of perioral defects with advancement flaps is primarily limited to case series (Table 5.4). Defects of the upper or lower cutaneous lower lip can commonly be reconstructed with O-to-L advancement flaps (5) [42]. V-to-Y advancement flaps have been described for upper lip defects of varying sizes (IV/C) [43, 44]. Defects that cross the vermillion border can be repaired with double V-Y advancement flaps—one flap for the cutaneous lip and one flap for the mucosal lip (4) [45]. For reconstruction of upper lip defects involving the philtrum, Paniker and Mellette described a modification of the *mucosal advancement flap* (4) [46]. This *Cupid's bow advancement flap* or *gull wing advancement flap* helps recreate the normal anatomy of the philtral crests. Another method for reconstructing the central upper lip involves a V-to-Y flap advanced inferiorly (4) [47].

Table 5.4 Summary of studies of advancement flap for perioral surgical defect reconstruction

Reference	Flap variant	Defect location	Sample size	Main findings
Carvalho et al. [43]	V-Y advancement	Upper lip	25	For aesthetic category, 16 with good and 4 with fair rating
Griffin et al. [44]	V-Y advancement	Upper lip	30	One revision surgery was performed in 14 patients (47%); alar or vermilion involvement, but not defect size, significant factor in revision
Huilgol et al. [45]	V-Y advancement (cutaneous and mucosal)	Upper or lower lip	10	Good or excellent cosmetic outcomes in all; minor hypertrophic scarring in two, small postoperative bleed necessitating takedown of flap
Paniker and Mellette [46]	Modified mucosal	Upper lip involving philtrum	4	Acceptable or very good cosmesis in all cases
Kaufman and Grekin [47]	V-Y advancement involving superior philtrum	Upper lip involving philtrum	4	Excellent cosmetic results with minimal distortion of the vermillion border or obliteration of the philtrum
Sand et al. [48]	RCT of mucosal advancement flap vs. simple primary closure	Lower lip	18	Better patient and surgeon-rated aesthetic outcomes for flap group; side effects rate significantly higher in flap group

For reconstruction of surgical defects of the lower vermilion lip, a *mucosal advancement flap* or primary closure may be used after vermilionectomy. The difference between these two closures is that the mucosal advancement flap uses undermining to increase tissue movement. In a randomized controlled trial comparing primary closure ($n = 8$) to mucosal advancement flap ($n = 10$) for surgical defects of the lower lip, patient-rated mean aesthetic outcome score were 8.4/10 for the advancement flap and 7.5/10 for primary closure (2b) [48]. Surgeon-rated mean aesthetic outcome scores were 7.8/10 and 6.4/10 for advancement flap and primary closure, respectively. However, the rate of side effects, including bruising, swelling, infection, partial flap necrosis, and small wound dehiscence, was significantly higher in the mucosal advancement flap group ($p < 0.05$).

Advancement Flaps for Reconstruction of the Scalp, Forehead, and Brow Region

Reconstruction of surgical defects of the scalp is difficult due to the convexity of the scalp and the inelasticity of the galea aponeurotica, resulting in high-tension defects with a risk of flap necrosis and subsequent alopecia. A limited number of studies have been published detailing the use of advancement flaps for reconstruction of this area (Table 5.5). A *superficial temporal fascia pedicle V-to-Y advancement scalp flap*, supplied by the superficial temporal vessels, has been described as yielding good cosmetic outcomes (4) [49]. Another case series reported no complications using *bilateral H-plasty advancement flaps* for small to medium scalp defects, but had no long term follow-up (4) [50].

Forehead defects can also be difficult to reconstruct due to limited tissue reservoirs, multiple free margins, and prominent relaxed skin tension lines. The *periglabellar advancement flap* has been described to reconstruct central forehead defects by placing standing cones in the superior forehead rhytides and the corrugator creases (4) [51]. Forehead defects can also be closed with *double-opposing rotation-advancement flaps*, in which one flap is designed to close the primary defect and a second flap is designed to close the secondary defect [52]. For surgical defects involving the eyebrow, a variety of closure approaches exist. Gardner et al. described their experiences in using a V-Y advancement flap in

Table 5.5 Summary of studies of advancement flap for scalp/forehead surgical defect reconstruction

Reference	Flap variant	Defect location	Sample size	Main findings
Onishi et al. [49]	Superficial temporal fascia pedicle V-Y advancement	Scalp	7	No complications observed; no baldness seen
Ibrahimi et al. [50]	Bilateral H-plasty advancement	Scalp	69	No long-term follow-up scheduled to evaluate final cosmetic outcome, but no complaints noted during 18 months postoperatively
Ransom and Jacono [52]	Double-opposing rotation-advancement flaps	Forehead	16	Brow position and hairline contour maintained in all cases; one case of cellulitis
Birgfeld and Chang [51]	Bilateral periglabellar Burow's triangle advancement flaps	Central forehead	6	One minor hematoma treated; all scars healed with patients satisfied with results
Boggio et al. [54]	Burow's triangle variant (also called double O-to-Z)	Forehead, mandible (adjacent lesions)	4	Good cosmetic results without postoperative complications
LeVasseur and Mellette [55]	Double O-to-Z	Forehead, temple, cheek, nose, neck	6	Good cosmetic results

reconstruction of medium or large eyebrow surgical defects (4) [53].

Double O-to-Z flaps, also called *Burow's triangle advancement flaps*, have been described for forehead defects but have utility in different anatomic areas, including the temple and cheek (4) [54, 55]. This closure technique is used for two defects of similar sizes that are in close approximation. Each defect is closed with a O-to-L advancement flap, with each defect acting as the Burow's triangle for the other [55].

Advancement Flaps for Reconstruction of the Periorbital and Cheek Region

For reconstruction of cheek-lower eyelid junction defects, a primary concern is ectropion. Table 5.6 reviews studies that reported on periorbital surgical defect reconstructions. The preferred choice for reconstruction in this area has traditionally been a variant of the *cervicofacial rotation-advancement flap* called a *Mustárde flap*, which recruits tissue from laterally. An alternative reconstruction option is a V-to-Y advancement flap recruiting tissue from inferiorly. A retrospective case series compared the Mustárde flap to V-Y advancement flap closure (n = 23) for reconstruction of moderate-size lid-cheek junction surgical defects (2b) [56]. Nine patients (82%) in the cervicofacial group and three patients (18%) in the V-Y advancement group experienced a postoperative complication (p = 0.0002). Three cases of ectropion were observed, including two patients in the cervicofacial group and one in the V-Y advancement group (4%, p = 0.24). V-to-Y advancement flaps have also been applied to medial canthal defects, with the flap donor sites in the medial canthus-glabella area (4) [57] and in the nasal area (4) [58]. A variety of flaps can be used to close cheek defects (5) [42, 59]. In recent years, V-to-Y flaps have been used to close larger cheek defects (4) [60, 61].

Advancement Flaps for Reconstruction of the Extremities

While the majority of the literature on advancement flap reconstruction is devoted to closure of facial defects, advancement flaps can also be used in other anatomic areas. V-to-Y flaps have been described for repair of surgical defects on the leg (4) [62, 63]. For larger defects or to increase flap mobility, fascial perforators can be identified with Doppler ultrasound when performing lower extremity V-to-Y advancement flaps (4) [64, 65]. A variant of the V-Y advancement flap based on fascial perforators, called a *Keystone flap*, can also be used for reconstruction of surgical defects on the extremities (4) [66–69].

Safety

The overall safety and low complication rates of outpatient dermatologic surgery is well established (2b) [3, 70]. There are no studies examin-

Table 5.6 Summary of studies of advancement flap for periorbital surgical defect reconstruction

Reference	Flap variant	Defect location	Sample size	Main findings
Sugg et al. [56]	Cervicofacial rotation-advancement vs. V-Y advancement	Cheek-lower eyelid junction	23	Nine (82%) in cervicofacial group and three (18%) in V-Y advancement group had postoperative complication (p = 0.0002); differences in ectropion development not significant
Skaria [57]	V-Y advancement	Medial canthus	16	Good to excellent results with no cases of web deformation/ectropion at 1-year follow-up
Cecchi et al. [58]	V-Y advancement	Medial canthus	8	Transient trapdoor effect occurred in two patients. No other complications. At mean follow-up of 13 months, very satisfactory functional/cosmetic outcomes in all patients
Gardner and Goldberg [53]	V-Y advancement	Eyebrow	Not reported	Excellent functional and cosmetic results in all patients

ing the complication rates of advancement flaps alone, but they are felt to overall be a safe and reliable reconstructive method. As with all tissue flaps, advancement flaps may develop ischemia and subsequent partial or complete necrosis of the flap. Flap ischemia can be prevented by flap design, undermining depth and suturing technique that minimizes flap tension and maintains an appropriate pedicle width and depth. Other causes of flap ischemia include postoperative complications such as seroma, hematoma, or infection. Care must also be taken when using advancement flaps near free margins to prevent complications such as ectropion or eclabion. Tension vectors should be oriented parallel to free margins to prevent such functional and cosmetic impairment. The dermatologic surgeon should also ideally plan the flap so that final scar lines fall within relaxed skin tension lines, cosmetic subunit borders, or rhytides to yield to most optimal final cosmesis. As with all flaps, advancement flap closure should be avoided if a defect may contain persistent malignancy or infection.

Postoperative Care and Follow-Up

Patients should be discharged after surgery with both verbal and written instructions on how to care for their surgical site. These instructions should include information on the signs and symptoms of complications such as infection, bleeding, and tissue necrosis. Some dermatologic surgeons will see patients back in their clinic for suture removal or assessment of the surgical site within days to weeks after surgery. Longer-term follow-up after advancement flap execution is at the discretion of the individual surgeon.

Alternative Procedures and Modifications

The choice of reconstructive modality will depend on multiple factors, including the size and location of the surgical defect, as well as patient factors, such as skin laxity, comorbidities, and medications. Alternatives to advancement flaps include other local flap procedures, interpolated flaps, and free tissue transfer. Other less complex reconstructive methods include skin grafting and primary closure. In some cases, second intention healing, with or without the aid of skin substitutes, may also be preferred for specific surgical defects.

Observations and Recommendations (Table 5.7)

Table 5.7 Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
The majority of evidence regarding advancement flap reconstruction exists in retrospective or case series format without comparison groups	C
These studies present surgical techniques and anatomic variants of advancement flaps that can greatly benefit reconstructive surgeons	D
The safety and effectiveness of advancement flaps is supported by these studies and a wealth of expert opinions from reconstruction surgeons	C and D

Self-Assessment Questions

1. An advancement flap cannot:
   (a) Recruit tissue from adjacent tissue reservoirs
   (b) Place incision lines in more cosmetically favorable locations.
   (c) Reorient wound tension
   (d) Avoid encroachment on key anatomic structures
   (e) Prevent distortion of free margins
2. In a randomized controlled trial comparing simple primary closure to mucosal advancement flap for lower lip reconstruction, what did the authors find?
   (a) Higher average patient and surgeon-rated aesthetic outcome scores and significantly lower side effects for flap group
   (b) Higher average patient and surgeon-rated aesthetic outcome scores and significantly higher side effects for flap group
   (c) Lower average patient and surgeon-rated aesthetic outcome scores and significantly lower side effects for flap group
   (d) Lower average patient and surgeon-rated aesthetic outcome scores and significantly higher side effects for flap group
3. V-to-Y advancement flaps require:
   (a) Removal of redundant tissue
   (b) Severing of the entire cutaneous attachment of the flap and maintaining a deep pedicle of subcutis and/or muscle
   (c) Billing as an island pedicle flap
   (d) Extensive undermining
   (e) Reorienting of tension vectors
4. In a retrospective chart review comparing V-Y advancement flaps to the Mustarde variant of the cervicofacial advancement-rotation flap for surgical defects of the cheek-lid junction:
   (a) Both groups had a similar rate of complications.
   (b) Both groups had a similar rate of ectropion.
   (c) The V-to-Y group had a higher rate of ectropion.
   (d) The V-to-Y group had a higher rate of complications.
   (e) The V-to-Y group had better aesthetic outcomes.
5. Advancement flap variants used on the nose include all of the following except:
   (a) Dorsal nasal advancement flap or east-west flap
   (b) Nasalis-based myocutaneous island flap
   (c) Peng flap
   (d) Rintala flap
   (e) Keystone flap

Correct Answers

1. c: Advancement flaps can recruit tissue from adjacent tissue reservoirs, place incision lines in more cosmetically favorable locations, prevent encroachment on key anatomic structures, and prevent the distortion of free margin. However, because an advancement flap only moves tissue in a linear direction, it cannot reorient wound tension vectors.
2. b: A RCT comparing primary closure to a mucosal advancement flap for surgical defects of the lower vermilion lip (after vermilionectomy) found that the mucosal advancement flap has better patient- and surgeon-rated aesthetic scores. However, the primary closure had acceptable aesthetic scores and a lower rate of complications.
3. b: V-to-Y advancement flaps rely on the severing of the entire cutaneous attachment of the flap and maintaining a deep tissue pedicle. V-to-Y flaps do not require the removal of redundant tissue and extensive undermining. They should be billed as an adjacent tissue transfer, rather than an island pedicle flap. Like all advancement flaps, V-to-Y flaps cannot reorient tension vectors.
4. b: This retrospective study found that V-to-Y flaps had a lower rate of complications than the Mustarde variant of the cervicofacial advancement-rotation flap. Both groups had a similar rate of ectropion. No analysis was made of the aesthetic outcome between the two groups.
5. e: All of the above are advancement flaps used for reconstruction on the nose-dorsal nasal advancement flap or east-west flap, nasalis-based myocutaneous island flaps, Peng Flap, and Rintala flap. The Keystone flap is a type of advancement flap based on the fascial perforator used for reconstruction of the extremities.

Transposition Flaps

6

Ian Maher and Ashley McWilliams

Abstract

Transposition flaps facilitate repair of a range of defects in anatomic locations with minimal inherent skin laxity, such as the nose. These flaps have the ability to reorient tension vectors and thus are particularly useful for avoiding distortion of free margins such as the alar rim or eyelid margin. Reservoirs with ample skin laxity are recruited in circumstances where primary closure or a sliding flap is not viable options due to tension at the primary defect. In patients who are at risk for bleeding, transposition flaps are ideal as less undermining is needed compared to sliding flaps. Core principles of successful transposition flap development are elaborated in Fig. 6.1.

Common transposition flaps include:

- Rhombic (single lobed).
- Bilobed.
- Trilobed.
- Nasolabial flaps.

A discussion of the indications, technique, efficacy, and alternatives for each of these transposition flaps will be presented in this chapter.

Transposition flap · Rhombic flap · Bilobed flap · Nasolabial flap

Introduction

Transposition flaps facilitate repair of a range of defects in anatomic locations with minimal inherent skin laxity, such as the nose [1, 2]. These flaps have the ability to reorient tension vectors and thus are particularly useful for avoiding distortion of free margins such as the alar rim or eyelid margin. Reservoirs with ample skin laxity are recruited in circumstances where primary closure or a sliding flap is not viable options due to tension at the primary defect [2]. In patients who are at risk for bleeding, transposition flaps are ideal as less undermining is needed compared to sliding flaps. Core principles of successful transposition flap development are elaborated in Fig. 6.1.

Common transposition flaps include:

- Rhombic (single lobed).
- Bilobed.
- Trilobed.
- Nasolabial flaps.

Preoperative Evaluation

Preoperative evaluation entails accounting for defect size, defect location, inherent elasticity of the neighboring tissue, qualities of the wound bed, and other comorbidities [2–4]. For example, the preoperative evaluation of one version of the rhombic flap, the Dufourmentel flap, necessitates that the tissue reservoir on the nasal sidewall and paranasal cheek is enough to accommodate flap movement without causing alar distortion (4) [5]. This assessment for donor site mobility is common to all flaps, transposition or otherwise. For multilaminar structures such as the distal nose or eyelid, where transposition flaps are frequently used, a thorough assessment of all layers is required: the external covering of the skin, supporting structural appendages, and internal lining and factored into the reconstructive strategy [3]. Additionally, obtaining a relevant history of prior skin cancer, any nearby irradiation, prior surgeries (for nasal defects), and presence of intervening scars will aid in selecting the appropriate reconstruction [2, 6]. Smoking status is also a critical factor. Flap or graft failure may increase with smoking and/or prior radiation exposure. Inconsistences in the survival of flaps or grafts may be due to differences in radiotherapy plan (fractionation, dosage, and timing) [7]. In these populations, raising flaps at the appropriate anatomic level and performing tension-free closures are crucial to reduce the risk of a failed reconstruction (5) [2]. Awareness of comorbidities such as chronic malnutrition, poorly controlled diabetes, uncontrolled hypertension, and bleeding diatheses is pertinent as these disorders increase the likelihood of post-reconstruction complications (5) [8, 9]. Hence, it is prudent to medically optimize the patient prior to any reconstructive surgery. Konofaos adds the optimal reconstructive approach takes into account racial, cultural, socioeconomic factors, and the patient's needs and concerns (5) [10]. Patient factors include age, expectations, and skin redundancy which are also part of the reconstructive preoperative evaluation (4) [11]. However, Shumrick et al. concluded in a study of 15 patients over the age of 80 who underwent nasal reconstruction that elderly age should not be a deterrent to nasal reconstruction as long as the surgery is not a significant risk to the patient's health and the patient has the capacity to appreciate the reconstruction (4) [12]. Additionally, surgeon factors such as experience and preference may also play a role. Assessment of the possibility of collapse of the ala prior to injection of the anesthesia is key (4) [4]. After a comprehensive review of these elements, the dermatologic surgeon should be apt to identify the appropriate repair of the cutaneous defect.

Procedures

Rhombic Transposition Flaps

Indications/Efficacy Classically based on a defect created in the shape of a rhombus or a diamond with four possible flaps drawn perpendicular to the long access of the diamond, the rhombic flap recruits tissue from tissue reservoirs that are immediately adjacent to the primary defect (5) [13]. Rhombic flaps can be used to repair defects in almost any head and neck cosmetic unit, such as the scalp, lateral upper 2/3 of the nose, small defects on the nasal tip, lateral forehead, eyelid, chin, neck, and medial canthus (5) [14, 15]. One case report of an elderly female who sustained a 1.6 × 1.6 cm defect on the nasal dorsum and supratip after excision of recurrent basal cell carcinoma found that bilateral rhombic flaps can be used to successfully repair large (>1.5 cm) central defects (4) [16]. Some reconstructive surgeons have found the bilateral Dufourmentel flap (double rhomboid flap) to be useful for the repair of nasal dorsum defects near or at the midline. These defects can be of any size, including up to 2 cm. Rhombic flaps also may repair defects involving the scalp, neck, and chin [17, 18]. The rhombic flap has successfully repaired deformities over the cheek and temple as well as defects involving the corners and free margins, given the use of adjacent tissue which ensures a tension-free closure. One case report found this workhorse flap is useful even in cheek reconstructions of previously irradiated skin, despite studies demonstrating that radiation can be a risk factor to flap viability (5) [6]. In a case series of 27 ophthalmology patients who underwent Mohs micrographic surgery for basal cell carcinoma (BCC) and underwent rhombic flap repair less than 24 h later, the authors found this flap to be appropriate for older patients with thin, less sebaceous skin. Increased skin laxity in this population decreased or minimized the traction necessary to move the flap into the defect (5) [15].

Technique In its various remunerations (Limberg, Dufourmentel, and Webster), this flap is created so that the corresponding sides and angles, ideally 90° or less, of the defect and flap are equivalent [19]. Measurements should account for facial convexities and concavities (5) [13]. The secondary tension vector perpendicular to the primary defect allows repair of the primary defect to occur without any wound edge tension. Thus, the standing cone and pedicle should be placed toward the side with the greatest tissue reservoir. The flap should then be transferred into the defect by pivoting on a base with movement over normal adjacent skin, creating a standing cutaneous deformity (SCD) at the base [20]. Depending on the location and shape of the defect, the rhombic flap may be duplicated in order to adequately repair a particular wound. When designing the bilateral Dufourmentel flap, the surgeon creates two superiorly oriented rhombic flaps designed from the midpoint of the lateral margins of the defect. Tension vectors are equal and symmetrical, resulting in no nasal tip or alar distortion (4) [5]. Besides offering an identical texture match of the unilateral rhombic flap, the vectors involved in a bilateral rhombic flap repair on the nose prevent twisting of the nose. There may be a slight upward lift of the nasal tip with this repair, but it may be useful in correcting ptosis [16]. Defects up to 1.5 cm in diameter of the inner canthal area or along the superior portion of the nasal sidewall should be approached with a superior-based rhombic flap (4) [21]. When resurfacing canthal defects, using a laterally based flap, with the SCD oriented toward the lacrimal caruncle, minimizes the necessity of excising a SCD, and the redundant tissue from the unexcised SCD helps to resurface the concavity of the medial canthal area (5) [22].

Complications The rhombic repair is a safe procedure given that the literature does not highlight circumstances of functional impairment. Rather, the complications associated with use of the rhombic repair are primarily cosmetic. Like the unilateral rhombic flap, the bilateral Dufourmentel flap has the possibility to introduce alar elevation if the design of the flap is performed incorrectly (5) [5]. Another common complication of the rhombic flap is alar groove blunting (5) [3]. Rhombic flaps have been used to repair skin-only defects of the eyelid; however, inherent to their design, some

of the flap incisions will fall outside of the relaxed skin tension lines (RSTL) (5) [23]. Unintended pivotal restraint, especially in areas of thick skin, may cause well-designed rhombic flaps to fail to reach their intended target in the primary defect. When this occurs, a double Z-plasty may aid in increasing flap movement [24]. Sclafani's case series of 446 Mohs defect repairs identified that rhombic flaps (RR = 1.541, $p = 0.0061$) are a risk factor associated with postoperative complications, especially pincushioning (RR = 4.405, $p < 0.0001$) (4) [25]. In this study, patients with the rhombic flap repair were more likely to need intralesional corticosteroid injections (RR = 2.734, $p = 0.0001$) postoperatively. Other risk factors identified included superiorly based nasolabial flap (RR = 2.153, $p = 0.0144$), bilobed flap (RR = 1.875, $p = 0.0491$), age < 60 years, Fitzpatrick skin type 3, nasal (alar) defect, glabellar flap, full-thickness skin graft (FTSG), and rotation flap [25]. Rhombic flaps are not amenable to repairs of the nasal ala due to the need to orient the repair cephalad with respect to the ala-free margin (5) [3]. The donor site of the flap needs to be on the skin of the nasal sidewall, superior to the alar groove. The tension to close the secondary defect at the donor site can obstruct the nasal valve due to medial deviation of the lower lateral cartilage (5) [3]. Individuals with thin noses or tightly adherent lateral sidewalls are most at risk for alar distortion with this reconstructive option. Hence, another repair should be considered for these patients [5].

Bilobed Transposition Flaps

Indications/Efficacy Compared to rhombic flaps, bilobed flaps are able to recruit donor sites more remote from the primary defect. First described by Esser in the German medical literature in 1918, this double-lobed flap with a pedicle was a fusion of the conventional flaps recruiting skin from the nasal dorsum and the sidewall used to repair nasal tip defects [23, 26]. The primary advantage of this flap is it distributes the tension involved in closure across a broad area, away from the original defect [27]. Additionally, this flap as a single-stage flap with color and texture match to adjacent tissues has a predictable flap viability, pushing movement of the flap toward the free margin, reliable vasculature, and restoration of contour over a convexity (4) [4, 23]. Iddings et al. found this reconstruction to be useful for large cheek defects (5) [28]. The bilobed flap is suited for repair of defects up to 1.5 cm in the distal half of the dorsum, sidewalls, and lateral tip and on the supra-tip that are located ≥5 mm from the free nostril margin (4) [2, 4, 14, 23, 27]. It is most useful for defects that are at the lower eyelid, lower 1/3 of the nose, especially for small-rounded defects at the nasal dorsum and lateral walls, including the anterior and middle nasal alae (4) [3–4, 14]. Reconstruction at these sites minimizes distortion of the ala (5) [2]. Garces et al. report a successful bilobed repair of a full-thickness nasal alar rim defect, a condition commonly corrected with a paramedian forehead flap and the nasolabial flap (5) [29]. The bilobed flaps work well in those with firm alae and is less ideal in those with soft, floppy alae (4) [4]. Bilobed flaps, compared to the skin grafts, are especially useful for defects where the depth extends into and past the subcutaneous fat, as the skin grafts tend to result in visible depressions over the nose in deeper defects and a less than desirable aesthetic result (5) [30]. However, Martinez contends that ipsilateral alar narrowing may result from tertiary defect closure of a laterally or medially placed bilobed flap [31]. As it pertains to eyelids, laterally placed bilobed flaps may be used for large defects on the eyelid. These repairs displace tension to the cheek and/or temple away from the lid margin [32]. However, one study concluded that bilobed flaps are minimally helpful in the repair defects that are larger than 1.5 cm, on the most distal aspect of the nasal tip or ala, or arise on patients with rigid, sebaceous nasal skin. In fact, these features are predictive of bilobed flap failure (5) [33]. Table 6.1 contains a summary of studies evaluating the efficacy and safety of the bilobed repair.

Technique In the design of this flap, the primary lobe is designed at an approximately 45-degree angle to a line bisecting the primary defect and

Table 6.1 Summary of published studies on bilobed flaps

Publication	Study design	Number of subjects	Efficacy	Safety	Level of evidence
Konofaos et al. [10]	Case series, retrospective chart review	419 patients	Bilobed flap for successful repair of 145/278 defects of nasal dorsum, sidewall, lateral tip, and supra-tip	Hypertrophic scar, bulky flap, flap pincushioning, and partial necrosis listed but unclear if these pertain specifically to the bilobed flap	4
Ibrahim et al. [11]	Case series, retrospective chart review	245 patients	Bilobed flap reconstructed 17/42 nasal ala defects, 19/41 nasal tip defects, and 8/25 nasal sidewall defects	No data on complications	4
Jellinek et al. [4]	Case series	6 patients	Bilobed flap for alar rim (<1 cm) defects	No complications listed for these patients, but possible complications include alar contraction, ecnasion, and alar asymmetry	4
Monarca et al. [44]	Cohort study	120 patients (60 patients received the island flap, 60 patients received the bilobed flap)	In the long term, bilobed flaps had nasal distortion. Patient and third-party assessments of island flap repairs were rated more favorably than the bilobed flaps and found to be statistically significant	Island flap: 6 cases of hematoma Bilobed flap: 10 cases of flap congestion, 5 cases of apical flap necrosis of which 2 cases required surgical revision, persistent edema, and 11 cases of trap door deformity	3
Xue et al. [35]	Case series	11 patients	All patients received bilobed flaps, no issues with flap survival or functional deformities	No post-operative complications, such as alar retraction	4

with a size approximately equal to the size of the primary defect. The height of the primary lobe should be equal to the height of the defect (4) [34–35]. The secondary lobe is then designed at an approximately 45-degree angle to the primary lobe giving the bilobed flap a total angle of rotation of about 90 degrees. The addition of a secondary lobe allows for placement of the tension bearing tertiary defect in an area of greater skin laxity, which may be closed easily with a buried, interrupted, absorbable suture (5) [36]. Zitelli found that lengthening of the primary lobe is helpful when there is a large defect (≥1.5 cm) or when the secondary lobe is in tight or immobile skin (5) [37]. This advantage enables repair in sites where tension proximal to the primary defect is excessive or creates an anatomic distortion (5) [38]. When designing this flap, it is important to avoid tension on the lower medial canthus while closing the tertiary defect in order to avoid ectropion. Closing of the tertiary defect pushes the flap toward the primary defect.

Next the primary lobe is positioned, trimmed as needed, and sutured into the primary defect with an absorbable, buried interrupted tacking suture extending from the underside of the primary lobe to the primary defect. The placement of deep sutures that incorporate the deep tissue of the flap and surrounding skin is critical. Improper placement of these key sutures results in distortion of the ala. Thus, one must reassess the position of the primary flap immediately after placement of this first suture and prior to further securing the primary flap [39]. The secondary lobe is trimmed as needed and sutured into the secondary defect with nonabsorbable running or interrupted sutures to approximate the superficial

skin edges of the entire flap (5) [36]. With further improvement of the design, a Burow's triangle next to the primary defect is anticipated and removed, without affecting the base of the pedicle and compromising the vascular supply. Removal of Burow's triangle obviates the need for a secondary procedure in the future to remove the SCD that would otherwise occur at the point of rotation.

Important design principles for this flap include creating a long, thin standing cone defect with a diameter that is 0.75–1.5 times the diameter of the primary defect (5) [37, 40–41] and removing the SCD prior to flap movement (5) [37, 40–41]. The distance between the distal primary defect and the apex of the SCD determines the bilobed's outer arc of rotation. This degree of rotation facilitates less secondary motion at the primary defect and less risk of elevating the alar rim. Incisions for the nose should be carried through the nasalis muscle, periosteum, and perichondrium and the flap is mobilized below the muscle. Wide undermining and meticulous closure decrease the possibility of a trap door deformity [39, 41–43]. In a case series, the author advocated that the bilobed flap may be used for small- to medium-sized defects on the helical rim as the flap may originate from a concealed site such as the posterior rim, and allows for faster wound healing of a defect with exposed cartilage, and provide excellent color and texture match with a one-stage repair. During the design of the bilobed flap, it is important for the surgeon to test airflow through the ipsilateral nostril of the patient and repeat after the first key suture to assess for looming nasal valve collapse due to horizontally oriented tension over the internal nasal valve (4) [4].

Complications The bilobed repair has a number of possible functional and aesthetic complications. For example, nasal obstruction may occur with this type of reconstruction, especially in patients with fragile skin, weak cartilage, and large nasal defects (5) [30]. Internal nasal valve constriction associated with suturing the tertiary defect is a known flaw some surgeons experience (4) [4]. Also, the improper placement of the flap pivot point over the internal nasal valve with these repairs may cause a functional deficit in the nostril (4) [15, 32]. If the nasal valve collapses, a pexing suture at the depth of the alar groove fixed to the sidewall periosteum will help open the valve if the suture is constricted (4) [4, 22]. In a head-to-head trial comparing island pedicle flaps to bilobed flaps for nasal reconstructions, bilobed flaps had statistically significant higher rates of early complications that included hematoma, flap necrosis, and hypertrophic scarring (3b) [44]. The impact of inappropriately designing the lobes can be dramatic. Undersizing of the flap causes contraction of the ala and upward ipsilateral alar retraction, whereas oversizing may result in alar asymmetry and depression (5) [39]. When the secondary lobe is too wide or too long, the tertiary defect cannot be reapproximated and excess skin must be disposed of in order to prevent trap door deformity or push the alar rim inferiorly (4) [29, 35–36]. While the exact etiology of trap door deformity or pincushioning is not definitively known, one hypothesis is that it arises when excess volume of the flap caused by a vascular obstruction at the surgical site creates a poor aesthetic outcome [36]. Sclafani argues that pincushioning is due to the circumferential formation of scars around the flap and the inward vectors produced by scar contractility [25]. It usually appears 3–6 weeks post-surgery (5) [36]. In Sclafani's study of 446 Mohs defects, bilobed flaps were 2.5 times more likely to pincushion ($p = 0.0286$) (4) [25]. Placing this lobe perpendicular to the nasal ala prevents alar displacement or distortion (4) [29, 35, 39]. Excess tension along the flap can result in flap tip necrosis along the free margin.

From a cosmetic perspective, differences in the lobe thickness may also result in visible depressions (5) [30]. Equally concerning, the multiple multidirectional scar lines associated with bilobed flaps, especially in a highly sebaceous rhinophymatous nose, may be difficult to conceal due to some of these lines opposing relaxed skin tension lines (3b) [23, 30, 36, 44]. Dermabrasion sanding with sterile sandpaper or scar revision may help decrease the appearance of scar lines (5) [36]. Wide undermining and

placement of deep sutures that incorporate the deep tissue of the flap and surrounding skin can minimize this complication. Other complications may include distortion of the nasal tip due to elevation of the tip or nasal margin as a result of wound closure. Patients who have a weak nasal structure have a higher likelihood for nasal (ala) distortion and elevation of the nostril free margin (5) [3, 30]. If used in a more cephalad position, the placement of the second lobe at the medial canthus or glabella may distort these structures. The main disadvantage at these locations is that the skin is thin, possibly compromising the viability of the flap (5) [36]. If used for central tip defects, tip contour distortion may occur [10].

Trilobed Transposition Flaps

Indications/Efficacy First described by Esser, these flaps are designed to correct defects of the lower third of the nose that necessitate recruitment of tissue from even more remote sites compared to bilobed flaps. These flaps are ideal for inferomedial alar and distal nasal tip defects (5) [45]. When used on the nose, tissue may be recruited from sites as distant as the nasal root [20]. Given that this is a single-staged flap for large, deep alar and nasal tip defects with possible involvement of cartilage, this is an alternative to the paramedian forehead flap or cheek-to-nose interpolation flap. The latter carries additional risks, costs, and morbidity especially in the elderly [33]. This flap may also be used in the repair of lateral alar defects with a more medially placed design (5) [33]. By displacing the quaternary defect on the nasal dorsum, repairs larger than 1.5 cm may be performed using the trilobed flaps (5) [20]. In a retrospective review of 31 patients, all patients underwent successful reconstruction with the trilobed flap if their defect was >1.5 cm, prominent on the nasal tip or ala, and availability of looser proximal nasal skin was not an option. While there were no reports of flap failure, hematoma, or surgical site infection, one anticoagulated patient required flap takedown after failure to obtain hemostasis through conservative measures. Electrocautery and flap replacement resolved this issue [33]. Finally, the unilateral nature of the trilobed flap creates a less visible scar because less subunits are involved (5) [33].

Technique When creating the trilobed flap, the surgeon begins by creating a vertically oriented dog ear toward the alar crease, allowing the lateral nasal tip to serve as the primary lobe donor. By placing the dog ear along less sebaceous and thinner tissue, this orientation toward the medial canthus reduces bulldozing or depression of the alar rim (4) [33]. The apex of the dog ear is placed within the alar crease, shifting the pivot point into the lower nasal sidewall, freeing up the flap's rotational movement. Additionally, Claiborne and Albertini argue that this dog ear should be designed as small as possible so that any excess tissue from the standing cone deformity at the apex will be inverted and hidden within the crease as an "inverted cone deformity." [45] With a more moveable pivot point, there is a decreased risk of bulldozing and distortion during rotation and insetting of the flap. Moreover, this design minimizes tissue waste, maintains the native ala as much as possible, and preserves the cosmetic subunit (5) [45]. Also, the closure tension vector is transverse across the nasal dorsum and alar distortion is minimized (5) [45]. Like the bilobed flap, each lobe of the trilobed flap rotates 45–50 degrees with an arc of flap rotation of 135–150 degrees (4) [33]. The smaller arc of the rotation in the trilobed flap reduces the Z-plasty like lengthening and thus minimizes the bulldozing of the ipsilateral ala [33]. Since these flaps tend to be in areas with greater skin laxity, the primary lobe should be equal in size to the primary defect. The secondary lobe should have a diameter that is 85–90%, and the tertiary lobe should have a diameter that is 75–80% of the primary defect (5) [45]. The smaller secondary and tertiary lobes help distribute tension, warding off the possibility of pincushioning [33]. Equally, these smaller lobes also allow for primary closure of the tertiary defect, which often lies close to the medial canthus, without distorting important anatomical features. Lobes derived from immobile skin

should not be undersized as the size adjustment is thought to add a small amount of tension, yet decrease pincushioning (5) [45].

Complications Disadvantages of these flaps include more lobes that increase the operating time and increase the risk of a more noticeable scar (5) [38].

Nasolabial (Melolabial) Transposition Flap

Indications/Efficacy Initially described by Dieffenbach for repair of partial nasal alae defects, this repair is the most widely used flap in the nasolabial fold and its adjacent structures (including the lip) due to the flap mobility and its ability to close the secondary defect via primary intention (4) [14, 25, 27]. Additionally, the donor site scar may be concealed within the nasolabial fold. It may be used to reconstruct full-thickness alar defects as large as 2.5 cm, including those on the alar margin (4) [46–47]. In Uzun's case series of 163 patients, the nasolabial flap was one of the preferred reconstruction methods for repair of distal lateral nasal defects involving the alar and domal-alar groove subunits for its reliable blood supply from the medial cheek skin and skin color and texture match of the previously excised tissue (4) [27]. For the nose, this flap facilitates recreation of the nasal ala via simultaneous insertion of cartilage grafts and prevents proximal retraction that may distort a natural-looking contour of the nose (5) [14]. It may be used for reconstruction of large defects or internal lining defects if the flap was turned over when septal mucosal flaps are not available or for large lining defects (4) [48–50]. Defects of the nasal sidewall can be repaired with the ample tissue reservoir of superiorly placed melolabial flaps (5) [3].

Technique Proper execution of the flap entails an excision of Burow's triangle in the direction of the medial canthus. The excised nasal sidewall skin should extend to the nasolabial crease at a 30-degree angle to eliminate the standing cone at the pivot point. For this reconstruction, the medial aspect of the flap begins at the lateral aspect of the defect where a point meets the nasolabial facial sulcus (5) [51]. Incisions may need to be placed into the nasolabial crease, alar crease, and junction between the nasal dorsum and nasal sidewall. The incision is planned to continue along the melolabial crease without entering the hairless triangle where the upper cutaneous lip meets the ala. The lateral incision, which is superior, should be several millimeters above the peninsula formed by the junction of the cheek, upper lip, and ala. The flap is elevated, defatted, and positioned medially over the peninsula of the alar fragment. Wide undermining of the donor site, recipient site, and adjacent tissues of the cheek and nasal dorsum allows a tension-free closure. Placement of buried sutures in the deep aspect of the flap anchored to the piriform aperture helps recreate the nasolabial sulcus and avoids tenting of the cheek onto the nose. A portion of the lateral ala must be present to secure the advancing cheek skin and reapproximate the donor site [3]. Then, the donor site is closed, and the flap is sutured to the recipient site to recreate the alar groove (5) [51].

Complications Careful attention must be made when designing these flaps in the cheek as there is a tendency for the soft supple skin to pincushion or to develop alar groove blunting (4) [10]. In the absence of meticulous suturing, the round scar where the flap insets at the ala tends to invert (5) [3]. Further complications are highlighted in a summary of nasolabial flaps in Table 6.2.

Combined Transposition Flaps

Some investigators used hybrid variants of transposition flaps for unique indications. Fujiwara created a bilobed nasolabial-nasal tip flap to repair a full-thickness defect of the alar rim larger than 20 mm. Besides providing a good texture and color match, this flap also gives the patient a scar concealed in the nasolabial sulcus (5) [52]. Kannan and John also report using a bilobed nasolabial flap for a 2.5 cm left ala defect of the nasolabial fold (5) [53]. Dinehart presents his experience of

Table 6.2 Summary of nasolabial transposition flaps

Publication	Study design	Number of subjects	Efficacy	Safety	Level of evidence
Konofaos et al. [10]	Case series, retrospective chart review	419 patients	69/74 of defects repaired with a nasolabial repair +/−cartilage graft for defects of the nasal ala, dorsum, and nasal sidewall	Flap bulkiness was a complication for some of the repairs	4
Ibrahim et al. [11]	Case series, retrospective chart review	245 patients	Nasolabial flap successfully reconstructed 3/41 nasal tip defects, 12/42 nasal tip defects	No data on complications	4
Carucci [51]	Case series	32 patients	32/32 repairs of the ala with single-staged melolabial flap	No trap door deformity appreciated	4
Han et al. [47]	Case series	17 patients	12/17 repairs of defects ≤2 cm were nasolabial flaps with various aesthetic outcomes from poor to excellent	Alar groove blunting, elevated alar margin, and flap contraction	4

ten patients receiving the rhombic bilobed flap, which produced minimal postoperative complications such as telangiectasias surrounding a spreading scar. No functional deformity resulted (4). A decreased incidence of pincushioning results with this flap due to the sharp angles and dispersion of tension produced by this flap (4) [54].

Postoperative Care and Follow-Up

Immediate postoperative care includes a 24–48-h pressure dressing and daily wound care including gentle cleansing with topical antibiotics or bland emollients. While some surgeons prescribe a short course of oral anti-staphylococcal antibiotics, evidence shows that routine antibiotics are unnecessary (1a) [55].

After reconstruction, some patients develop unsightly scars at the donor site or the site of the primary defect. It is recommended to delay any surgical scar revision for 6–12 months to allow time for scar maturation. Dermabrasion or laser therapy ameliorates this problem and may be used in the early post-operative period to correct for more minor defects in appearance (5) [2, 56]. Dermabrasion may improve the color and texture match of a nasal reconstruction and may be performed as early as 6 weeks after the initial reconstruction (5) [2]. Pulsed dye laser therapy can be safely performed as early as 1 week post-surgery [56].

Alternative Procedures and Modifications

There are alternative repair options that may be reasonably chosen for almost any cutaneous defect. While advancement flaps, rotation flaps, V-to-Y island pedicle flaps, interpolated nasal flaps, interpolated melolabial flaps, and paramedian forehead flaps are covered in more detail in subsequent chapters, this chapter will briefly highlight the indications, advantages, and complications associated with these flaps as alternatives to transposition flaps. Alar advancement rotation flaps are a viable option for 3–4 mm defects in the anterior half of the ala. They offer a fitting color, texture, and thickness match and the scars can be concealed in the alar groove. Closure with this reconstructive option may result in a downward displacement of the free margin, buckling of the alar rim, and obliteration of the alar groove, especially for defects that are too large in the horizontal dimension, if the standing cone is too small or insufficient undermining has occurred (5) [57]. As an alternative to the bilobed flap, the advancement and inferior rotation flap of the nasal sidewall (AIRNS) is a single-stage repair for horizontal defects of the nasal tip or the lower nasal dorsum. Using the upper nasal sidewall and cheek, this flap has less of a tendency to pincushion. However, this repair results in a single curvilinear scar (4) [58]. In

certain circumstances, the bilobed flap remains a better option for certain defects, such as a lateral ala defect (4) [58].

The V-Y island pedicle advancement flap may be used for similar small <0.5 cm in horizontal diameter medial alar defects. Sliding flaps on the ala are only amenable for defects nearer the alar crease and relatively remote from the free margin. Like the transposition flaps, these flaps provide a good color, texture, and thickness match to the native skin. Additionally, the V-to-Y flap has a reliable blood supply, offers ease of harvest, and has a broad pedicle. Compared to the bilobed flap, some authors feel decreased edema results in less chance of a trap door deformity. When this repair is utilized near the free margin, flap movement is limited, and the circulation in this area becomes very much compromised near the margin [3]. The design of the island flap is versatile, able to be crafted into the shape of the defect without disrupting the natural contours of the nasal tip. It can also avoid nostril notching or nasal asymmetry (3b) [44].

For defects that span more than one cosmetic subunit, options include the paramedian forehead flap and composite grafts. Despite its use in providing coverage over large defects, a major drawback of the paramedian forehead flap reconstruction is the creation of a long forehead scar that some patients find aesthetically displeasing (5) [3]. Composite grafts repair large full-thickness defects (defects that involve the skin, structural framework, and the internal lining) of multiple nasal subunits or related to nasal vestibule stenosis (4) [59–60]. It may be used for secondary reconstruction in patients with an unsightly scar resulting from scar contracture or a previous surgery for a congenital defect. However, composite grafts have a high metabolic demand and high risk for necrosis (5) [3].

Full-thickness skin grafts (FTSG) may be used for the repair of alar defects in patients whose comorbidities do not permit them to undergo a long procedure [2]. Full-thickness skin graft is another option that works well in patients with thin skin who require repairs of the cephalic sidewall, dorsum, and infratip lobule. They help to repair superficial defects and provide total nasal coverage in patients with several significant medical comorbidities (5) [2]. However, these grafts are oftentimes a mismatch in the color, texture, and thickness of the native skin (5) [3]. In a retrospective chart review of 186 cases of surgical defects of the nasal ala, FTSG were used to repair defects of at least 1.0–1.4 cm; eight cases involved lesions of 2 cm or greater. With this reconstruction, there was no loss of ala patency, distortion of the free margin, nor complications that may arise with bilobed, trilobed, or nasolabial flaps. Post-operative wound infection occurred with two cases, resulting in antimicrobial use. Two patients had failure of full thickness graft uptake ameliorated with dermabrasion. Dermabrasion was used in 36% of cases to improve the postoperative cosmesis (4) [61].

As an alternative to the melolabial flap for lateral ala defects, the hinge cheek subcutaneous flap is helpful for resurfacing intermediate thickness defects of the lateral nasal ala or sidewall (5) [2].

Additionally, a melolabial interpolated flap can also be used to reconstruct alar defects. As opposed to the cheek transposition flaps, these interpolated flaps are an alternative to the single-staged nasolabial flap for defects that affect the entire nasal ala because of the ample tissue available within the nasolabial fold. The reconstruction is indicated for deep alar defects. It preserves the alar-facial sulcus and offers a close skin and texture match for the ala. It entails the placement of a cartilage batten graft to brace the alar rim against tension vectors that cause flap contraction and the flap provides vascularization of the cartilage graft [2–3]. Key disadvantages of this flap are that the flap, in men, may transfer hair-bearing skin from the donor site to the ala and that melolabial fold asymmetry may result from harvesting broad cheek flaps—limiting the vertical height of the primary defect that the flap is amenable to (5) [62]. Also, there is an apparent extensive pedicle care and a need for a second procedure to detach the flap pedicle and to inset the flap (5) [2].

Nasal defects <1 cm of the middle third of the nose or caudal dorsum and sidewall may be closed primarily (5) [2]. This reconstructive approach is ideal for elderly patients with significant skin laxity that allows tension-free closure (5) [2].

Another alternative for repair of alar defects includes healing by secondary intention. Zitelli found that areas involving the alar crease can be reasonable for healing by secondary intention, whereas other surgeons have found this approach to be useful for small defects (<5 mm) adjacent to the nasolabial sulcus or in the alar-facial crease (5) [3]. For small defects in patients who are poor surgical candidates, healing by secondary intention is a viable option (5) [2]. However, this option is avoided for large, deep defects, particularly those near the alar rim as there is a higher likelihood of alar retraction or nasal valve compromise (5) [2–3]. Concave surfaces may or may not be surfaces amenable for healing by secondary intention. Webbing in concave surfaces is also a well-known complication of wounds that heal from secondary intention (5) [3].

Defects of less than or equal to 2.5 cm of the middle and lower nose involving the nasal dorsum, tip, and sidewall may be repaired with a dorsal nasal flap recruiting ample glabellar skin (5) [2].

Decision Trees on Nasal Reconstruction

While based on surgeon experience, various papers publish decision trees that indicate repair options for specific defects. This information may be helpful for novice surgeons to use until a randomized clinical trial, systematic review, or clinical guidelines develop that validate particular repairs for certain defects. Uzun et al. have an algorithm based on whether the size of the defect and location of the defect are on the nose [27]. Konofaos presents a similar decision tree in his 2014 publication [10].

Conclusion

Transposition flaps are a staple reconstructive tool in the armamentarium of dermatologic surgeons. They are versatile in repairing a multitude of defects as reflected in Table 6.3, which contains various clinical scenarios in which transposition flaps facilitated the re-approximation of tissues

Table 6.3 Summary of studies of multiple transposition flaps

Publication	Study design	Number of subjects	Efficacy	Safety	Level of evidence
Uzun et al. [27]	Case series	163 patients	−31.5% defects of the middle 1/2 of the nose repaired with nasolabial flaps without flap necrosis −39.6% defects of the distal 1/2 of the nose successfully repaired with nasolabial flaps −17.0% of defects of the distal 1/2 of the nose successfully repaired with bilobed flaps −5.48% of defects of the middle 1/3 of the nose successfully repaired with rhombic (Limberg) flaps −7.55% of defects in the distal 1/3 of the nose successfully repaired with the rhombic (Limberg) flap	No complications noted	4
Yoon et al. [50]	Case series	35 patients	3 successful repairs with bilobed flaps, 5 cases of successful repair of nasolabial flaps. No functional impairment	One case of composite free-flap necrosis, tip necrosis of paramedian forehead flap	4

while preserving functional aesthetics. Use of these workhorse flaps is predicated on the proximity of the primary defect relative to the tissue reservoirs. For example, a rhombic flap for a defect on the proximal nose or sidewall with tissue reservoirs immediately adjacent to it may work well as the single lobe of this flap may reach adjacent tissue reservoirs. Defects on the supratip and proximal nasal tip may require a bilobed flap, and very distal defects may require a trilobed flap. Defects of the lateral ala may be addressed with the nasolabial flap. These flaps are overall safe with well-known complications that surgeons have identified strategies to remedy. Further investigation into the indications and techniques for transposition flaps in the future will help generate clinical guidelines that will assist dermatologic surgeons in selecting the most evidence-based approach for addressing the repair of cutaneous defects.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE).

Findings	GRADE score: quality of evidence
A thorough assessment of all layers, the external covering of the skin, supporting structural appendages, and the internal lining, must be done and factored into the reconstructive strategy [3]	D
Obtaining a history of prior skin cancer, history of head and neck irradiation, nasal surgery (for nasal defects), and presence of intervening scars helps with selecting the appropriate reconstruction [2]	D
Consider rhombic transposition flaps for virtually any head or neck cosmetic subunit with a defect that is less than 2 cm with adjacent healthy, mobile tissue reservoirs [14–15]	C
The bilobed flap is well-suited for repair of defects up to 1.5 cm in the distal aspect of nasal subunits and lower eyelid [2, 10, 14, 23, 27]	A
Nasolabial transposition flaps are ideal for the reconstruction of defects along the lateral ala, ala margin, and lip in which the donor site scar may be concealed within the nasolabial fold [14, 25, 27]	A
Careful execution in the design, undermining, and suturing of these flaps minimizes the risk of pincushioning, alar retraction, alar elevation, and nasal valve compromise	A
Whereas it is important to base the selection on patient characteristics (especially considering the size and location of the defect), awareness of the complications and best practices in the utility of transposition flaps can be further strengthened through randomized clinical trials, systematic reviews, and clinical guidelines	B

Summary of Observations

- Transposition flaps have a wide range of applications in the repair of cutaneous defects in anatomic locations with minimal inherent skin laxity.
- The decision on which transposition flaps to use is dependent on local tissue characteristics.
- Reconstructions involving transposition flaps are safe.
- These reconstructions do not require discontinuation of anticoagulation or initiation of antibiotics.

Self-Assessment Questions

1. Compared to rhombic flaps, bilobed flaps are better served for defects in which:
   (a) The tissue reservoir is in a remote location relative to the defect.
   (b) The tissue reservoir is in close proximity to the defect.
   (c) The defect is greater than 2 cm.
   (d) The defect is located on the superior aspect of the nasolabial fold.
   (e) The defect is the result of secondary reconstruction.
2. Optimization of the appearance of scar lines of transposition flaps may entail:
   (a) Dermabrasion only.
   (b) Low or medium potency corticosteroids.
   (c) Dermabrasion and pulsed dye laser therapy.
   (d) Phototherapy.
   (e) Re-exploration of the surgical site.
3. Defects that involve destruction of the internal nasal lining may be repaired with:
   (a) Trilobed flaps.
   (b) Rhombic flaps.
   (c) Bilobed flaps.
   (d) Nasolabial flaps.
   (e) Island pedicle flaps.
4. The type of transposition flap that is most likely to have pincushioning is:
   (a) Bilobed flaps.
   (b) Rhombic flaps.
   (c) Trilobed flaps.
   (d) Nasolabial flaps.
   (e) Advancement flaps.
5. Assessing nasal patency is a critical intraoperative step for this type of repair(s):
   (a) Rhombic and nasolabial transposition flaps of the nasal sidewall.
   (b) Rhombic transposition flaps of the nasal dorsum.
   (c) Rotation flaps on the glabella.
   (d) Advancement and inferior rotation flap of the nasal sidewall.
   (e) Bilobed and rhombic transposition flaps on the lower nasal sidewall or ala.

Correct Answers

1. a: Bilobed transposition flaps are maximally effective when the tissue reservoir is in a remote location. In contrast, rhombic flaps are ideal for repairs of defects in which the tissue reservoir is in close proximity to the defect. The primary flap movement of the rhombic flap is predicated on the free edge of the flap being within a short distance of the primary defect, resulting in minimal pivotal restraint during insetting of the flap.
2. c: Dermabrasion and/or pulsed dye laser therapy may improve the cosmesis of the scar lines of the transposition flaps. They may be used in the early postoperative period to correct for more minor defects in appearance (5) [2, 56]. Dermabrasion may improve the color and texture match of a nasal reconstruction and may be performed as early as 6 weeks after the initial reconstruction (5) [2]. Pulsed dye laser therapy can be safely performed as early as 1 week post-surgery [56].
3. d: Nasolabial flaps may repair defects that have internal nasal lining involvement as these flaps may be turned over when septal mucosal flaps are not available or large lining defects are present.
4. b: Despite dogma that posits that flaps with rounded edges are more likely to pincushion, Sclafani's case series reviewing the complications from 446 Mohs defect repairs found that rhombic flaps were 4.4 times ($p < 0.0001$) more likely to pincushion than bilobed flaps (RR = 2.488, $p < 0.0286$) flaps [25]. The study did not comment on the likelihood for pincushioning with other types of transposition flaps or advancement flaps.
5. e: Jellinek and Cordova assert that it is critical for the surgeon to test airflow through the ipsilateral nostril of the patient in bilobed reconstructions and repeat the assessment after the first key suture to assess for looming nasal valve collapse due to horizontally oriented tension over the internal nasal valve (4) [4]. For rhombic defects, the tension to close the secondary defect at the donor site can obstruct the nasal valve due to medial deviation of the lower lateral cartilage [2]. Hence, it is prudent to check nasal patency for rhombic defects as well. Reconstruction of defects over the bony nasal skeleton that are more proximal on the nose should not affect the nasal valves.

Rotation Flap

7

Farhaad R. Riyaz and David M. Ozog

Abstract

A rotation flap is a procedure carried out in cutaneous surgery in order to close a defect in the skin by recruiting cutaneous tissue from a nearby reservoir (5) (LoPiccolo, Dermatol Surg 41(Suppl 10):S247–S254, 2015). Akin to many other flaps, rotation flaps are reputable workhorse flaps first described in 1978, (5) (Albom, J Dermatol Surg Oncol 4(12):906–907, 1978) often used to repair defects on the head and neck but can also be useful for bodily sites such as the hand, forearm, and nail bed (5) (O'Neill, Litts, Clin Plast Surg 31(1):113–119, 2004). They are performed in a single stage and are widely regarded as highly reliable, efficient, and straightforward (2c) (Moore et al, Head Neck 27(12):1092–1101, 2005). They are executed in a sliding fashion but are distinguished from other sliding flaps, such as advancement flaps, by moving at an angle about a pivotal point, and are therefore useful for redirection of tension vectors. They recruit tissue from adjacent sites. This distinguishes them from transposition flaps, where recruited tissue is transferred over another portion of skin.

Indications for Rotation Flaps

A rotation flap is a procedure carried out in cutaneous surgery in order to close a defect in the skin by recruiting cutaneous tissue from a nearby reservoir (5) [1]. Akin to many other flaps, rotation flaps are reputable workhorse flaps first described in 1978, (5) [2] often used to repair defects on the head and neck but can also be useful for bodily sites such as the hand, forearm, and nail bed (5) [3]. They are performed in a single stage and are widely regarded as highly reliable, efficient, and straightforward (2c) [4]. They are executed in a sliding fashion but are distinguished from other sliding flaps, such as advancement flaps, by moving at an angle about a pivotal point, and are therefore useful for redirection of tension vectors. They recruit tissue from adjacent sites. This distinguishes them from transposition flaps, where recruited tissue is transferred over another portion of skin.

When used in dermatology, a rotation flap consists most often of the epidermis, dermis, and subcutaneous fat but also can contain underlying muscle. The rotation flap is known to have a rich vascular pedicle and usually is a random pattern

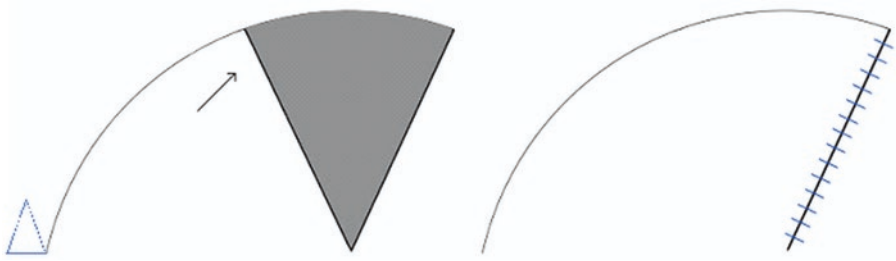

Fig. 7.1 The simplified movement of a rotation flap, closing a triangular defect

flap with no named artery to supply blood, although in a few case reports there are named arteries recruited as a blood supply with an unknown difference in outcomes (4) [5].

Rotation flaps can be used to hide incision lines within curved relaxed skin tension lines or at the border of cosmetic subunits and can move standing cones anywhere along the arc of the flap or even retroauricularly (2a, 5) [6, 7].

Rotation flaps were classically described as arcuate flaps used to repair triangular defects (Fig. 7.1). They can be used for small or full-face defects. Other than being used for facial reconstruction, they have been used in all age groups to repair pilonidal sinuses and are considered superior to primary closure for this purpose (1b) [8]. They have also been used to repair sacral pressure ulcers but may have higher rates of complication than perforator flaps when used for this purpose (2b, 3b) [9, 10]. Also, rotation flaps are used to recruit the laxity of the ulnar forearm toward the radial forearm in children with radial longitudinal deficiency (2b) [11].

Modifications of the rotation flap include bilateral rotation flaps used for large forehead wounds or chin defects (2c) [12], "O to Z" rotation flaps used for defects of the scalp (5) [13], dorsal nasal flaps used for defects of the distal nose (4) [14, 15], and Tenzel and Mustarde flaps for lower eyelid reconstruction (4, 5) [16, 17]. A lateral eyelid rotation flap has also been described in one case for reconstruction of full-thickness eyelid defects (2b) [18]. In three reported cases, one rotation flap has been used to repair multiple adjacent defects on either the cheek or nose (4) [19–21]. Finally, a modification of the rotation flap called the "reverse Yu flap" has been studied in a cohort fashion with good oral competence and aesthetic outcome at a mean of 20 months of follow-up (4) [22].

Effectiveness of Rotation Flaps

One of the largest case series of rotation flaps described effectiveness in closing circular defects in 178 patients after removal of malignant neoplasms (4) [23]. The widespread use of rotation flaps and their resilience to major change over time are a testament to their effectiveness and reliability (5) [24]. Despite this, there is a paucity of data on this subject. Experts consider them effective for the repair of defects with an adjacent tissue reservoir, sitting in an area with curved relaxed skin tension lines or a curved cosmetic subunit within which to hide incision lines. The effectiveness of rotation flaps is not believed by many experts to be markedly affected by patient demographics such as age, comorbidity, or smoking status (5, 3a) [1, 25].

As with all scars, their appearance can be expected to improve over the first 6–24 months, but unfortunately there is no data comparing this property in rotation flaps with other types of surgical scars.

Preoperative Evaluation

Preoperative evaluation for this procedure is anecdotal and begins with assessing the size, location, shape, and depth of the wound that requires repair and finding an appropriate adjacent reservoir of tissue. Adjacent reservoirs of tissue can be pre-

dicted by assessing the laxity and movement of the skin surrounding the defect. Identification of nearby cosmetic subunits and relaxed skin tension lines is also helpful in determining patient suitability for a rotation flap (3a) [25].

As rotation flaps typically have broad vascular pedicles, there is believed to be low risk of ischemia and high survival of the flaps even in patients who have vascular comorbidities, are elderly, are on blood thinners, or who smoke (5) [1]. Although there is no evidence to support these claims, the authors believe it is widely understood that rotation flaps, as with other flaps, will survive when placed directly over exposed bone or cartilage (5) [26]. There does not appear to be any evidence regarding the appropriateness of a rotation flap in patients with active infection, though chronic infections such as HIV or hepatitis C do not appear to be contraindications. As flaps create geometric scars, it is reasonable to consider other options before carrying out a rotation flap in patients with a tendency to form keloid scars.

A reconstructive differential is often discussed to compare reconstructive techniques and their predicted outcome for the defect at hand. The appropriate closure may be selected from options including primary closure, advancement flap, rotation flap, transposition flap, full or split thickness skin graft, and healing by secondary intention. These techniques have not been evaluated side-by-side, likely due to their nuanced use depending on size, shape, and position of the defect, variation in training and reconstructive choice among surgeons, and difficulty in obtaining long-term follow-up.

Best Techniques and Performance

The first step in performing a rotation flap is to remove any beveled edges of the defect if created during Mohs surgery or other excisional techniques. Some surrounding skin in the vicinity is removed as well to create a triangular defect (3a) [25]. This can be drawn and performed as one of the initial surgery steps or the tissue can be rotated into place and the redundancy identified/removed.

Classically, the recommended ratio of length to width of a given rotation flap was around 2:1 (2b, 5) [27, 28]. The flap should also be designed with length around four times the width of the base of the triangular defect. This ratio is thought to allow for redistribution of tissue along unequal lengths of the arc and can eliminate the need to remove a standing cone by using the rule of halves. Depending on the situation, the flap may be shortened for better concealment or lengthened in cases of limited mobility, but it may be beneficial for the leading edge of the flap to extend beyond the distal edge of the defect to reduce tension on the flap and enable it to rotate into place without force (2c) [4]. Mathematical models suggest flaps are best if they have ¼ circle arc, because too much or too little of an arc hypothetically creates unwanted tension on the flap (5,2b) [17, 27]. In the case of cervicofacial rotation flaps, a small study of 13 patients showed that rates of flap loss were similarly low whether the flap was rotated in a forward fashion or a reverse fashion (4) [29].

For optimal flap motion, experience dictates that the pivotal area of restraint must be undermined (5) [7]. The subcutaneous plane is preferred by experts over a deep plane because it has comparable tip necrosis rates and potentially lower ectropion rates (3b) [30] and is thought to preserve nerves such as the supratrochlear, supraorbital, and facial nerves (3a) [25]. This is in contrast to earlier opinions that the blood supply and reliability of cervicofacial rotation-advancement flaps could be improved significantly by dissecting the flap in a deeper plane (4) [31]. An exception to this is the expert opinion that scalp flaps should be dissected in the subgaleal plane and that cheek flaps should be dissected below the SMAS (5) [26, 32]. A back cut into the body of the flap can improve motion as well. It is not known whether this compromises the vascular supply of the pedicle, but it is anecdotally useful in freeing restraint (2b) [33]. This classical back cut has not been compared in a systematic fashion to the modified "crescentic" back cut, which is designed to minimize the scar line (4) [34]. Other techniques designed to increase the motion of rotation flaps, including pivot point modification, cyclic loading, galeal scoring, and skin stretching, have also not been studied in a controlled, comparative, or outcome-oriented fashion (2b) [35]. A series of nine patients

with limited cheek skin laxity were treated with "Yin-Yang" modifications of the Mustarde flap for infraorbital defect repair. This counter-rotation of the temporoparietal scalp in a direction opposite to the Mustarde flap for increased movement showed good aesthetic quality at 36 months (4) [16].

When closing the wound, dermal vertical mattress sutures are placed first, starting with the first stitch at the advancing edge of the flap as classically recommended for all advancement and rotation flaps, using 4-0 polydioxanone or polyglactin 910. Unfortunately, this dogmatic principle has no published evidence to support it (5, 3a, 5) [1, 25, 28]. And in some cases, it is appropriate to begin suturing at the base of the flap to advance tissue and minimize stress on the leading edge. Another adjunct, particularly in large facial flaps, is to place plication sutures in fascial planes to support the flap and transfer tension vectors. Afterward, more dermal sutures are placed approximately every 8 mm along the flap using a size 5-0 suture. Periosteal suspension sutures can be used to prevent ectropion, but it is uncertain how effective this technique may be. The optimal epidermal layer of sutures and technique for placement have not been outlined in the literature.

Safety

Likely due to the wide pedicle, properly designed rotation flaps have good blood supply, and distal tip necrosis rates across all sites are reported in the range of 0–23% (3b) [30, 36].

In one study of 33 patients who underwent cervicofacial and cervicothoracic rotation flaps, minor wound complications occurred in 11 patients, most commonly epidermolysis of the distal skin flap. There was no statistically significant association between wound complications and a history of smoking, diabetes mellitus, peripheral vascular disease, or preceding radiation therapy (2c) [4]. However, this is not sufficient evidence to conclude that these factors do not affect flap survival.

In another study of 30 patients undergoing lateral cheek rotation flap, the overall complication rate was 23%. Thirteen percent of all patients had hematoma formation and 10% had partial flap necrosis. Two-thirds of patients who had partial flap necrosis were active smokers. No patient developed a wound infection, and there was no complete flap loss. Ten percent of patients had transient facial nerve branch palsy and all recovered spontaneously. Twenty-eight of 30 patients had a final reconstruction that was functionally satisfactory, and the same number had a reconstruction that was cosmetically satisfactory to both patient and surgeon. Two patients underwent revision of Burow's triangle to improve cosmesis. There was no periprocedural mortality (2c) [37]. It is unlikely that the closures also had suspension/plication sutures, which in our opinion would reduce these complication rates. In a separate study of nine lateral cheek rotation flaps combined with z-plasty to enhance movement and decrease tension, all flaps survived without any developing hematoma, wound infection, distal flap necrosis, or lower lid ectropion (4) [38]. There is a known increased risk of postoperative lower lid ectropion if eyelid skin is involved in a defect covered by a rotation flap as shown in an evaluation of 31 patients undergoing periorbital reconstruction by a cheek rotation flap (2b) [39].

The frequency of complications such as bleeding, pain, nerve damage, wound dehiscence, wound infection, persistent Burow's triangle formation, hypertrophic scar development, ectropion, and functional or cosmetic skin restriction due to scarring is not discussed further in the available literature. When widely undermining any flap, these risks are present.

Postoperative Care and Follow-Up

Compression dressings should be placed for 24–48 h and that the wound be examined at that time to ensure no hematoma has developed. Suture removal at 5–7 days for facial flaps and 10–14 days for cervical and scalp flaps is appropriate if nonabsorbable superficial sutures are used (3a) [25].

Residual standing cones may be excised immediately at the time of procedure but may also be managed with an intraoperative z-plasty or monitored for 6 weeks. Deformities that do not flatten after 6 weeks may necessitate excision. These methods have not been studied or compared with each other specifically for rotation flaps (3a) [25].

If trap-door deformity occurs, physical massage or injection of the area deeply with triamcinolone may encourage resolution. Expert opinion is that surgical revision should not be considered for 9–12 months following the flap surgery (3a) [25].

Alternative Procedures and Modifications

Experienced surgeons believe that rotation flaps have their greatest utility on the scalp, temple, cheek, and nose. On the scalp, rotation flaps must be quite long due to poor skin mobility but are widely believed by experts to be next in line for defects that cannot be closed primarily (5) [40]. On the temple and medial cheek, the large reservoir of skin from the lateral cheek can be recruited (5) [17]. Rotation flaps performed to reconstruct the lateral and central cheek, however, may pull hair-bearing skin of the sideburn medially onto the malar eminence.

Aside from the dorsal nasal flap, most small dorsal nasal defects are better repaired with other flaps such as the bilobed or rhombic flap because the skin of the nasal tip is inelastic. Despite this, a case report shows good results with a bilateral version of this versatile flap on the nasal tip (5) [41]. Rotation flaps recruiting cheek skin to repair nasal sidewall defects can create unfavorable and conspicuous distortion of the nasolabial fold. The same principle applies for defects of the lateral lip and obstruction of the melolabial fold (5) [28].

A "dog-ear rotation flap" has been described for large defects wherein the surgeon attempts to perform a linear repair from one end of a wound and creates a rotation flap out of the standing cone left at the other end when the two edges can no longer be approximated. This method has not been compared to the standard rotation flap, but the authors claim that it creates a low-tension repair with extremely low rates of flap necrosis (5) [42].

In the repair of cleft lip, the rotation-advancement repair has been studied in comparison to the philtral ridge repair with respect to the height and symmetry of Cupid's bow, width and height of the nasal vestibule, height of the vermilion, and alar base position. Both the rotation-advancement and philtral ridge techniques produced outcomes with a comparably high degree of facial symmetry in a study of 26 patients who were analyzed with facial points mapped out by imaging software (1c) [43].

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
Rotation flaps can be used to close cutaneous defects on the head, neck, and other bodily sites	D
Rotation flaps are widely regarded as highly reliable, efficient, and straightforward	D
Rotation flaps require an adjacent tissue reservoir in order for proper execution	D
Standing cones may be placed anywhere along the arc of the flap	C
The effectiveness of rotation flaps is not believed to be markedly affected by age, comorbidity, or smoking status	B
Identification of nearby cosmetic subunits and relaxed skin tension lines is helpful in determining patient suitability	A
It may be beneficial for the leading edge of the flap to extend beyond the distal edge of the defect	C
The recommended ratio of length to width of a given rotation flap is around 2:1	D
For optimal flap motion, experience dictates that the pivotal area of restraint must be undermined	C
Residual standing cones may be excised immediately at the time of procedure but may also be monitored	D
If trap-door deformity occurs, physical massage or triamcinolone injection of the area may encourage resolution	C

Self-Assessment Questions

1. Expert opinion suggests that rotation flaps are useful for defects on all of the following parts of the body except the:
   (a) Nasal dorsum
   (b) Nasal sidewall
   (c) Temple
   (d) Medial cheek
   (e) Medial lip
2. Rotation flaps:
   (a) Recruit tissue from distant locations to close wounds
   (b) Are often performed in more than one stage
   (c) Require a named artery to supply blood
   (d) Have narrow vascular pedicles
   (e) Can be placed over exposed cartilage
3. The defect shape that is most suitable for repair by rotation flap is:
   (a) A circle
   (b) A square
   (c) A triangle
   (d) A rectangle
   (e) An ellipse
4. Which of the following risk factors have been established as exclusion criteria for undergoing a rotation flap?
   (a) Current smoker
   (b) History of insulin-resistant diabetes mellitus
   (c) Hypertriglyceridemia
   (d) Elderly age
   (e) None of the above
5. Which of the following is not true regarding rotation flaps?
   (a) Z-plasty can be used to extend the rotation of the flap into the defect.
   (b) Standing cones do not have to be excised at the time of surgery.
   (c) c. Mathematical models state that 90° of rotation arc is ideal for rotation flaps.
   (d) High-level evidence has shown that back cuts may damage the vascular pedicle of rotation flaps.
   (e) Ectropion is more likely in patients who undergo rotation flaps if their defect requiring repair has a portion which sits on the lower eyelid.

Correct Answers

1. b: The nasal sidewall is believed to lack the laxity necessary for a rotation flap, and skin rotated from the cheek to the nasal sidewall can blunt the nasolabial fold.
2. e: Experts say that most skin flaps have the necessary vascular supply to survive on top of exposed cartilage.
3. c: Geometrically, a triangular defect is the ideal wound to be repaired by rotation flap.
4. e: None of the listed factors has been shown to be significantly detrimental to the survival of rotation flaps.
5. d: Only expert opinion has suggested that a broad vascular pedicle is preventative against adverse complications, such as distal flap tip necrosis.

Pedicle Flaps

8

H. William Higgins II and Jeremy Bordeaux

Abstract

Skin cancers of the head and neck treated by Mohs micrographic surgery often leave wound defects requiring advance reconstruction. Interpolation flaps, including the pedicled melolabial, paranasal, and retroauricular, are sophisticated and reliable options for large defects in facial areas. The paramedian forehead flap is a classic example of an interpolation flap, and it will be discussed in another chapter. The melolabial flap, also known as the cheek-to-nose interpolation flap, is a two-stage flap classically utilized for defects involving the nasal ala, inferior nasal tip, or columella. One limitation to the use of this flap is the resulting asymmetry of the melolabial folds. The paranasal flap overcomes this pitfall and is an excellent option for small to medium alar defects. Both flaps are generously vascularized by tributaries of the angular artery. The retroauricular flap is useful for full-thickness defects of the ear. Classically, this flap is used for defects on the middle third of the ear. However, it can also be utilized for defects on the inferior aspect of the ear, closer to the earlobe. These interpolation flaps, when utilized skillfully, can provide excellent cosmetic results and offer viable options for repair of defects of the nose and ear.

Interpolation flap · Paranasal interpolation flap · Cheek-to-nose interpolation flap · Postauricular interpolation flap · Mohs surgery · Reconstruction · Melolabial interpolation flap

Introduction

Skin cancers are commonly located on the head and neck, and surgical removal still remains the gold standard for the majority of these tumors. Many cutaneous head and neck tumors will be treated by Mohs micrographic surgery (MMS) , which involves tumor extirpation, confirmation of clear histologic margins, and, if necessary, surgical repair of the resulting tissue defect. When repairing defects on cosmetically sensitive locations of the head and neck, the surgeon must have a broad knowledge and essentially algorithmic approach to the various repair options in order to provide the optimal esthetic and functional outcome.

Options for repair range from second-intention healing to complex surgical reconstruction. Depending on the size and location of the defect, particularly in relation to surrounding anatomic structures, a flap repair or tissue rearrangement may be employed. A well-designed and properly executed flap provides reconstructive advantages in that it ensures a cosmetically optimal tissue match, maintains function, and ideally allows for a well-camouflaged donor site.

The caudal third of the nose and the ear are areas with complex topography given the intricate interplay of convexities and concavities. In addition, these sites lack apposite neighboring donor tissue often necessitating the use of more distant tissue reservoirs when repairing medium- to large-sized defects. Interpolated flaps are staged repairs that have long been utilized to overcome the unique features of these anatomic locations. These sophisticated flaps are generously supplied by a named artery or its immediate branches and have a donor site separated from the defect by an intact bridge of skin. Patient preoperative education and assessment of social support are prerequisite. Counseling regarding the extent of wound care, the need for multiple visits, activity limitations, and simply the mental preparation for having a pedicle in place for weeks are key to a smooth postoperative course.

Repair options vary from minimalistic to complex. Second intention requires no surgical reconstruction, but involves an extended healing process. Complex surgical reconstruction requires an understanding of head and neck anatomy, as well as limitations of the skin. When chosen properly, flaps offer superb cosmesis and outcomes (4, 2c, 4) [1–3]. An appropriately designed and well-executed flap offers reconstruction advantages, as flaps often offer a source of richly vascularized tissue to repair the wound (1b, 2a) [4, 5].

This chapter will discuss the use and proper execution of pedicled melolabial, paranasal, and retroauricular flaps with step-by-step recommendations for optimizing their outcome (4) [6]. The forehead paramedian flap is a classic example of an interpolation flap. It will be discussed in Chap. 10.

Interpolation Flap Considerations

In contrast to advancement flaps, the interpolation flap pivots into the defect. In contrast to transposition flaps, the base of the interpolation flap is located a significant distance from the defect that it is repairing. As such, the pedicle, or viable tissue of the flap, often passes through intervening tissue. For pedicles that pass over intervening tissue, a takedown stage is often required, necessitating a second surgical procedure. This feature of interpolation flap results in a longer postoperative period and requires extensive patient counseling on what to expect between each stage of the flap and after let-down of the second stage of the flap.

Melolabial Interpolation Flap

With its densely sebaceous texture, inelasticity, and elaborate contour, the nasal ala can be a unique and challenging region to reconstruct. Moreover, its conspicuous location and important functionality provide higher stakes when choosing the appropriate repair. The dearth of immediately adjacent donor tissue limits options for linear closure and adjacent tissue rearrangement. Graft repair, while reasonable for shallow defects, may not provide the optimal tissue match or structural support achieved with other reconstructive options. Interpolated flaps are valuable tools for overcoming the inherently challenging features of the ala in that they allow the recruitment of well-matched skin from a more distant donor site.

The melolabial interpolation flap, also known as the cheek-to-nose interpolation flap, is primarily used for medium to large defects of the nasal ala that do not involve the alar-facial sulcus. It can also be utilized for defects involving the inferior nasal tip or columella. This two-staged repair provides tissue akin in color and sebaceous texture to the native skin of the caudal nose while hiding the donor scar within the natural valley of the melolabial fold. In addition, the cheek-to-nose interpolation flap maintains the natural concavity of the alar-facial sulcus, which can be

blunted with other repair options such as the melolabial transposition flap.

While the melolabial interpolation flap is traditionally regarded as an axial pattern flap, the pedicle does not contain a named artery. It is instead supplied by perforating branches of the angular artery, making its vascular network more random than axial (3b, 3b) [7, 8]. Consequently, the blood supply is less robust than an axial pattern flap but still generous enough to reliably perfuse the flap during the healing period (Fig. 8.1a–d).

Description of Technique

For alar defects, any remaining tissue of the cosmetic subunit needs to be first excised to provide a more esthetic resurfacing of the entire alar lobule. Ideally, a 1 mm margin of skin should be left on the lateral-most aspect of the ala to preserve the natural contour of the alar-facial groove.

The nasal ala is composed of firm fibrofatty tissue, essentially devoid of cartilage, and functions as the external nasal valve. When repairing a medium to large soft tissue defect in this region, cartilage grafts are often used to maintain the complex contour of the nasal ala and prevent collapse of the nasal valve. These grafts also counter against contraction of scar tissue resulting from the overlying flap (2b, 4, 4) [9–12].

For defects with loss of nasal mucosa, restoration of the nasal lining is often required. However, this subject is beyond the scope of this chapter (2b) [13].

For defects with cartilage loss, cartilage grafts are typically harvested (2b, 2b) [14, 15]. Oftentimes, the conchal bowl or the antihelix of the ear can serve as a source of cartilage for this

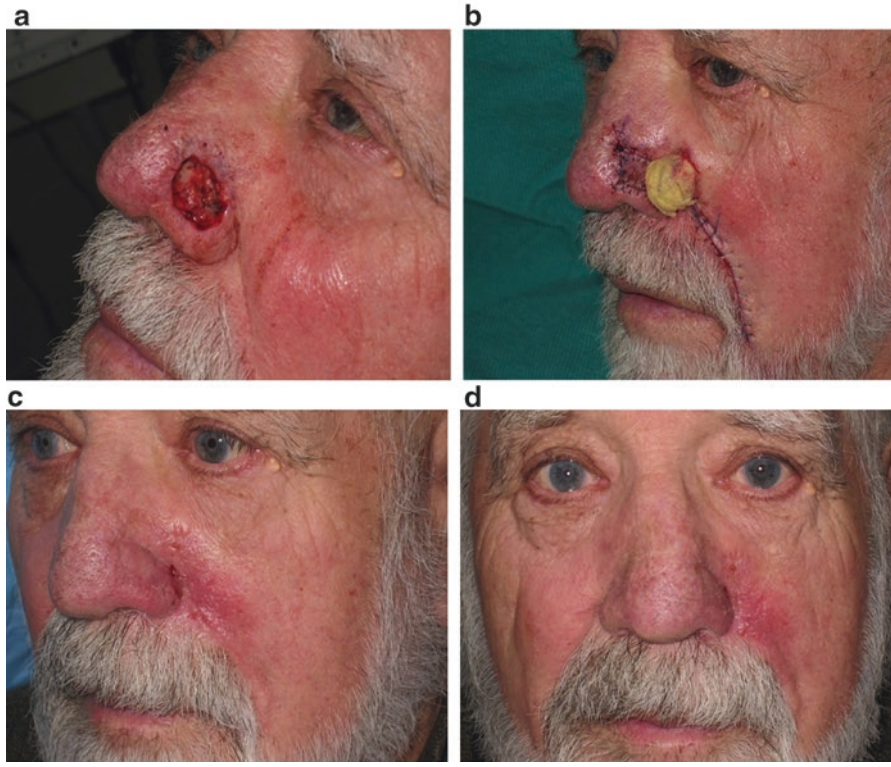

Fig. 8.1 (**a**) Defect of the left ala after Mohs surgery. (**b**) Interpolation flap sutured in place with emollient-impregnated dressing wrapped around the pedicle. (**c**) Left-sided view of patient after pedicle takedown with nice preservation of the natural concavity of the lateral nose and medial cheek. (**d**) Frontal view of patient after pedicle takedown

purpose. Conchal bowl cartilage can be harvested via an anterior or posterior approach and are ideal for larger defects that require more restoration of curvature and structural support. The conchal bowl contralateral to the defect is often chosen given it better mimics the bowed contour of the contralateral alar rim. Cartilage from the antihelix is useful for defects that may require a less curvilinear strut for contour restoration. Small tissue pockets are incised on the medial and lateral aspect of the defect, and the graft should be slightly oversized by 3–5 mm on either end to fit into these pockets. Non-absorbable sutures are then placed in a horizontal mattress or figure-of-eight fashion to secure the graft into the medial and lateral pockets as well as the inner alar lining. Because of the avascular nature of cartilage, the vascular supply provided from the overlying flap is essential for healing (3b) [16]. For more detailed description of cartilage grafting, see Chap. 11.

After placement and securing the cartilage graft, the contralateral alar subunit is then measured. A template can be made with various materials, such as using foil from a suture packet or a small sheet of a non-stick dressing such as Telfa. This template is then inverted and traced along the melolabial fold ipsilateral to the surgical defect. The inferior border of the template, which will eventually be transferred to the anterior aspect of the alar defect, should be positioned just superior to the oral commissure. The inferomedial border of the template, which will be mobilized to meet the superior aspect of the alar defect, should run along the valley of the melolabial fold. The larger flap pedicle is then designed, incorporating the templated area, as either an elliptical island, detached from all surrounding cutaneous tissue, or as a peninsula with a superiorly based cutaneous pedicle. When using the elliptical island design, the superior most border of the pedicle should be no higher than the inferior border of the alar-facial sulcus to minimize distortion of this natural concavity. With the peninsular design, the superior border of the pedicle may be as high as the alar crease to allow for adequate pivoting motion of the flap. The superior end of the island design will taper like the end of an ellipse, whereas the superior end of the peninsular design will have a wider width matching that of the alar template. With either design, a rolled piece of gauze may be employed to mimic desired flap motion, which will be a clockwise pivot from the left cheek and counterclockwise from the right, and ensure adequate flap length.

The inferior tissue cone of the pedicle is then excised and discarded allowing for easier closure of the donor site. Starting distally, the remainder of the pedicle is then elevated. The plane of dissection for the peninsular variant is more superficial, leaving a thin 3–4 mm layer of subcutaneous tissue on the undersurface of the flap. For the island design, the plane of dissection becomes progressively deeper toward the flap's pivot point. There the depth of dissection should reach the surface of the levator labii superioris alaeque nasi and zygomatic major muscles. Some advocate including fibers of the levator labii to ensure adequate blood supply from the perforating branches of the angular artery (5) [17].

The remaining steps of the first stage are essentially the same regardless of which design variant is used. The cheek donor site is widely undermined and closed in a layered fashion to help push the flap superomedially toward the ala. The primary defect may be undermined and debeveled to ensure even apposition of the flap edges with the recipient site. Subcutaneous tissue may also be trimmed from the flap to better match the depth of the primary defect. The flap is then meticulously sutured in place with 5-0 or 6-0 cutaneous sutures [16]. Buried dermal sutures are not typically utilized. The pedicle is then wrapped with Vaseline-impregnated gauze or Xeroform, and a pressure dressing may be placed.

At 3 weeks, the patient will return for the second stage, division and inset of the pedicle. The pedicle is severed at the base and the cheek defect may be closed primarily for the island design pedicle or in a V-shape for the peninsular design pedicle. For the nose, the lateral aspect of the flap is debulked of subcutaneous tissue and excess skin is trimmed to match the size of the defect. The flap may then be secured in place with interrupted cutaneous sutures.

On occasion, the patient may return for a contouring procedure in 3 months to thin the flap and/or further refine the natural concavity of the alar-facial sulcus. Minor trapdooring of the flap can often be addressed with intralesional steroid injections. Pain is often controlled with local anesthesia or by performing nerve blocks.

The island design may offer certain advantages over the peninsular design. The island design's deeper pedicle incorporates more tributaries from the angular artery and therefore has a more robust blood supply. In addition, the island's lack of cutaneous attachment allows for easier mobility when pivoting the flap to the recipient site. Lastly, the island's tapered superior pole allows for simpler closure of the superior aspect of the donor site during takedown. Ultimately, both designs provide reliably good results and the variant chosen will hinge on surgeon preference and comfort level with the technique.

Paranasal Interpolation Flap

While the melolabial interpolation flap is a mainstay for alar restoration, there are limitations to its use. One potential shortcoming is consequent asymmetry of the melolabial folds, which may detract from an otherwise excellent esthetic outcome on the ala. A limitation in males is that the flap pedicle typically incorporates terminal hair-bearing skin which may then be transferred to the ala (2b) [18].

The paranasal interpolation flap circumvents these potential pitfalls and is a reliable reconstructive option for alar defects that are small to medium in size. It also allows for a shorter donor scar and may avoid resurfacing of the entire alar subunit. Like the melolabial interpolation flap, the paranasal interpolation flap is a random-pattern flap generously vascularized by tributaries of the angular artery. The donor site provides an excellent color and texture match for the ala with the added benefit of not having terminal hair (Fig. 8.2a–h) [18].

Description of Technique

Before committing to using the paranasal interpolation flap for surgical repair, adequate laxity of the medial cheek must be assessed in order to avoid distortion of the nose, medial cheek, or ipsilateral lower lid when closing the donor site. When designing the flap, the vertical diameter of the defect must match the width of the flap [18]. The paranasal pedicle rotates 90° toward the primary defect, and this measurement ensures an appropriate fit for the flap at the recipient site.

If structural support is needed, a cartilage strut may first be placed and secured in the manner previously described above in the section on melolabial flaps. Two vertical and essentially parallel incisions are made that continue superiorly along the nasofacial sulcus and then meet at a 30° taper. The medial incision line should begin immediately adjacent to the alar-cheek junction, and the lateral incision line should originate at a distance equal to the vertical diameter of the alar defect. Starting superiorly, the flap pedicle is elevated along a subcutaneous tissue plane. The plane of dissection becomes progressively deeper moving inferiorly toward the flap's pivot point. The pedicle tip should be trimmed to be marginally thinner than the depth of the alar defect, and its diameter should equal or be slightly less than the recipient site diameter to reduce the risk of pin-cushioning. After wide undermining, the medial cheek donor site is closed in a layered fashion. Absorbable buried vertical mattress sutures are placed to secure the flap to the recipient site followed by a layer of epidermal sutures.

Flap division is performed at 3 weeks. If the entire alar subunit was not replaced, the flap pedicle is incised along the lateral aspect of the defect, thinned, and sutured in place in a layered fashion. In cases where the entire cosmetic subunit is resurfaced, pedicle division is performed and appropriately sized to replace the larger surface area of the entire alar lobule. In cases where the entire cosmetic subunit is resurfaced, pedicle division and inset may be more involved [18].

Once the remainder of the cosmetic subunit is removed, the pedicle is divided to match the size of the larger primary defect. The lateral aspect of the pedicle and the primary defect may both be generously thinned to match in thickness and depth. The flap edges are then appropriately trimmed and inset with layered closure. Similar

Fig. 8.2 (**a**) Defect of the left ala after Mohs surgery. The proposed flap pedicle is marked to hide closure of the secondary defect between the nasal sidewall and medial cheek. (**b**) Interpolation flap sutured in place. (**c**) Well-healed pedicle along the left ala prior to takedown. (**d**) Lateral view after takedown of pedicle from the left ala. (**e**) Frontal view after takedown of pedicle from the left ala. (**f**) Left-sided view of patient showing excellent color and contour restoration of the left ala. (**g**) Frontal view of patient after repair. (**h**) Contralateral view for comparison

to the melolabial interpolation flap, some patients may require further contouring procedures or intralesional steroid injections for further refinement. Limitations to this flap include alar defects with a larger vertical diameter and patients with poor laxity of the medial cheek donor site (2b) [19]. In these cases, the melolabial interpolation flap may be a better repair option.

Retroauricular Flap

The staged retroauricular flap is a useful and reliable option for large full-thickness defects of helix. This repair is classically used for defects on the middle third of the ear but may also be utilized for defects located more inferiorly near the lobe. This random-pattern flap is based on the plentiful blood supply of the postauricular scalp and provides excellent restoration of the rounded contour of the lateral ear (Fig. 8.3a–d).

Description of Technique

In designing this repair, the width of the flap's leading edge should be equivalent or slightly larger than the vertical axis of the primary defect. The flap is elevated along the adjacent skin of the posterior ear and extends to the retroauricular sulcus and neighboring scalp. When further structural support is needed, a cartilage graft may be taken from the conchal bowl of the opposing

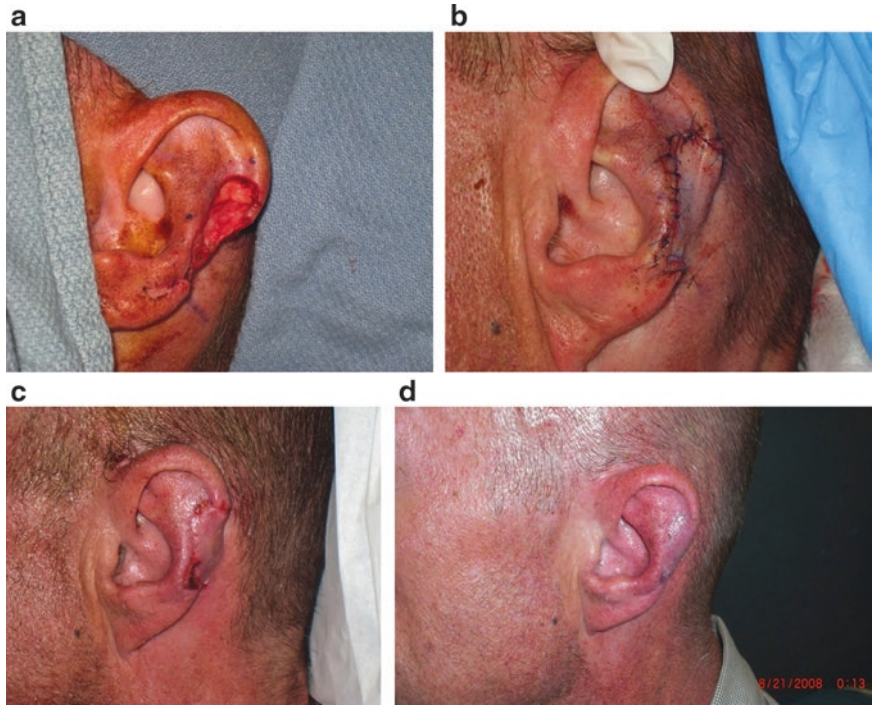

Fig. 8.3 (**a**) L helix with defect after Mohs surgery. (**b**) Interpolation flap sutured in place. (**c**) Pedicle prior to take down. (**d**) Well-healed flap restoring natural contour of the ear

ear and anchored to the intact auricular cartilage of the primary defect with absorbable sutures.

The flap is then dissected along the subcutaneous tissue plane, advanced to cover the primary defect, and secured in place via layered closure. Ideally, the flap length should be three to four times the width to ensure sufficient mobility while maintaining adequate perfusion. The exposed portion of the retroauricular pedicle is usually dressed with emollient-impregnated gauze.

Flap division is performed at 3 weeks. The pedicle is incised at the base and the medial aspect of the flap is rolled to cover the cartilage graft and native cartilage of the posterior ear. The retroauricular donor area may be closed primarily, grafted, or allowed to granulate.

A variation of this design may be performed in which the flap is elevated more posteriorly from the retroauricular scalp and mobilized to close the helical defect while leaving the skin of the posterior ear and sulcus intact. Division and inset is done at 2–3 months at which time a cartilage graft may be placed if additional support is needed. Potential benefits of this design are less exposed tissue of the posterior ear between the first and second stages of repair and a smaller secondary defect to resurface at flap division. However, the obvious trade-off is significantly longer time to takedown. This design may be used for large defects of the mid or inferior helix.

Conclusion

Staged pedicle flaps are invaluable tools in the reconstructive surgeon's assemblage of repair options. The interpolation flaps, when executed properly, offer safe and effective options for reconstruction of Mohs defects (2b) [20]. Major complications are exceedingly rare, and minor complications fall in the realm of the expected: minor bleeding, infection, dehiscence, and flap necrosis.

Careful planning, measurement, and methodical execution are required for flap success. An

understanding of skin texture, anatomy, and the patient's comorbidities is also essential. Preoperative patient counseling and detailed framing of the postoperative course cannot be overlooked and work in concert with excellent technique to provide the best patient outcomes. Postoperative patient instructions are also essential to minimize flap necrosis or infection. Given the potential bulkiness of these flaps, there should be a low threshold for employing cartilage support. The generously vascularized pedicle ensures survival of the cartilage graft as well as overlying multilayered flap. This versatile flap allows the surgeon to restore the patient's natural skin topography after procedures related to tumor extirpation.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE).

Findings	GRADE score: quality of evidence
Interpolation flaps have a demonstrated record of safety.	B
Interpolation flaps offer excellent cosmetic results for repair of nasal defects.	B
Complications of interpolation flaps include bleeding, infection, necrosis, dehiscence, and pin-cushioning/hypertrophic scar.	B

Self-Assessment Questions

1. Which of the following statements regarding cheek-to-nose interpolation flaps is false?
   (a) For alar defects, remaining tissue of the cosmetic subunit may be first excised for better cosmetic outcome.
   (b) A 1 mm margin of skin should be left on the lateralmost aspect of the ala to preserve the natural contour of the alar-facial groove.
   (c) At baseline, the nasal ala is essentially devoid of cartilage.
   (d) Cartilage grafts can be used in conjunction with a pedicle flap to prevent collapse of the nasal valve and counter contraction of scar tissue.
   (e) Takedown is usually performed 4 weeks from the first stage of the repair.
2. The paranasal interpolation flap is supplied by:
   (a) The dorsal nasal artery
   (b) The facial artery
   (c) Perforating branches of the angular artery
   (d) Perforating branches of the ophthalmic artery
   (e) The angular artery
3. The pedicle of the cheek-to-nose interpolation flap may be carried out in an island or peninsular design. What advantages are offered by the island design?
   (a) The island design's deeper pedicle incorporates more tributaries from the angular artery and therefore has a more robust blood supply.
   (b) The island's lack of cutaneous attachment allows for easier mobility when pivoting the flap to the recipient site.
   (c) The island's tapered superior pole allows for simpler closure of the superior aspect of the donor site during takedown.
   (d) (a) and (b)
   (e) All of the above
4. Which of the following is not an example of a pedicle flap?
   (a) Melolabial interpolation flap
   (b) Paranasal interpolation flap
   (c) Peng interpolation flap
   (d) Retroauricular interpolation flap
   (e) Paramedian forehead flap
5. What best describes the vascular supply pattern for the retroauricular interpolation flap?
   (a) It's an axial pattern flap based on a named blood vessel.
   (b) It's a random-patterned flap.
   (c) It's supplied by the cartilage of the recipient defect site on the ear.
   (d) (a) and (c)
   (e) None of the above

Correct Answers

1. e: Takedown and inset of a cheek-to-nose interpolation flap is typically performed at 3 weeks from the first stage of repair.
2. c: While commonly thought of as an axial pattern flap, the paranasal interpolation flap is actually supplied by the perforating branches of the angular artery and not the artery itself.
3. e: While the island design offers the advantages above, both designs provide reliably good results, and the variant chosen will hinge on surgeon preference and comfort level with the technique.
4. c: The Peng flap is not an interpolation flap. Rather, it is a sliding flap and is commonly used on the nose. There is no such thing as a Peng interpolation flap. The addition of the word "interpolation" is a distractor.
5. b: The staged retroauricular flap is a random-pattern flap based on the plentiful blood supply of the postauricular scalp.

Forehead Flaps

Introduction

The forehead flap has been a staple in nasal reconstructive surgery dating back to 700 B.C. and continues to serve as a workhorse for sizeable nasal defects [1, 2]. Its roots trace back to India, where the rudimentary version of today's forehead flap was employed as a reconstructive modality following nasal amputations as a form of punishment [2–4]. Over the centuries, the forehead flap has evolved and been refined by reconstructive pioneers [1, 5]. The current version serves as an effective, reliable, reproducible flap providing a robust blood supply and excellent texture and quality match for nasal defects [4, 6]. Herein, we review the forehead flap and describe the scientific evidence supporting this flap as well as modifications, variations in execution and design, and complications. We will focus on recent advances in the literature in this area.

Indications for Forehead Flaps

The forehead flap is a reliable and predictable reconstructive technique used for sizeable nasal defects. Generally, this flap is used for defect size larger than 1.5–2 cm and/or for full-thickness defects requiring multilayered reconstruction, nasal lining, and structural support (5) [5, 7–9]. The forehead flap is an excellent option in cases where local flaps are insufficient and where

reconstruction requires a flap with its own blood supply (4) [8]. Forehead flaps can also be used in periocular reconstruction, particularly when there is a concomitant nasal defect (4) [10, 11]. Reconstruction following exenteration is another indication for forehead flap use (4) [12].

This flap can be used in all demographic groups but most commonly is employed in adults with nasal defects of various etiologies. In the majority of cases, nasal defects of this size are secondary to nonmelanoma skin cancer (NMSC) surgery (generally Mohs micrographic surgery) but less commonly can be caused by removal of other malignancies such as melanoma [8, 13–15]. In other scenarios, the forehead flap can be a reconstructive tool in traumatic nasal defects [16, 17]. Forehead flaps can be performed on pediatric patients; however, this is a small proportion of patients [17]. In the pediatric population, the need for forehead flap is most commonly due to malformations, benign tumors, and traumatic injury (4) [17].

History and Efficacy

From its inception in ancient India, nasal reconstruction using the forehead flap was brought to Europe in the 1500s and to the United States in the 1800s [5]. The modern version of the forehead flap was popularized in the United States in the 1930s by Kazanjian using a midline approach involving paired supratrochlear arteries [5, 16]. Since then, the techniques have been fine-tuned and finessed by aesthetic masters such as Millard, Gillies, Converse, Menick, and Burget to arrive at the current state of unilateral forehead flap for nasal reconstruction, most commonly termed the paramedian forehead flap [5, 6].

The forehead flap is the most dependable and aesthetically acceptable reconstructive option for large nasal defects, particularly of the lower nose (5) [6, 7]. Due to the robust blood supply, this flap is extremely reliable and provides excellent restoration of function and cosmesis due to the comparable texture and adnexal composition of the forehead skin as compared to the nasal skin (5) [4, 7]. Since the forehead flap is the superior choice in appropriate defects by expert consensus, there is a paucity of data on relative efficacy of the forehead flap as compared to other reconstructive options (second intention healing, grafting, local flaps, etc.). The forehead flap is generally reliable, although certain factors can lead to suboptimal results in the form of vascular compromise [4, 18]. This includes excessive flap thinning, inadequate time between the first stage and takedown, and strangulation of the flap due to excessive torsion of the base of the pedicle. Aesthetically, inadequate results can be noted from insufficient distal flap thinning resulting in a bulky appearance, insufficient undermining of the recipient site leading to pincushion deformity, or inadequate structural support and nasal lining [19, 20]. Patient factors that lead to suboptimal outcomes include poor nutritional status, tobacco use, and inability to properly care for the surgical site prior to takedown [4, 16, 20].

Preoperative Evaluation

The preoperative assessment before consideration of forehead flap first involves determination if this reconstructive technique would be appropriate for the given patient. Generally, health status, age of the patient, and ability to receive appropriate postoperative care are at play. The forehead flap is a relatively rigorous surgery that necessitates multiple stages and thus requires commitment on the part of the patient. Additionally, the forehead flap is an excellent choice in situations where local nasal flaps or skin grafts would provide unacceptable cosmetic and functional outcomes (5) [4].

Prior to operating, patient health status should be optimized. Tobacco users should be counseled regarding the deleterious effects of nicotine on wound healing and flap viability [8, 9, 14, 20, 21]. Diabetics are at risk for tissue necrosis (3b) [1, 9, 22] and thus should be counseled to maintain tight glucose control. Individuals on anticoagulants or with hematologic disorders should be forewarned regarding bleeding risks, and internataional normaliszed ratio (INR) should be in reference range for warfarin users preoperatively. Doppler ultra-

sound may be utilized to confirm the supratrochlear artery location and path for traditional paramedian forehead flap design; however, this is typically not necessary and can be accomplished using anatomic landmarks (4) [15]. The use of Doppler might be of added benefit in cases where pedicle design approaches a 1 cm stalk, to assess blood supply when forehead scars are present, and in suspected abnormalities in vasculature (5) [4].

Relative contraindications for the forehead flap include anatomic issues that might compromise the blood supply to the flap. For example, presence of deep horizontal scars across the base of the forehead might impede adequate perfusion in a forehead flap (5) [4]. Interestingly, due to the robust collateral blood flow of the glabellar and mid-forehead region, previous history of a forehead flap is not a contraindication, as the contralateral side can be used. Lastly, as in the case of all therapies, comorbidities must be considered and risks and benefits weighed to deem appropriateness for forehead flap.

Best Techniques and Performance

The forehead flap, originally derived as a median forehead flap and now performed as a more streamlined and advanced paramedian forehead flap, is well-described in the literature. The basic techniques and execution of this reliable flap are rather consistent; however, numerous variations exist, which will be described herein.

Approaching the Defect

The first step involves addressing the extranasal portions of the defect. For example, if a defect extends onto the medial cheek, cheek advancement might be considered prior to performing a forehead flap to maintain and respect cosmetic subunits (Fig. 9.1) [4, 6]. Next, the defect to be repaired should be optimized prior to flap insertion. This involves creating a uniform base of the defect (generally dissected down to perichondrium or periosteum) and cleaning wound edges to debevel and create more squared off edges. Angular defects are less likely than curvilinear defects to result in trapdoor deformity through concentric scar contraction (5) [23]. The defect should also be adequately undermined to allow plate-like scar formation and further decrease risk of trapdoor or pincushion phenomenon (5) [4].

The principle of defect only versus subunit reconstruction is another consideration. If a defect involves great than half of a cosmetic subunit (Fig. 9.2), it might be prudent to excise the

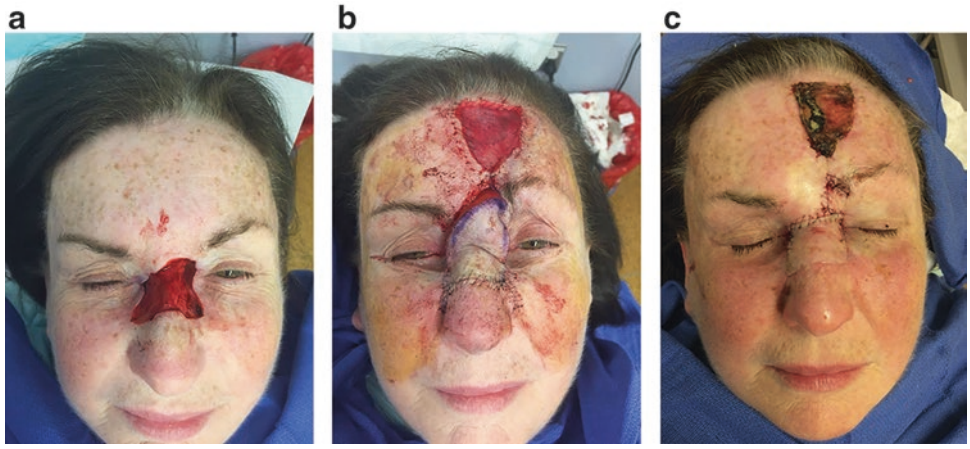

Fig. 9.1 An example of paramedian forehead flap design and execution. (**a**) A defect of the nasal bridge and bilateral medial cheeks following Mohs micrographic surgery for removal of basal cell carcinoma. (**b**) Bilateral cheek advancement and paramedian forehead flap were used to close the defect, addressing distinct cosmetic subunits. (**c**) Excellent contour achieved at takedown

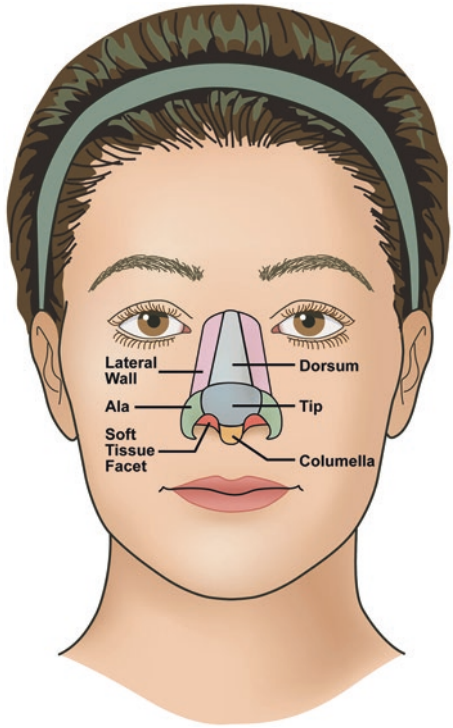

Fig. 9.2 An illustration of the subunits of the nose

remainder of the cosmetic subunit so that the entire subunit is replaced by the forehead flap (4) [3, 9, 24, 25]. This strategic control of the shape of the defect, the flap shape, and the resultant scars allows for favorable and inconspicuous results (5) [4]. However, the alternative perspective cautions against removal of excessive amounts of healthy skin and formation of larger defects (5) [8]. Randomized data is lacking on this topic given the variable and subjective nature of reconstructive surgery.

Addressing Nasal Lining

Next, nasal lining should be reconstituted in the case of full-thickness defects. If small, this can be closed primarily. In the case of larger defects, several techniques can be employed. Turndown flaps, such as the "hinge flap" or "bucket handle flap," have been described (5) (Fig. 9.3) [4, 26]. For defects that do not involve the free margin, split- or full-thickness skin grafts can be used.

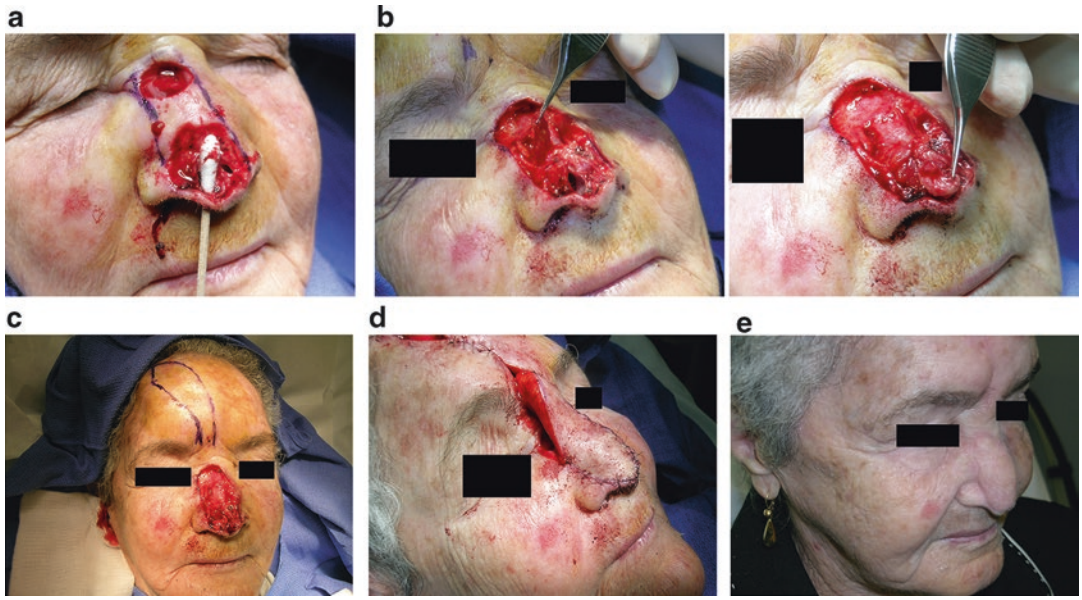

Fig. 9.3 An example of paramedian forehead flap design and execution addressing nasal lining, structural support, and cutaneous cover. (**a**) Following Mohs micrographic surgery for multiple basal cell carcinomas, patient left with full-thickness defect on the nasal root and a through and through defect on the nasal tip. (**b**) Hinge flap performed using "page of book configuration" to address nasal lining. (**c**) Following cartilage graft from conchal bowl, forehead flap design is illustrated. (**d**) Paramedian forehead flap sutured in place. (**e**) 8-month follow-up showing excellent functional and cosmetic outcome

Split-thickness skin grafts have a risk for contraction and nasal collapse, while full-thickness skin grafts carry a high risk of necrosis [26]. Full-thickness skin grafts should thus be ideally used when the forehead flap is placed directly on the graft's deep surface in the same stage to optimize contact and thus survival (5) [26]. A folded forehead flap may also be used to assist with reconstitution of nasal lining (5) [5].

Structural Support

Once nasal lining is restored, the framework and structural support must be addressed [6]. In the case of nasal reconstruction, this generally involves cartilage grafting (Fig. 9.3). The septum can be used as a donor site if exposed; alternatively, auricular cartilage is ideal with the use of templates for precision (5) [4, 9]. Of note, cartilaginous struts must be secured carefully to surrounding tissue so that they maintain adequate vascular supply. In the case of alar structural support, stab incisions allow for creation of pockets and use of tongue in groove placement [4, 9]. In more substantial defects, rib cartilage might be needed to recreate structural support [5].

Anatomic Considerations in Flap Design

The forehead flap design is considered next, and in this step, great variability exists. Despite the variations in technique, the premise of the forehead flap based in the robust vasculature of the medial forehead is the unifying element. Traditionally, the forehead flap has been deemed an axial flap based off of the supratrochlear artery [1, 6, 7, 9]. Shumrick et al. studied the supratrochlear artery and showed that the artery routinely exits the orbit at 1.7–2.2 cm from midline (3b) [2]. Further study has demonstrated that the supratrochlear artery lies directly beneath the glabellar frown line in nearly 50% of cases and within 6 mm lateral to the frown line in the remainder (3b) [27]. This provides another reliable landmark; stalk design can thus center around this anatomic landmark, with a total width of 1–1.2 cm (average, 10.9 mm) [27]. As mentioned previously, Doppler ultrasound is not necessary for confirmation of supratrochlear artery location and path for traditional paramedian forehead flap design [15, 26].

While long-standing dogma exists that the forehead flap is based off of the supratrochlear artery, multiple studies have shown the complex and vessel-rich nature of the medial forehead, including supraorbital, supratrochlear, infratrochlear, dorsonasal, and angular arteries (Fig. 9.4) [28–31]. McCarthy et al. [32] demonstrated filling of the dorsal nasal arteries after ligation of the supratrochlear and supraorbital arteries; these were felt to be terminal branches of the facial artery and of sufficient quality to supply vertically oriented forehead flaps (3b). An extensive central forehead cadaveric study in 2007 performed on 60 hemiheads confirmed localization of the supratrochlear artery 5 mm medial or lateral to the medial canthal line (3b) [28]. Additionally, medial to the supratrochlear artery, numerous axial vessels were identified that supplied the central forehead and glabellar region, termed the central and paracentral arteries [28]. Faris et al. [22] subsequently studied three forehead flap designs (classic paramedian, glabellar paramedian, and central artery flap design), finding that the central artery forehead flap was as reliable in terms of vascularity as the glabellar and classic paramedian forehead flap (3b). This more midline approach is associated with less transposition of frontal hair than its more laterally based counterparts [22]. Further supporting the success of variably localized forehead flaps, Stigall et al. [15] reported equivalent outcomes in paramidline versus Doppler-based paramedian forehead flaps, with no significant difference in flap survival or complication rates (3b). Interestingly, in both groups, small arteries predominated, with large arteries infrequently identified; number and size of arteries did not correlate to flap survival. Ultimately, this study deemed that the complex vascular plexus of the glabella was responsible for the success of the flap rather than a single axial vessel [15].

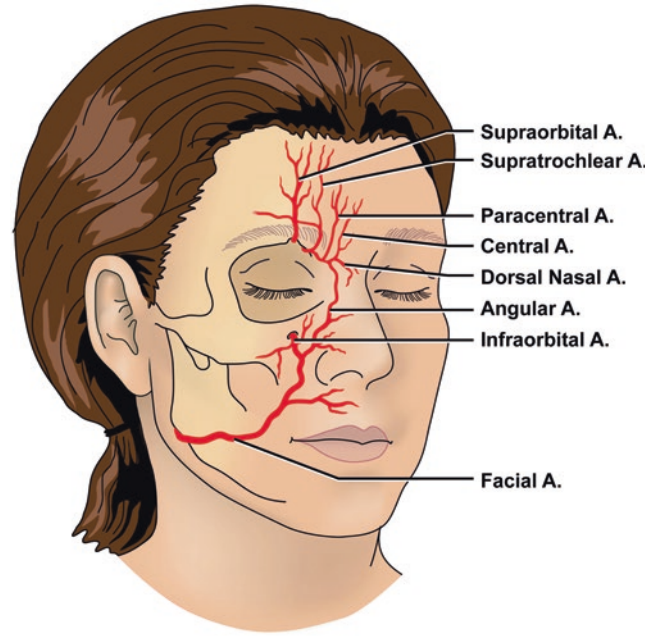

Fig. 9.4 The vasculature of the glabellar complex. The anastomoses of the supraorbital, supratrochlear, paracentral (angular artery (AA) continuing superiorly medial to the medial canthus), central, dorsonasal, and angular arteries create a vascular plexus that allows for reproducible reliability of the forehead flap

Flap Elevation and Insetting

Once the path of the forehead flap has been established, the defect is templated to the upper forehead, ideally avoiding hair-bearing skin, and distance is measured to achieve adequate reach of the flap. Incisions are made using the rule of thirds. The distal third is maintained at the level of the superficial fat plane, and the middle third dives to the plane between fat and pre-muscular fascia, while the proximal third plunges superficial to the periosteum. Careful dissection to the orbital rim, in addition to maintaining a narrow pedicle stalk, allows for adequate reach and decreased risk of torsion (5) [4]. The base of the pedicle ranges from 1 to 1.5 cm (5) [4, 6]. Generally, midline defects can be repaired from either left- or right-sided stalks. Lateral defects are optimally repaired with ipsilateral pedicles, to decrease the reach of the stalk (5) [33]. Nevertheless, other surgeons prefer a contralateral approach in an effort to decrease torsion on the base of the pedicle; these two principles of reach and torsion are in opposition of one another and are generally dependent on the surgeon's preference and the patient scenario. Variations on the traditional vertically oriented forehead flap include those that cut transversely once the upper forehead has been reached or slant across the forehead; the benefit is added length, while the downside is decreased vascular reliability and thus increased risk of necrosis [33]. Frequently, the benefit of added length can lead to flap design into hair-bearing skin; in this case, the benefit of greater reach for optimal flap design outweighs the hair's presence on the nose. At the time of flap incision, these hair bulbs can be individually cauterized or postoperatively removed using laser, shaving, or plucking [16, 33].

After elevation of the flap and adequate distal thinning, the flap can be sutured in place using well-placed dermal and epidermal sutures. The superior portion of the nasal defect is not sutured to allow adequate blood flow to the distal flap. The forehead defect is closed in a layered fashion as much as possible following undermining in the submuscular plane [4]. Excessive tension may result in a higher risk of necrosis [13]. Many times, the superior aspect of the defect is left to heal by second intention [4, 16]. Alternatively, a porcine xenograft may be used to facilitate wound healing of the forehead defect and assist in hemostasis. It is important to avoid excessive

suturing inferiorly on the forehead as to avoid impingement on the vascular pedicle [13].

A novel technique was recently published by Ullmann et al. [34] in which a subcutaneous forehead lift was performed to allow direct visualization of the supratrochlear vessels resulting in a thinner flap as well as ability to more easily close the donor site. This technique involves incision along the hairline and subcutaneous dissection of the forehead skin. The flap is tailored by turning the forehead onto the nasal defect. The donor site is closed with rotation and advancement of the remaining lateral portions of the forehead flaps toward midline (4).

Takedown

The takedown of the pedicle classically occurs 3 weeks following the initial stage in a traditional two-stage procedure (4) [6]. This duration generally allows for adequate neovascularization from the recipient nasal tissue to the flap. The various stages of the forehead flap are illustrated in Figs. 9.1, 9.3, and 9.5. Modifications in the takedown and number of stages have also been discussed at length. In high-risk individuals, such as smokers and poorly controlled diabetics, a three-stage flap may be more seriously considered, with final takedown at 6 weeks (4) [22]. Other suitable candidates for this technique include repairs requiring complex contouring or major defects involving multiple subunits (3b) [6, 33]. In this situation, the forehead flap may be elevated with all its layers, including frontalis, to maintain maximal vascular viability. Then, thinning occurs at 3 weeks after the initial stage. This involves elevation of the skin of the flap with minimal subcutaneous fat and subsequent debulking of the fat and frontalis to optimally contour the nasal topography. The skin is then inset and sutured in place, with the additional benefit of quilting sutures.

Some research shows that pedicle division can occur even at 1 week after the initial stage, particularly in young, healthy patients who would be

Fig. 9.5 An example of paramedian forehead flap design and execution. (**a**) A defect on the right nasal sidewall and dorsum from Mohs micrographic surgery. (**b**) Paramedian forehead flap was sutured in place in the first stage, with good results at 1-week postoperative visit (**c**). (**d**) Takedown was performed at 3 weeks following the first stage, with favorable long-term cosmetic and functional outcome (**e**)

negatively affected by prolonged presence of the external trunk (4) [18, 35]. In these cases, takedown occurs at 1 week, with subsequent debulking and contouring at 3 weeks; therefore, this becomes a three-stage procedure. During the third stage, the superior portion of the flap might require debulking to achieve a more appropriate match of thickness. The base of the pedicle is excised during the second stage, with goals to reposition the eyebrow after its medial and downward displacement. The use of laser-assisted indocyanine green (ICG) angiography to assess flap perfusion has also been reported with takedown performed 2 weeks after the first stage. In this report, an ischemic threshold of 25–30% was used intraoperatively, together with surgical judgment, to allow earlier pedicle division in low-risk patients, thus reducing the morbidity of eyebrow displacement (3b) [36].

Single-stage forehead flaps can also be considered in certain occasions. This procedure is generally employed in unique patient populations, such as mission work that does not allow multiple repeated procedures, elderly patients, or those who do not tolerated a pedicle (4) [37, 38]. Originally, this was performed by tunneling a flap pedicle under dorsal nasal skin (4) [39]. Side effects of venous obstruction were noted. Modification of this technique included transection of the procerus muscle and wide undermining of the glabellar complex (3b) [40]. Single-stage procedures can also avoid skin tunneling and be performed as transposition flaps (4) [37]. The benefit is avoidance of the burdens of an external pedicle, such as bleeding, inability to wear glasses, and more challenging dressing changes [37].

Safety

Overall, the forehead flap is successful due to its excellent blood supply. The most common complications include bleeding, postoperative pain, infection, and, less likely, superficial necrosis or epidermolysis [14, 19]. Flap edema and vascular congestion can also be noted in the short-term postoperative period [9, 13]. Flap failure in the form of necrosis is rare given the robust blood supply of the forehead flap. A study of 290 paramedian forehead flaps at a single center quoted the most common complication of bleeding among 33 patients, all within 24 h of the procedure, and not requiring hospitalization (3b) [14]. This same study identified 11 cases of necrosis (3.8%), ranging from total full thickness in 2 cases to 6 cases of partial thickness of the flap; 8 of these 11 were tobacco users [14]. Paddack et al. [20] reported an overall paramedian forehead flap failure rate of 6.1% among 82 patients, with a complete failure rate of 1.2% (4), similar to Little et al.'s [41] overall and complete failure rate of 4.9% and 1%, respectively, in a series of 205 patients (4). While Little et al. [41] did note statistical significance between smoking and flap failure, Paddack et al. [20] did not replicate these findings, although five of six failures were in smokers. Rohrich et al. [8] reported 1.7% necrosis risk among 532 paramedian forehead flaps (4). In another large retrospective study of 187 paramedian forehead flaps, partial necrosis rates of 3.4% and 5% were identified in two-stage and three-stage flaps, respectively (4b) [42]. In other studies, tobacco use is commonly implicated in partial flap loss (4) [8, 20, 21].

Long-term complications include pincushioning and trapdoor deformity resulting from inadequate thinning of the distal flap or insufficient undermining of the recipient site [13, 20]. Furthermore, contracture causing retraction or notching of the ala can be noted. The maintenance of nasal patency is of utmost importance as well, to maintain a clear nasal pathway through the nasal valve; this is greatly facilitated through the use of cartilage struts to preserve structural support of the nose [16]. Nevertheless, complications of nasal obstruction are occasionally observed [9, 20].

Lastly, while the emphasis is placed on the aesthetic outcomes and complications associated with the nasal defect and its repair, patients should also be made aware of associated sensory changes due to forehead incisions that disrupt the supratrochlear neurovascular bundle. Patients can be counseled that these deficits are usually temporary.

Postoperative Care and Follow-Up

Postsurgical cares for forehead flaps involve achieving adequate hemostasis, frequent follow-up, and excellent wound care. Once hemostasis is successfully obtained, the pedicle should be wrapped with nonstick gauze, and a 24-hour postop check should be performed. The use of porcine xenografts has been advocated to optimize pedicle care in interpolated flaps (4) [47]. The xenograft is sutured in place around the exposed pedicle taking care to avoid compromising the vascularity of the pedicle [47]. Gelatin sponges can also be applied directly to the unepithelialized surface of the pedicle as a hemostatic tool (4) [48]. In cases of suspected vascular compromise, topical nitroglycerin paste every 4–6 h can be used, although benefit has not been shown in the literature (4) [9].

Postoperative and/or preoperative antibiotics are recommended in the case of forehead flaps [4, 14, 16]. Flap takedown generally occurs at 3 weeks. However, time range of takedown varies from 1 to 6 weeks [22, 36]. Some surgeons prefer to perform a flap refinement at 3 weeks with takedown at 6 weeks [6, 49]. The details of the various takedown modifications are outlined above.

Follow-up occurs over several months, in addition to suture removal 1 week after each stage. Several months following takedown, the patency of the nasal airway can be assessed. Revisions can be considered on a case-by-case basis. Excessive bulk of the flap can be addressed with surgical revision. Intralesional corticosteroids can also be used to minimize pincushioning or excessive flap thickness [9, 14, 19, 21]. Nonsurgical options for scar revision include resurfacing procedures and/or vascular lasers [1]. Dermabrasion and fractionated CO_2 laser can reduce hypertrophic scarring (4) [14, 50].

Alternative Procedures and Modifications

Alternatives to the forehead flap include grafting and local skin flaps. However, when considering sizeable defects of the nose, none of these options are comparable in quality to the paramedian forehead flap [5]. The melolabial interpolation flap can be considered for laterally based smaller alar defects in patients with good cheek skin laxity [8, 43].

Modifications

While there are no excellent alternatives to the forehead flap, various subtle modifications exist in forehead flap design. One such modification, named the cross-paramedian forehead flap, provides a smoother arc of rotation, increased length, and avoidance of any eyebrow distortion. The flap begins axially, but as it traverses across the forehead, the distal portion is random pattern. The pedicle is based on the contralateral side to decrease the arc of rotation (4) [21].

For extensive nasal defects encompassing the majority of the nose, bilateral paramedian forehead flaps can be used. The initial forehead flap is used for recreation of the nasal lining, with a subsequent stage involving the opposite side paramedian forehead flap for the external nasal repair in a later stage (4) [44]. This is particularly useful when intranasal local flaps are not favorable or in the case of patients with extensive tobacco abuse history, where the reliable axial blood flow of the forehead flap creates an advantageous vascular environment [44].

The principle of vascular delay can also be employed in forehead flaps, particularly in high-risk populations, such as heavy tobacco abusers, poorly controlled diabetics, and patients with history of irradiation (4) [1, 8, 9, 16, 45, 46]. This involves an intermediate phase prior to flap transfer aimed at improving blood flow into transferred tissue. Technical execution involves elevation of the flap with vertical incisions, and subsequent epidermal suturing back into the native bed, producing relative ischemia to the flap with sustained axial blood flow. The proximal and distal ends of the flap are left intact until the flap is transferred 7–14 days later (4) [45, 46]. The mechanism of action is felt to involve development of a hyperadrenergic state upon severing sympathetic innervation, creating relative ischemia of the tissue and metabolic changes allowing for increased flap survival. Additionally, neovascularization is

observed through angiogenesis [1, 45, 46]. In the indicated situations, the benefit of higher chance of flap success can outweigh the additional surgeries and time.

Conclusions

For reconstruction of large and complex nasal defects, the forehead flap is frequently the optimal choice. Although this flap requires multiple stages, its reliability and texture match provides consistent and cosmetically pleasing outcomes for patients. With numerous modifications, variations, and nuanced techniques, the forehead flap can be fine-tuned and tailored to address the depth and extent of nasal defects in each unique patient situation. By understanding the anatomy, flap design, and execution, as well as acknowledging patient-specific challenges, facial reconstructive surgeons can confidently achieve excellent function and aesthetics through the forehead flap.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE).

Findings	GRADE score: quality of evidence
The forehead flap is the optimal reconstructive option for medium to large defects of the nose and can also be used for periocular defects.	C
The forehead provides an excellent texture and adnexal quality match for nasal reconstruction.	C
The rich vasculature of the medial brow and central forehead is responsible for the high success rate of this flap. The supratrochlear artery has traditionally been felt to be the main blood supply to the paramedian forehead flap; however, collateral axially oriented vessels allow for reinforced blood supply and ultimate reliability of this flap.	B
This interpolated flap is generally performed in two to three stages. Three stages are utilized in higher-risk patients, such as tobacco users, or in more substantial nasal defects.	C
The use of vascular delay can be a valuable tool for forehead flap reconstruction in patients who are considered high risk for flap necrosis.	C
Disadvantages include need for multiple stages, alteration of medial brow placement, and donor site scarring.	C
Complications include postoperative bleeding, flap necrosis, pincushion deformity, and impaired nasal valve function.	C
Doppler ultrasound is not necessary for forehead flap planning; anatomic landmarks can be used with success.	B
The subunit principle can allow for more strategic defect control and more favorable reconstructive outcomes.	D
The forehead defect can be closed primarily; any portion that remains can be left to heal by second intention.	D
Takedown ranges from 1 to 6 weeks following the first stage.	C
Flap necrosis is rare due to the excellent blood supply of the forehead flap and ranges from 3% to 6%.	C

Self-Assessment Questions

1. What technique and flap modification can be utilized in cases considered at high risk for flap necrosis?
   (a) Hinge flap.
   (b) Postoperative porcine xenograft surrounding pedicle.
   (c) Subunit principle.
   (d) Takedown at 1 week.
   (e) Vascular delay.
2. What is the approximate rate of flap necrosis in paramedian forehead flaps?
   (a) 0%; the flap never fails
   (b) 5%
   (c) 10%
   (d) 15%
   (e) 20%
3. What is the current presumed role of Doppler ultrasound in paramedian forehead flap design?
   (a) Doppler can be beneficial in certain cases, but is not necessary for flap design or success.
   (b) Doppler is necessary for confirming flap viability and course.
   (c) Doppler is used to identify the supraorbital artery in paramedian forehead flap design.
   (d) Doppler provides no benefit in forehead flap design.
   (e) Doppler use increases the width of the forehead flap.
4. What is the most appropriate reason for creating a slanted forehead flap extending diagonally rather than vertically?
   (a) To access skin of greater adnexal quality match.
   (b) To avoid disturbance of vertically oriented nerves.
   (c) To create a more appealing and aesthetic scar.
   (d) To follow the path of the supratrochlear artery.
   (e) To increase flap length.
5. What is the typical width of the stalk of the forehead flap?
   (a) Less than 0.5 cm.
   (b) 0.5–1 cm
   (c) 1–1.5 cm
   (d) 1.5–2 cm
   (e) Greater than 2 cm.
6. Which patient factor puts the forehead flap at greatest risk of necrosis?
   (a) Diabetes.
   (b) Hematologic malignancy.
   (c) Hypertension.
   (d) Poor nutrition.
   (e) Tobacco use.

Correct Answers

1. e: Vascular delay. Although the mechanism is not entirely understood, adrenergic response, angiogenesis, and changes in tissue metabolism are felt to contribute to increased viability of flaps using vascular delay. The other answer choices are modifications in technique used in forehead flaps. A, B, and C are not generally associated with increased or decreased risk of tissue necrosis. D is not generally utilized in patients at risk for necrosis; rather a longer interval between stages would be elected.
2. b: 5%. Reports range from approximately 3% to 6% rate of necrosis.
3. a: Doppler can be beneficial in certain cases, but is not necessary for flap design or success. Doppler ultrasonography can be used to trace the path of the supratrochlear artery and verify its localization on the forehead, but is not necessary in forehead flap design. Recent studies have shown that using anatomic landmarks is sufficient in creating a reliable forehead flap. Additionally, the vascular plexus and anastomoses of various axial vessels, including supratrochlear, supraorbital, and dorsal nasal arteries, are responsible for the reproducible success of the forehead flap.
4. e: To increase flap length. Other reasons for slanting or diagonally orienting the forehead flap are achieving a smoother arc of rotation, avoidance of eyebrow distortion, and avoiding transfer of hair-bearing skin.
5. c: 1–1.5 cm.
6. e: Tobacco use. While the evidence is mixed and some studies do not show statistical significance, tobacco use is most associated with risk of both partial- and full-thickness necrosis.

Cartilage Transfers

10

Julie Jefferson and David Zloty

Abstract

In dermatologic surgery cartilage transfers are widely used in auricular, nasal, and eyelid reconstruction in both children and adults (2a) (Liu and Cao, Chapter 20: Repair, grafting, and engineering of cartilage. In: Neligan PC (ed) Plastic surgery: volume 1, principles, 3rd edn. Elsevier, New York, p 398–424, 2013; Otley and Sherris, J Am Acad Dermatol 39:982–992, 1998). Other indications for use include nipple reconstruction, rhinoplasty, and chin contouring (Liu and Cao, Chapter 20: Repair, grafting, and engineering of cartilage. In: Neligan PC (ed) Plastic surgery: volume 1, principles, 3rd edn. Elsevier, New York, p 398–424, 2013). Experience with cartilage grafting is extensive in reconstructive surgery, complications are uncommon, and results are typically excellent (Otley and Sherris, J Am Acad Dermatol 39:982–992, 1998). Cartilage grafts serve two primary purposes: to restore natural contour and architecture to a site of cartilage loss and to preserve a free margin position against the contractural forces of wound healing (Otley and Sherris, J Am Acad Dermatol 39:982–992, 1998). Both structure and function of key free margins can be optimized with well designed and executed cartilage grafting (Otley and Sherris, J Am Acad Dermatol 39:982–992, 1998).

Indications for Cartilage Transfers

In dermatologic surgery cartilage transfers are widely used in auricular, nasal, and eyelid reconstruction in both children and adults (2a) [1, 2]. Other indications for use include nipple reconstruction, rhinoplasty, and chin contouring [1]. Experience with cartilage grafting is extensive in reconstructive surgery, complications are uncommon, and results are typically excellent [2]. Cartilage grafts serve two primary purposes: to restore natural contour and architecture to a site of cartilage loss and to preserve a free margin position against the contractural forces of wound healing [2]. Both structure and function of key free margins can be optimized with well designed and executed cartilage grafting [2].

Cartilage is classified into three types: (1) elastic cartilage, (2) fibrocartilage, and (3) hyaline cartilage [1, 3]. Elastic cartilage is primarily found in the structure of the outer ear and also in

the larynx and epiglottis [1, 3]. It is characterized by high elasticity and great flexibility that can withstand bending owing to its large network of elastic fibers intertwined with collagen fibers [1, 3]. It is surrounded with perichondrium [1, 3]. Fibrocartilage, composed of thick bundles of collagen fibers along with intervening unicellular islands, has high tensile strength and serves to support structures that are subjected to frequent stress such as intervertebral discs, menisci, symphyseal joints, and joint portions of bone, tendon, and ligaments [1, 3]. Hyaline cartilage is built to withstand compressional loading and is characterized by stiffness as it is rich in glycosaminoglycans [1, 3]. It is the most common type of cartilage and is found in nasal, costal, articular, and tracheal cartilage [1, 3]. Hyaline cartilage is covered with perichondrium with the exception of articular cartilage [1, 3].

Partial- or full-thickness nasal alar defects that compromise the rigid alar form can result in medial sagging due to contractural wound healing [2]. Indeed, even modest nasal valve constriction can cause objectionable airway obstruction without appropriate cartilage support [2]. The need for cartilage support can be assessed by compressing the contralateral ala with a finger while the patient inspires deeply in supine position. If the ala exhibits increased collapse relative to the contralateral ala on deep inspiration, cartilage grafting should be considered to avoid issues with both form and function. Similarly, if airway obstruction of a nasal sidewall defect is apparent, cartilage grafting should be considered to avoid nasal valve obstruction.

Indications for cartilage repair of large auricular defects include cosmesis as well as providing support for the purpose of eyeglasses, or hearing aids [2]. Partial-thickness lower eyelid defects with tarsal plate loss but preservation of the conjunctiva are at risk for contraction and ectropion without cartilage grafting [2]. Pulling down on the eyelid skin to gauge lid laxity can be performed to assess the need for possible cartilage grafting.

Demographics Very little demographic data is available in the literature concerning patients treated with cartilage grafts. From our personal experience, patients requiring cartilage transfers are typically elderly (mean age 67) with Fitzpatrick 1–3 skin and advanced tumors extending through cartilage on the nose or ear. More specifically, no data is available correlating age to success of cartilage transfer. Given the broad range of applications for cartilage transfer, all age and ethnic groups can benefit from the procedure.

Effectiveness of Cartilage Transfers

The first autologous cartilage graft was reported in 1896, but cartilage grafting has only gained the favor of dermatologic surgeons over the past 20 years [2, 4]. Notably, cartilage has a low metabolic rate owing to its relatively sparse cell population and avascular structure [1]. The tissue is primarily sustained through diffusion and its oxygen consumption and glycolytic activity nears anaerobic levels [1]. Hence, cartilage grafts can be associated with long-term survival rates of up to 95% after 20 years (2a) [2, 5]. In addition, covering a cartilage graft with a microvascularly transferred interpolation flap, which provides a robust blood supply to the graft, can increase graft survival to greater than 97% (4) [1, 6].

Beyond what has been outlined above, the cartilage and skin survival percentages for the different clinical uses of cartilage transfer are not available in the literature. Within the author's own surgical center, survival rates have been estimated by careful photographic assessment of almost all of their cartilage transfers over the past 20 years. Cartilage used as a support for a wound healing by secondary intention or as a structural support under transposition or interpolation flaps have demonstrated greater than 95% survival. Cartilage used to support or provide volume under a full-thickness skin graft has exhibited approximately 90% survival, while the overlying skin has a greater than 80% survival in 75% of the cases. Composite grafts of skin and cartilage harvested from the ear and used to correct full-thickness nasal tip/ala defects have shown 80% survival of cartilage and 70% survival of associated skin (5).

Preoperative Evaluation

The preoperative consultation is integral to the success of a potential cartilage graft. Obtaining a thorough medical history, assessing the cartilage donor site for necessary characteristics including degree of memory and pliability, assessing the recipient site for size and necessary contour, and discussing the surgery in detail with the patient can reduce surgical complication risk and improve the physician-patient relationship. The patient should be informed of the possible treatment options, complications, and the expected postoperative course (2a) [7, 8].

A preoperative questionnaire inquiring about past medical and surgical history, allergies, medications, responses to prior procedures, and social and family history completed by the patient prior to the consultation can facilitate the visit and provide useful information in a concise manner. The questionnaire can also help the physician allocate the appropriate amount of visit time to addressing potential complications and prevention planning [7].

Patients with diabetes can be assessed for disease control with a random or fasting blood glucose level and hemoglobin A1C. Diabetics, smokers, and patients with ischemic heart disease have compromised microvasculature and are at an increased risk of delayed wound healing, wound dehiscence, and wound necrosis particularly of flaps or grafts [7, 8]. It is important that disease is under good control. For diabetes, the physician should also be keen to monitor for signs of hypoglycemia throughout the procedure [8]. Sweetened juices or glucose tablets should be on hand at the time of the procedure [8]. Ideally, patients should discontinue smoking prior to surgery and during wound healing. If they are unwilling or unable to completely discontinue smoking, consumption should be decreased to less than 1 PPD for 1 week prior to surgery and for 3–4 weeks afterward [7]. Sublingual nitroglycerin should be readily available for patients with a history of ischemic heart disease or angina [7].

Hypertension is another disease that should be well managed at the time of the procedure. When under poor control, hypertension can lead to an increased risk of intraoperative and postoperative bleeding (2b) [8, 9]. The patient's blood pressure should be checked prior to the procedure on the operative day and it may be necessary to postpone the surgery for systolic pressures over 180 mmHg and diastolic pressures over 100 mmHg [7].

In general, medically necessary anticoagulants should be continued (2a) [7, 10]. However, it is important to note that guidelines cannot adequately address the particulars of all patient scenarios, and clinical judgment has a key role in the consideration of all patient care factors. If the patient is on warfarin per physician order or due to history of myocardial infarction (MI), angina, or transient ischemic event, an INR should be obtained [7]. An INR between 2 and 3.5 is acceptable for surgery [7]. Patients who are on aspirin for pain control or to prophylactically prevent an MI or stroke can discontinue the medication 7 days prior to the procedure [7]. Similarly, NSAIDs should be discontinued 3 days prior to the procedure [7]. Both aspirin and NSAIDs may be resumed 3 days postoperatively [7]. It is important to note that patients on aspirin with a normal bleeding time appear to have no increased risk of complications [7].

It is recommended that patients who drink socially discontinue consumption 48–72 h prior to surgery to prevent unnecessary bleeding [7]. Patients who suffer from alcoholism should be asked to decrease their consumption if possible, but not discontinue completely, as this may precipitate life-threatening alcohol withdrawal symptoms [7].

Best Techniques and Performance

An auricular cartilage graft composed of elastic cartilage is quite versatile as it can be easily contoured into different shapes for a variety of purposes [1]. In addition, auricular cartilage is easily accessible, and the distinct contours of different portions of the ear can be quite useful for certain reconstructions [1, 2]. The conchal bowl and antihelix donor sites are used most

Fig. 10.1 Conchal bowl cartilage harvested using an anterior approach

commonly [2]. An anterior or posterior approach can be taken when harvesting cartilage from the ear (Fig. 10.1) [1, 2]. Local anesthesia should be injected into the perichondral plane both anteriorly and posteriorly, and then the skin hydrodissected off the cartilage [2]. When harvesting conchal bowl cartilage anteriorly, the incision should be made along the inner aspect of the antihelical fold to expose the conchal cartilage [2]. The cartilage can be harvested using either a No. 15 or 11 blade or fine scissors [2]. Auricular cartilage should be harvested gently as it can be susceptible to fracture with excess tension [2]. When harvesting antihelix cartilage, care must be taken to leave adequate residual cartilage to prevent helical distortion [2]. Composite chondrocutaneous grafts are harvested by performing a wedge excision from the helical rim and closed primarily [10]. In particular, the junction of the anterior helical rim adjacent to the cheek is ideal for alar composite grafts [2]. After the cartilage has been harvested, accurate and precise hemostasis should be obtained and the incision site sutured [2].

Other cartilage donor sites include nasal septal cartilage and costal cartilage [2].

In dermatologic surgery, septal cartilage harvesting is primarily an option in instances of full-thickness nasal defects that provide direct access to the septum [2]. Septal cartilage can also be harvested as a free graft after elevating a mucoperichondrial flap [2]. In order to perform a mucoperichondrial flap, a unilateral mucosal flap is elevated and cartilage is harvested directly from the septum with a scalpel through the nostril [2]. The mucoperichondrial flap is sutured through and through to the residual contralateral mucosa [2]. One centimeter of both caudal and dorsal septal cartilage should be left intact to provide adequate nasal support and prevent morbidities such as saddle-nose deformity and columellar retraction [2].

Costal cartilage harvesting is rarely performed by dermatologic surgeons and comes with increased risks of morbidity when compared with septal and auricular harvest sites [2]. Risks include pneumothorax and postoperative atelectasis, which must be excluded by a postoperative chest x-ray (2b) [1, 2, 11]. Costal cartilage does provide a large cartilage reservoir that can be utilized when performing complete auricular reconstruction [1, 2], as well as reconstruction of significant saddle-nose deformity (4) [12], nipple reconstruction (2b) [13], septorhinoplasty(4) [14], tracheal reconstruction (4) [15], and treatment of maxillonasal dysplasia (Binder's syndrome) (4) [16]. Cartilage is typically harvested from the sixth, seventh, eighth, or ninth ribs through an oblique incision made superior to the desired costal margin [2]. Muscular attachments must be freed from the cartilage prior to removal [2].

Following the harvesting of the cartilage graft, excess soft tissue should be removed [2]. There is no general consensus on whether or not to remove perichondrium, but we prefer to leave it in place as does Otley and Sherris [2]. However, tumefactive graft proliferation was noted by Reiter et al. in four cases, and they recommend that the perichondrium be removed to avoid this complication (4) [17]. Grafts can then be shaped carefully to fit [2]. Grafts can be crushed with a cartilage press or nicked at the lateral edges to improve pliability although this may increase the risk of fracture and/or graft viability [2].

Nose

Cartilage grafts for nasal alar defects can be placed in 2–3 mm-deep recipient pockets that can be made with a scalpel (or undermining scissors depending on surgeon preference) for each of the distal ends [2]. After inserting the tips of the graft into the

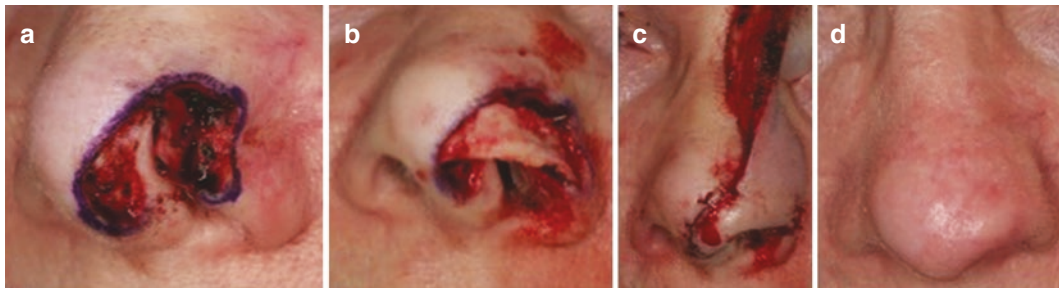

Fig. 10.2 (**a**) Nasal defect following Mohs surgery. (**b**) Placement of cartilage graft. (**c**) Placement of paramedian forehead flap atop cartilage graft. (**d**) Surgical outcome after 1 year

recipient pockets, the graft should be secured into place with absorbable suture [2]. Preferably the graft is then covered with a transposition or interpolation flap. Less desirable is coverage with a skin graft, which when placed over avascular cartilage is prone to necrosis (Fig. 10.2) (4) [2, 18, 19]. When using cartilage grafts to repair full-thickness alar defects, it is important to repair or reconstruct a vascularized mucosal lining to improve the chances of the cartilage graft survival [2]. Full-thickness composite grafts from the anterior helix can be used to reconstruct some full-thickness alar rim defects, but given their bulk and complex composition, these grafts have high metabolic demands (4) [2, 20]. It is recommended that these composite grafts not exceed 1.5 cm in diameter to minimize the risk of ischemia and necrosis [20]. For nasal sidewall defects, cartilage grafts should generally extend from the dorsal septal cartilage to the maxillary bone or soft tissue of the nasofacial sulcus [2]. Another option to repair small- to medium-sized defects of the alar subunit that do not involve the alar margin is a free cartilage graft followed by secondary intention healing (4) [21].

Reconstruction of the nasal tip can include several cartilage grafts which can be secured to one another for enhanced stability with absorbable suture [2]. Bilateral lateral nasal cartilage batten grafts can be placed proximally and secured between the maxillary bone and dorsal septal cartilage [2]. A dorsal nasal cartilage graft is often placed to provide the nose with a smooth contour [2]. Distal structural support can be provided with a columellar strut graft secured to the anterior nasal spine and between the medial crural feet, or to the caudal end of the septum when medial crural feet have been resected [2]. Atop the columellar strut graft, a tip graft is often employed to improve the aesthetic projection of the nose [2]. Alar batten grafts secured from recipient pockets created in the lateral alar soft tissue as described above can be secured medially to the columellar strut graft [2].

Ear

Large helical defects can be repaired with cartilage grafts followed by overlay with a cutaneous flap, or less commonly, by the use of composite grafts (4) [20, 22]. As with composite grafts of the alar rim, the maximum recommended diameter is 1.5 cm [20].

Eyelid

Full-thickness defects of the lower eyelid are frequently repaired with a tarsoconjunctival flap from the apposing eyelid rendering cartilage grafting unnecessary. However, placement of an auricular cartilage graft with attached perichondrium in contact with conjunctiva followed by a vascularized cutaneous or musculocutaneous flap is another option that works well (4) [23]. The cartilage graft should be sutured to the free edges of the remaining tarsal plate with buried absorbable suture. Reepithelialization of any exposed perichondrium can take up to approximately 3 weeks depending on size.

Other reconstruction options include auricular chondrocutaneous composite grafts, but again, given the high metabolic demands, composite grafts are susceptible to ischemia and subsequent necrosis [20].

Safety

Complications of cartilage grafts are rare [2]. Risks associated with cartilage grafting include resorption, deformation, or displacement of the graft after placement and extrusion [2]. Recipient sites such as the ear that are frequently subject to trauma or movement are at an increased risk of resorption [2]. Depending on recipient site, resorption can result in helical notching, ectropion, alar retraction, or nasal collapse [2]. Placing a cutaneous flap with good vascularity overtop of a cartilage graft is currently thought to improve cartilage graft survival [2].

If cartilage grafts are not sufficiently anchored into place, they can migrate when exposed to the constant force of contractural scarring [2]. Hence, it is recommended that they be anchored with either a slowly absorbing or permanent suture [2]. Cartilage grafts should be of sufficient thickness, length, and stiffness to prevent deformation during contractural wound healing [2]. Extrusion is an uncommon complication, and risk can be minimized by providing adequate, well-vascularized cutaneous flap coverage [2]. Tumefactive cartilage graft proliferation has also been reported with rhinoplasty in the otolaryngology literature [17]. The authors believed that the presence of perichondrium increases the likelihood of this complication, citing an unpublished observation that irregular, unpredictable growth of rabbit auricular cartilage occurs when implanted with its perichondrium intact [17]. They also believed that tumefactive proliferation was also due in part to trauma [17].

All cartilage donor and recipient sites are susceptible to infection, but this is uncommon. The avascularity of cartilage can impair the delivery of systemic antibiotics, and infections of cartilaginous structures can become serious [2]. Gram-negative bacteria such as *Pseudomonas* are often present in the external auditory canal and should be considered when selecting empiric antibiotic coverage for conchal donor sites [2]. Septal cartilage harvesting is most often complicated by *Staphylococcus* infections [2].

Location-specific complications of cartilage transfer can include septal perforation, auricular distortion, sterile chondritis, and pneumothorax [2]. Sterile chondritis may be symptomatic for up to a year postoperatively and can be managed with trauma avoidance, NSAIDs, cool compresses, and time [2].

Other Complications Complications can arise when performing total distal nasal cartilage reconstruction with auricular cartilage [2]. While the nasal grafting is reliable, the auricular restoration following the harvesting of the donor cartilage can often result in loss of auricular definition [2]. Alar and lower eyelid cartilage grafting using auricular donor sites can sometimes appear too thick and require thinning [2]. The positioning of the conjunctival/cutaneous junction during lower eyelid restoration with cartilage may sometimes also require revision [2].

Postoperative Care and Follow-Up

There is no consensus on postoperative wound care and follow-up visits. In our office, we apply a pressure dressing directly after surgery for 24 h at which time it can be removed and the wound gently cleansed with sterile saline twice daily. We typically see patients back in 1 week. During this visit, we assess both donor and recipient sites for infection, stability of graft location, and presence/severity of any perichondritis. Should these complications occur, they are treated as outlined within the safety section. Barring any complications, patients are assessed again in 3–4 months, and then as needed.

Alternative Procedures and Modifications

Alternatives to autologous cartilage transfers that currently exist include alloplastic implants composed of silicone, polytetrafluoroethylene,

polyethylene, metals, and calcium phosphate ceramics [2]. However, these implants can be complicated by foreign body reactions, infection, and/or extrusion [2]. In addition both basic and applied research are ongoing in regard to cartilage engineering. Few preliminary clinical trials have been conducted to date in this area and much work remains in order to offer cartilage engineering as a realistic option in clinical practice [1].

The volume of chondrocytes that can be harvested from auricular, nasal, and costal cartilage is limited and the ability to develop cartilage from stem cells would have great utility [1]. Using adult mesenchymal stem cells derived from bone marrow and adipose tissue, chondrogenic differentiation can be achieved with co-culture with chondrocytes (2b) [24], growth factor induction (2b) [25], or chondrogenic matrices (2b) [26]. In order to facilitate chondrogenic differentiation and cartilage formation, researchers are aiming to mimic the molecular signaling and histoarchitecture of the cartilage microenvironment [26].

Cartilage can develop both in vivo and in vitro. In vivo cartilage engineering uses the human body as the bioreactor. Once the cartilage block has formed, it is harvested, shaped, and then implanted into the desired site. In vivo engineering requires patients to undergo at least two operations and they must also take proper care of the developing cartilage block (2b) [27]. In vitro cartilage engineering is preferred because it requires less surgery and patient suffering. However, in vitro-engineered cartilage is relatively weak compared to in vivo-engineered cartilage owing to differences in the surrounding microenvironment (2b) [28]. The in vivo-engineered cartilage microenvironment promotes further maturation of cartilage with differential expression of collagen IX and pyridinoline, providing it with enhanced mechanical strength [28]. While the exact mechanism has not been fully elucidated, researchers have found that dynamic loading of articular cartilage increased Young's modulus and the production of cartilage oligomeric matrix protein and collagens II and IX (2b) [29].

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE).

Findings	GRADE score: quality of evidence
Cartilage grafts serve to preserve both form and function and are commonly used in auricular, nasal, and lower eyelid reconstruction in dermatologic surgery [1, 2]	A
Cartilage grafts can be associated with long-term survival rates of up to 95% after 20 years (B) given the tissues' low metabolic rate, sparse cell population, and avascular structure (A) [1, 5]	B, A
Donor sites for cartilage grafts include the auricular cartilage, nasal septal cartilage, and costal cartilage [1, 2]	A
Composite grafts have a higher metabolic demand and should be restricted to 1.5 cm in widest diameter to decrease the risk of ischemia [20]	B

Self-Assessment Questions

1. Cartilage transfers can be used in reconstruction of the following areas except:
   (a) Nasal defects
   (b) Auricular defects
   (c) Eyelid defects
   (d) Nipple defects
   (e) Lip defects
2. Long-term survival rates of cartilage grafts approximate:
   (a) 95%
   (b) 85%
   (c) 75%
   (d) 65%
   (e) 55%
3. Cartilage donor sites used in dermatologic surgery include all of the following except:
   (a) Conchal
   (b) Costal
   (c) Septal
   (d) Articular
   (e) Helical rim
4. For patients on coumadin, an INR between what two values is considered acceptable for surgery?
   (a) 1–2.5
   (b) 1.5–3.0
   (c) 0–1
   (d) 2–3.5
   (e) 1–2
5. Given high metabolic demands, the diameter of a composite graft used in auricular or nasal reconstruction should not exceed what length to avoid ischemia?
   (a) 0.5 cm
   (b) 1 cm
   (c) 1.5 cm
   (d) 2 cm
   (e) 2.5 cm

Correct Answers

1. e: Cartilage transfers are not used in the reconstruction of lip defects.
2. a: Long-term survival rates of cartilage grafts approximate 95%.
3. d: Articular cartilage is not typically used in dermatologic reconstructive surgery.
4. d: An INR between 2 and 3.5 is considered acceptable for dermatologic surgery.
5. c: Composite grafts have a higher metabolic demand and should be restricted to 1.5 cm in widest diameter to decrease the risk of ischemia.

Skin Grafts

11

Shauna Higgins and Ashley Wysong

Abstract

Skin grafts have become a mainstay of the reconstructive ladder with primary subtypes being full-thickness, split-thickness, composite, and free cartilage skin grafts. Full-thickness skin grafts (FTSGs) contain the complete epidermal and dermal layers of the skin. Split-thickness skin grafts (STSGs) comprise the epidermis and a portion of the dermis and are characterized as thin, medium, or thick, based on the amount of dermis they contain. Composite grafts comprise two types of tissues, usually skin and cartilage, and free cartilage grafts are exclusively composed of cartilage. Here we discuss the indications, techniques, and outcomes associated with each of the skin graft subtypes.

Introduction

Skin grafting was first performed in India approximately 3000 years ago, with widespread interest emerging only after the nineteenth century [1]. Ollier and Thiersch first described the use of split-thickness skin grafts (STSGs) in 1872 and 1886, respectively. In 1942, Brown and McDowell used the STSG to treat burn wounds [2]. Today, skin grafts have become a mainstay of the reconstructive ladder with the primary subtypes being full-thickness, split-thickness, composite, and free cartilage skin grafts.

Full-thickness skin grafts (FTSGs) contain the complete epidermal and dermal layers of the skin. This includes all dermal adnexal structures, which have important surgical and aesthetic considerations. Split-thickness skin grafts (STSGs) comprise the epidermis and a portion of the dermis and are characterized as thin (0.005–0.012 inches), medium (0.012–0.018 inches), or thick (0.018–0.030 inches), based on the amount of dermis they contain [2, 3]. Composite grafts comprise two types of tissues, usually skin and cartilage, and free cartilage grafts are exclusively composed of cartilage [4].

Procedures

Full-Thickness Skin Grafts

The earliest record of FTSG use is by J. Mason Warren in 1843 with modern aspects developed

predominantly by J. Staige Davis and V.P. Blair [5]. Full-thickness skin grafts (FTSGs) contain numerous nutrient-requiring structures in the dermis such as sebaceous glands, sweat glands, nerves, hair follicles, and the arrector pili muscle. They consequentially require a sufficiently vascular bed to meet their metabolic demands and are therefore indicated in smaller repairs. Thin grafts are typically taken from the eyelid or post-auricular sulcus, medium grafts are taken from the preauricular cheek or cervical regions, and thick grafts are taken from clavicular or preauricular areas [4, 6]. The grafts from these areas are often utilized to reconstruct facial defects after definitive skin cancer removal; however, they should not be used if there is elevated risk for recurrence. Other indications include clinical scenarios in which cosmesis is prioritized as FTSGs typically have better cosmetic outcomes when compared to STSGs. In addition, FTSGs are also considered in patients with tissue reservoirs surrounding the defect that is insufficient for local flap reconstruction. The literature details a variety of additional uses including head and neck reconstructions, reconstruction status post-degloving injuries, release of burn scar contractures, and reconstructions after excisions for a variety of other cutaneous pathologies [4].

The general technique begins with creation of a template for the graft. An outline of the defect is typically drawn at the donor site. To accommodate for graft shrinkage, a graft 3–5% larger than the template is usually harvested. Grafts used for lower eyelid reconstruction should be harvested to allow for a greater amount of shrinkage to allow for contraction and to avoid possible ectropion. Once the donor site is marked, anesthesia should be injected. Injection prior to marking may distort the shape and size of the graft. The graft is then excised, typically at the level of the subcutaneous fat. The donor site is customarily closed primarily with a layered closure. Although it is best to use the graft immediately, it can be held for up to 1–2 h if placed in a dish with normal saline or saline-soaked gauze. Prior to placement in the recipient site, the graft should be trimmed and defatted down to the white glistening dermal surface (Fig. 11.1). Surgeons should avoid excessive thinning that may destroy adnexal structures and have

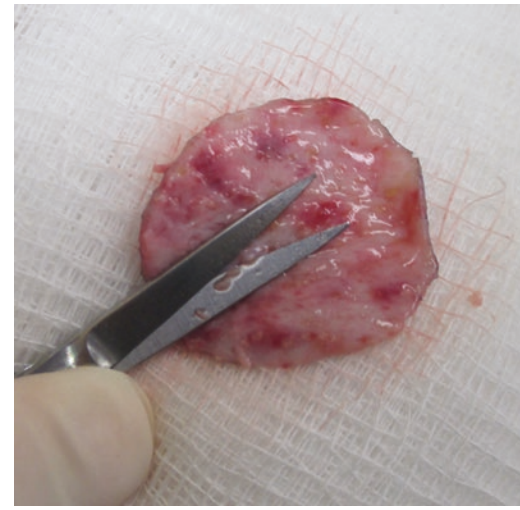

Fig. 11.1 A FTSG is defatted with iris scissors. The yellow fat should be removed to expose the intact white and glistening dermal surface

Fig. 11.2 Bolster consisting of antibiotic ointment, petrolatum-impregnated gauze, and moistened cotton balls anchored with tie-over suture

cosmetic implications. Once the graft is placed in the defect, it can be anchored with sutures around the perimeter. Bolsters may then be used to further anchor the graft to the recipient bed (Fig. 11.2). After bolstering, a light dressing and pressure dressing are applied. The pressure dressing usually remains for approximately 24–48 h. The bolster is left in place for approximately 1 week [7].

One of the main head and neck applications of the FTSG is nasal reconstruction. The nose is a unique reconstructive quandary in that it is a three-layered structure comprising the skin, cartilage or fibrofatty tissue, and mucosa. Replacement of each

tissue layer is indicated for an optimal cosmetic and functional result. Different techniques are utilized to achieve this, and they depend on the type of defect and patient. For enhanced structural support, a variety of flaps have been reported in combination with overlying FTSGs. Fader et al. described a muscle hinge transposition flap with overlying local FTSGs for repair of deep nasal defects in a single-stage procedure (4) [8]. In a separate study of 12 patients, basal cell carcinomas were excised by Mohs micrographic surgery (MMS), and a template was cut to mirror defect dimensions; it was then placed superior to the defect and outlined to incorporate it into the anticipated defect. The outlined area was excised down to subcutaneous fat. The muscle flap is then incised and elevated above the periosteum or perichondrium with the inferior base at the superior margin of the defect. The muscle flap is then transposed and secured into the defect with the graft secured on top of the flap. The donor site is closed primarily. This method is most effective in small to medium, 1–2 cm soft tissue defects of the nasal dorsum, sidewall, supratip and ala lobule, and in areas of sufficient skin laxity superior to the defect but which lack a sufficient adjacent tissue reservoir for a single-stage local flap procedure. This method resulted in no cases of infection or necrosis. Cosmetic and functional outcomes were graded from good to excellent by both patients and surgeons with cosmesis provided by similar color, thickness, texture, and sebaceous density similar to the excised tissue [8]. A similar combination of a muscular hinge flap with an overlying FTSG has been reported for reconstruction of the complex oral commissure area (5) [9]. In this case report, a 73-year-old male had a recurrent squamous cell carcinoma of the right oral commissure excised to leave a deep, vertically oriented defect measuring 4.0 by 1.5 cm. Given the complexity of the anatomy and a resulting paucity of reconstructive options, authors opted for a turnover muscular hinge flap with a Burow's FTSG for best possible cosmetic and functional results. To achieve this, an incision was made through the skin and subcutis at the inferior aspect of the defect, creating a Burow's triangle from the junction of the inferior aspect of the oral commissure to the medial edge of the defect. This skin was saved as a Burow's graft. An incision was then made through the orbicularis oris and depressor anguli oris muscle, undermining the area below the muscle to create a triangular hinge flap. The flap was draped over the commissure and upper lip defect and sutured into place while the defect was advanced laterally and closed primarily. The Burow's STSG was defatted, trimmed, and sutured over the muscular hinge flap to recreate the right upper cutaneous lip and right upper oral commissure. Excellent cosmetic and functional results were obtained at 1-, 3-, and 6-month follow-ups with the overall oral aperture being minimally reduced and no functional compromise being reported [9].

In addition to muscular hinge flaps, FTSGs have also been reported in combination with mucosal and dermal hinge flaps. Bickle and Bennett reported use of a combined mucosal hinge flap and FTSG for a through-and-through non-rim nasal defect with no other adverse effects other than persistent erythema treated with pulsed dye laser (5) [10]. A dermal flap with overlying FTSG can also be used in the reconstruction of nasal defects. In cases of burned nasal ala, using rolled dermal flap with overlying FTSG provided reliable reconstruction (4) [11]. In these cases the lateral surface of the nose was used as the dermal flap donor site and was de-epithelialized. An incision was then made 6–10 mm above the free edge; the distal skin was detached and then inverted to constitute the internal aspect of the nostril. The inferior pedicle dermal flap was then detached from the deep plane, rolled, and sutured to nostril margin. A FTSG was then used to cover the reconstruction and dermal donor site. Of the seven patients, one developed necrosis of the tip of the nose and another developed retraction of the nasal ala during growth. Both cases required surgical revision [11].

In 2013, Zopf and colleagues evaluated the utility of a FTSG overlying a separately harvested auricular cartilage graft for nasal alar reconstruction (4) [12]. In this case, cartilage augmentation was indicated due to deep cutaneous defects of the ala that made retraction or collapse probable. The cartilage graft helps resist contraction, improve contouring, enhance volume, and stabilize the external nasal valve [12]. This technique can also be utilized in a delayed

fashion whereby the cartilage graft is placed and followed by the FTSG 1–2 weeks later.

Forehead defects can have various etiologies including skin cancer resection, trauma, or iatrogenic causes such as the creation of a paramedical forehead flap. These are historically closed primarily or allowed to heal by secondary intention (5) [13]. These approaches, however, may result in significant downtime and may provide a suboptimal aesthetic outcome, particularly in large defects. In a recent report, Osorio et al. report on a technique to reconstruct the forehead using a frontalis-pericranial flap and a FTSG. In the case, a patient was left with a 3x3 cm defect extending to the bone on the midline forehead after MMS for a sarcomatoid SCC. The cortex of the bone was drilled to improve the eventual graft recipient bed. After a 5-week attempt at granulation, a frontalis-pericranial flap was performed. An excision was made posteriorly into the hair, and the flap was exposed via elevation of the skin and subcutaneous tissue in a plane above the frontalis muscle and deep to the hair follicles. Supraorbital and supratrocheal vascular pedicles were maintained and the flap was transposed into the defect. The scalp was then closed with subsequent placement of a FTSG from the supraclavicular fossa over the flap. The bolster dressing was removed 1 week postoperatively with good functional and cosmetic outcomes. Alternatives include a local flap, which may have led to alteration of the hairline. A free flap would have also been a viable option in this case, but the patient refused [13].

Full-thickness skin graft donor sites are generally numerous given the relatively small surface areas required. In 2005, Dimitropoulos et al. detailed a novel donor site for nasal reconstructions utilizing a FTSG harvested from the forehead (4) [14]. While nasal defects are often repaired with tissue from the preauricular, post-auricular, supraclavicular, clavicular, conchal bowl, melolabial fold, and upper eyelid skin, forehead grafts may be a thicker and more appropriate match for deeper nasal defects than traditional graft sources (Fig. 11.3). It may also provide apt camouflage of donor site in forehead rhytids if present. In the three patients presented, function and cosmesis were reported to be excellent at follow-up (>6 months). The three patients had minimal scarring with no secondary revision or dermabrasion [14]. Surgical considerations for all FTSGs but particularly for thicker grafts include a requirement for a well-vascularized recipient bed. Thus, these should not be considered as first-line therapy for diabetics, smokers, and vasculopaths.

Finally, methods to decrease the size of the defect and therefore increase the clinical situations in which the FTSG can be utilized and improve the viability of the grafts in cases in which they are already being used include a purse-string assisted closure (Fig. 11.4) [15].

Split-Thickness Skin Grafts

Split-thickness skin grafts have much broader applications than FTSGs and can be utilized for significantly larger defects. This is by way of their thinner nature and therefore smaller metabolic and vascular demands. The larger harvest area brings with it several surgical considerations to be cognizant of in addition to several possible adverse effects. The STSG results in a second

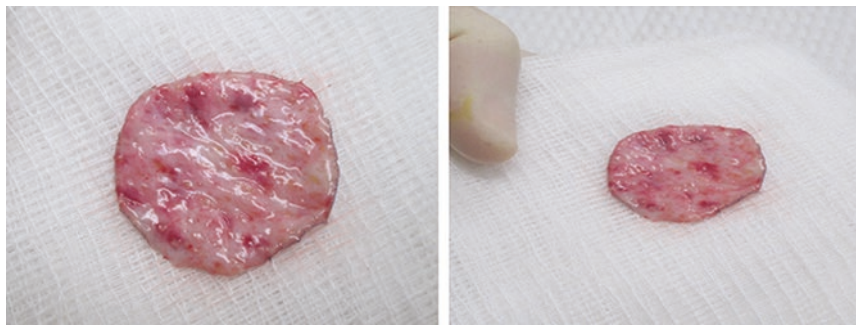

Fig. 11.3 Dermal surface of a FTSG collected from the supraclavicular region

Fig. 11.4 FTSG on the scalp with delayed purse-string closure

defect that can result in fluid loss, excessive pain, a prolonged period of healing and immobilization, hypertrophic scarring, and undesirable pigmentation (1) [16]. Because the STSG is thin and somewhat fragile, they usually do not suitably withstand subsequent stressors such as radiation. Additional considerations include that they contract quite a bit, tend to be hypo- or hyperpigmented, have texture irregularities, and lack hair growth. Thus, these grafts are indicated for cases in which a large coverage area is required and when function is prioritized over cosmesis.

The general technique for the STSG begins with harvesting the graft with either electric dermatomes or freehand devices such as a scalpel, razor blades, or Weck knife (Figs. 11.5 and 11.6). The order comprises marking, anesthetizing, and

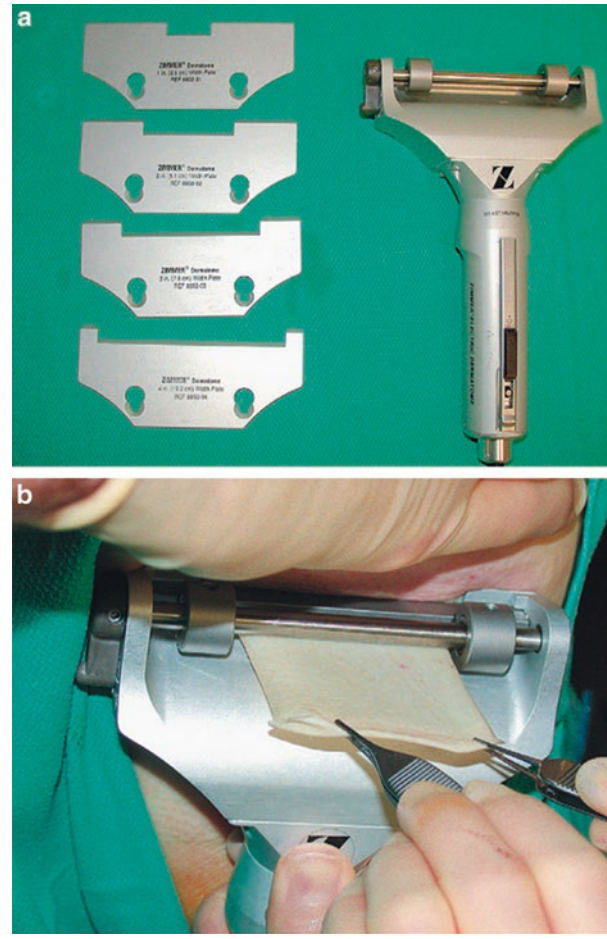

Fig. 11.5 (**a**) The Zimmer electric dermatome and its four-width blades and (**b**) harvesting a graft with the Zimmer electric dermatome [17]

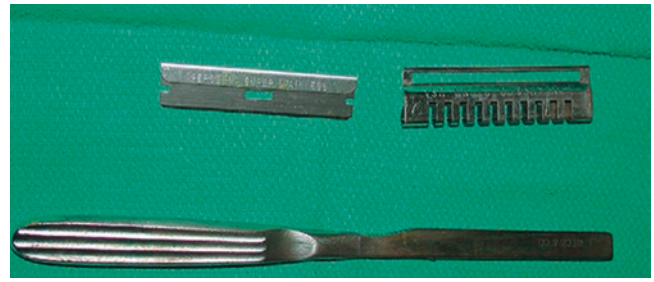

Fig. 11.6 Weck blade components including the knife handle, blade, and a template to control the STSG [17]

then harvesting. Although the harvest technique varies with the instrument used, the electrically powered dermatome has gained popularity. Prior to dermatome-assisted harvest, the donor site should be lubricated typically with mineral oil to ensure a smooth pass over the skin. While an assistant applies traction, the surgeon gently glides the machine over the skin at a 30°–45° angle to the donor site with depth determined by the desired graft thickness. As the graft emerges, it is gently lifted away with forceps or hemostats. Once completed, the machine is removed and the graft is placed in saline. If additional surface area is required from the STSG, such as in burn patients with extensive surface area involvement, the graph can be scored to create a meshed appearance prior to being placed at the recipient site. The meshing of the graft allows release of serosanguinous fluid that would interfere with graft take if allowed to accumulate between the graft and its recipient bed. After the graft is placed at the donor site, it is secured with peripheral sutures. Basting sutures are also recommended to ensure central adherence, particularly in larger grafts. A bolster with pressure dressing is then applied. The sutures are typically removed after 7–10 days [7].

Uses reported in the literature include reconstruction of head and neck wounds including scalp wounds and oral defects, reconstruction of abdominal wounds, genital defects, degloving injuries, burn injuries, and other extremity defects [18–48]. Scalp reconstructions can be challenging for a variety of reasons. Reconstructive options include second-intention healing, primary closure, local flaps, tissue expansion with subsequent flap repair, FTSG, STSG, or free-tissue transfer (4) [18]. Second-intention healing is noted as the simplest wound management method, but this has several drawbacks including the need for prolonged downtime and wound care. Resulting scars may also be atrophic or telangiectatic, hair-bearing areas will usually be alopecic, and contraction may limit use in the periocular region. The scalp is also relatively inelastic and lacks substantial surrounding tissue reservoirs making primary closure difficult, although it can be performed for defects under 3 cm with galeal undermining. This inelasticity also makes local flaps difficult for larger defects; however, closure of the donor site with the STSG can address this problem [18]. In addition, STSGs may be utilized on the bone with limited periosteum given the lower metabolic demand in comparison with FTSGs. This method has been reported to be effective for defects up to 150 cm^2 with complications in 3.4% of cases [18]. Disadvantages of the combined flap and graft technique include a predictable area of cicatricial alopecia associated with the placement of a hairless graft [18].

Additional applications of the STSG in the head and neck region include management of helical and non-helical defects, mastoid, mandible, and maxilla reconstruction. Helical rim defects are typically reported to be repaired with FTSGs or advancement flaps. Helical rim defects for which STSGs may be indicated include large keloids (4) [43]. The combination of the pathology and location makes these cases particularly challenging. Keloids are large and disfiguring. In addition, the helical rim is a three-dimensional and easily deformable structure. In a series of five patients with moderate (4–10 cm) and large (>10 cm) keloids, Rasheed and Malachy report the use of excision followed by STSG. In their

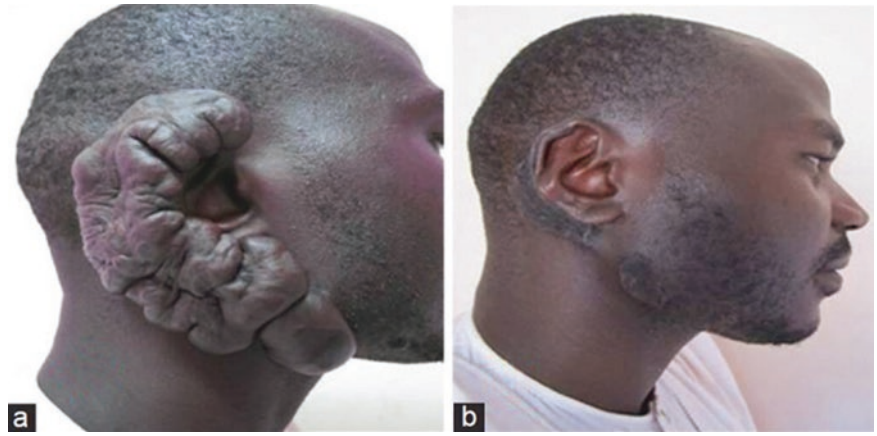

Fig. 11.7 (**a**) Helical rim keloid before treatment and (**b**) helical rim keloid after treatment [43]

series, the periphery of the keloid was anesthetized followed by full-thickness excision with a thin rim of the lesion remaining. A STSG was then applied over the defect with edges sutured. Forty milligrams of triamcinolone were injected into the residual rim of the keloid at 2 weeks status post-operation and this was repeated every two weeks for a total of six injections. All grafts survived although there was evidence of keloid recurrence in two patients. Aesthetic results were reported to be satisfactory with no secondary surgical revision required to improve the contour of the reconstructed helical rim (Fig. 11.7) [43].

Defects of the non-helical rim and ear defects devoid of perichondrium may also be challenging to reconstruct. These include locations of antihelix, crura of antihelix, scaphoid fossa, triangular fossa, antitragus, and the posterior surface of the ear. Full-thickness skin grafts may be too thick for these regions. Two-staged flap procedures are time-consuming, and second-intention healing may not be ideal due to risk of cartilage desiccation and webbing of the contoured surface of the ear. This leaves the STSG as the ideal option to treat non-helical defects of the external ear (5) [30].

In utilization of the STSG, final cosmesis can be reportedly optimized with slight softening of the cut angle. Traditionally, cutaneous lesions are excised with the scalpel held at a 90° angle when local skin flaps or primary closure is possible. In the context of STSG, however, a more pleasing

Fig. 11.8 Scalpel at a 45° angle to produce a beveled excision [20]

cosmetic result may be attained when the edge of the skin is beveled up to 45° to create a saucer-shaped defect, resulting in several distinct advantages (Fig. 11.8) (4) [20]. Among these is the ability of the beveled graft edge to better adapt to the edges of the wound by draping over the wider soft tissue defect and decreasing the propensity for poor take that may occur at right angles [20].

The STSG also has wide-reaching applications in the genital region both in males and in females. A recent 2016 case study responded to the paucity of data on pediatric penile reconstruc-

tion by evaluating the use of the STSG in this regard (5) [24]. Traditional approaches to this reconstruction include the use of excess preputial skin and rotation skin flaps from areas of redundancy. In cases in which there exists no excess or redundant skin, however, the STSG may present a good option. The donor site utilized for this procedure was the lateral thigh due to its glabrous skin and proximity to the genitals. Outcomes were promising with good penile graft elasticity and sensation at 7 months [24].

Further applications of the STSG in the penile area come from data on the treatment of concealed penis in young males (4) [28]. Concealed penis most commonly seen in neonates and moderately obese prepubertal boys can exist with varying severities and etiologies. Thus, the surgical approach differs accordingly. In this case, the authors used a transverse suprapubic incision to excise fat or loose elastic tissue and anchor the base of the penis to the periosteum of the pubis. Alternative procedures include freeing the abnormal dartos attachments and covering the penile shaft with inner preputial skin or using multiple Z-plasties to rearrange and lengthen the penile skin. Additional options for patients with denuded penis after excess circumcision include vascularized flaps, scrotal flaps, multiple Z-plasties, and skin grafts. In the case of patients who have insufficient skin to resurface the penile shaft, the STSG proves to be a good option. In these cases, the graft is anastomosed to the glans margin. There were no cases of lymphedema in the STSG patients. Important surgical considerations include an assessment of the cause of concealment and the appropriate timing of the surgery. In this series, the procedure was performed before the patient reached school age. Recovery of sensation will need to be prospectively followed, although most adults recover adequate to completely normal sensation in the treated area [28].

The STSG can further be utilized status postglansectomy for squamous cell carcinoma or other penile carcinoma (4) [38]. After glansectomy, a 1.2–1.5-mm-thick skin graft was harvested from the thigh and transplanted to cover the tip of the distal corpora cavernosa. The graft was then sutured proximally to the neurovascular bundles. This series reported two patients with early partial loss of the graft, one of them requiring surgical re-grafting. Two late complications occurred, one being meatal stenosis and the other being postoperative phimosis. Functional results were extremely satisfactory at 36 months. Preserved orgasm and ejaculation and reduced glans sensitivity were reported by all patients. No local recurrences were noted [38].

For females, the STSG has been utilized often in vulvo-vaginal reconstruction. In 22% of these cases, however, infection and sloughing may occur with the standard techniques that are used, especially at irradiated recipient sites. To address this, the authors of a 2005 study report on a novel method of vulvo-vaginal reconstruction comprising the use of fibrin tissue adhesives and vacuum-assisted closure (VAC) devices to improve the viability of the grafts (4) [23]. Fibrin tissue adhesives were first used with skin grafts in 1944. It was reported that surgeons coated the graft with fibrinogen containing plasma and coated the recipient bed with a thrombin solution. Improved wound healing occurs via stronger initial mechanical bond. Fibrin tissue adhesives typically comprise a highly concentrated, autologous fibrinogen with albumin, fibronectin, plasminogen, aprotinin, and factor XII along with thrombin and calcium chloride. The combination converts fibrinogen to fibrin monomers that polymerize and form an adhesive fibrin matrix. The wound VAC devices have been reported to improve wound viability by decreasing wound edema, improving graft-recipient site tissue apposition, stimulating granulation tissue, and decreasing bacterial colonization [23].

This technique involves harvesting a STSG from the inner thighs or buttocks to a desired thickness of 13–19/1000 of an inch. The STSG is meshed and trimmed. Thrombin is diluted with isotonic saline to a concentration of 5 IU/ml and applied to the graft. Diluted and aerosolized fibrin tissue adhesive, Tisseel®, was applied to the recipient site followed by application of the graft. Direct pressure was then applied for 3 min to allow adhesion. The wound VAC was set to a

pressure of 100 mm Hg at an intermittent setting and removed at postoperative day 3 or 4. Practicality issues that may arise include ability to achieve a good occlusive dressing while maintaining the ability for urination and defecation. This method resulted in great outcomes with 80% take noted on the vulva, vagina, and perianal area. No surgical site infections were noted [23]. A 2014 study also reported on the use of the wound VAC in place of conventional bolsters for the STSG in the burn population (3) [49]. In their retrospective review, they reported use of 125-mmHg suction for 5 days. Sixty-seven patients were included in this analysis. Zero returns to the operating room for repeat STSG were reported. Return to the operating rates for re-grafting with conventional bolstering is reported to be up to 19% [49].

Clinical outcomes of the wound VAC versus conventional therapy in regard to STSG viability were evaluated in a 2010 retrospective study of 142 patients (4) [50]. Conventional therapy comprised a cotton bolster, sterile compressive, or stainless steel gauze dressing used for at least 5 days. Results demonstrated significantly fewer repeated STSGs required in the wound VAC group in addition to fewer complications such as seroma, hematoma, and infection. Another recent report demonstrated the benefit of a suction drain to assist in the take of the STSG (5) [51]. An antimicrobial-impregnated dressing combined with a wound VAC has been reported to increase STSG engraftment as well (3) [52]. In a recent case-control study, one group used conventional bolsters to secure the skin graft, while the second group received an antimicrobial-impregnated dressing in combination with a wound VAC for 5 days, changed as frequently as required by the amount of exudates. All skin grafts used in conjunction with the antimicrobial-impregnated dressing achieved 100% take. No hematoma or seroma formation was observed. In the conventional therapy group, success rate was 85%. Three patients had partial loss of the skin graft, one of which was from infection [52]. These studies support the wound VAC as a viable option for increasing graft viability.

The STSG is also indicated for large defects on the extremities in the context of degloving injuries, burn injuries, and defects status post skin cancer extirpation. A recent case series in the journal *Burns* reports on the treatment of degloving injury of the finger with a pedicled split-thickness skin graft (4) [32]. The pedicled STSG benefits from two blood supplies, the pedicle and the wound bed. As a result, the survival rates of these grafts are extremely high such that they can be used in the context of bone or tendon exposure, which is a common scenario in degloving injuries. Additional advantages include the thickness of the graft relative to that of the fingers and that the time to severing the pedicle and immobilization are short. Immobilization, however, is extremely important. In this case series, the authors sutured the normal skin of a finger to the abdominal skin to avoid avulsion as the blood pressure in the tiny blood vessels is lower and small extravascular pressure may lead to skin-graft death. As always, the color of the graft should be monitored to evaluate its survival or death [32].

For burns, there is no clear consensus on whether the STSG is superior to the FTSG. A 2015 study placed the STSG against the FTSG for resurfacing the volar aspect of pediatric-burned hands. The six studies reviewed reported lower contracture rates in the hands of patients in the FTSG group when compared to those in the STSG group. These results, however, should be interpreted in the context of several key differences between the groups that include more severe (i.e., larger and deeper) burns being evaluated in one STSG study. Nonetheless, the use of the FTSG is usually preferred due to belief of lower contracture rates and thus decreased need for secondary reconstructions. The FTSG, however, has drawbacks that limit its use such as limited donor sources and its inability to cover large surface areas such as those usually typical of burns. The FTSG also has a lower take rate when compared to the STSG. Thus, there is no agreement on which the reconstructive method is superior and the decision should be case-specific.

Another study evaluated the use of spray keratinocytes and autologous meshed STSG in the treatment of acute burn injuries (4) [46]. In

this study, the authors prospectively compared the use of an autologous cell-harvesting (ACH) device with a meshed split-thickness skin graft to treat partial thickness burns in patients with two 320 cm^2 areas. The authors compared these patients on the basis of graft take, pigmentation, color match, scarring, and pain. Outcomes were similar for both methods at 52 weeks although for the ACH methods, patients benefited from smaller donor sites with comparable outcomes [46].

Thus, it becomes evident that the STSG has wide-reaching applications and can be used in a variety of anatomical locations. Once the decision has been made to utilize a STSG, however, other considerations arise. These include methods to improve graft take/survival and also, care of the donor site.

Graft survival is determined by a number of factors. The initial "take" or incorporation occurs by diffusion of nutrition from the recipient site. This process is termed "plasmatic inhibition" during which a thin fibrin network anchors the graft to the recipient site. Revascularization generally occurs within 48–72 h, and full vascularization is restored in approximately 4–7 days. Revascularization can occur via several mechanisms that include reconnection of blood vessels in the graft to recipient site vessels and growth of vessels from the recipient site into the graft [50]. Because graft survival is so largely dependent on its vascular supply, grafts generally do not take on poorly vascularized beds such as bare tendons, cortical bone without periosteum, heavily irradiated areas, or infected wounds. Any hematomas or seromas also interfere with revascularization and thus graft survival. Consequentially, graft survival is also contingent upon graft immobilization to prevent shearing, which may cause seroma or hematoma formation beneath the graft. The impact of hematoma formation was elucidated in a recent study that reported late failure of a STSG in the setting of the homozygous factor V Leiden mutation (5) [53]. Furthermore, graft survival is dependent on the presence of uniform pressure over the entire grafted area provided by a non-adherent, semi-occlusive, absorbent dressing [50].

Various methods have been utilized to address graft survival and graft "take." Argon beam coagulation has been reported to be a fast, precise, and minimally destructive manner in which to decrease bleeding between the recipient bed and the STSG (5) [54]. Platelet-rich plasma (PRP) has also been reported to be effective in this regard by improving hemostasis in addition to possessing adhesive and healing properties (1) [55]. In a 2015 randomized controlled trial, 200 patients were divided into an autologous PRP group and a conventional therapy or control group which comprised staple and suture use. Incidentally, surgical tape has also been used as a means of adhering the graft to the recipient bed (5) [56]. In the PRP group, blood was drawn into two 10 ml syringes and transferred into vacutainers containing citrate phosphate dextrose-adenine (CPD-A). Six ml of blood was transferred into each vacutainer by pouring gently along its walls to avoid damage to cells. Blood was then centrifuged at 1000 revolutions/min for 5 min. It was separated into supernatant PRP and buffy coat with approximately 5 ml of PRP used for a wound area of 100 cm^2. Graft adherence to the wound bed was found to be statistically improved in the PRP group. Another split-wound study of 20 patients demonstrated 100% graft uptake in the PRP area at 6 weeks. In the control area, there was complete graft loss in four cases, partial loss in seven cases, and complete uptake in nine cases (2) [57]. In this study, the PRP was collected via apheresis and frozen at −80 °C and then thawed at room temperature prior to its use [57].

There have also been reports of use of synthetic adhesives such as cyanoacrylate and fibrin glue. Medical honey has also been utilized as a natural alternative to enhance the attachment of the STSG to the recipient bed (4) [58]. Honey exerts its adhesive properties via its antibacterial activity, therefore addressing infection risk, which is the second-most common cause of graft failure. Wounds that contain more than 105 organisms per gram of tissues will not support a skin graft. In addition to its antimicrobial effect, honey also possesses inherent adhesive properties. One consideration is that the sterility and medical grade honey that has been previously

sterilized should be used. Low-level laser therapy (LLLT) has also been reported to improve the survival of the STSG (5) [59]. This has been reported to be particularly useful in patients with high rates of expected graft failure such as those with vascular disease. Low-level laser therapy (LLLT) has been reported to improve tissue perfusion and fibroblast proliferation, increase collagen synthesis, and accelerate wound healing in vitro studies. In the current series of cases, this method was performed using a 650-nm red laser light, 2 J/Cm for the recipient bed, and 810-nm infrared laser light, 6 J/Cm^2 for the margins, along with the intravenous laser therapy with 660-nm red light, before and after STSG. Therapy included three clinic visits a week for a total of 10–15 sessions. Results demonstrated complete healing of diabetic ulcers in all patients for at least 2 months. Healing time for the STSG in non-diabetic patients is noted to be approximately 2–4 weeks. Graft failure in this study was 2.8%. Thus, LLLT using both visible and infrared light are appropriate treatments for diabetic rats, although visible light is reported to work better (in animals) [59]. An animal model was also used to demonstrate the potential of a newly developed collagen scaffold under the FTSG as a way to improve graft quality (5) [60, 61]. A rat-based intervention demonstrated that when used with a collagen scaffold underlayment, wounds demonstrated a thicker epidermis and significantly higher epidermal cell count when compared to wounds treated exclusively with STSG [62].

For complicated wounds, cadaveric skin has been reported to be useful as a means to predict success of a STSG (4) [63]. Complicated wounds in the case of this method are reported to be infected as indicated by a positive culture swab. Whereas this usually necessitates prolonged antibiotic therapy, authors recommend cadaveric donor skin be applied, and if the donor skin has good take, antibiotic therapy is not necessary and a normal STSG can be performed with acceptable results. In their case series, 25 of 35 patients had full take of the cadaveric donor skin. In 22 of these 25 patients, a STSG was performed, which led to 91% complete graft take. These patients were not generally treated with antibiotics; however, if they were, surgery was not postponed [63].

Optimal management of the donor sites for the STSG has also become a high-yield topic in the skin graft literature. Techniques to minimize pain include ice, tumescent injection of the donor site, and PRP [16, 64, 65]. Optimal dressing materials have been evaluated in a number of studies. A recent 2010 study evaluated Aquacel®, AG, Bactigras ® with Melonin ®, Cmfeel® plus transparent, Opsite® Flexigrid, and Adaptic® (2) [66]. It reported earliest complete epithelialization with Aquacel ® AG and the latest for Bactigras ® with Melolin®. Comfeel® Plus Transparent was the most painless dressing and Bactigras ® with Melonin was the most painful. Incidence of infection was highest with Bactigras ® with Melonin ®. Opsite ® Flexigrid was the most economical and Aquacel ® AG was most expensive [66]. A subsequent randomized controlled trial evaluated the use of Helicoll with Scarlet Red and Opsite (1) [67]. Results demonstrated shorter healing time of the donor site in the Helicoll group when compared to the Scarlet Red group, however comparable to the OpSite group [67]. A "graft-back" procedure has also been suggested in which an additional graft is taken adjacent to the initial donor site and meshed 4:1 to cover both donor sites at once (4) [68]. Furthermore, honey has also been reported as an adjunct in the healing process of the skin graft donor site (2, 4, 2) [69, 70, 71]. PRP was also reported to aid in epithelialization and angiogenesis of graft donor sites as well (2) [72].

Composite Grafts

Composite skin grafts were first described by F. Konig in 1902 with subsequent modification by ensuing authors and physicians [73]. They are those comprising two types of tissues that may include cartilage, subcutaneous fat, and overlying skin; however, the most common combination is the skin and cartilage. Because these partially comprise avascular cartilage and exclusively rely on the bridging phenomenon, they are

limited in size due to risk of necrosis. In the literature, success rates for composite grafts are reported to range between 50% and 89% [73]. Their size should generally not exceed 2 cm as graft loss has been reported to rise when it exceeds 1.5 cm. The graft should never be over 1 cm from a vascular source. This requirement in turn informs the anatomic locations in which these grafts are most beneficial, which is generally the head and neck region with particular emphasis on the nose. They are often used to repair small full-thickness defects of the nasal ala and are also used for repair of the ear's helical rim. Composite grafts can also be used in defects that extend too deep for a FTSG to heal without leaving a concave defect. Donor sites for composite grafts are typically the helical crus, helical rim, and conchal bowl [7].

The general technique for harvesting a composite graft generally involves oversizing the cartilaginous portion relative to the overlying skin so as to supply cartilaginous pegs for insertion into the recipient site. The graft is then sutured although the cartilaginous portion does not need suturing, as it will heal on its own. A bolster or pressure dressing should be used. If the graft is being used to repair an alar defect, an intranasal antibiotic-impregnated gauze should be used to stabilize the graft. This is used due to the elevated baseline risk of composite graft failure in addition to the high bacterial colonization of the nares. Oral antibiotics may also be utilized [7].

For nasal defects, FTSGs are a viable option however because they must be defatted and thinned; these grafts often result in sunken areas that do not match the contour of the surrounding skin. For an aesthetically pleasing result, it has been reported that up to 3–4 mm of subcutaneous fat is needed at the base of grafts. This has also been reported to be most ideal as a component of a dermal fat graft as opposed to a free fat graft (4) [74]. Authors report two cases demonstrating the use of composite full-thickness grafts combined with fat grafts as a reliable technique for nasal reconstruction. Graft take is reported to be similar to that of skin-only grafts, however, with improved contour and match [74].

Through-and-through defects of the nose may particularly benefit from the use of composite skin grafts due to the depth of the defect and the complex structure of the nose. On the exterior surface, the nasal ala is usually plane or slightly convex, whereas the inside is more concave. This structural complexity usually requires the use of three-layer composite grafts [73]. Additional options for through-and-through defects of the nasal tip include skin grafts obtained from the earlobe, helical rim, root of the helix, local or distant flaps, and microvascular transplants (5) [75]. These options, however, have donor-site morbidity and may require several stages. A recent study reports on the use of auricular composite grafts for repair of nasal defects (4) [76]. Authors report that the composite graft of the auricle is an ideal choice due to similar anatomic structure, two skin layers, and one cartilage layer. The revascularization of the free auricular composite graft limits the distance from point of vascular contact to 5 mm. In a series of patients, the authors successfully reconstructed larger tip defects using the composite auricular skin graft by removing the skin between the columellar and composite graft and suturing the two surfaces together to increase the contact area between the composite graft and recipient tissue. After the operation, patients also had hyperbaric oxygen therapy for 7 days to improve graft oxygenation. Outcomes were positive. All grafts obtained revascularization successfully. Two patients had epidermal necrosis, although both were smokers who quit 2 weeks prior to the procedure. Thus, longer courses of hyperbaric oxygen may be required in patients with vascular pathology. This method, however, should not be used if the graft must exceed 2.5 cm, as there is a significant risk of necrosis in these cases [76].

Another study reinforced the utility of the composite graft for three-layer defects of the nostril margin (5) [73]. In this case, authors transferred a composite graft from the helix of the ear to cover a three-layer defect of the nasal ala. The helix is an ideal donor site due to the color and texture match in addition to the graft's decreased propensity for shrinkage. There is also minimal morbidity associated with a helix donor site. The

authors excised the nasal alar tumor, created a template of the defect, and used that template to excise the graft on the helix of the ear. The graft was placed in the recipient bed and fixed with simple sutures. The composite graft was also punctured with a scalpel blade to prevent venous congestion. The wound was then dressed with gauze moistened with heparin. Dressing was replaced every 12 h. At postoperative days 1–2, when the graft becomes blue as an indication of venous congestion, additional puncturing can be completed at this time. Patients should be advised that bleeding from the edge of the wound is normal due to the heparin dressings [73].

Reconstruction of full-thickness alar rim defects is reported to be particularly challenging when multiple cosmetic subunits are involved, especially the soft ones (5) [77, 78]. Common pitfalls in this area include collapse of the nasal valve and notching or thickening of the alar rim. To address these, one manuscript describes the use of a cheek interpolation flap and composite skin graft. The flap was used in conjunction with the graft to improve blood supply and thus graft survival. Composite grafts predominantly draw their nutritional supply from the wound edges, and thus large alar rim defects such as those with high metabolic requirements would likely eventuate in graft failure if used alone. Other options include nasalis-based subcutaneous island pedicle flap, a turndown nasal hinge flap (to recreate mucosal lining), a FTSG, as well as combination repairs that utilize mucosal advancement flaps plus batten cartilage graft and overlying interpolation flaps. Paramedian forehead and cheek interpolation flaps with distal flap folding to provide nasal lining are also useful although they would result in excessive tissue bulk. For this combined flap and graft procedure, the cartilage was harvested with the skin en bloc with underlying cartilage being approximately 5 mm oversized. Two subcutaneous pockets were created on the alar rim to allow insertion and anchoring of cartilage. The interpolation flap was inserted into the de-epithelialized outer surface of the graft. The inner concave surface of the graft became the internal lining of the nasal vestibule. The partial de-epithelialization enhanced graft viability by allowing imbibition of nutrients through the anterior surface of the graft in addition to wound edges. The interpolation flap was designed along the cheek such that it would reach the nasal tip without tension. The flap was undermined between the dermis and subcutaneous fat along the distal third and in the mid-fat for the middle third and deeply dissected at the proximal third to ensure fibers of the levator labi remained attached to the flap base. Additional flap thinning was performed at 2 weeks. At 3 months, the reconstruction demonstrated excellent contour and color match with no notching. Nasal aperture was patent [77]. Another application of the composite graft includes nasal perforation (2) [79].

Another study evaluated the use of the auricular composite graft in the context of secondary cleft lip nasal deformities (3) [80]. The procedure begins with marking of the auricular tissue and injection of anesthetic without epinephrine around the designed graft. Care is taken to avoid hydrodissection. The graft should be excised with the cartilage component being a few millimeters bigger than the skin component. The affected alar nose is then incised and the scar tissue is removed. The graft is carefully positioned and aligned with the edges of the defect. Measurements of nostril size were taken before and after the procedure on the right and left side. The study found statistically significant differences between the cleft and noncleft nostril at 1 year postoperatively, suggesting this technique may be a good alternative to address such nose deformities with rhinoplasty for the benefit of gaining additional alar length [80].

Columella lengthening also provides an appropriate clinical context for composite graft use and many techniques have been utilized in this regard. McIndo and Reese describe techniques that include the V-Y advancement flaps of prolabial scars. This method is efficacious; however, it creates significant scars and an abnormally wide columella. Forked flaps have also been described; however, these are also limited by an abnormally widened and scarred columella. Composite grafts are a viable option. In this case, a technique was used using conchal composite graft in the case of scar contracture of the upper

lip. Complications included necrosis in 3 cases (2%) and partial necrosis in 12 cases (8.7%). No infection and hematoma were reported (5) [81]. Additional uses of the composite graft include digital reconstructions and eyelid and eyebrow reconstructions.

Free Cartilage Graft

The free cartilage graft is comprised exclusively of cartilage and its overlying perichondrium. It is used to address both functional and aesthetic concerns. They are particularly useful in deep defects that require additional structural support to maintain function and aesthetically pleasing contours. They are therefore often used on the nose, particularly the distal nasal tip or ala and deep sidewall defects that involve loss of the lower lateral cartilage. They are also used on the eyes, lips, and ears. Donor cartilage is usually taken from the antihelix or conchal bowl but can also be taken from the nasal septum and costal joints [7].

Free cartilage grafts harvested from the conchal bowl may be taken from either the anterior or posterior aspects. In either approach, an incision of the skin is made after which a strip-, disk-, or oblong-shaped piece of cartilage is harvested. The antihelical donor site is typically harvested anteriorly. The method for securing the graft is case dependent. For narrow strips, the recipient bed tissue is undermined medially and laterally to allow insertion of either end of the graft. Sutures are used to further secure the graft.

A 2016 case series reports on the use of the scapha cartilage graft with small skin on a vascularized propeller flap, the latter of which have been reported to be increasing in popularity. One of their most important advantages is that they are easy to manipulate and may be harvested from less invasive sites on relaxed skin tension lines (4) [82]. For the lips, a recent study reports on the correction of the lower lip with cartilage graft and lip resection in patients with muscular dystrophy (4) [83]. For the first time, these authors report use of an auricular cartilage graft for this repair which boasts of several advantages that include the less invasive nature of the procedure and the longevity of its effects [83]. In regard to the ears, Friedman and Coblens report on the use of a conchal cartilage butterfly graft for repair of nasal valve collapse, which has been reported to be superior to other options such as spreader grafts in regard to cosmetics of the nasal tip and supratip (4) [84]. On the ears, reconstruction of moderately constricted ears has been reported by combining a V-Y advancement of helical root, conchal cartilage graft, and mastoid hitch (5) [85]. For the nose, recent reported indications include nasal septum perforation and full-thickness alar defects when used in combination with a reverse nasolabial flap (5) [86, 87]. The free cartilage graft has also been reportedly utilized without being paired with a flap but, rather, with second-intention healing (5) [88]. In this case, a 42-year-old male presented with a 1-cm full-thickness right-alar surgical wound after removal of a basal cell carcinoma by Mohs surgery. The anterior auricular skin was incised and elevated, and cartilage graft was excised in full thickness, removed, and placed in saline-soaked gauze, after which the skin was reapproximated and closed primarily. The graft was then secured into the recipient site using 5–0 Monocryl. Petrolatum was then placed liberally on both the skin and nasal vestibule mucosal surfaces and covered with Telfa. The patient was instructed to remove the dressing after 48 h and gently cleanse the wound twice daily followed by liberal reapplication of petrolatum to skin and mucosal surfaces followed by coverage with a Band-Aid. Once the adhesive strips on the ear began to fall off, the patient was instructed to cover the wound with petrolatum and a Band-Aid for 1 week. After 6 weeks, the full-thickness alar defect completely healed and did not require revision. There were no functional or cosmetic complaints [88].

Conclusion

Since their first use approximately 3000 years ago, skin grafts have undergone an evolution that has secured their position in the reconstructive ladder. They have become increasingly versatile

and can be utilized in a variety of patient-specific scenarios. The widest breadth of uses exists for the STSG due to their size and decreased metabolic demands, although the FTSG and free cartilage grafts are also utilized in an increasing assortment of clinical settings.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development, and Evaluation (GRADE).

Findings	GRADE score: quality of evidence
In the context of skin cancer, the FTSG should not be utilized if there is increased risk for recurrence, as view of the site and chances of visualizing will be obstructed	D
Grafts should be considered in patients without sufficient surrounding tissue reservoirs to allow local flap reconstruction	D
Recently reported options for deep nasal defects include a flap (muscle[B], dermal[B], mucosal[C]) with overlying FTSG or cartilage graft	B,B,C
While nasal defects are often repaired with tissue from preauricular, post-auricular, supraclavicular, clavicular, conchal bowl, melolabial fold, and upper eyelid skin, forehead grafts may be thicker and a more appropriate match for deeper nasal defects than traditional graft sources	C
Cosmesis for the STSG may be improved by softening the cut angle from 90° to 45°. This allows for the graft edges to drape over and better adapt to the edges of the wound	C
The wound VAC has been reported in various studies to improve take and viability of grafts by decreasing wound edema, improving graft-recipient site tissue apposition, stimulating granulation tissue, and decreasing bacterial colonization	B
Techniques reported for optimal management of the STSG donor site include ice, tumescent anesthesia, and PRP	B

Self-Assessment Questions

1. Relative to the STSG, the FTSG should be used for _____ repairs.
   (a) Larger.
   (b) Smaller.
   (c) Size of the defect need not be considered when choosing a type of graft for repair.
2. Which type of skin graft results in better cosmesis?
   (a) FTSG.
   (b) STSG.
3. T/F: It is important to cut the graft such that it almost exactly matches the size of the defect.
   (a) True.
   (b) False.
4. What anatomic location should be harvested to allow for the greatest amount of shrinkage?
   (a) Anti-helix.
   (b) Free edge of nasal ala.
   (c) Lower eyelid.
   (d) Lip.
5. What surgical techniques are important considerations for primary closure on the scalp?
   (a) Galeal undermining.
   (b) Ensuring the defect is under 3 cm.
   (c) Avoid primary closure in the periocular region due to contraction.
   (d) All of the above.

Correct Answers

1. b: Smaller. The FTSG has higher metabolic need due to the presence of adnexal structures, and therefore the risk of necrosis increases with size of the graft.
2. a: FTSG.
3. b: False. To accommodate for graft shrinkage, a graft 3–5% larger than the template is usually harvested.
4. c: Lower eyelid. Graft should be harvested to allow for a greater amount of shrinkage to allow for contraction and avoid ectropion. Other locations have increased risk for poor cosmetic outcomes given that they are free margins; however, ectropion has the capacity to lead to functional impairment as well.
5. d: All of the above.

Linear Repairs

12

Reason Wilken, Farzam Gorouhi, Samantha Ellis, and Daniel B. Eisen

Abstract

For surgeons, there are multiple factors informing the decision of which techniques and epidermal closure materials should be used when closing specific defects in the skin. Major factors include the functionality and appearance of the scar, as well as the incidence of complications (e.g., infection, wound dehiscence, suture abscesses) among different surgical techniques. Other important considerations include the time taken to perform the closure, the cost of materials, and patient-specific factors, such as differences in postoperative care regimens and the need to return for removal of non-absorbable sutures.

Introduction

For surgeons, there are multiple factors informing the decision of which techniques and epidermal closure materials should be used when closing specific defects in the skin. Major factors include the functionality and appearance of the scar, as well as the incidence of complications (e.g., infection, wound dehiscence, suture abscesses) among different surgical techniques. Other important considerations include the time taken to perform the closure, the cost of materials, and patient-specific factors, such as differences in postoperative care regimens and the need to return for removal of non-absorbable sutures.

In this chapter, we will review the level of evidence supporting various primary closure techniques. These techniques pertain to repairing simple cutaneous defects resulting from traumatic lacerations, extirpation of cutaneous malignancies, and excision of benign neoplasms. This includes comparisons of deep dermal suture materials and associated suturing techniques as well as comparison of techniques for epidermal closure with sutures versus adhesive strips, tissue adhesives, or staples.

In conducting this review, a total of 35 articles comparing various methods of linear closure were assessed to determine eligibility for inclusion. These articles consisted of randomized controlled trials (RCTs) comparing two or

more techniques for linear repair of cutaneous defects on the scalp, face, and body resulting from traumatic lacerations, Mohs micrographic surgery, excision of malignant cutaneous tumors, or excision of benign neoplasms. The demographics and comparability of the study subgroups, characteristics of the defects (size and anatomic site), methods of randomization, outcome measures, and methods of statistical analysis were evaluated in all studies. Six studies were excluded based on lack of true randomization (two studies), defects not resulting from cutaneous surgery or laceration repair (one study), comparison of outcomes resulting from different excision methods rather than closure methods (two studies), and evaluation of a homemade suture material that is not commercially available in the United States (one study). Thus, a total of 29 randomized controlled trials were included in this chapter.

Comparison of Single-Layer Closure (Transcutaneous Suture Traversing Both the Epidermis and Dermis) Versus Bilayer Closure (Single-Layer Closure with the Addition of a Buried Subcuticular Suture Layer)

Four studies were reviewed that compare single-layer closures to bilayer closures for linear repair of cutaneous defects (Table 12.1).

Indications for Procedure

Both single- and bilayer closures are considered when two important criteria are met: the patient, or caregiver, desires the wound to be closed and there is enough skin laxity to accomplish this type of wound closure. It was previously thought that bilayer closures result in less epidermal wound tension and thus generate more aesthetically pleasing scars. Consequently, if the treating surgeon had the training to perform a bilayer closure, this technique would be preferred by those who prioritize cosmetic results.

Effectiveness of Procedure

Singer et al. examined the cosmetic outcomes in 65 patients following facial laceration repairs with single-layer closures (32 patients) and bilayer closures (33 patients) [1]. All patients completed the study follow-up. The primary outcome measure was cosmetic appearance at 3 months as judged on a 100 mm visual analog scale (VAS) by both patients and blinded physician evaluators. There was no significant difference in the patient (95% confidence interval (CI) of 68.9, for single-layer versus 68.5 for bilayer closure, $p = 0.88$) or physician-reported (76.8 versus 75.8, $p = 0.73$) VAS scores at 3 months. In addition, there was no significant difference in scar width at 3 months (mean width of 1.2 mm for single-layer versus 1.4 mm for bilayer closure, $p = 0.11$) noted between the two groups. However, it was noted that the average time of closure for single layers was significantly shorter (14.7 min) as compared to bilayer closures (21.6 min, $p = 0.007$). For facial lacerations, single-layer closures are significantly faster and result in similar cosmesis as bilayer closures (*Level of evidence: 1b*).

Sadick et al. compared the outcomes of conventional bilayer closure compared to single-layer closure with a modified vertical mattress suture (VMS) technique on cutaneous defects in a high-tension area of the body (the upper back) resulting from excision of benign or atypical nevi [2]. One hundred patients were enrolled in the trial (50 patients per group), with the primary outcome measures being patient satisfaction and complication rate (infection, hypertrophic scarring, suture reaction, and scar spread >3 mm). All patients completed follow-up, and no significant differences were noted regarding patient satisfaction, infection, wound dehiscence, or suture reaction between the two groups. Patients in the modified vertical mattress suture group had significantly decreased incidence of hypertrophic scarring (2% compared to 16% in the bilayer group, $P = 0.031$) and scar spread (6% versus 24% in the bilayer group, $P = 0.02$). However, this study did not specify the follow-up duration (*Level of evidence: 2b*).

Table 12.1 Suture versus suture

Study: first author and year	Study design	Number of patients who enrolled and completed study (% follow-up)	Outcome measures	Follow-up interval	Results	Level of evidence
Singer 2005 [1]	Parallel-group RCT comparing single-layer and bilayer closures of facial lacerations	65 (32 single layer, 33 bilayer) enrolled. 65 completed follow-up (100%)	Cosmetic appearance on 100 mm VAS rated by patients and blinded physician observers	3 months	No significant difference in patient-reported (68.9 versus 68.5, $P = 0.88$) or physician-reported (76.8 versus 75.8, $P = 0.11$) VAS scores for single- and bilayer closure	1B
Sadick 1994 [2]	Parallel-group RCT comparing single-layer with modified vertical mattress (VMS) to bilayer closure	100 (50 single layer, 50 bilayer) enrolled. All completed follow-up (100%)	% of patients satisfied Complication rate (infection, wound dehiscence, hypertrophic scarring, suture reaction, and scar spread >3 mm)	Not specified	No significant difference in patient satisfaction between single-layer closure and modified VMS No significant difference in infection, wound dehiscence, or suture reaction Significantly less hypertrophic scarring (2% versus 16%, $P = 0.02$) and scar spread (6% versus 24%) in single-layer modified VMS group	2B
Ling 2015 [3]	Randomized split-scar study comparing single-layer (1LT) versus modified bilayer (M2LT) versus standard bilayer (S2LT)	Total of 214 excisions (in 161 patients) enrolled: 116 excisions in the 1LT:S2LT group and 98 excisions in the S2LT:M2LT group 83 of 1LT:S2LT (72%) and 79 of the S2LT:M2LT (81%) excisions completed 6-month follow-up	Cosmetic appearance on 100 mm VAS, the Observer's Scale (OS), Patient Scar Scale (PS), and Stony Brook Scar Evaluation Scale (SB) rated by patients and blinded physician observers at 6 months	Suture removal at 2 weeks 6 months	S2LT slightly superior to 1LT on all four rating scales, but not statistically significant M2LT superior to S2LT on the VAS (85.9 versus 83.3, $P = 0.04$) and SB Scale (4.4 versus 3.3, $P = 0.0001$) Due to split-scar design, could not compare rates of wound complications between groups	2B

(continued)

Table 12.1 (continued)

Study: first author and year	Study design	Number of patients who enrolled and completed study (% follow-up)	Outcome measures	Follow-up interval	Results	Level of evidence
Kannan 2016 [4]	Parallel-group RCT in scalp lacerations comparing bilayer closure to single-layer closure with pulley sutures	21 patients enrolled (11 to bilayer, 10 to pulley suture). All patients completed 6-month follow-up (100%)	Scar assessment with Patient and Observer Scar Assessment Scale (POSAS) at all follow-up visits Single blinded assessor rating on 10 mm VAS of photographs from 6-month follow-up visits Mean repair time	Suture removal at 2 weeks Long-term at 2 months and 6 months	POSAS score for pulley suture deemed superior to bilayer closure at the 2-month (3.1 ± 1.5 versus 6.6 ± 2.3, $P < 0.001$) and 6-month visits (11.9 ± 3.2 versus 19.0 ± 7.7, $P = 0.015$) No significant difference in VAS scores of photographs (4.8 ± 2.6 in pulley versus 4.2 ± 1.9 in bilayer) Pulley suture group with significantly shorter mean time of repair (4.6 ± 1.5 min versus 10.0 ± 1.5 min, $P = 0.001$) No infections on either group. One hematoma and one wound dehiscence in pulley group (not significant)	1B
Wang 2015 [5]	Randomized split-scar study comparing subcuticular set-back sutures to buried vertical mattress sutures (BVMS) followed by adhesive tape for epidermal closure	46 patients enrolled, 42 completed 3-month follow-up (91%)	Cosmetic scar outcome on 7-point Likert Physician Global Scar Assessment scale and POSAS	3 months	Set-back sutures provided statistically significant wound eversion Set-back sutures deemed overall superior to BVMS (median score of 1 on Likert scale) Superior outcomes for set-back side in the POSAS score (13 ± 8.7 set-back versus 16.2 ± 12.0, $P = 0.039$) Near-significant decrease in spitting sutures on set-back versus BVMS sides (3 versus 11, $P = 0.058$) No significant difference in dehiscence (one wound, both sides) and infection (no patients)	1B

Table 12.1 (continued)

Study: first author and year	Study design	Number of patients who enrolled and completed study (% follow-up)	Outcome measures	Follow-up interval	Results	Level of evidence
Regan 2013 [6]	Parallel-group RCT comparing poliglecaprone 25 and polyglactin 910 for subcuticular closure	155 patients enrolled, 140 patients completed follow-up (90%)	Cosmetic appearance on 10 mm VAS Rates of suture extrusion and degree of scar lumpiness	1-week suture removal 1 month 2 months 3 months	No significant difference in VAS scores (1.8 poliglecaprone 25 versus 2.1 polyglactin 910) at 3 months Significant decrease in suture extrusion in poliglecaprone 25 group (3.1% versus 11.4%, $P < 0.01$) No significant difference in degree of scar lumpiness (both groups rated 22%) No reported infections or dehiscence	2B
Kia 2013 [7]	Randomized split-scar study comparing subcuticular closure with Poly-4 hydroxybutyrate (P4HB) versus polyglactin 910 suture	22 patients enrolled, 20 patients (23 defects) completed follow-up (91%)	Cosmetic outcome rated with 100 mm VAS and Hollander Wound Evaluation (HWE) scales Quantitative measurement of scar spread	Suture removal (time not specified) 3 months 2 months	Significantly decreased scar spread in P4HB group at 3 months (0.7 ± 0.7 mm versus 1.7 ± 2.5 mm, $P = 0.008$) and 12 months (0.9 ± 1.5 mm versus 3.2 ± 4.3 mm, $P = 0.001$) No clinically significant differences noted in the VAS scores at 3 months (69 ± 16 versus 62 ± 17, $P = 0.03$) or 12 months (72 ± 13 versus 62 ± 19, $P = 0.001$), though some components reached statistical significance No clinically significant differences in HWE scores at 3 months (4.2 ± 1.1 versus 3.8 ± 1.3, $P = 0.07$) or 12 months (4.0 ± 1.2 versus 3.7 ± 1.4, $P = 0.02$) Significantly more local suture reaction on P4HB halves compared to polyglactin 910 (35% versus 9%, P not specified)	1B

(continued)

Table 12.1 (continued)

Study: first author and year	Study design	Number of patients who enrolled and completed study (% follow-up)	Outcome measures	Follow-up interval	Results	Level of evidence
Kappel 2015 [8]	Randomized split-scar study comparing everted and planar closures	50 patients enrolled, 43 completed follow-up (86%)	Cosmetic appearance of scar on POSAS Scar height and width	3 months 6 months	No significant difference in total POSAS scores for everted and planar closures at 3 months (13.73 ± 5.41 versus 13.33 ± 6.06, $P = 0.62$) or 6 months (12.42 ± 4.73 versus 13.05 ± 5.60, $P = 0.10$)	1B
Rosenzweig 2010 [9]	Randomized split-scar study comparing epidermal closure with poliglecaprone 25 versus non-Prolene	52 patients enrolled, 44 patients (48 defects) completed follow-up (85%)	Global cosmetic appearance of wound halves relative to each other	1-week suture removal 4 months	85% of patients did not demonstrate any difference between two halves at 4 months. 10% had superior outcomes with non-absorbable Prolene®, and 4% had superior outcomes with poliglecaprone 25. None of the above were deemed significant ($P = 0.63$)	1B
Moody 2015 [10]	Randomized split-scar study comparing epidermal closure with running horizontal mattress (RHM) and simple running suture	55 patients enrolled, 47 completed study follow-up (86%)	Global cosmetic appearance of wound halves relative to each other	1-week suture removal 6 weeks 6 months	At 6-month follow-up, RHM was deemed superior in 53% of patients, equivalent in 36% of patients, and inferior in 11% ($P < 0.05$)	1B
Alam 2006 [11]	Parallel-group RCT comparing four types of epidermal closure: simple running Prolene® removed after 14 days, subcuticular Prolene® removed after 14 days, subcuticular Prolene® left in place, and subcuticular polyglactin 910 left in place	Enrolled 36 patients (each with 2 excisions for total of 72 wounds). All completed follow-up (100%)	Cosmetic appearance measured on 5-point ordinal scar scale and scar width (primary) Cosmetic appearance based on Vancouver Scar Scale (VSS) and Hollander Wound Evaluation (HWE) scores	2-week suture removal, where applicable 3 months 9 months	Statistically significant differences were detected in overall scar appearance between groups at 3 and 9 months ($P < 0.001$), vascularity ($P = 0.001$ at 3 months, $P < 0.001$ at 9 months), scar distortion ($P = 0.04$ at 3 months, $P < 0.001$ at 9 months), contour irregularity ($P < 0.001$ at 3 months), and wound edge eversion ($P = 0.01$ at 3 months) Subcuticular running polyglactin 910 left in place produced the best cosmetic outcome, followed by subcuticular Prolene® left in place.	1B

Ling et al. performed a randomized split-scar study following elliptical excision of benign and malignant cutaneous lesions on the head and neck, trunk, and extremities with three different interventions. One hundred and sixty-one patients (214 excisions) were enrolled comparing single-layer wound closure (1LT, consisting of simple interrupted monofilament nylon), modified two-layer closure (M2LT, consisting of interrupted deep dermal monofilament polyglyconate suture followed by cuticular closure with adhesive tape), and standard two-layer closure (S2LT, interrupted deep dermal monofilament polyglyconate suture followed by cuticular closure with simple interrupted monofilament nylon suture) [3]. Half of each wound was randomized to receive the standard two-layer closure and the other half would either receive the single-layer or modified two-layer closure. A total of 116 excisions compared 1LT:S2LT and 98 excisions compared S2LT:M2LT. A total of 83 of the 1LT:S2LT (72%) and 79 of the S2LT:M2LT (81%) of excisions completed 6-month follow-up, and outcomes assessed included cosmetic appearance of the scar as interpreted by the patient and blinded observers (measured with multiple validated instruments including a 100-point VAS, the Observer's Scar Scale (OS), Patient Scar Scale (PS), and Stony Brook Scar Evaluation Scale (SB)). At the 6-month follow-up, the standard two-layer closure was slightly superior to single-layer closure in the above outcome measures, but this was not statistically significant. Comparing the standard two-layer and modified two-layer closures (using adhesive tape for cuticular layer), the modified two-layer closure was shown to be statistically superior in terms of patient VAS score (85.9 versus 83.3, $P = 0.04$), Observer's Scar Scale ($p = 0.04$), and Stony Brook Scar Evaluation Scale (4.4 versus 3.3, $P = 0.0001$). This was attributed to the lack of cross-hatching when adhesive tape was used for the cuticular closure (*Level of evidence: 2b*).

Kannan et al. evaluated the closure of post-surgical scalp defects in 21 patients, comparing the use of a standard bilayer closure with 4-0 polyglactin 910 (Vicryl®) buried vertical mattress sutures (BVMS) to 3-0 nylon monofilament pulley sutures (11 randomized to the bilayer and 10 to the pulley suture group) [4]. The duration of the repair procedure was recorded, and follow-up assessments with the Patient and Observer Scar Assessment Scale (POSAS) were completed at three points in time (2 weeks, 2 months, and 6 months). All patients completed study follow-up. There was lack of consistency in the observer scores which the authors attribute to having different blinded observers perform the follow-up evaluations, and this was remedied by having a single blinded physician observer rate before and after photographs of the scars at the initial 2-week and 6-month follow-up visits according to a visual analog scale (VAS). The time for repair was found to be significantly shorter with the pulley suture technique as compared to bilayer closure (4.6 ± 1.5 min versus 10 ± 1.5 min, $p = 0.001$). The pulley suture technique was deemed superior to bilayer closure in terms of the blinded observer score at the 2-week and 6-month follow-up points (3.1 ± 1.5 and 11.9 ± 3.2 in pulley group compared to 6.6 ± 2.3 and 19.0 ± 7.7 for bilayer closure, $p < 0.001$ and $p = 0.015$, respectively). The VAS scores of before and after photographs failed to show any statistically significant difference between the bilayer and pulley groups (4.8 ± 2.6 and 4.2 ± 1.9). No infections were observed in either group, and two patients in the pulley group had wound-healing complications (one hematoma and one wound dehiscence). The conclusion of the study was that for scalp reconstruction, single-layer pulley sutures resulted in time and cost reduction compared to standard bilayer closure and there was no significant difference in scar appearance (*Level of evidence: 1b*).

Preoperative Evaluation

Determination of the most appropriate method of reconstruction (secondary intention healing, primary closure, or repair with a tissue flap or skin/cartilage graft) is primarily based on clinical evaluation by the treating surgeon. Variables such as the location and position of the defect relative to anatomic free margins, defect size, laxity of the surrounding tissue, and patient health (including comorbidities such as smoking and diabetes,

which may impact the success rate of reconstruction with a tissue flap or graft) will all factor into the surgeon's clinical decision-making process when selecting a mode of reconstruction. Evaluation of the thickness of the patient's dermis will determine if they are eligible for deep dermal sutures. Patients who are of advanced age or on long-term glucocorticoids may have extremely atrophic dermal tissue that will not hold deep dermal sutures. In general, single-layer and bilayer closures may be considered in cutaneous defects eligible for primary closure based on the surgeon's clinical determination of the above factors.

Best Techniques and Performance

In the study by Singer et al. [1], single-layer closure consisted of interrupted 6-0 polypropylene (Prolene®, Ethicon Inc.) cuticular sutures. Bilayer closure was performed with inverted deep dermal 5-0 polyglactin 910 (Vicryl®, Ethicon Inc.) sutures and interrupted 6-0 polypropylene (Prolene®) cuticular sutures.

Sadick et al. [2] performed bilayer closure with interrupted buried deep dermal 4-0 or 5-0 polyglactin 910 (Vicryl®) or polydioxanone (PDS®, Ethicon Inc.) suture followed by cuticular sutures. Single-layer closure was performed with a modified vertical mattress suture technique using 4-0 or 5-0 Vicryl® or PDS® suture. The modified vertical mattress suture was performed by inserting the needle in the near side of the wound through the deep reticular dermis at a depth of 5–8 mm, bringing the suture out to the skin surface 4–6 mm from the wound edge, and reinserting the needle through the same puncture site while angulating the suture to be placed more superficially in the dermis. The needle was then inserted into the far side of the wound at the equivalent superficial sub-epidermal level and brought out through the epidermis. Finally, the suture was reinserted through the same puncture site and angulated to exit at the equivalent level of the reticular dermis at a depth of 5–8 mm and finished with a buried surgeon's knot.

Single-layer wound closure in the study by Ling et al. [3] was performed with simple interrupted monofilament nylon. Modified two-layer closure was performed with interrupted deep dermal monofilament polyglyconate (Maxon™, Covidien) sutures followed by cuticular closure with adhesive tape. Standard two-layer closure was performed with interrupted deep dermal monofilament polyglyconate suture followed by cuticular closure with simple interrupted monofilament nylon suture.

In the study by Kannan et al. [4] bilayer closure was performed with 4-0 polyglactin 910 (Vicryl®) buried vertical mattress sutures followed with running 5-0 fast-absorbing plain gut suture (Fastgut®, Ethicon Inc.) for epidermal closure. Pulley sutures were performed by placing interrupted pulley sutures using 3-0 nylon monofilament suture (Ethilon®, Ethicon Inc.) in the center of the wound to reduce tension and subsequent placement of horizontal mattress sutures on the wound ends with the same 3-0 nylon suture.

Safety

In the study by Singer et al. [1], there were no incidences of wound infection or dehiscence reported in either the single-layer closure group (32 patients) or the bilayer repair group (33 patients) during the 3-month follow-up period.

Sadick et al. [2] compared the rates of infection, hypertrophic scarring, wound dehiscence, suture reaction, and wound spread (defined as scar diameter >3 mm) between the bilayer closure (50 patients) and modified vertical mattress (50 patients) groups. It was noted that the rate of wound infection was not significantly different in the bilayer closure (4%) and modified vertical mattress suture (6%, P = not statistically relevant) groups. In addition, the rates of wound dehiscence (2% versus 6%) and suture reaction (4% versus 6%) were not significantly different between the two groups. However, it was noted that the incidence of hypertrophic scarring was significantly higher in the bilayer closure group

(16% versus 2%, $P < 0.031$), as was development of a spread scar (24% versus 6%, $P < 0.02$).

Due to the split-scar design of the study by Ling et al. [3], it was not possible to directly compare the rates of complications (including wound infection, dehiscence, and hematoma) between the single-layer closure, standard bilayer closure, and modified bilayer closure groups. The study had an overall infection rate of 3%, with two of the six wound infections occurring in the defects closed with single-layer/standard bilayer closure (95 wounds) and four occurring in the modified bilayer/standard bilayer closure group (83 wounds). The overall rate of suture spitting was 1.5% and occurred in a total of three wounds (two in the single-layer/standard bilayer group and one in the modified bilayer/standard bilayer cohort). Wound dehiscence occurred in total of three patients (1.5%), and all occurred in the modified bilayer/standard bilayer group.

In the study of scalp wounds by Kannan et al. [4], the incidence of wound infection, dehiscence, and bleeding complications was compared between the bilayer closure (11 patients) and pulley suture groups (10 patients). No wound infections were reported in any of the study patients. One case of wound dehiscence occurred in the pulley suture group, as did one hematoma.

Postoperative Care and Follow-Up

If non-absorbable cuticular sutures are used in the repair, follow-up in 5–14 days (depending on anatomic site) is required for suture removal. If the epidermis is closed with absorbable sutures (either in a standard or subcuticular fashion) or adhesive tape is used, no return visit for suture removal is required.

Alternative Procedures and Modifications

Alternatives to linear repair with single or bilayer closure include healing via secondary intention, placement of a tissue (skin and/or cartilage) graft, and reconstruction with a cutaneous flap.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE).

Findings	GRADE score: quality of evidence
For closure of uncomplicated facial lacerations, repair with a single-layer closure may yield nearly equivalent cosmetic and functional outcomes to standard bilayer closure (which was found to be slightly superior, but not significantly so, in terms of scar appearance), with the advantage of saving a significant amount of time [1].	B
Single-layer closure using a modified vertical mattress technique may provide equivalent functional outcomes to standard bilayer closures, with the potential benefits of improved scar appearance (decreased hypertrophic scarring and development of a spread scar) [2].	C
Comparison of a standard two-layer closure (with absorbable deep dermal and interrupted non-absorbable cuticular sutures) was slightly superior to single-layer closure with non-absorbable cuticular sutures in terms of scar appearance (but not statistically significant). Scar appearance following modified two-layer closure (using adhesive tape for the cuticular layer) was statistically superior to standard two-layer closure in terms of scar appearance assessed through multiple validated assessment tools. The modified two-layer closure was also significantly faster to perform [3]. The study was limited by a high dropout rate (28% of the excisions comparing single-layer and standard two-layer and 19% of the excisions comparing the standard and modified two-layer closures), and by the split-scar study design, it was not possible to compare rates of dehiscence, postoperative symptoms, or wound infection between the three groups.	C
For closure of scalp defects, single-layer repair using a pulley suture technique was shown to be non-inferior to standard bilayer repair in terms of cosmetic outcome and complication rates. The pulley suture technique also decreased procedure duration and material cost compared to bilayer closure [4]. However, conclusions regarding the efficacy and safety of this technique are limited by the small number of enrolled subjects in this study.	C

Comparison of Types and Techniques for Placement of Deep Dermal Sutures

A total of four studies were reviewed comparing various techniques and materials for placement of deep buried subcuticular sutures in determining the functional and aesthetic scar outcomes (Table 12.1).

Indications for Procedure

Indications for the placement of deep dermal sutures are similar to single- or bilayered wound closure.

Effectiveness of Procedure

Wang et al. [5] conducted a split-wound study in 42 patients evaluating the scar appearance and wound eversion achieved with subcuticular set-back sutures compared to buried vertical mattress sutures for deep dermal closure. The cosmetic outcomes were evaluated by two blinded observers at the 3-month follow-up visit using the Likert physician global scar assessment scale. Additionally, observers and patients completed the total Patient and Observer Scar Assessment Scale (POSAS), where lower scores are given to scars that appear most similar to normal skin. The set-back suture provided statistically significant wound eversion, and the set-back suture side was rated 1 point better than the buried vertical mattress side. Moreover, the patient and observer total POSAS scores were significantly lower for the set-back suture side (mean score of 13 ± 8.7 compared to 16.2 ± 12.0, $P = 0.039$) (*Level of evidence: 1b*).

Regan and Lawrence [6] performed a parallel-group study in 140 patients comparing poliglecaprone-25 (Monocryl®, Ethicon Inc.) and polyglactin 910 (Vicryl®) deep dermal sutures for closure of Mohs defects. The method of epidermal closure was via placement of cuticular sutures, but the type and technique varied among the participants in the trial. The rates of suture extrusion, degree of scar lumpiness, and cosmetic appearance of scars at 3-month follow-up (on a 10-point visual analog scale) were compared between the two groups. A significant decrease in the rate of suture extrusion was observed in the poliglecaprone-25 group as compared to polyglactin 910 (3.1% versus 11.4%, $P < 0.01$). There was no significant difference in scar lumpiness between the two groups (both 22%) or scar appearance at 3 months (10-point VAS scores of 1.8 and 2.1, respectively) (*Level of evidence: 2b*).

In a split-scar study of 23 wounds in 20 patients, Kia et al. [7] examined the use of long-acting absorbable suture composed of poly-4-hydroxybutyrate (P4HB, MonoMax®, B. Braun Melsungen AG) to standard polyglactin 910 (Vicryl®) for closure of high-tension defects resulting from cutaneous malignancy excisions on the trunk. Outcome measures included quantitative scar spread as well as qualitative assessment with a 100-point visual analog scale (VAS) and Hollander Wound Evaluation Scale (HWE) at 3- and 12-month follow-up points. Significantly lower average scar spread was noted in the P4HB wound halves at 3 and 12 months (0.7 mm ± 0.7 mm and 0.9 mm ± 1.5 mm, respectively) as compared to polyglactin 910 (1.7 mm ± 2.5 mm and 3.2 mm ± 4.3 mm, respectively). Investigators did not note any clinically significant differences in the VAS (PH4B scores of 69 ± 16 and 72 ± 13 versus 62 ± 17 and 62 ± 19 in polyglactin group, $P = 0.03$ and $P = 0.001$) or HWE scores (4.2 ± 1.1 and 4.0 ± 1.2, in PH4B halves versus 3.8 ± 1.3 and 3.7 ± 1.4 for polyglactin 910, $P = 0.07$ and $P = 0.02$) at 3 and 12 months, respectively. Though some of the components reached statistical significance, the difference did not reach a predetermined level of clinical significance (*Level of evidence: 1b*).

Kappel et al. [8] performed a randomized, split-scar study in 43 patients comparing cosmetic outcomes of everted (accomplished via dermal set-back or inverted vertical mattress sutures) versus planar closure (with simple buried cuticular suture) following treatment for cutaneous malignancy with either a Mohs surgical

procedure or elliptical excision. The main outcome measure was scar appearance as judged by two blinded observers on the POSAS scale at the 3- and 6-month follow-up visits. In addition, scar height and width were measured at each follow-up visit. No significant difference in total POSAS scores was seen for everted and planar closures at 3 months (13.73 ± 5.41 versus 13.33 ± 6.06, $P = 0.62$) and 6 months (12.42 ± 4.73 versus 13.05 ± 5.60, $P = 0.10$). In addition, no statistically significant differences in scar height and width were observed between the everted and planar closure halves at the 3- and 6-month follow-up times (everted heights 2.17 ± 1.07 mm and 2.0 ± 0.96 mm compared to planar heights 1.90 ± 0.98 mm and 2.03 ± 1.10 mm, respectively, $P = 0.20$ and $P = 0.77$; everted width 2.40 ± 1.17 mm and 1.93 ± 0.97 mm compared to planar width 2.18 ± 1.2 mm and 2.08 ± 1.16 mm, respectively, $P = 0.29$ and $P = 0.27$) (*Level of evidence: 1b*).

Preoperative Evaluation

Preoperative evaluation for the placement of deep dermal sutures is similar to single- or bilayered wound closure.

Best Techniques and Performance

In the split-scar study by Wang et al. [5] comparing subcuticular set-back sutures to buried vertical mattress sutures (BVMS), polyglactin 910 (Vicryl®) suture was used for all subcuticular closures except for one in which a protocol violation occurred and polydioxanone (PDS®) was used. The size of the subcuticular suture varied according to wound location and surgeon preference but was kept consistent between both sides of each wound. The set-back sutures were placed on the underside of the dermis at the dermal-subcutaneous junction to produce wound eversion upon securing the buried knot. The first throw of the set-back suture enters and exits the undermined surface of the dermis. The BVMS were placed in standard fashion, with the first throw entering the undermined surface of the dermis on the near side of the wound and exiting through the vertical edge of the dermis, before entering the dermis at the equivalent level on the far side and exiting on the undermined dermal surface where the final knot was buried. The protocol dictated cuticular closure with adhesive strips to minimize any confounding factors such as track marks from epidermal placement of sutures. Adhesive strips were used to close all but six wounds in which protocol violations occurred and cuticular closure was accomplished with rapid absorbing gut or polyglactin 910 sutures (however, these were still included in the analysis because the treatment was consistent on both sides of the wound).

In the parallel-group study by Regan et al. [6], subcuticular closure was accomplished via placement of interrupted deep dermal sutures with either poliglecaprone-25 (Monocryl®) or polyglactin 910 (Vicryl®). The authors did not specify the suture sizes used in the study. Epidermal closure was accomplished via placement of cuticular sutures, which was variable according to surgeon preference and not specified in the study.

In the split-scar study by Kia et al. [7], wound halves were randomized to subcuticular closure with 3-0 intradermal P4HB (MonoMax®) or 3-0 intradermal polyglactin 910 (Vicryl®). Cuticular closure was accomplished with polypropylene suture (size and cuticular suture method not specified by the authors).

In the split-scar study by Kappel et al. [8], the deep dermis on the everted wound halves was closed with either dermal set-back sutures (described previously in the study by Wang et al. [5]) or inverted vertical mattress sutures using 3-0, 4-0, or 5-0 polyglactin 910 (Vicryl®) sutures depending on the surgeon's judgment. The wound halves in the planar closure group received subcuticular closure with a simple buried cuticular suture. For all wounds, cuticular closure was accomplished with adhesive strips (Steri-Strips™, 3 M™).

Safety

In the study by Wang et al. [5] of 42 patients, no wound infections occurred. One wound located on the nuchal neck dehisced (on both sides). There was noted to be a decrease in the incidence of spitting sutures on the wound halves closed with set-back sutures (three patients) as opposed to the BVMS wound halves; this approached but did not reach significance (11 patients, $P = 0.058$).

Regan et al. [6] did not report any cases of wound infection or dehiscence in the 140 patients studied. The only postoperative complication reported was the rate of suture extrusion, which was found to be lower in the poliglecaprone-25 group as compared to the polyglactin 910 group ($P = 0.058$).

In their comparison of P4HB and polyglactin 910 sutures, Kia et al. [7] reported significantly more local suture reactions on the PH4B wound halves. In total, 8 out of 23 (35%) of PH4B wound halves developed erythema consistent with local suture reaction compared to 2 out of 23 (9%) of the polyglactin 910 halves. The authors theorized that the extended duration of the PH4B suture was the major factor contributing to the increase in local suture reactions observed. One patient developed a postoperative hematoma complicated by secondary dehiscence that was isolated to the polyglactin 910 side of the wound.

No postoperative complications (including wound infection, hematoma, and wound dehiscence) were reported by the authors in the split-scar study of wound eversion versus planar closure by Kappel et al. [8]

Postoperative Care and Follow-Up

As the deep dermal sutures are composed of absorbable material such as polyglactin 910 (Vicryl®), poliglecaprone (Maxon®), and poly 4-hydroxybutyric acid (P4HB, MonoMax®), a postoperative visit for suture removal is only indicated if non-absorbable cuticular sutures were placed. Placement of absorbable subcuticular sutures may however result in suture "spitting" if the suture material extrudes through the skin during the healing process, necessitating removal of the extruded suture as well as drainage of any purulent material that may have accumulated. In addition, postoperative antibiotics may be required in the event of suture abscess development at the discretion of the treating surgeon.

Alternative Procedures and Modifications

Alternatives to bilayer wound closure include healing via secondary intention as well as single-layer closure.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE).

Findings	GRADE score: quality of evidence
Use of dermal set-back sutures for subcuticular closure as described by Wang et al. [5] was associated with superior wound appearance as well as a significant decrease in the incidence of spitting sutures when compared to buried vertical mattress sutures (BVMS). Surgeons should consider their use. However, future studies would help better define both the benefits and harms of the set-back and buried vertical mattress suture technique.	B
Comparison of poliglecaprone 25 (Monocryl®) and polyglactin 910 (Vicryl®) subcuticular sutures as described by Regen et al. [6] demonstrated equivalent scar appearance and lumpiness at 3-month follow-up; however, use of poliglecaprone 25 was associated with a significant decrease in the incidence of spitting sutures as compared to polyglactin 910, indicating poliglecaprone 25 may be a superior choice. Future studies collaborating the results of Regen et al. would help improve the confidence of their conclusions.	C

Findings	GRADE score: quality of evidence
Comparison of long-acting absorbable suture poly-4-hydroxybutyrate (P4HB, MonoMax®) versus polyglactin 910 (Vicryl®) by Kia et al. [7] demonstrated equivalent scar appearance at 3 and 12 months as measured on a visual analog scale. Though the P4HB suture was associated with decreased scar width, it also demonstrated a significantly increased incidence of local suture reactions. Given equivalent cosmetic outcomes and higher complication rates with P4HB, surgeons may consider polyglactin 910 to be preferable, until further studies can be conducted.	B
Split-scar comparison of everted versus planar closure by Kappel et al. [8] failed to demonstrate a significant difference in scar appearance, scar height, and scar width at 3 and 6 months. Since many of the closures were performed off the head and neck area, more study is needed before final conclusions can be drawn on the efficacy of wound edge eversion in those locations.	B

Comparison of Types and Techniques for Placement of Cuticular Sutures

A total of three studies comparing the scar outcomes achieved with various suture types (absorbable versus non-absorbable) and techniques for cuticular closure were reviewed (Table 12.1).

Indications for Procedure

Re-approximation of the epidermis is thought to be important for ensuring optimal cosmetic outcome of the resultant scar and quick wound healing. It is indicated where cosmetic outcomes are valued or where there is a gap between the wound edges after placement of buried deep dermal sutures.

Effectiveness of Procedure

Observing that there is often enough absorbable suture remaining to utilize for cuticular closure following placement of the subcuticular sutures, Rosenzweig et al. [9] conducted a split-scar study that examined the cosmetic results of facial Mohs defects following superficial closure with 5-0 poliglecaprone-25 absorbable suture (Monocryl®) compared to 6-0 polypropylene (Prolene®) placed in a simple running fashion. A total of 52 patients with 52 Mohs defects were enrolled, and 44 patients (48 Mohs defects) completed the study. The outcome measure was the global cosmetic appearance of each wound half relative to the other at the 1-week (following suture removal) and 4-month mark, by a blinded physician evaluator. At the 4-month follow-up, 85% of patients did not demonstrate any difference between the 5-0 poliglecaprone and 6-0 polypropylene sides of the wounds. A total of 10% of patients had cosmetically superior outcomes with 6-0 polypropylene, and 4% demonstrated better cosmetic appearance with 5-0 poliglecaprone. Neither of these differences in cosmetic outcome were statistically significant between the two suture types ($P = 0.63$). The authors advocated for consideration of using remaining absorbable suture to complete cuticular closure to reduce waste and promote cost savings (estimated $6.00 per package of 6-0 polypropylene per patient), but did not directly compare mean cost of repair in this study (*Level of evidence: 1b*).

In a split-wound study, Moody et al. [10] compared the cosmetic outcomes of a running horizontal mattress (RHM) suture and simple running suture for epidermal closure of facial Mohs defects in 55 patients, 47 of which completed the study. All defects had the same method of deep dermal closure with interrupted 4-0 or 5-0 poliglecaprone (Monocryl®), and wounds were randomized to have either the superior or inferior half closed with the RHM suture technique. The outcome was global cosmetic appearance of the wound halves at 1-week, 6-week, and 6-month follow-up points, and the wounds were assessed by a blinded observer to determine the cosmetically superior half. At the 6-month follow-up, the RHM half was deemed superior in 53% of patients, cosmetically equivalent in 36%, and worse in 11% of patients ($P < 0.05$). The authors postulated that the primary reason for the observed cosmetic superiority of RHM over simple running in this study was the

increased wound eversion afforded by the RHM suture (*Level of evidence: 1b*).

In a parallel-group randomized controlled study, Alam et al. [11] compared the cosmetic and functional outcomes of four types of epidermal closures following elliptical excision of atypical nevi on the trunk or extremities in 36 patients (who each had 2 atypical nevi that were excised for a total of 72 wounds): simple running polypropylene suture (Prolene®) removed after 14 days (control arm, 18 wounds); subcuticular running polypropylene suture removed after 14 days (18 wounds); subcuticular running polypropylene suture left in place (18 wounds); and subcuticular running polyglactin 910 sutures (Vicryl®) left in place (18 wounds). All patients completed the 9-month follow-up. The primary outcome measures were scar width and blinded observer ordinal scale assessment of overall scar appearance at 3- and 9-month follow-up points. Secondary endpoints included scores on the Vancouver Scar Scale and Hollander Scar Scale. No difference in scar width was noted between groups at 3 and 9 months. Statistically significant differences were detected in overall scar appearance ($P < 0.001$ at 3 and 9 months), vascularity ($P = 0.001$, $P = <0.001$ at 3 and 9 months, respectively), scar distortion ($P = 0.04$, $P < 0.001$), contour irregularity ($P < 0.001$ at 3 months), and wound edge eversion ($P = 0.01$ at 3 months). Subcuticular running polyglactin 910 left in place produced the best overall scar appearance followed by subcuticular running polypropylene left in place. The authors also performed a secondary analysis matching high-tension sites (back and lower leg) to high- and moderate-tension sites (chest and shoulders), which was consistent with the main analysis (*Level of evidence: 1b*).

Preoperative Evaluation

Consultation with the patient regarding their expectations regarding cosmetic outcomes, willingness to return for suture removal, and tolerance for extended procedure time will help the surgeon determine which cuticular suture technique, if any, would best meet the patient's needs.

Best Techniques and Performance

In the split-wound study by Rosenzweig et al. [9], the deep dermal layer of all wounds was closed with interrupted 5-0 poliglecaprone (Monocryl®) suture, and wound halves were randomized to receive epidermal closure with either the remaining 5-0 poliglecaprone suture or 6-0 polypropylene (Prolene®) suture placed in a simple running fashion.

In the split-scar study by Moody et al. [10], comparing the running horizontal mattress (RHM) technique to simple running epidermal closure, all wounds received the same deep dermal closure with buried vertical mattress 4-0 or 5-0 poliglecaprone (Monocryl®) sutures. The superficial layer was closed using 6-0 polypropylene (Prolene®) in all defects, with half of each wound randomized to receive RHM closure and the other half to receive simple running closure. The RHM suture was performed starting with a traditional interrupted suture at the wound apex, and then the needle was reinserted on the near side of the wound 2–4 mm along the long axis and 1–2 mm from the wound edge, exiting at an equivalent point on the opposite (far) wound edge. The needle position was then reversed in the needle holder and reinserted near the skin edge of the far side of the wound, exiting at an equidistant point on the near side. The process was repeated until the midpoint of the wound was reached at which point the suture was tied off. The remaining half of the wound was closed with a simple running suture.

In the study by Alam et al. [11], all wounds received comparable deep dermal closure with vertical deep 3-0 (for sites on the back) and 4-0 (for all other trunk and extremity sites) polyglactin sutures. All four cuticular closure subgroups were performed with 5-0 caliber suture: simple running polypropylene (Prolene®) removed in 14 days, subcuticular running polypropylene (Prolene®) removed in 14 days, subcuticular running polypropylene (Prolene®) left in place, and subcuticular running polyglactin 910 (Vicryl®) left in place.

Safety

In the study by Rosenzweig et al. [9], no wound complications (infection, hematoma, wound dehiscence) occurred in any of the 44 patients (48 defects) who completed the 4-month study follow-up.

In the study of running horizontal mattress (RHM) suture compared to simple running suture for epidermal wound closure, no instances of wound infection or dehiscence were reported in the 47 patients who completed the 6-month follow-up.

In the parallel-group comparison of four methods of cuticular closure by Alam et al. [11], the only adverse events reported out of a total of 72 wounds (18 per subgroup) were partial wound dehiscence and erosion in the center of wounds closed with running subcuticular polypropylene suture left in place that were noted at the 3-month follow-up visit.

Postoperative Care and Follow-Up

When non-absorbable cuticular sutures are placed, removal is required at a separate follow-up visit, ranging from post-op day 5 (defects on the face) to post-op day 14 (defects on the trunk and extremities).

Alternative Procedures and Modifications

Alternatives to placement of cuticular sutures for epidermal closure in wounds that are closed primarily include no epidermal intervention, the use of tissue adhesives (such as Dermabond®), adhesive strips (Steri-Strips™), or staples.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE).

Findings	GRADE score: quality of evidence
As described in the study by Rosenzweig et al. [9], cuticular closure with absorbable suture produced an equivalent cosmetic outcome to epidermal closure with non-absorbable suture in 85% of patients, 4 months postoperatively. This study supports the equivalence of absorbable suture (5-0 poliglecaprone) to non-absorbable suture (6-0 polypropylene) for epidermal closure of facial Mohs defects. Thus, surgeons need not incur the added expense of polypropylene sutures when already using poliglecaprone for subcuticular suturing.	B
In the comparison of a running horizontal mattress (RHM) suture versus simple running non-absorbable suture for epidermal closure of facial Mohs defects, Moody et al. [10] demonstrated cosmetically superior outcomes at 6 months with the RHM suture in 53% of patients and equivalence to simple running suture in 36% of patients. Though more studies are preferred before drawing final conclusions, RHM suturing appears to be superior to simple running cuticular suturing in terms of cosmetic results.	B
Looking at four different methods of cuticular closure (simple running polypropylene removed in 14 days, subcuticular running polypropylene to be removed in 14 days, subcuticular running polypropylene to be left in place, and subcuticular running polyglactin 910 to be left in place), Alam et al. [11] demonstrated the best cosmetic outcome with subcuticular running polyglactin 910 left in place, followed by subcuticular running polypropylene left in place. The authors observed that the absorbable polyglactin 910 suture produced less contour irregularity than the non-absorbable polypropylene when placed in a subcuticular fashion. Overall cosmetic outcomes for the polypropylene subcuticular sutures were improved when they were left in place instead of being removed on day 14. Given only one study has compared these three running subcuticular suturing interventions with traditional running cuticular suturing, more studies are again needed before final judgment can be determined regarding their comparative efficacies. However, it is reasonable to recommend that running subcuticular suturing with polyglactin 910 left in place be the preferred method of this type of suturing in patients with high cosmetic standards, until more studies are conducted.	B

Comparison of Sutures Versus Staples for Closure of Lacerations

A total of two studies were reviewed that compared the outcomes, time, and cost of laceration repair using either a disposable staple gun or a single layer of non-absorbable sutures (Table 12.2).

Indications for Procedure

Uncomplicated lacerations that are limited to the dermis and subcutaneous tissue without involvement of underlying structures (fascia, muscle, tendons, major vessels, and nerves) may be amenable to repair using staples or single-layer suture closure. More complex lacerations requiring a deep layer of sutures due to involvement of one of the abovementioned structures, as well as lacerations in cosmetically sensitive patients, may not be well-suited for closure with staples or a single layer of sutures.

Effectiveness of Procedure

Kanegaye et al. [12] compared the total costs and physician time requirements for repair of scalp lacerations with a disposable staple gun

Table 12.2 Sutures versus staples

Study: first author and year	Study design	Number of patients who enrolled and completed study (% follow-up)	Outcome measures	Follow-up interval	Results	Level of evidence
Kanegaye 1997 [12]	Parallel-group RCT comparing cost and repair time for laceration repair with staples versus single-layer suture	88 patients enrolled, 80 completed follow-up (91%)	Wound closure time and total cost of repair (materials and physician time) Patient-reported postoperative discomfort, provider-reported issues with removal	1 week for suture or staple removal	Stapling resulted in significantly shorter wound closure time (mean 65 s for staples versus 397 s for sutures, $P < 0.0001$) and lower cost of repair materials ($12.55 versus $17.59) and physician time ($23.55 versus $38.51, $P < 0.0001$) No significant difference in patient-reported postoperative pain ($P = 0.925$) Staples were more associated with increased difficulty of removal (9.8% of patients compared to 2.8% in suture group), not significant ($P = 0.24$)	1B
Orlinsky 1995 [13]	Parallel-group RCT comparing cost and repair time for laceration repair with staples versus single-layer suture	141 patients enrolled, 128 patients (161 lacerations) analyzed (91%)	Wound closure time (calculated as seconds per centimeter) Total cost of repair (materials and physician time)	No follow-up visit	Stapling resulted in significantly shorter wound closure time (8.3 s/cm versus 63.2 s/cm, $P = 0.0001$) and lower total cost of repair ($17.69 for stapling with suture kit, $7.84 without suture kit versus $21.58 for sutures) Repair time per centimeter decreased with increasing wound length	2B

compared to closure with a single layer of simple interrupted non-absorbable suture in 88 pediatric patients (aged 13 months to 16 years, 45 randomized to receive staples and 43 to suture closure) in an emergency department setting. A postoperative evaluation of the wounds was performed at 7 days in 80 patients (91% follow-up) at the time of suture or staple removal, and wounds were assessed for evidence of infection or dehiscence. In addition, parents were queried regarding the presence of postoperative symptoms (persistent pain), and the provider noted any difficulty with removal of the staples or sutures. No cosmetic or infectious complications were noted in either group, and no significant difference was noted in postoperative pain or complaints between the two groups ($P = 0.925$). There was a difference in the percentage of patients for whom the providers reported difficulties with removal (9.8% of patients in the staple group versus 2.8% in the suture group), but this was not statistically significant ($P = 0.24$). The authors found that stapling resulted in significantly shorter wound closure time (mean closure time of 65 s versus 397 s for sutures, $P < 0.0001$). In addition, the cost of staple repair was significantly less both in terms of equipment ($12.55 versus $17.59, $P < 0.0001$) and physician time ($23.55 versus $38.51, $P < 0.0001$), assuming an average compensation of $100/h for emergency department physicians (*Level of evidence: 1b*).

Orlinsky et al. [13] compared the cost and closure time for laceration repair using staples or single-layer closure with interrupted nylon sutures for wounds on the scalp, trunk, and extremities in 141 adult patients in an emergency department setting, and after excluding patients for which there was incomplete recording, a total of 161 lacerations in 128 patients were analyzed. The wound lengths, skin closure times, and number of sutures/staples used in each repair were recorded, and the cost for materials (subdividing the staple group into those in which a suture kit containing forceps, a needle driver, and scissors was used to assist with staple repair versus not used) as well as physician time (based on an hourly average of $74 for an emergency department physician) was calculated. The authors found that stapling was significantly faster than suturing (8.3 s/cm versus 63.2 s/cm, $P = 0.0001$) and that the time per centimeter decreased with increasing length of the laceration as plotted on a regression line, with the speed increasing at a more rapid rate in the staple group than the suture group ($P = 0.0001$). The average total cost for materials and labor per case was significantly lower in the staple group ($17.69 with suture kit and $7.84 without compared to $21.58 for suture repair). Notably, there was no follow-up visit or assessment of scar appearance, wound complications, or patient-subjective complaints discussed in this study. The authors stated that there was no difference in the cosmetic appearance or incidence of wound complications (infection, dehiscence) between the suture and staple groups; however, they did not report their data since some data was based on telephone reports and not direct observation (*Level of evidence: 2b*).

Preoperative Evaluation

In deciding the optimal method for laceration repair, the evaluating physician must do a thorough evaluation of both the patient and the wound to ensure that no foreign bodies are present (especially if the wound was sustained because of trauma) and there is no involvement of deeper structures such as fascia, muscle, tendons, major blood vessels, and nerves that require repair prior to closure of the skin. In addition, the location of the laceration should be considered, as wounds located in cosmetically sensitive areas such as the face may be better suited for bilayer closure. It is common practice for lacerations obtained from human or animal bite to remain open and heal by secondary intention.

Best Techniques and Performance

In the study by Kanegaye et al. [12], staples were placed using an automatic disposable sta-

pler (Precise DS-5 and DS-15, 3 M™, St. Paul, Minnesota). Wounds in the suture group were closed with a single layer of simple interrupted non-absorbable monofilament nylon or polypropylene sutures (size and manufacturer not specified).

Orlinsky et al. [13] utilized a disposable staple gun (Cricket 35 W, US Surgical Corporation, Norwalk CT) for the stapled closures and 4-0 nylon (Ethilon®) suture placed in an interrupted fashion (both simple interrupted and interrupted mattress) for cuticular closure.

Safety

Kanegaye et al. did not report any wound complications (infection or dehiscence) in either the staple or suture groups in the 80 patients (91%) that returned for 7-day follow-up and removal of staples/sutures.

Orlinsky et al. [13] did not report follow-up data (duration of follow-up, incidence of complications) but stated that there was no significant difference in the incidence of wound complications (infection, dehiscence) between the suture and staple groups. Because the actual data was not reported, it is not possible to assess the validity of this claim.

Postoperative Care and Follow-Up

If staples or non-absorbable sutures are used for the cuticular closure, the patient will need to return for a follow-up visit for removal, usually in 5–14 days, depending on the location of the laceration. If absorbable sutures were used, then the patient would not be required to return for removal.

Alternative Procedures and Modifications

Alternatives to single-layer closure with staples or sutures include bilayer repair with a deep subcuticular layer of absorbable sutures to reduce wound tension and re-approximate the dermis, as well as single-layer closure with tissue adhesive (such as Dermabond®), adhesive strips (Steri-Strips™) if it is determined that the patient is an appropriate candidate for a single-layer repair, or healing by second intention.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE).

Findings	GRADE score: quality of evidence
For closure of pediatric scalp lacerations in the emergency department setting, Kanegaye et al. [12] reported significant savings in wound repair time as well as equipment and physician time cost in the staple group as compared to single-layer suture closure, and there was no significant difference in the rate of wound complications (none in both groups), patient-reported postoperative pain, or provider-reported difficulty of removal. However, this study did not objectively evaluate the cosmetic outcome of staple versus single-layer suture closure and this may be a significant factor in deciding the optimal method of repair in certain patients.	C
Orlinsky et al. [13] reported significant decreases in the cost and time of laceration repair with staple closure as compared to interrupted single-layer closure in the emergency department setting. However, this study had several major limitations including lack of defined patient follow-up as well as absence of data evaluating the cosmetic appearance and incidence of wound complications in the two groups. Therefore, beyond the observations that stapling is significantly faster than suturing and is associated with significantly lower material and physician time costs, it is not possible to draw any conclusion related to wound outcomes for stapled closures versus single-layer suture repairs from this study.	C

Comparison of Tissue Adhesives Versus Sutures for Closure of Lacerations or Excisions

A total of five studies were identified that compared cutaneous defects repaired with various tissue adhesives, all containing a cyanoacrylate base, versus various suture types (Table 12.3).

Indications for Procedure

N-butyl-2-cyanoacrylate (n-BCA) and 2-octyl-cyanoacrylate (OCA) adhesives are indicated for closure of clean surgical incisions and uncontaminated or thoroughly cleaned lacerations that are limited to the dermis and superficial subcutaneous tissue [14]. Generally, defect size (less than 5 cm for lacerations), skin properties including

Table 12.3 Sutures versus tissue adhesives

Study: first author and year	Study design	Number of patients who enrolled and completed study (% follow-up)	Outcome measures	Follow-up interval	Results	Level of evidence
Göktas 2002 [15]	Parallel-group assessor-blind, single-center, randomized trial comparing N-BCA with 5-0 or 6-0 polypropylene cuticular suture	Unknown number enrolled, 52 patients completed the study (?%)	Patient and physician 10-point VAS overall assessment, satisfaction rate, cost	3 months	Comparable VAS score for patient satisfaction: 8.12 ± 1.32 versus 7.46 ± 1.20, $p > 0.05$ Higher satisfied patients in general in the adhesives group, 23 patients (95.8%) versus 18 (43.9%, $p = 0.007$) Higher assessor satisfaction for adhesives (24 [63.2%] versus 14 [36.8%], $p < 0.001$) Lower cost for adhesive: 15 of 24 in adhesive group had costs less than $10, versus none in suture group ($p < 0.0001$) No complications in either group reported	2B

Quinn 1993 [16]	Parallel-group assessor-blind, single-center, randomized trial comparing N-BCA with non-absorbable monofilament sutures	41 versus 40 enrolled in adhesive versus suture group; 37 versus 38 patients completed the study in their respective groups (90% and 95%)	Mean closure time Patient VAS overall assessment VAS pain score	Day 5 for suture removal 3 months	Lower mean closure time for adhesives (7.9 min versus 15.6 min, $P < 0.001$) No significant difference for100-point VAS patient global assessment (60.6 versus 57.2, $P = 0.45$) Lower VAS pain score for adhesive (24.7 versus 43.7; $P < 0.01$) Comparable complications: Wound infection (1/37 [2.7%] versus 1/38 [2.6%], $p > 0.05$) Wound dehiscence (3/37 [8.1%] versus 2/38 [5.3%], $p > 0.05$)	2B
Kim 2015 [17]	Within-patient assessor-blind, single-center, randomized trial comparing n-butyl and 2-octyl-cyanoacrylate, with fast-absorbing gut cuticular running suture	14 versus 14 half defects were enrolled in this study; all finished the trial (100%)	10-point VAS for overall cosmesis	3 months	No significant difference in 10-point VAS scores for cosmesis (7.47 ± 0.81 versus 7.97 ± 1.25, $p > 0.05$) No complications reported in either group	2B

Table 12.3 (continued)

Study: first author and year	Study design	Number of patients who enrolled and completed study (% follow-up)	Outcome measures	Follow-up interval	Results	Level of evidence
Tierney 2009 [18]	Within-patient assessor-blind, single-center, randomized trial comparing 2-octylethylcyanoacrylate with rapid absorbing gut cuticular suture	8 versus 8 half defects were enrolled in this study; all finished the trial (100%)	4-point physician overall assessment 4-point pigmentation and thickness	10 days 3 months	Comparable 4-point physician overall assessment (3.19 versus 3.56, $p > 0.05$. More pigmentation with adhesives, (2.75 versus 3.5, $p < 0.05$) and comparable thickness (3.75 versus 3.88, $p > 0.05$). No complications in either group	2B
Toriumi 1998 [19]	Parallel-group assessor-blind, single-center, randomized trial comparing 2-octyl-cyanoacrylate with vertical mattress nylon cuticular suture	54 versus 57 patients enrolled in adhesive versus suture group; unknown number completed the trial (?%)	Average closure time 100-point VAS overall cosmesis Mean modified Hollander scale	Suture removal at 5–7 days 3 months 12 months	Lower average closure time in adhesives (55 s versus 237 s, $p < 0.0001$) Better 100-point VAS overall cosmesis favoring adhesive group (21.7 ± 16.3 versus 29.2 ± 17.7, $p = 0.03$) Comparable mean modified Hollander scale (0.306 versus 0.235, $p = 0.51$) No wound infections or dehiscence in either group. One acute peri-wound erythema in suture group; more erythematous suture reactions in the suture group (but was not documented)	2B

tensile properties (ultimate tensile strength, strain energy, failure stretch rate, elastic modulus rate-avoiding high-tension areas), and degree of bacterial colonization (avoiding intertriginous and hair-bearing areas) are determining factors for a dermatologic surgeon to decide whether to use tissue adhesives for epidermal closure. It has been reported to be a less effective method of closure if the deeper structures, such as deep adipose tissue or fascia, are involved.

N-butyl and 2-octyl-cyanoacrylate solution is currently approved to treat minor cuts, scrapes, burns, and minor skin irritation. As described below, some surgeons use it for superficial repair of cutaneous defects following Mohs surgery or excision. When used for this indication, it is applied after buried subcuticular sutures have been placed.

Effectiveness of Procedure

Göktas et al. [15] performed a parallel-group assessor-blind trial to compare N-BCA (Histoacryl® Blue; Braun Melsungen AG, Melsungen, Germany) to 5-0 or 6-0 polypropylene cuticular suture in a Turkish cohort population with traumatic lacerations anywhere on the body measuring less than 5 cm. Patient overall satisfaction using a 1–10 VAS score showed no significant difference between two groups at the 3-month follow-up (8.12 ± 1.32 versus 7.46 ± 1.20, $p > 0.05$ for adhesive versus suture groups, respectively). Additionally, 23 patients (95.8%) in the adhesives group, as opposed to 18 patients in suture group (43.9%), were satisfied with the results at 3-month follow-up, and this difference was statistically significant ($p = 0.007$). A similar trend was observed when the assessors were asked about the overall satisfaction regarding the outcome (24 [63.2%] versus 14 [36.8%] for adhesive versus suture groups, respectively, $p < 0.001$). Furthermore, 15 out of 24 procedures that used adhesives had costs less than 10 dollars, whereas none of the patients in suture groups ended up having less than 10-dollar costs ($p < 0.0001$). This study lacks clear descriptions of the anatomical sites of the lacerations and when and how they used 5-0 versus 6-0 sutures, and more importantly, the study has a very high dropout rate (43.4%), which decreases the generalizability of the results (*Level of evidence: 2b*).

Quinn et al. [16] in another randomized assessor-blind controlled trial compared the efficacy and safety of N-BCA with 5-0 or 6-0 nonabsorbable monofilament sutures. The study included pediatric patients with clean facial lacerations that were less than 4 cm in length and 0.5 cm in width that did not need deep subcuticular closure. The mean laceration length for both groups was about 1.5 cm (0.5–3.5). The wounds involved the hair-bearing areas, and the ones that crossed the mucocutaneous juncture were excluded in this study. Interestingly, the study only included the patients who presented between 12 p.m. and 10 p.m. All wounds were covered with an unknown subtype of Elastoplast® bandage. Mean closure time differed significantly in favor of the adhesive group (7.9 min versus 15.6 min for adhesives, the suture group, respectively, $P < 0.001$). The patient global assessment using a 1–100 VAS showed comparable results (60.6 versus 57.2, $P = 0.45$). When the patients were asked their opinion of the result 3 months after the procedure, 59% found it acceptable and 30% found it excellent in the adhesive group versus 71% and 16%, respectively, in the suture group ($P = 0.76$). Adhesive was perceived as a significantly less painful procedure using a 1–100 VAS score (24.7 versus 43.7; $P < 0.01$) (*Level of evidence: 2b*).

Kim and colleagues [17] in a randomized within-patient study included a total of 14 patients who underwent Mohs micrographic surgery for non-melanoma skin cancer (NMSC) of the forehead, temple, or cheek. They compared n-butyl and 2-octyl-cyanoacrylate (both adhesives are present within the same solution) with fast-absorbing gut cuticular running suture. The patients additionally received 5-0 polyglactin 910 (Vicryl®) buried intradermal absorbing suture as well as Steri-Strips™ for both treatments. All patients returned for the final 3-month follow-up visit. All photographs were taken in the same clinic and under the same lighting conditions. Mean closure length was 4.2 cm. These photographs were rated by six blinded individuals (one general dermatologist, one Mohs surgeon, two

nurses, and two lay persons) using a 1–10 VAS for overall cosmesis. This assessment demonstrated no significant difference between treatments in terms of 10-point VAS scores (7.47 ± 0.81 versus 7.97 ± 1.25, for adhesive versus suture group, respectively, $p > 0.05$). Most patients indicated no preference for epidermal closure technique (64%, $n = 9$), but four patients favored cyanoacrylate and only one patient favored fast-absorbing gut suture (*Level of evidence: 2b*).

In a within-patient study, Tierney and colleagues [18] evaluated the efficacy and safety of 2-octylethylcyanoacrylate cuticular closure in comparison to rapid absorbing gut closure in eight patients with Mohs defects on the chest and upper extremities. The defects were all closed with 4-0 polyglactin 910 (Vicryl®) subcuticular suture. The lesion sizes were between 3.5 and 6.7 cm. A 4-point physician overall assessment score showed comparable results (3.19 versus 3.56, for adhesive versus suture treatments, respectively, $p > 0.05$). The four-point scale for pigmentation (2.75 versus 3.5, $p < 0.05$) and thickness (3.75 versus 3.88, $p > 0.05$) showed more pigmentation and thickness post-procedure in the adhesive group than the suture group, but only the pigmentation comparison reached statistical significance at the 3-month follow-up. A similar insignificant trend was observed when the assessors evaluated wound approximation (3.63 versus 3.75, $p > 0.05$). The observations at day 10 were not blind to the assessors (*Level of evidence: 2b*).

Toriumi and coworkers [19] studied utilization of OCA in 54 patients versus vertical mattress nylon sutures for epidermal closure in 57 patients with or without subcuticular closure for linear repair of excisions or scar revisions on the face and neck in a parallel-group project. Thirty-two out of 54 patients in the adhesive group (59%) and 34 out of 57 patients in the suture group (59%) received subcuticular sutures. The mean closure volume was 112 mm^3 (range: 1–1350 mm^3). The average closure time was significantly lower in the adhesives group (55 s versus 237 s, $p < 0.0001$). Using a 1–100 VAS for overall cosmetic outcome assessed by investigators showed significantly better results in the 2-OCA group as opposed to the suture group at 1-year follow-up (21.7 ± 16.3 versus 29.2 ± 17.7, $p = 0.03$). Mean wound evaluation scores measured by the modified Hollander scale were 0.235 for the suture group and 0.306 for the 2-octyl-cyanoacrylate group ($p = 0.51$) at 3-month follow-up (*Level of evidence: 2b*).

Preoperative Evaluation

In traumatic, uncomplicated, uninfected simple lacerations, the evaluating physician must irrigate and explore the wound and ensure there is no foreign body within the defect. Also, one must determine the depth of the involvement in deciding which method should be chosen for the closure. However, in complicated wounds such as those resulting from animal and human bites, the timing and method of closure are debatable. Some experts prefer to let these defects remain open and heal by secondary intention. Moreover, it is deemed more appropriate to use adhesives and adhesive tapes in the pediatric population, as this will provide the pediatric patient and the parents with a timelier and better-tolerated experience during the laceration repair and post-procedure follow-up.

In excision or Mohs defects, closure with adhesives is best avoided in the areas including skin over the joints, intertriginous, and hair-bearing areas. However, some surgeons choose to use adhesives or adhesive tapes as adjunct support methods.

It is also important to confirm that the patient does not have a history of a contact allergy to cyanoacrylates.

Best Techniques and Performance

Göktas and coworkers [15] used N-BCA (Histoacryl® Blue) as the tissue adhesive. Patients were advised not to moisten the area for at least 2 days. They used 5-0 or 6-0 polypropylene cuticular sutures as the comparator. No further information was provided regarding the manufacturing company for the sutures or the method of suturing.

Quinn et al. [16] utilized N-BCA (Histoacryl® Blue) as the adhesive of choice. The areas were sterilized with chlorhexidine, held with gauze and man-

ual pressure to achieve hemostasis, and then the adhesive was applied with the wound edges being apposed manually. This was then held in place for 30 s to complete the application. In the comparator group, lacerations were cleaned with chlorhexidine and anesthetized with 1% lidocaine and were closed with 5-0 or 6-0 monofilament sutures. The patients were asked to return to the emergency department later to have the sutures removed.

In the Kim 2015 study [17], n-butyl and 2-octyl-cyanoacrylate (GluSeal® Tissue Adhesive, Skinstitch Corporation) cuticular closure was used as the first treatment method and was compared with 5-0 or 6-0 fast-absorbing gut simple running suture (Fast Absorbing Plain Gut, Ethicon Inc.). Both halves of the linear wound were closed with buried intradermal absorbing suture, 5-0 polyglactin 910 (Polysorb®, Covidien), and Steri-Strips™. The patients were asked to return in 7 days to have the adhesive strips removed.

Tierney et al. [18] used a bilayered closure method where the buried interrupted subcuticular absorbing sutures (4-0, polyglactin 910) were placed, and then the wound was divided into two sides. The epidermal closure was achieved by rapid absorbing gut suture in one half and with 2-octylethylcyanoacrylate tissue adhesive on the other half.

In the study performed by Toriumi and colleagues [19], patients in the first group underwent skin closure using octyl-2-cyanoacrylate. Forceps were used to maintain eversion of the skin edges during application of the adhesive when no subcutaneous suture was placed. The second group underwent vertical mattress skin closure with 5-0 or 6-0 nylon suture. An everting subcutaneous suture was used to decrease the tension of the wound edges after full-thickness skin excisions. Partial-thickness skin incisions did not require subcuticular closure.

Safety

Göktas and coworkers did not report any complications in their study (including infection or dehiscence) in either group.

Quinn et al. found an insignificant increase in peri-wound erythema in the suture group (1 of 37 [2.7%] versus 4 of 38 [11.5%], $p > 0.05$). Wound infections occurred in one patient in each group, and there was no significant difference in the rate of wound dehiscence (3 of 37 [8.1%] versus 2 of 38 [5.3%], $p > 0.05$).

Kim et al. [17] reported no incidence of wound infection, wound dehiscence, nor hematoma, seroma, or spitting sutures in any treatment groups.

Tierney and colleagues [18] also reported no side effects including infection, allergic reaction, wound inflammation, or dehiscence.

Toriumi et al. [19] reported no evidence of infection, dehiscence, or hematoma in either group. Only one patient in the adhesive group showed a significant inflammatory reaction 2 days after the procedure. Many closures with sutures showed increased redness around the wound at the 5–7-day follow-up visit, whereas the incision sites treated with octyl-2-cyanoacrylate demonstrated a lower reaction rate (data not presented in the paper). Wound approximation was achieved in both groups satisfactorily.

Postoperative Care and Follow-Up

Optionally, the patients can follow up 5–7 days after the surgery to ensure there are no complications such as wound dehiscence or wound infection. Otherwise, the patient does not require a follow-up visit for operative site evaluation.

Alternative Procedures and Modifications

Alternatives to adhesive closures include simple running or interrupted sutures, as compared above. Adhesives can also be used as a supplement to strengthen the closure in high-tensile areas. Specifically, adhesive tissue glue can be used in conjunction with adhesive tapes (Kim et al. [17]) or epidermal sutures.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE).

Findings	GRADE score: quality of evidence
In uncomplicated lacerations, less than 5 cm, N-BCA (Göktas et al. [15], and Quinn et al. [16]) or 2-octyl-cyanoacrylate can be used in areas with low tension. Deeper lacerations can be adjunctly treated with subcuticular sutures. N-BCA application is a quicker epidermal closure method than suturing. Based on the inclusion criteria of randomized trials, the use of adhesives is not advisable in lacerations with florid contamination or in hair-bearing or intertriginous areas. The rate of wound dehiscence or infection is not higher in this specific patient population. Some experts prefer manual approximation of the wound edges for at least 30 s to ensure that the fast-acting adhesives can achieve full strength before the defect returns to its previous level of tension.	B
Mohs defects closed on the forehead using n-butyl and 2-octyl-cyanoacrylate were evaluated ($M = 6.33$, SD = 0.24) as being significantly worse ($p < 0.05$) than those closed on the cheeks or temple. There was also a marginal, insignificant tendency of worse outcomes with cyanoacrylate treatment as the length of the repair increases. Based on these findings some suggest restricting the use these adhesives to smaller wounds and to those not on the forehead [17]. However, subgroup analyses of small trials are typically discouraged due to the high risk of spurious findings [20].	C
2-Octylethylcyanoacrylate was found to be comparable in most outcomes (except post-procedure pigmentation) with fast-absorbing gut cuticular sutures in the presence of additional subcuticular closure for Mohs defects on the chest and upper extremities. The relatively lower performance of 2-octylethylcyanoacrylate in terms of pigmentation was likely due to higher tension in the chest or upper extremities as opposed to the face, which is the more common site for Mohs surgery. Tierney et al. [18] support the use of cyanoacrylate adhesives for epidermal closure of Mohs defects, though their study had only a very small number of enrolled patients. No adverse events were reported in this trial.	C
Octyl-2-cyanoacrylate application is less time-consuming than vertical mattress nylon cuticular sutures in linear closures of face and neck excisions. Additionally, although octyl-2-cyanoacrylate was comparable to suturing in 3-month follow-ups, it was cosmetically superior at 1-year mark. Octyl-2-cyanoacrylate has some advantages over other cyanoacrylate derivatives including less tissue toxicity, increased 3D strength, easier application, and higher pliability. The octyl-2-cyanoacrylate's plasticizer decreases the possibility of cracking and early peeling that are more commonly seen in short-term cyanoacrylates [19].	C

Comparison of Sutures Versus Adhesive Tapes for Epidermal Closure

A total of two studies were reviewed that examined the aesthetic outcomes of wound repair using adhesive tapes in comparison to sutures for epidermal closure (Tables 12.4 and 12.5).

Indications for Procedure

The criteria determining whether wounds may be eligible for closure with adhesive strips are similar to those for the use of tissue adhesives discussed in the previous section. In addition, adhesive tapes may be appealing for eligible defects in pediatric patients as they may eliminate the need for injection of local anesthesia.

Effectiveness of Procedure

In a split-scar study, Plotner et al. [21] compared the cosmetic outcomes of post-Mohs defects on the cheek when epidermal closure was accomplished with 6–0 nylon suture versus adhesive strips. A total of 50 patients were enrolled in the study and 38 completed all follow-up endpoints.

Table 12.4 Sutures versus adhesive tape

Study: first author and year	Study design	Number of patients who enrolled and completed study (% follow-up)	Outcome measures	Follow-up interval	Results	Level of evidence
Plotner 2011 [21]	Randomized split-scar study comparing epidermal closure with 6-0 Ethilon® suture versus adhesive strips	50 patients enrolled, 38 completed follow-up (76%)	Cosmetic outcome assessed with 100 mm VAS	Average 3.75 months (variable between 2 and 6 months)	No significant differences in the overall VAS scores (90.1 ± 7.8 for suture, 89.1 ± 10.3 for adhesive strips, $P = 0.884$) No postoperative wound complications (infection, dehiscence) reported	2B

Table 12.5 Adhesive strips versus no cuticular closure

Study: first author and year	Study design	Number of patients who enrolled and completed study (% follow-up)	Outcome measures	Follow-up interval	Results	Level of evidence
Custis 2015 [22]	Split-scar, assessor-blind, single-center trial comparing adhesive strips plus subcuticular sutures to subcuticular sutures alone	48 patients enrolled, 45 patients completed the study	Scar assessment with Patient and Observer Scar Assessment Scale (POSAS) at all follow-up visits Patient and physician global assessment scale	3 months	No significant difference between groups for POSAS scores: physician (12.3 [4.8] versus 12.9 [6.3] 0.32) and patient (14.0 [7.6] versus 14.7 [7.6], $p = 0.39$) Overall assessments: Physician (2.6 [1.3] versus 2.8 [1.7] $p = 0.31$) and patient (3.4 [2.5] versus 3.4 [2.4], $p = 0.86$) No wound infections, hematomas, or seromas in either group. Wound dehiscence: 1 versus 2, $p = 0.31$. Suture abscess: 3 versus 6 ($p = 0.18$)	1B

All wounds received equivalent deep dermal closures with buried vertical mattress polyglactin 910 sutures. Outcome measures were cosmetic appearance of the wound halves on a 100-point VAS at a postoperative follow-up visit occurring after suture removal. The average follow-up time was 3.75 months. No significant differences were observed in the VAS scores between the two wound halves, including overall cosmesis (90.1 ± 7.8 for suture, 89.1 ± 10.3 for adhesive strip, $P = 0.884$), erythema (93.1 ± 8.0 for suture, 91.9 ± 10.3 for adhesive strips, $P = 0.840$), and wound contour (88.1 ± 10.5 for suture, 86.9 ± 12.3 for adhesive tape, $P = 0.811$). The authors noted that the planned study follow-up was 2 months after the procedure, but many patients followed up at different intervals due to scheduling conflicts, and this may limit the validity of the observed VAS scores as they were obtained at different postoperative points in time (*Level of evidence: 2b*).

In another split-scar study, Custis et al. [22] compared Mastisol® liquid adhesive-coated adhesive strips plus subcuticular buried vertical mattress sutures to subcuticular buried vertical mattress sutures alone. By default, side A of the defect was either superior or to the left, from the surgeon's perspective, in all treated wounds. Forty-eight split wounds were enrolled in this study, and only three wounds were lost to follow-up. This study included Mohs and excision defects in a wide range of anatomical locations. The mean length of lesions was 5.3 (SD: 2.3). Patients were advised to use petroleum to both sides of the repair defect twice daily for 7 days with a sterile cotton-tipped applicator. Physician (2.6 [1.3] versus 2.8 [1.7] $p = 0.31$) and patient (3.4 [2.5] versus 3.4 [2.4], $p = 0.86$) global assessment failed to show any difference between two groups. Scar assessment with Patient and Observer Scar Assessment scale (POSAS) did not demonstrate any significant difference between two groups based on physician (12.3 [4.8] versus 12.9 [6.3] $p = 0.32$) and patient scoring (14.0 [7.6] versus 14.7 [7.6], $p = 0.39$). This insignificant difference also includes all sub-scores (*Level of evidence: 1b*).

Preoperative Evaluation

Evaluation of subjects for the use of deep dermal sutures only or deep dermal sutures and adhesive strips is similar to that of single transcutaneous suturing and bilayered suturing.

Best Techniques and Performance

In the study by Plotner et al. [21], all wounds received equivalent deep dermal closure with buried vertical mattress (BVMS) polyglactin 910 sutures. The wound halves were then randomized to receive superficial 6-0 nylon sutures to one half and adhesive strips (brand and manufacturer not specified) to the other half.

Custis et al. [22] used interrupted subcuticular buried vertical mattress sutures for both sides of the defects. In the half assigned to adhesive strips a supplemental adhesive (Mastisol®, Eloquest Healthcare Laboratories, Ferndale Pharma Group, Inc.) was first applied and allowed to dry. Then the adhesive strips (Steri-Strips™) were applied to this half of the defect, while the wound edges were everted using Adson forceps. All dressings were applied by nurses with at least 5 years of experience and who had recently undergone one refresher course prior to the commencement of the trial. The other half of the excisions were closed with subcuticular sutures only.

Safety

No postoperative wound complications were reported in any of the 38 patients that completed the split-scar study by Plotner et al. [21].

Custis and coworkers [22] noted no wound infections, hematomas, or seromas in any study patient. They did report one patient in the adhesive strip group (2.2%) and two in the suture-only group (4.4%, $p = 0.31$) with wound dehiscence. Suture abscesses occurred in three patients in the adhesive strip plus suture group, versus six in the suture-only group ($p = 0.18$). Only one patient in the suture-only group had a spitting suture.

Postoperative Care and Follow-Up

If the epidermis is closed using tissue adhesive or adhesive strips, no return visit is required for removal, and the first postoperative visit will be determined at the discretion of the surgeon, typically occurring 2–3 months following the procedure unless specific postoperative complications arise.

Alternative Procedures and Modifications

Alternatives to the use of tissue adhesives or adhesive strips for epidermal closure include conventional cuticular closure with absorbable or non-absorbable suture or no cuticular closure after placement of deep dermal sutures.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE).

Findings	GRADE score: quality of evidence
In a split-scar comparison of the cosmetic outcomes of cuticular closure with non-absorbable 6-0 sutures versus adhesive strips, Plotner et al. [21] did not demonstrate any significant differences in overall cosmesis, erythema, or wound contour on a 100-point VAS. However, as mentioned by the authors, the validity of this result may be significantly limited by the variability in patient follow-up duration (planned follow-up was at the 2-month time point, but average follow-up duration was 3.75 months, potentially limiting comparability of the VAS scores). In addition, all the patients in the study were Caucasian and studied at a single center, limiting generalizability of the study result to patients from varying ethnic backgrounds.	C
In the Custis et al. study [22], addition of Steri-Strips™ with Mastisol® did not provide any benefit in efficacy or safety based on the overall assessments by the patient and assessor nor in any of the different variables present in POSAS scoring system including patient-related factors (pain, itching, color, stiffness, thickness, irregularity) or physician-assessed factors (vascularity, pigmentation, thickness, relief, pliability, surface area). This study did not show any increase in wound dehiscence or infection in patients with only buried vertical mattress suture. Though confirmatory studies should be performed, the use of adhesive strips as an adjunct closure method to subcuticular buried vertical mattress sutures does not appear to be necessary to achieve good cosmetic results.	D

Comparison of Tissue Adhesive to Standard Wound Closure Methods (Sutures, Staples, and Adhesive Tapes)

A total of three studies were reviewed that compared the outcomes of wound repair using either OCA tissue adhesive or standard methods of epidermal closure (sutures, staples, or adhesive tapes) (Table 12.6).

Indications for Procedure

Please refer to the Indications section for *Comparison of Sutures Versus Adhesive Tapes for Cuticular Closure* section, as discussed previously.

Effectiveness of Procedure

Sniezek et al. [23] performed a split-scar study in 14 patients comparing the aesthetic outcomes of

Table 12.6 Tissue adhesives versus standard methods of closure

Study: first author and year	Study design	Number of patients who enrolled and completed study (% follow-up)	Outcome measures	Follow-up interval	Results	Level of evidence
Sniezek 2007 [23]	Randomized split-scar study comparing epidermal closure with 5-0 Prolene® suture versus tissue adhesive (Dermabond®)	14 patients enrolled and all completed study follow-up (100%)	Cosmetic outcome assessed with 10 mm VAS Patient preference	1 week for suture removal 3 months	No significant difference in mean overall VAS scores (6.77 ± 1.88 for suture versus 6.64 ± 1.55 for OCA adhesive, $P = 0.35$) All patients preferred closure with OCA adhesive based on ease of postoperative care No wound complications (infection or dehiscence) reported	1B
Singer 1998 [24]	Parallel-group RCT comparing tissue adhesive to standard methods of closure (sutures, staples, and adhesive tapes)	124 patients enrolled, 112 completed follow-up endpoints (90%)	Cosmetic outcome assessed on a 100 mm VAS HWE scale	1 week for suture removal 3 months	No significant difference in VAS scores for the OCA tissue adhesive (83.8 ± 19.4) and standard closure methods (82.5 ± 17.6, $P = 0.72$) No significant difference in the percentage of wounds receiving optimal HWE score of 6 (77% of tissue adhesive, 80% of standard closure, $P = 0.67$)	2B
Singer 2002 [25]	Parallel-group RCT comparing tissue adhesive to standard methods of closure (sutures, staples, and adhesive tapes) to determine factors associated with suboptimal wound outcomes	814 patients enrolled, 769 patients completed follow-up (94%)	Cosmetic outcome assessed by score on HWE scale	3 months	Closure with OCA adhesive not a significant determinant of cosmetic outcome (OR 1.1, 95% CI 0.8–1.4) Most important variables associated with suboptimal cosmetic outcome: location on an extremity (odds ratio [OR] 2.1, 95% confidence interval [CI] 1.2–3.7), wide wounds (OR 1.08, 95% CI 1.01–1.14), incompletely apposed wounds (OR 2.9, 95% CI 1.7–5.0), associated tissue trauma (OR 3.9, 95% CI 1.4–10.7), use of electrocautery (OR 3.4, 95% CI 1.8–6.5), and infection (OR 3.2, 95% CI 1.8–5.6)	2B

epidermal closure with high-viscosity OCA (HVCOA) tissue adhesive to sutured closure of linearly repaired facial Mohs defects. Follow-up was at 7 days for suture removal and assessment of postoperative complications and at 3 months for evaluation of the cosmetic scar outcome as judged on a 10-point VAS by five blinded dermatologist observers who evaluated standardized postoperative photographs taken at the 3-month time point. The authors did not find a significant difference in the mean VAS ratings for the HVCOA wound halves (6.64 ± 1.55) compared to the sutured halves (6.77 ± 1.88, $P = 0.35$). In addition, paired comparisons of rater preferences showed no significant cosmetic differences between the HVCOA and sutured sides. All 14

patients preferred the HVCOA over sutured closures due to increased ease of postoperative care (*Level of evidence: 1b*).

Singer et al. [24] conducted a randomized controlled trial in 124 patients with traumatic lacerations comparing the cosmetic outcome and complication rates of epidermal closure with OCA to other standard cuticular closure methods (including sutures, staples, and adhesive strips). The outcome measures included the complication rate seen at the 5- to 10-day follow-up visit, as well as cosmetic appearance of the scar as determined by scores on a 100-point VAS and the Hollander Wound Evaluation (HWE) scale at the 3-month visit. A total of 112 patients (57 in the OCA arm, 55 in the standard closure arm) completed the long-term follow-up visit. There was no significant difference in cosmetic appearance between the wounds closed with OCA (83.8 ± 19.4 mm) and those closed with one of the standard methods (82.5 ± 17.6 mm, $P = 0.72$) at the 3-month mark. The percentage of wounds receiving the optimal HWE score of 6 at the 3-month visit was calculated for both the OCA and standard closure defects and failed to demonstrate a statistically significant difference (77% of the OCA group and 80% of the standard closure wounds, $P = 0.67$) (*Level of evidence: 2b*).

Singer et al. [25] conducted a large (814 patients, 924 wounds), multicenter follow-up study to compare the cosmetic appearance of wounds closed with OCA adhesive (455 wounds) to that of defects closed with one of the standard wound closure methods (469 wounds closed with sutures, staples, or adhesive tapes) with the aim of identifying specific wound characteristics that were associated with poor cosmetic outcomes. The patient group in this study was more heterogeneous and included not only traumatic lacerations but also surgical incisions resulting from minimally invasive abdominal surgery and excisions of benign and malignant cutaneous neoplasms. Multiple wound characteristics were recorded including size, shape, location, mechanism (traumatic versus iatrogenic), degree of contamination, and method of wound closure. The outcome was the score on the 6-point Hollander Wound Evaluation (HWE) scale at the 3-month follow-up (all wounds receiving a score of less than 6 were considered suboptimal), which was completed in 769 patients (94%). The authors found that closure with OCA (OR 1.1, 95% CI 0.8 to 1.4) and the use of subcuticular sutures were (OR 0.8, 95% CI 0.6 to 1) not significantly associated with the cosmetic outcome. The most important variables, in terms of cosmetic outcome, were location on an extremity (odds ratio [OR] 2.1, 95% confidence interval [CI] 1.2–3.7), wide wounds (OR 1.08, 95% CI 1.01–1.14), incompletely apposed wounds (OR 2.9, 95% CI 1.7–5.0), associated tissue trauma (OR 3.9, 95% CI 1.4–10.7), use of electrocautery (OR 3.4, 95% CI 1.8–6.5), and infection (OR 3.2, 95% CI 1.8–5.6) (*Level of evidence: 2b*).

Preoperative Evaluation

Please refer to the Preoperative Evaluation discussion under the *Comparison of Sutures Versus Adhesive Tapes for Cuticular Closure* section, as described previously.

Best Techniques and Performance

In the split-scar study by Sniezek et al. [24], all defects were closed in a linear fashion with buried polyglactin 910 sutures. Half of the wound was randomized to receive epidermal closure with HVCOA (Dermabond®, Ethicon Inc., Summerville NJ) applied in two layers extending 2 mm on each side of the wound. The other wound half was assigned to epidermal closure with interrupted 5-0 polypropylene suture.

In the study by Singer et al. [24], patients with eligible wounds (defined as being appropriate for closure with 5-0 cutaneous suture, which the authors equated to the approximate tensile strength of the OCA adhesive) were randomized to receive wound closure with either topical OCA or via one of the standard methods (sutures, staples, or adhesive tape). Deep sutures were placed prior to epidermal closure in a total of nine patients (six in the OCA group and three in the standard closure group).

In the follow-up study by Singer et al. [25], 814 patients with 924 wounds of multiple etiologies

(traumatic lacerations, dermatologic surgical procedures, abdominal incisions from laparoscopic surgery, and excisions of benign or malignant cutaneous neoplasms) were enrolled, and approximately half (406 patients) were randomized to receive closure with OCA and the remainder (408 patients) received one of the standard methods for epidermal closure (sutures, staples, or adhesive tapes). A total of 769 patients (871 wounds) completed the 3-month study follow-up. Deep sutures were placed in a total of 492 patients, but the number of patients receiving deep sutures in the OCA and standard groups was not specified.

Safety

No cases of postoperative bleeding, infection, or wound dehiscence were reported in the study by Sniezek et al. [23] at either the 7-day or 3-month follow-up visits.

In the study comparing OCA to standard methods (sutures, staples, adhesive strips) of cuticular closure, Singer et al. [24] reported a wound infection in one patient (1.8%) in the OCA group and no infections in the standard closure group. In addition, two patients in the OCA group (3.6%) developed wound dehiscence noted at the early follow-up visit, necessitating a second wound closure. Notably, these two patients had not received subcutaneous sutures. No cases of dehiscence were noted in the standard closure group.

In the multicenter study by Singer et al. [25], a total of 12 infections (1.5%) were reported, with 9 occurring in the OCA cohort and 3 in the standard closure group. Wound dehiscence was reported in a total of 10 patients, but the proportion occurring in the OCA versus standard closure groups was not specified.

Postoperative Care and Follow-Up

In instances where non-absorbable sutures or staples are used for wound closure, removal is required. In the above studies, the initial visit for suture or staple removal took place between 5 and 10 days after the procedure.

Alternative Procedures and Modifications

Alternatives to the use of tissue adhesives for epidermal closure include adhesive strips, staples, as well as placement of cuticular sutures.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE).

Findings	GRADE score: quality of evidence
In the split-scar study of linear facial Mohs defects, Sniezek et al. [23] demonstrated no significant difference in cosmetic appearance or postoperative complication rate following epidermal closure with either HVCOA tissue adhesive or 5-0 polypropylene suture. The study utilized five blinded dermatologists performing the scar assessments using standardized photographs taken at the three-month follow-up visit, and had a 100% patient follow-up rate. However, the study is limited by its small and demographically homogenous sample size, which may limit generalizability of the results, and the use of photographs instead of in-person evaluations.	C
When the use of OCA tissue adhesive was compared to other standard methods of wound closure (sutures, staples, adhesive tape), Singer et al. [24] failed to show a statistically significant difference in the rate of wound complications or cosmetic appearance of the scar at 3 months, as quantified by scores on a 100-point VAS and the HWE scale. However, as the study combined several standard closure methods (sutures, staples, and tissue adhesives) into a single group and did not separate out the components during data analysis, the validity of the data may be limited by the heterogeneity of the standard wound closure group, as multiple variables were not controlled for prior to comparison with OCA.	C

Findings	GRADE score: quality of evidence
In the large (769 patient) multicenter study by Singer et al. [25] examining factors that were significantly associated with suboptimal wound outcomes, wound closure with OCA versus a standard technique (sutures, staples, or adhesive tapes) was not shown to be a significant predictor of suboptimal wound outcome. Rather, the most significant predictors of suboptimal wound outcome included location on an extremity (odds ratio [OR] 2.1, 95% confidence interval [CI] 1.2 to 3.7), wide wounds (OR 1.08, 95% CI 1.01 to 1.14), incompletely apposed wounds (OR 2.9, 95% CI 1.7 to 5.0), associated tissue trauma (OR 3.9, 95% CI 1.4 to 10.7), use of electrocautery (OR 3.4, 95% CI1.8 to 6.5), and infection (OR 3.2, 95% CI 1.8 to 5.6). However, the heterogeneity of the study population (containing wounds from multiple etiologies including trauma and elective surgical procedures) introduces the possibility of significant confounding factors that could be contributing to wound outcomes. In addition, as with the previous Singer et al. study [24], the individual methods of standard closure (suture, staples, and adhesive tapes) are not compared directly with OCA, which may also induce multiple confounding factors and limit the applicability and validity of the results.	C

Comparison of Tissue Adhesives Versus Adhesive Tapes or Tissue Adhesives for Epidermal Closure of Lacerations

Two studies were reviewed comparing the cosmetic outcomes of epidermal closure with standard-viscosity OCA tissue adhesive to that achieved with adhesive tapes (Steri-Strips™), as well as results using two different forms of tissue adhesive (high- and low-viscosity OCA) (Table 12.7).

Indications for Procedure

Please refer to the Indications discussion under the *Comparison of Sutures Versus Adhesive Tapes for Cuticular Closure* section, as described previously.

Effectiveness of Procedure

Mattick et al. [26] compared the cosmetic outcomes achieved with single-layer closure of lacerations in 60 children aged 1–14 years using either OCA tissue adhesive (Dermabond®) or tissue adhesive strips (Steri-Strips™) in pediatric patients who presented to the emergency department. Wounds were photographed preoperatively, and following repair all parents were asked to quantify the level of distress their child experienced during the procedure on a 100-point VAS, with 0 defined as "very distressing" and 100 as "perfect, no distress." Providers also rated the ease of application of either the tissue adhesive or adhesive strips on the VAS. The first postoperative review was between days 5 and 7, at which time parents were contacted to inquire about any wound complications. Long-term follow-up was completed in 44 children between months 3 and 12, at which time a photograph of the scar was obtained and evaluated by both the parents and a blinded plastic surgeon physician observer and rated on the 100-point VAS. The study failed to show any significant differences between the two techniques in the parents' opinions of the treatment (median 95 [range 70–100] for tissue adhesive, 96 [34–100] for adhesive strips, $P = 0.96$), parents' opinions of the scar (median 84 [range 70–100] for tissue adhesive, 80 [43–100] for adhesive strips, $P = 0.62$), or the blinded physician observer's opinion of the scar (median 87 [range 65–93] for tissue adhesive, 87 [62–96] for adhesive strips, $P = 0.81$). However, the adhesive strips were rated as easier to apply by the providers, a difference that was significant to the 95%

Table 12.7 Comparison of tissue adhesives and adhesive strips

Study: first author and year	Study design	Number of patients who enrolled and completed study (% follow-up)	Outcome measures	Follow-up interval	Results	Level of evidence
Mattick 2002 [26]	Parallel-group RCT comparing tissue adhesive (Dermabond®) to adhesive strips for epidermal closure	60 patients enrolled, 44 completed follow-up (73%)	Parent-reported patient distress on 100 mm VAS Cosmetic outcome evaluated on a 100 mm VAS	1 week 3–12 months	No significant differences between OCA adhesive and adhesive strips in parents' opinion of treatment (median 95 [70–100] for tissue adhesive, 96 [34–100] for adhesive strips, $P = 0.96$) No significant difference in surgeon's opinion of scar (median 87 [65–93] for tissue adhesive, 87 [62–96] for adhesive strips, $P = 0.81$)	2B
Singer 2003 [27]	Parallel-group RCT comparing two types of tissue adhesive (high- and low-viscosity OCA (Dermabond®)) for epidermal closure	84 patients enrolled, 78 completed study follow-up (93%)	Evaluation of adhesive migration >1 cm from wound Assessment of patient-subjective complaints at time of application	2 weeks	High-viscosity OCA significantly less likely to migrate than low-viscosity adhesive (21% versus 78%, $P = 0.0001$) High-viscosity OCA was associated with an increase in patient sensation of heat during application (44% versus 26%, $P = 0.11$) One dehiscence observed in the high-viscosity OCA group (2.8%), no infections	2B

confidence interval (CI) (median 91 [range 50–100] for tissue adhesive, 95 [10–100] for adhesive strips, $P = 0.07$) (*Level of evidence: 2b*).

Singer et al. [27] compared two types of tissue adhesives, high-viscosity (Dermabond® HV Topical Skin Adhesive, Ethicon Inc., Somerville NJ) and low-viscosity (Dermabond® Topical Skin Adhesive, Ethicon Inc.) OCA for epidermal closure of uncomplicated traumatic lacerations in a total of 84 patients (42 patients in each arm of the study) in an emergency department setting. Four patients (three in the high-viscosity OCA and one in the low-viscosity OCA groups) required placement of deep sutures prior to cuticular closure with the adhesives. The main outcome measure was evaluation of the tendency of the adhesive to migrate on the skin (defined as migration >1 cm from the wound) following application to the wound edges. Secondary outcomes included assessment of patients' subjective complaints (warmth, burning) at time of application and incidence of complications (infection, dehiscence) assessed 14 days following the procedure. A total of 78 patients (36 in the high-viscosity OCA group and all 42 in the low-viscosity OCA group) completed the 2-week follow-up. The authors found that the high-viscosity OCA was significantly less likely to migrate than the low-viscosity adhesive (21% versus 78%, $P = 0.0001$). However, it was also noted that the high-viscosity OCA was associated with an increase in patient sensation of heat during application (44% versus 26%, $P = 0.11$), but all patients who experienced this adverse sensation reported that they would receive treatment with OCA adhesives again (*Level of evidence: 2b*).

Preoperative Evaluation

Please refer to the Preoperative Evaluation discussion under the *Adhesive Tapes Versus Sutures for Cuticular Closure* section as described previously.

Best Techniques and Performance

In the study by Mattick et al. [26], eligible wounds were cleansed and randomized to receive either closure with OCA (Dermabond®) or adhesive tissue strips (Steri-Strips™). No subcuticular sutures were used for wound closure.

In the study by Singer et al. [27], wounds were selected based on eligibility for closure with topical skin adhesive, and the following were used as exclusion criteria: bite wounds, punctures, decubitus ulcers, stellate lacerations, crush injuries, evidence of active local or systemic infection, and location involving hair-bearing skin, mucous membranes, or the vermillion border of the lip. Eligible lacerations were then randomized to receive application of either high-viscosity OCA or low-viscosity OCA for re-approximation of the epidermis. Prior to application of the adhesive, wounds were evaluated to determine need for subcuticular sutures, which were placed in three patients in the high-viscosity OCA and one in the low-viscosity OCA group.

Safety

No wound complications (infection, bleeding, or wound dehiscence) were reported in the study by Mattick et al. [26] in the 44 children for which long-term (3–12-month) follow-up was obtained.

At the 14-day follow-up in the study by Singer et al. [27], there were no wound infections observed in either group. One patient in the high-viscosity OCA group (2.8%) developed wound dehiscence (of note, the authors did not specify if the patient had received subcuticular sutures during wound closure).

Postoperative Care and Follow-Up

As no sutures are placed that require removal, patients may return postoperatively on an as-needed basis following closure with tissue adhesive or adhesive strips.

Alternative Procedures and Modifications

Single-layer repair with cuticular suture, bilayered closure, staples, or healing by second intent

are alternatives to repair with tissue adhesives or adhesive strips in superficial lacerations.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE).

Findings	GRADE score: quality of evidence
Mattick et al. [26] failed to show any significant difference between OCA tissue adhesive and adhesive strips for closure of superficial lacerations in a pediatric population in terms of parental ratings of distress caused by the procedure or final scar outcomes (as judged by both parents and a blinded physician observer at 3–12 months). The only significant difference noted between the two techniques in this study was that the adhesive strips were regarded as easier to apply by the providers. However, this study was limited by the variable time of follow-up (ranging from 3 to 12 months), which limited comparability between participants who returned at different intervals for scar evaluation. No recommendations can be made based upon the results of this study.	C
The study by Singer et al. [27]. comparing high- and low-viscosity tissue adhesives demonstrated a significant decrease in reported adhesive migration with the high-viscosity product at the time of application (21% versus 78%, $P = 0.0001$) and there was no significant difference in the incidence of wound infection or dehiscence. It was noted that the high-viscosity adhesive was associated with a higher incidence of patient-reported sensation of warmth at time of application (44% versus 26%, $P = 0.11$), but affected patients reported this would not be a barrier to future use. However, the study had a relatively small sample size of 84 patients and thus may be underpowered to detect significant differences in the incidence of wound complications between the two groups. Also, it is unclear how important the issue of adhesive migration is to patient-centered outcomes such as cosmetic outcome or wound care. Thus, recommendations regarding the use of high versus low-viscosity adhesives cannot be made based upon the findings of this study.	C

Comparison of Sutures Versus Closure Devices

Two studies were reviewed that compared the aesthetic outcomes of wound repair using either closure devices or sutures for epidermal closure. The ClozeX™ (ClozeX™ Medical LLC, Wellesley, MA) is a wound closure adhesive film consisting of two independent parts that have an adhesive underside and multiple interlocking filaments attached to pulling ends to facilitate wound edge approximation. The Zipline® 3 system (Zipline® Medical Inc., Campbell, CA) is a noninvasive surgical skin closure device consisting of a sterile single-use adhesive sheet coupled to a releasable ratcheting device, which is used to approximate wound edges and dissipate tension at the incision site for optimal healing. Both devices are designed for closure of the epidermis following placement of deep dermal sutures, if indicated, and are left in place for 7–14 days and then removed (Table 12.8).

Indications for Procedure

The ClozeX™ and Zipline® 3 systems are sterile single-use adhesive devices designed to facilitate wound closure while also minimizing tension on the wound edges while the device is in place. The indications are similar to those for epidermal closure with either tissue adhesives or adhesive strips and are best suited to clean, uncomplicated linear lacerations that are not located in hair-bearing areas or involving mucosal surfaces.

Effectiveness of Procedure

In a split-scar study, Kuo et al. [28] compared the aesthetic outcome of bilayered suture closure to that achieved with placement of the ClozeX™ device for epidermal closure (in combination with deep dermal sutures) in patients who underwent excision of benign and malignant cutaneous neoplasms on the trunk and extremities. A total of 15 patients were enrolled and completed the scheduled follow-up visits at 2 weeks and at 4–6 weeks. The main outcome of the study was

Table 12.8 Sutures versus closure devices

Study: first author and year	Study design	Number of patients who enrolled and completed study (% follow-up)	Outcome measures	Follow-up interval	Results	Level of evidence
Kuo 2006 [28]	Randomized split-scar study comparing epidermal closure with 4-0 Prolene® and ClozeX™ device	15 patients enrolled and completed all follow-up (100%)	Cosmetic appearance evaluated on a global 4-point scale Wound closure time	2 weeks for suture/device removal 4–6 weeks	Significantly more ClozeX™-treated halves received a score of 2 or 3 corresponding to "extremely satisfied" and "satisfied" (66% versus 36%, $P = 0.007$) Closure time with ClozeX™ significantly shorter ($P = 0.007$) than suture placement Wound complications: two suture halves developed track marks, one suture half developed allergy to bacitracin; no infections or dehiscence	2B
Mitwalli 2016 [29]	Parallel-group RCT comparing bilayered closure with nylon cuticular sutures to the Zipline® 3 system with and without subcuticular sutures	20 patients enrolled, 17 completed follow-up (85%)	Closure time with sutures versus Zipline® 3 system Cosmetic outcomes assessed on a 10 mm VAS	2 weeks for suture/device removal 3 months	Closure time significantly shorter with Zipline® 3 device placement (1.83 ± 1.05 min versus 3.88 ± 1.3 min for suturing, $P = 0.001$) No significant difference in cosmetic outcome (mean VAS 8.5 ± 1.02 for suture versus 8.5 ± 1.14 for Zipline® 3, $P = 1$) Zipline® 3 only arm ($N = 1$) complicated by dehiscence in first patient; trial arm abandoned	2B

cosmetic appearance of the wound halves at the 4–6-week visit as judged by both blinded observers and patients on a 4-point satisfaction scale, with a score of 0 indicating "not satisfied" and score of 3 corresponding to "extremely satisfied." Secondary outcomes included comparison of the skin closure time and complication rate for each method. The percentage of wound halves receiving blinded physician assessment scores of 2 or 3 (corresponding to "satisfied" and "extremely satisfied") was 66% for the ClozeX™ halves and 36% for the sutured halves ($P = 0.007$), indicative of higher satisfaction with the appearance of the ClozeX™-treated wounds. Patient satisfaction was determined via administration of a questionnaire at the 4–6-week visit, which was completed by 13 patients and showed a preference for the ClozeX™ wound halves (69% of patients rated the ClozeX™ side higher than the suture side, with a median score difference of 1, $P = 0.02$). Finally, the median closure time with ClozeX™ was sig-

nificantly shorter (127 s, $P = 0.007$) than that of cuticular suture placement.

Mitwalli et al. [29] evaluated the cosmetic outcomes and complication rates using the Zipline® 3 system for epidermal closure in a total of 20 patients following excision of non-melanoma skin cancer (NMSC) or dysplastic nevi on the trunk or extremities. Patients were randomized to three groups: a bilayered control group that received deep dermal sutures followed by interrupted nylon cuticular sutures and two treatment arms in which the Zipline® 3 system was utilized with and without dermal suturing (however, the second treatment arm consisting of Zipline® 3 system alone was dropped after the first patient developed wound dehiscence). A total of 17 patients completed the 3-month study follow-up (eight controls, eight in the Zipline® 3 plus dermal sutures group, and one in Zipline® 3 without dermal sutures group). The primary outcome measure of the study was assessment of cosmetic outcome at 3 months using a 10-point VAS, based on assessment by three blinded observers. Secondary outcome measures included the surgeon time required for device application versus suture placement and removal, as well as the incidence of complications (infection, wound dehiscence) in the suture versus Zipline® 3 groups. The study failed to demonstrate a significant difference in scar appearance at 3 months (mean VAS 8.5 ± 1.02 for suture ($n = 8$) versus 8.5 ± 1.14 in the Zipline® 3 study arms ($n = 9$), $P = 1$). However, the time required for Zipline® 3 device placement was significantly shorter than that required for cuticular suturing (1.83 ± 1.05 min compared to 3.88 ± 1.3 min, $P = 0.001$). Similarly, the Zipline® 3 system was associated with a faster time for removal than cuticular sutures (8.2 ± 1.16 s compared to 58.1 ± 14.9 s, $P < 0.001$).

Preoperative Evaluation

Examination of the laceration to evaluate the size, depth, location, and contamination of the wound is indicated prior to determining if the defect can be appropriately closed with an adhesive closure device. Linear, opposed to stellate, lacerations allow for better alignment of tension vectors to facilitate wound edge approximation. Because the devices are occlusive, they are best suited for clean, uncontaminated wounds.

Best Techniques and Performance

Kuo et al. [28] performed a split-wound study in which the entire defect received interrupted deep dermal polyglactin 910 sutures for subcuticular closure, followed by randomization of wound halves to closure with either 4–0 polypropylene (Prolene®) in a simple running fashion or application of the ClozeX™ adhesive device. The sutures and device were removed at the 14-day postoperative visit.

In the study by Mitwalli et al. [29], the control group ($n = 8$) received bilayered closure with buried deep dermal sutures followed by interrupted nylon cuticular sutures. The Zipline® 3 system arm received deep dermal sutures followed by device application ($n = 8$) or application of the device without a subcuticular suture layer ($n = 1$, terminated due to dehiscence in the first patient).

Safety

In the split-wound study by Kuo et al. [28], there were no reports of wound infection or dehiscence in either the sutured or ClozeX™ halves of the 15 patients who completed the study. One patient developed an allergic contact dermatitis to bacitracin on the suture half of the wound, and two sutured halves developed track marks noted at the 4–6-week follow-up visit.

Mitwalli et al. [29] reported wound dehiscence in one patient in the Zipline® 3 closure group that was randomized to closure with the device alone without the use of subcuticular sutures, resulting in elimination of that arm of the study. None of the patients randomized to bilayered suture closure or subcuticular sutures plus the Zipline® 3 system experienced dehiscence.

No patients developed a postoperative wound infection in this study.

Postoperative Care and Follow-Up

Both the ClozeX™ and Zipline® 3 systems are designed to stay in place on the wound for a period of 7–14 days and are removed at a follow-up visit in the office.

Alternative Procedures and Modifications

Standard bilayer closure with placement of cuticular sutures and modified bilayer closure using tissue adhesives or adhesive tapes for the cuticular layer are alternatives to the use of adhesive epidermal closure devices such as the ClozeX™ and Zipline® 3 systems.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE).

Findings	GRADE score: quality of evidence
In their split-scar study, Kuo et al. [28] found cuticular closure with ClozeX™ to be rated cosmetically superior to that with running non-absorbable suture by both blinded physician assessors and patients on a 4-point satisfaction scale. In addition, median skin closure time with the ClozeX™ device was significantly shorter (127 s) than closure time for the sutured halves. No reports of wound quality or dehiscence were noted in the study, although due to the small sample size (15 patients) the study was not adequately powered to detect significant differences in complication rates between the two methods. More studies with larger cohorts are required before definitive recommendations can be made regarding this device.	C
At 3-month follow-up, Mitwalli et al. [29] did not demonstrate any significant difference in the cosmetic appearance of wounds closed with standard bilayered suture closure compared to bilayered repair utilizing the Zipline® 3 system for cuticular closure. The authors did demonstrate that placement of the Zipline® 3 system required significantly less time than cuticular suturing, as did the time required for the Zipline® 3 removal. Notably, the authors deemed the Zipline® 3 system inappropriate for single-layer closure based on dehiscence in the first patient who was treated in this manner. The overall conclusion of the study was that the Zipline® 3 system plus dermal suturing is more efficient than conventional bilayered suture closure, with equivalent cosmetic outcomes at 3 months. However, due to the small size of the study, it may not adequately detect significant differences in cosmetic outcomes or complication rates between the Zipline® 3 and conventional cuticular sutures.	C

Comparison of Circular Versus Elliptical Excision Methods

One study was reviewed that compared the cosmetic outcomes achieved following circular (via a standard trephine punch) excision and elliptical excision of atypical nevi on the trunk and extremities (Table 12.9).

Indications for Procedure

Circular excision is considered in the setting where the lesion to be removed is small (able to fit within the diameter of a punch instrument) and time efficiency is valued. Elliptical excision is considered for any situation where a full-thickness removal of cutaneous tissue is warranted and time is available to complete the procedure.

Table 12.9 Circular versus elliptical excision

Study: first author and year	Study design	Number of patients who enrolled and completed study (% follow-up)	Outcome measures	Follow-up interval	Results	Level of evidence
Ek 2004 [30]	Parallel-group RCT comparing circular and elliptical excision	45 patients enrolled (56 excisions); all patients completed follow-up (100%)	Median scar area Cosmetic outcome evaluated on 100 mm VAS by patients and observers	2 weeks for suture removal 6 months 12 months	Median scar area significantly less in circular group compared to elliptical at 6 months (48.7 mm^2 versus 87.2 mm^2, $P < 0.05$) and 12 months (64.8 mm^2 versus 102.2 mm^2 $P < 0.05$) No significant difference in the patient VAS scores at 12 months (57.9 versus 73.7) Elliptical excision scars rated cosmetically superior by observers on VAS (49.0 for circular excision versus 61.0 for elliptical, $P < 0.05$)	2B

Effectiveness of Procedure

Ek et al. [30] compared the scar area and cosmetic outcome of circular versus elliptical excisions of clinically atypical nevi located on the trunk or extremities. A total of 56 procedures were performed in 45 patients. Nevi were randomized to receive circular excision with an 8-mm punch ($n = 29$) or elliptical excision ($n = 27$). Sutures were removed after 14 days, and the scar area was calculated based on measurements at the 6- and 12-month follow-up visits. Cosmetic appearance was evaluated on a 100-point VAS at 12 months by both the patients and blinded observers. In addition, the incidence of early (infection, wound rupture) and late (erythema, hyperpigmentation, hyperpigmented scarring) complications was recorded in both groups.

The authors found that the median scar area was significantly smaller in the circular excision group compared to elliptical excision at both 6 months (48.7 mm^2 versus 87.2 mm^2, $P < 0.05$) and 12 months (64.8 mm^2 versus 102.2 mm^2, $P < 0.05$). There was no significant difference in the patient VAS scores for circular and elliptical excisions at 12 months (57.9 versus 73.7); however, the observers rated the elliptical excision scars as more cosmetically pleasing and this was statistically significant (49.0 for circular excision versus 61.0 for elliptical, $P < 0.05$). The circular excision group had a higher incidence of both early and late complications (28%) than the elliptical excision group (7.4%), but this did not reach statistical significance. The authors noted that complications were associated with poorer cosmetic outcome (lower patient and observer VAS scores), and when the ten excisions that had developed complications were excluded from the study, there was no longer a significant difference in the observer's cosmetic assessment of the scars (54.7 for circular, 60.3 for elliptical). However, the exclusion of this data violates the intention to treat principle and is not in keeping with good data analysis (*Level of evidence: 2b*).

Preoperative Evaluation

Clinically atypical nevi may be excised by the clinician to ensure that no histopathologic evi-

dence of malignancy is present. As the lesions are presumed to be benign, optimizing the cosmetic outcome of the scar becomes a priority. The need for complete removal of the lesion via excision, with higher incurred risks and morbidity, needs to be justifiable compared to a simple shave biopsy or shave excision.

Best Techniques and Performance

Circular excisions were performed using an 8-mm punch biopsy instrument and closed with a single non-absorbable 4-0 polybutester (Novafil™, Covidien Ltd.). Elliptical excisions were performed in standard 3:1 length-to-width ratio and closed with subcutaneous polyglycolic acid (Dexon™, Covidien Ltd.) sutures followed by interrupted 4-0 polybutester (Novafil™) sutures.

Safety

In the circular excision group (n = 29 lesions), a total of eight complications were noted consisting of four cases of wound dehiscence, two wound infections, one keloid scar, and one hyperpigmented scar. In the elliptical excision group, two patients developed wound infections; no other complications were noted.

Postoperative Care and Follow-Up

Non-absorbable sutures require removal. For excisions on the trunk and extremities, the recommended time for suture removal is 14 days.

Alternative Procedures and Modifications

Alternatives to excision include clinical monitoring, shave biopsy, or scoop shave excision.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE).

Findings	GRADE score: quality of evidence
In their comparison of circular and elliptical excisions of clinically atypical nevi, Ek et al. [30] observed an increased incidence of early and late wound complications in the circular excisions but this was not statistically significant. Though the circular excisions had a smaller scar area than the elliptical excisions, the elliptical excision scars were rated as being slightly cosmetically superior by blinded physician observers at the 6- and 12-month follow-up (there was no significant difference in patient VAS scores between the two groups). More studies with larger numbers of patients are necessary before recommendations can be made regarding circular excisions versus elliptical excisions.	C

Self-Assessment Questions

1. Based on the reviewed studies comparing two methods of wound closure, staples versus single-layer closure with suture (Kanegaye et al. and Orlinsky et al.), which one of the following statements is true?
   (a) There was no significant difference noted in the laceration repair time between stapling and suturing.
   (b) The cosmetic outcomes of wounds evaluated at 3 months were superior in the patients who underwent wound closure with sutures.
   (c) The average cost of laceration repair with staples was significantly lower than with sutures.
   (d) The average laceration repair time per centimeter increased with increasing length of lacerations.
   (e) Patients reported more postoperative discomfort following staple closure as compared to suture closure.
2. Regarding the cosmetic outcomes of using the set-back suture technique (as reported in Wang et al.), which of the following statements are true?
   (a) The cosmetic outcomes of wound halves repaired with set-back sutures were superior to the use of buried vertical mattress sutures.
   (b) The incidence of spitting sutures was lower in the wound halves repaired using the buried vertical mattress sutures.
   (c) Set-back sutures enter and exit the wound only though the wound edge.
   (d) Buried vertical mattress sutures produce better wound edge eversion than set-back sutures.
   (e) There were significantly more infections in the wound halves closed with set-back sutures.
3. During preoperative evaluation of a laceration, which type of wound defect would be deemed most suitable for cuticular closure with tissue adhesive or adhesive strips?
   (a) 6 cm clean, linear laceration of the forehead extending into the hair-bearing scalp
   (b) 3 cm jagged laceration of the dorsal hand following a dog bite
   (c) 3 cm linear laceration of the upper arm
   (d) 6 cm stellate laceration of the cheek
   (e) 2 cm linear laceration over the elbow
4. In terms of tensile strength, standard-viscosity octyl-cyanoacrylate (OCA) tissue adhesive is comparable to what type of suture for epidermal closure?
   (a) 6-0 polypropylene
   (b) 5-0 nylon
   (c) 5-0 fast-absorbing gut
   (d) A and B
   (e) B and C
5. Which of the following suture materials is more commonly associated with complications of suture reactions, based on published randomized trials?
   (a) Poliglecaprone-25
   (b) Polyglactin-910
   (c) Poly-4-hydroxybutyrate
   (d) Polydioxanone
   (e) Polypropylene

6. Which statement is true regarding the comparison between octyl-2-cyanoacrylate and vertical mattress nylon cuticular sutures in the presence of subcuticular closure in head and neck surgeries based on a study performed by Toriumi et al.?
   (a) Cosmesis is superior in the adhesive group at 12-month follow-up.
   (b) Cosmesis is superior in the adhesive group at 3-month follow-up.
   (c) Wound dehiscence is higher in the adhesive group.
   (d) Time to closure was not a differential factor.
   (e) Peeling of adhesive is more commonly seen in octyl-2-cyanoacrylate than other adhesives.

Correct Answers

1. (c) As reported by both Kanegaye et al. and Orlinsky et al., repair of lacerations with staples was significantly faster and more cost-effective than suturing. Orlinsky et al. noted that the time per centimeter for laceration repair decreased with increasing length of the lacerations. In the study by Kanegaye et al., no significant difference in postoperative pain was noted between the staple and suture groups at the suture/staple removal visit.
2. (a) Cosmetic outcomes were statistically better in the wound halves closed with set-back sutures. The incidence of spitting sutures was lower in wound halves closed with set-back sutures. There was a lower incidence of spitting sutures on the set-back suture sides. Set-back sutures enter and exit the underside of the undermined wound, not the wound edges. Set-back sutures result in significantly more wound edge eversion than buried vertical mattress sutures. There was no difference in terms of infections between the two suture halves.
3. (c) Tissue adhesives and adhesive strips are best suited for clean, linear lacerations located in areas that are not hair-bearing, involving mucous membranes, under high tension, or overlying a dynamic structure (such as a mobile joint). Two studies using adhesives restricted patients to those with lacerations that were 5 cm or less.
4. (e) The tensile strength of standard OCA tissue adhesive is roughly equivalent to that of 5-0 caliber suture (absorbable or non-absorbable).
5. (c) Although scars were significantly narrower on wound halves sutured with poly-4-hydroxybutyrate, there was no difference in cosmetic outcome compared with polyglactin 910 sutures and significantly more local suture reactions.
6. (a) Cosmetic outcomes are not statistically different at 3 months between wounds closed with octyl-2-cyanoacrylate adhesive and those closed with vertical mattress nylon sutures. However, at 1-year follow-up, results significantly favored wounds closed with octyl-2-cyanoacrylate adhesive. The octyl-2-cyanoacrylate's plasticizer decreases the possibility of cracking and early peeling, which is more commonly seen in short-term cyanoacrylates.

13 Sutures, Adhesives, Staples, and Other Closure Technologies

Christina Correnti, Kaitlin Blankenship, Nicole Ufkes, and John Strasswimmer

Abstract

The history of surgery, and therefore wound closure, is that of human social evolution. Social cohesion for *Homo sapiens* (which led to our species dominating other humanoid species including *H. neanderthalensis* and *H. erectus*) depended upon caring for the infirm. Some of the earliest surgical needles, dating back to at least 20,000 BC, were made of bone, and primitive sutures were made of plant material and linen (5). Middle-Kingdom Egyptians used strips of linen coated with honey and flour as some of the first documented adhesive material for wound closure. South American cultures even used the pincers of decapitated ants as a means of wound closure. The use of gut as suture material was first mentioned in ancient Greece around the time of Galen, a material still used today.

significant advances in the field of surgical dermatology. Over the past several decades, there has been increasing interest in seeking the evidence behind traditionally passed down surgical tenets (such as wound eversion for improved scar cosmesis). Indeed, many times no differences are found for the effects of the choice of closure material or technique on wound healing. This chapter attempts to synthesize evidence in the literature regarding closure materials and common closure techniques.

Indications for Wound Closure and Preoperative Evaluation

Surgical wounds are closed in order to increase rate of healing, to preserve function, and to optimize cosmetic outcome. Wounds may be allowed to heal by primary intention, meaning that the surgeon will place appropriate closure devices, such as sutures. Alternatively, wounds may be allowed to heal by secondary intention, which implies that no sutures or other devices are placed. The choice of whether to close a wound primarily may depend on factors related to healing such as a patient's overall health, comorbidities, nutrition, and smoking status; more practical factors such as nearby free margins that may distort, repair cost, the need for a suture removal visit, and the restriction of physical activity after primary closure; the risk of bleeding due to blood thinners; and patient preference with regard to wound care, healing time, and scar appearance. Regardless of the choice, the surgeon continues to direct and intervene as necessary to ensure complete wound healing (5) [2] (3b) [3] (5) [4].

Preoperative evaluation should include a review of vital signs, patient allergies, medications, the presence of devices that may influence the method of hemostasis (pacemaker, defibrillator, or cochlear implant), and factors influencing whether preoperative antibiotics should be given (e.g., history of recent joint replacement) (5) [5] (4) [6]. In general, prescribed anticoagulant medications should be continued if possible. Detailed justification can be found in evidence-based reviews of patient safety in dermatologic surgery [5] and in antibiotic guidelines for dermatology surgery [6].

Alternatives to Wound Closure: Second Intent Healing

Wound closure is not always necessary for satisfactory healing; patient or surgeon preference may become more important in these cases. Studies have shown no difference between the healing of punch biopsy sites when sutured versus when allowed to heal by second intent. Christenson and coauthors examined scar appearance after a punch biopsy using secondary-intention versus primary closure with 4-0 nylon sutures (1b) [7]. For smaller 4-mm size punch biopsies, there was no significant preference by participants for either method. However, for the larger 8-mm biopsies, participants preferred primary closure. No difference was noted in the rate of complications between the two closure options. Although sutures may be preferred at larger biopsy sites, eliminating use of sutures for punch biopsies can result in reduced costs and time saving for both patients and medical institutions.

A retrospective survey of 1250 patients showed no difference in patient satisfaction for Mohs defects closed primarily versus healed with secondary intention (3b) [8]. The only factor associated with decreased long-term patient satisfaction was age younger than 68 years. This age group had a slightly lower satisfaction with outcome regardless of closure method, consistent with earlier studies showing older patients are typically more satisfied with surgical outcome than younger patients.

Becker and coauthors have also completed a number of studies on second intention healing in Mohs defects. Based on this experience, they conclude that most defects heal by secondary intention within 3–6 weeks on average, wounds in areas likely to cause distortion (near free margins) are better closed surgically, and scars may be more cosmetically pleasing with second intent healing (5) [9, 10].

In a prospective study of 102 Mohs defects of the head and neck allowed to heal by second intent, scar location was the most important factor for the final cosmetic outcome [3]. Concave surfaces of the nose, eye, ear, and temple (NEET) and forehead, antihelix, and eyelids and the remainder of the nose, lips, and cheek (FAIR) areas showed equivalent rates of wound contraction (74%) and acceptable cosmesis (97%). Convex surfaces of the nose, oral lips, cheeks and chin, and the helix of the ear (NOCH) showed lower rates of wound contraction (66%) and acceptable cosmesis (78%).

Alternatives to Wound Closure: Partial Wound Closure

A third approach is partial wound closure. The most documented is the use of purse-string suture, to aid in second intent healing by decreasing the lateral dimensions of the surgical defect. The technique is most commonly deployed using nonabsorbable material in a subcuticular or cuticular approach. Alternatively, absorbable suture may be placed in a subcuticular manner.

Intradermal purse string with nonabsorbable sutures clearly decreases the surgical defect. In 51 consecutive patients (ages 26–93), Patel et al. treated large circular or oval defects of the head and neck with the purse-string suture (3b) [11]. When the wound could not be closed completely with the suture, any residual defect was closed with a skin graft ($n = 11$) or second intent healing ($n = 5$). Overall, the mean defect size reduction was 89%. The nonabsorbable sutures were left in place at least 4 weeks. Ridges were flattened after 2–3 weeks. The resultant scars were often linear and along relaxed skin tension lines (except when grafted). Alopecia occurred in one scalp lesion. Infection occurred after the loss of a full-thickness skin graft in one case. The authors suggest the best results occurred in the neck and retromandibular region due to lax skin, the worst results being on the scalp.

Intradermal purse string with absorbable suture may be employed as well. Spencer et al. assessed 54 wounds managed with running intradermal purse-string closures with 3-0 or 4-0 polyglactin for circular wounds after Mohs surgery (4) [12]. Immediate wound areas decreased by 60–100%, with most improvement, especially in the neck and arm. Long-term cosmetic results were calculated on a 4-point scale in 52 cases and were best in head and neck locations (face and neck, mostly excellent; trunk, fair to good; shin, fair to good; thigh, good; upper arm, good; forearm, good; ear, excellent; and scalp, fair) with caution in areas near a free tissue margin [12].

Cuticular purse-string closure may have the added benefit of increased hemostasis compared to subcuticular purse-string closure. In a retrospective review of 98 patients where cuticular purse-string sutures were placed, wound area decreased by a large variation (6–90%, mean 60% (3b)) [13]. Anticoagulant or antiplatelet medications were noted in over 50% of patients, suggesting that this approach may be suitable even in patients at increased risk of bleeding. The purse-string suture was usually removed after 3–4 weeks. Six patients (6%) had complications including one hypertrophic scar, one exuberant granulation tissue, two wound infections, and two cases of allergic contact dermatitis. All healed completely with round or linear scars. The authors conclude the cuticular purse-string technique is particularly useful in patients who want to maintain an active lifestyle or who are on one or more anticoagulant or antiplatelet medications.

In a discussion of purse-string approaches, Scholl et al. described that cuticular purse strings with nonabsorbable suture are preferably used on the scalp with a main benefit of hemostasis, whereas subcuticular purse-string sutures are preferable on the forehead, temples, neck, and extremities where they are indicated for defect reduction and accelerated secondary intention healing and/or completed with absorbable monofilament sutures (5) [14].

In summary, primary closure methods are most common, but partial closure and secondary intention wound management are used for specific circumstances. Considerations such as activity restrictions for sutures and the requirement and cost for a suture removal visit come into play. Physicians can consider the patient's abili-

ties, expectations, and preferences when deciding between methods [3, 7, 8].

Introduction to Sutures and Suture Materials

Sutures are the most commonly used closure material in procedural dermatology. In 2006, a prospective survey of closure techniques and suture types used by 101 members of the American Society of Dermatologic Surgeons was completed with a response rate of 60% (4) [15]. Respondents most often used simple interrupted sutures (38–50%) to close the epidermis, followed by simple running sutures (37–42%), and vertical mattress sutures (3–8%). On the trunk and extremities, subcuticular sutures were more often used (28%). Superficial sutures were mostly nylon (51%), followed by polypropylene (44%). Absorbable suture was most commonly polyglactin 910 (73%). At least 90% of the time, a bilayered closure with undermining and electrocoagulation was used. Primary closures were the most common (54%) followed by local flaps (20%), and skin grafting (10%). The remaining 15% of wounds healed by second intent (10%) or were referred for reconstruction (5%). Dermatologic surgeons repair defects themselves at least 90% of the time, even among the quartile of those practitioners who are most likely to refer reconstructive procedures to other specialists. In bilayered closures, vertical deep sutures were used 90% of the time compared to horizontal deeps (5%) or oblique deeps (1%). Interestingly, larger wounds were significantly more likely to be treated by surgeons with more years of experience, and more experienced surgeons were significantly less likely to use bilayered closures or undermine on the face.

Time to suture removal varies by surgeon experience and preference. The choice can depend on many factors such as wound tension, wound location, and anticipated patient activity level. In general, sutures on the face are removed after 5–7 days; of particular concern is for the potential to develop "train track" scars for sutures left in for longer or under high tension. Sutures in the scalp, trunk, and extremities are removed after 7–14 days and potentially longer on the hands and feet (5) [16] (5) [17].

Due to the expansive variability in suture products, it is important to understand suture properties and characteristics to be able to choose an appropriate suture for each closure scenario. Pertinent suture properties include tensile strength (dependent on suture diameter), knot security, capillarity (which can increase infection risk), elasticity, plasticity, memory, pliability, tissue reactivity, and coefficient of friction (ability to slide through tissue). Dyed sutures increase visibility and the color fades over time after embedding in tissue (5) [18].

Suture size is classified based on the US Pharmacopeia designation. Suture sizes in dermatologic surgery generally range from 2-0 to 6-0. The more zeros the suture material has, the thinner it is. Sutures have either natural (e.g., silk or gut) or synthetic (e.g., nylon) composition, with natural materials more prone to cause inflammatory tissue reactions and less even strength distribution. Natural suture materials are degraded by proteolysis, whereas hydrolysis degrades synthetic suture materials. A suture is said to be absorbable if it loses most of its tensile strength by 60 days after implantation and nonabsorbable if it retains most of its strength past 60 days [4, 18]. For tables comparing the detailed properties of absorbable versus nonabsorbable sutures, see the review authored by Regula et al. in 2015 [18].

Sutures can either be monofilament or multifilament braided or twisted. Multifilament sutures tend to handle well due to greater pliability and lower memory; they also have increased tensile strength. They have a higher coefficient of friction (creating drag) and high capillarity and inflammatory potential (which is thought to increase the risk of infection). Monofilament sutures have minimal tissue drag (low coefficient of friction), lower inflammatory potential, and theoretically lower infection risk; however, they are more difficult to handle due to high memory [4, 18]. Silver et al. demonstrated that knot security appears to depend on technique (surgeons knots > square knots > slip knots), the number

of throws, and suture material independent of suture size or whether the suture is monofilament or multifilament; for example, out of four materials, two multifilaments had the both the highest (Vicryl) and lowest (silk) knot security in comparison with chromic gut and nylon (5) [19].

Traditionally suture surfaces are smooth; however, barbed sutures are a newer wound closure technique. Barbed sutures offer three advantages over traditional sutures. First, barbed sutures eliminate the need for knot tying, potentially saving time. Second, interrupted knots are a focus of high tension with gaps of low tension in between the individual suture knots. In contrast, barbed sutures are placed in a continuous looping fashion, which distributes tension more evenly. Third, barbed sutures are used to close using the pulley principle, whereby tension vectors during the act of wound edge approximation are evenly distributed. Therefore, barbed sutures can be used to close wounds where the skin is very fragile, such as photo-damaged arms. Likewise, barbed absorbable sutures can be used to close large wounds which otherwise would not close primarily (4) [20].

Barbed sutures may be endo- or exobarbed. Endobarbed sutures are nicked monofilaments; thus their diameter is functionally decreased along with tensile strength (5) [21]. Thus upsizing endobarbed sutures may be prudent to achieve a strength comparable to the smooth suture size that is typically preferred for a given body location. Barbed 2-0 polypropylene suture has been found to have same strength as at least 3-0 non-barbed polypropylene suture and greater stiffness according to a rater in a blind controlled trial using a tensile testing device (5) [22]. In contrast, exobarbs are attached to the core suture and strength is not decreased. Barbs also come in uni- or bidirectional forms (changing direction at the midpoint). Barbed sutures distribute tension more evenly along their length, eliminating ischemic foci of suture loops, and have the potential to reduce dehiscence (3b) [23–25]. They are more expensive than traditional sutures, but will save procedure time and empower the surgeon to close challenging wounds [20, 22, 23], (2b) [26].

Introduction to Tissue Adhesives and Surgical Strips

Surgical glues (cyanoacrylate tissue adhesives) are useful wound closure tools for wounds under minimal tension (with or without deep sutures) and give comparable cosmetic outcomes. They are fast to apply and avoid a visit for suture or staple removal. They also do not require anesthesia for wound closure, making them ideal for use in children or patients with low pain tolerance. Wounds must be perfectly approximated before application. The cost can be comparable to one rapid absorbing suture if purchasing multiuse vials. Surgical glue should not be used over joints or areas that experience repetitive motion, unless the area is immobilized. Surgical glue should also not be used on contaminated wounds, mucosal junctions, hair-bearing areas, or contaminated or infected skin. Other disadvantages include drying time, glue seeping into the wound impairing healing and approximation, and peeling due to repetitive movement [4, 16–18, 27].

Surgical adhesive strips are another alternative to conventional wound closure with sutures. Like surgical glue, surgical strips should be used to close wounds that are already well approximated, with or without deep sutures, and under low tension. Surgical strips can also be used to reinforce wounds that are superficially closed with sutures; however, there is little evidence to support any added benefits (1b) [28], (3a) [29]. Disadvantages and benefits of using surgical strips are very similar to those of surgical glue mentioned above, with the additional consideration of risk of adhesive tapes causing allergic or irritant reactions [16, 17, 29]. Adhesive liquid agents, such as Mastisol, can be used to better secure surgical strips and can allow for prolonged adhesion across the wound [4, 18].

Introduction to Staples

Stainless steel staples are rapidly applied, have the highest tensile strength of closure materials, have low reactivity, and are an efficient means of closing long- or high-tension wounds such as those on the scalp [18].

Evidence-Based Review of Suture Materials: Selection, Effectiveness, and Safety

Literature Search Strategy

PubMed (1809 to present) was searched and limited by human species and English language. Articles unavailable in full text were excluded. The remaining articles were screened by title and abstract for relevance to cutaneous closure materials in terms of selection, effectiveness, and safety. Examples of excluded topics were studies focused solely on subcutaneous or deeper closure techniques, burn wounds, ptosis correction, traumatic lacerations, rejuvenation/lifting (non-closure) sutures, laparoscopic trocar wounds, and graft immobilization. Relevant articles were reviewed and references were cross-checked. Single-case reports and narrative reviews (without systematic methods or data analysis) were excluded, but references were cross-checked. Duplicative studies were excluded, such as individual studies sufficiently covered in meta-analyses. Duplicates also included older meta-analyses if all studies overlapped and the conclusions of the two meta-analyses were concordant. Numerous dermatologic expert technical pearls and modifications for unique closure challenges were beyond the scope of this review. Rather, this chapter aims to synthesize the larger body of evidence related to dermatologic closure materials and their common applications.

Sutures

The following search parameters were used: ("Sutures"[Mesh] OR "Suture Techniques"[Mesh]) AND "Dermatologic Surgical Procedures"[Mesh] AND (sutur*[Title/Abstract]. Of 764 results, 601 full text articles were screened.

Staples

The following search parameters were used: "Wound Closure Techniques"[Mesh] AND ("surgical staples"[Title/Abstract] OR "surgical staple"[Title/Abstract] OR "staple"[Title/Abstract] OR "staples"[Title/Abstract]) AND "Reconstructive Surgical Procedures"[Mesh]. Of 90 results, 66 full text articles were screened.

Adhesives and Tape

The following search parameters were used: "reconstructive surgical procedures"[Mesh] AND ("tissue adhesives"[Mesh] or "surgical tape"[Mesh]) AND "wound closure techniques"[Mesh]. Of 102 results, 77 full text articles were screened.

Other Closure Devices

The following search parameters were used: ("reconstructive surgical procedures"[MeSH Terms] AND "wound closure techniques"[MeSH Terms]) AND ("film"[Title/Abstract] OR "coaptive"[Title/Abstract] OR "sutureless"[Title/Abstract] OR "op-site"[Title/Abstract] OR "opsite"[Title/Abstract] OR "zipper"[Title/Abstract] OR "closure device"[Title/Abstract] OR "adhesive device"[Title/Abstract]). Of 50 articles, 35 full text articles were screened.

Overall

After screening, removal of duplicative studies, and cross-checking references, 129 articles were identified for inclusion.

Evidence-Based Review: Sutures

1. *Five systematic reviews and meta-analyses comparing suture techniques and/or materials were reviewed. Topics addressed included triclosan-coated sutures, barbed sutures in knee arthroplasty, barbed sutures in hip and knee arthroplasty, absorbable versus nonabsorbable sutures in surgical and laceration wounds, and continuous versus interrupted sutures in non-obstetric surgery.*

In a 2015 systematic review and meta-analysis of 6 randomized controlled trials in 2168 patients (1102 treated and 1066 controls), the analysis found no protective effect of triclosan-coated sutures on the rate of surgical site infections after elective colorectal resections. Further large randomized controlled trials are needed

before introducing this technology into clinical practice (1a) [30].

Two 2015 systematic reviews and meta-analyses studied barbed sutures versus traditional sutures in orthopedic surgery. In the first meta-analysis, four randomized trials, one prospective trial, and five retrospective trials of mostly moderate and one high quality were included. In 1729 knee arthroplasty patients, knotless barbed sutures ($n = 814$) allowed for significantly shorter wound closure times (saving 3.56 min, CI = −5.05 − 2.08, $p < 0.01$) and lower total cost (considering the costs of operating room time) compared to traditional sutures ($n = 915$). There was no significant difference in postoperative Knee Society Scores or complication rates compared to traditional sutures. Subgroup analysis appeared to show that closure of arthrotomy, subcutaneous, and subcuticular tissues with knotless barbed sutures decreased the total complication rate. If the arthrotomy itself was closed by traditional methods, there was a higher complication rate (1a) [31].

In the second 2015 meta-analysis, 588 patients in 4 randomized controlled trials of hip and knee arthroplasty were included. Barbed sutures were 6.3 min faster to place than conventional sutures ($p < 0.05$), major complication rates (deep infections) and minor complication rates (superficial infections, prominent sutures, stitch abscesses, erythema) were similar (both $p > 0.05$), and the overall cost savings (considering operating room time) was US$ 298 per case. Twelve suture breaks and 1 needle stick were reported in the barbed closure cohort versus 3 suture breaks and 5 needle sticks in the conventional cohort (1a) [32]. Cost-savings may be less immediately evident for the dermatologic surgeon who is rarely in the operating room, since barbed sutures cost more than traditional sutures.

In a 2013 systematic review and meta-analysis of 1748 patients from 19 randomized controlled trials, there was no significant difference between nonabsorbable and absorbable sutures in terms of wound infection incidence, cosmesis, scarring, dehiscence, and patient or caregiver satisfaction. Wounds were secondary to surgery (across multiple specialties) and lacerations. Subgroup analysis suggested intradermal absorbable suture may yield better cosmesis; however, insufficient follow-up may have influenced these results. Absorbable sutures could be recommended for cost and time savings; however, further research is needed to clarify whether intradermal absorbable sutures provide better cosmesis in the repair of lacerations or surgical wounds (1a) [33]. The results agree with an older meta-analysis of a subset of the above studies (1b) [34].

In 2013, a Cochrane database systematic review and meta-analysis of non-obstetric randomized controlled trials were performed to evaluate the benefits and harms of continuous compared to interrupted skin closure techniques. All randomized trials were eligible for inclusion. The final analysis included five trials for abdominal or groin operations with unclear or high risk of bias. For a total of 827 participants, outcomes were available for 730 (interrupted $n = 346$ and continuous $n = 384$). Overall, 6.5% of participants developed wound infections, with no significant difference between groups. Superficial wound dehiscence occurred in a statistically significantly lower proportion of the group closed with continuous sutures compared to the interrupted group (RR 0.08; 95% CI 0.02–0.35). Most of the dehiscence occurred in trials where absorbable subcuticular sutures were left in place and compared to nonabsorbable interrupted sutures that were removed after 7–9 days. Length of hospital stay was equivalent between the two groups. The results suggest continuous subcuticular sutures may reduce the risk of wound dehiscence; however, uncertainty exists due to the low quality of the evidence (1b) [35].

2. *Twenty-nine randomized trials were reviewed, of which 23 represented Level 1b evidence. Six trials were downgraded to Level 2b due to <80% follow-up or poorly described methods for at least one follow-up interval making the quality and conclusions of the study uncertain.*

Several Studies Comparing Outcomes Based on Varying the Suture Technique Only

In 2005, Moody et al. compared the cosmetic results of traditional simple running nonabsorb-

able sutures with running horizontal mattress sutures (1b) [36]. Forty-seven patients completed the prospective randomized split-wound trial of 55 patients with facial Mohs surgery defects over 2 cm in length. Repairs were bilayered using 4-0 or 5-0 poliglecaprone deeply and 6-0 polypropylene superficially. Sutures were removed at 1 week. Cosmesis was determined by partially blinded ratings of three discrete possibilities: superior half better (1), inferior half better (−1), or no difference (0). Cosmesis was superior in the portion of the scar repaired with the running horizontal mattress suture at all time points. At 6 months, 25 (53%) patients did better, 5 (11%) did worse, and 17 (36%) had no difference ($p < 0.05$). The scars appeared smoother, flatter, and narrower. Scores at 6 weeks correlated with those at 6 months. The authors prefer to remove running horizontal mattress sutures at 5 days since they find them more difficult to remove over time (5) [36]. They have also found that interrupted horizontal mattress sutures seem to cause superficial vascular constriction which may relate to wound edge necrosis, and the authors no longer use them for most flaps and grafts (5) [36].

In 2002, a randomized clinical trial reported the results of comparing running nylon sutures ($n = 31$) to interrupted vertical mattress sutures ($n = 27$) in 58 patients (mean age 52 years) undergoing lower midline laparotomies. Interrupted vertical mattress sutures took an average of 5.3 min longer than running sutures to perform ($p < 0.001$), caused significantly less suture markings at 2 weeks and 6 months, less pronounced color at 1 year, and had a significantly better mean scar score at all time points. The 6-month score was equivalent to the score at 1 year. The mean difference of 1.0 on their assessment scale could be the difference between minimal to marked color differences compared to adjacent skin or between minimal scar elevation and hypertrophic scar (1b) [37].

In a 2015 prospective randomized controlled trial, 34 patients (mean age 51.5 years) with upper blepharoplasty wounds had closure by starting the running intradermal suture either externally or internally. After 1 week, 12 suture abscesses (40%) were found medially in externally started suture lines and 4 abscesses (13.3%) were found in internally started intradermal suture lines ($p = 0.02$). Erythema and edema were also lower in the internally started suture lines ($p = 0.02$). All differences resolved by 6 weeks (1b) [38].

A widespread surgical tenet holds that everted closures are necessary in order to counteract scar inversion that may result from wound contraction. This may not be true. In a prospective, randomized, split-scar intervention in cutaneous surgery patients, everted versus planar repairs of defects of at least 3 cm in length were compared. There was no restriction for location, and 10% of procedures were performed on the face. Eversion was carefully achieved with dermal setback or interrupted vertical mattress sutures alone. The comparator was simple subcuticular sutures for planar closure. Both sides were covered with adhesive strips to re-approximate the epidermis and avoid the confounding of track marks. Out of 50 patients enrolled (mean age 61.8 ± 11.9 years), 47 and 43 completed the 3- and 6-month follow-ups, respectively. The 3- and 6-month patient scores and two blinded observer scores were not significantly different between groups using the Patient Observer Self-Assessment Scale. There was also no significant difference in scar height, depth, or width at follow-up (1b) [39].

A second study directly measuring eversion was a prospective split-wound randomized study of 46 elliptical dermatologic surgical wounds of at least 3 cm in length. Forty-two patients (mean age 65 ± 13.5 years) completed the trial comparing 3-month cosmetic outcomes and eversion between the setback suture and buried vertical mattress suture. Polyglactin 910 and adhesive strips were used on the surface to prevent confounding by track marks. Nineteen percent of procedures were performed on the face, and 66.7% were performed by an attending surgeon. Both eversion (height and width) and scores on the Patient and Observer Scar Assessment Scale were significantly superior on the setback suture side (patient mean 13.0 ± 8.7 vs 16.2 ± 12.0 [$P = 0.039$]; two blinded observers mean 24.5 ± 10.4 vs 27.7 ± 13.6 [$P = 0.028$], respectively). Complications included 3 spitting

sutures on the setback side and 11 on buried vertical mattress side and 1 case of dehiscence on both sides (1b) [40].

In a randomized controlled multi-center trial of 142 patients, simple interrupted sutures (n = 73) versus running subcuticular sutures (n = 69) were compared as the superficial layer for bilayered closures of the face after Mohs or excisions. Cosmetic results at 3 and 12 months and associated complications were recorded. Cosmesis was evaluated by the Patient and Observer Scar Assessment Scale with a blinded observer. The deep layer was closed with absorbable suture in all patients and the two superficial arms were closed with nonabsorbable monofilament sutures. Wounds were supported by adhesive strips, and sutures were removed at 7 days. Of 69 assigned to subcuticular closures, 8 patients received interrupted instead of subcuticular sutures due to inability to close the wounds with subcuticulars, and 2 subcuticular closures were converted to interrupted closures later due to wound dehiscence and re-excision. Overall, 13 patients were lost to follow-up by 12 months. In the interrupted suture group, 16% of the patients developed permanent suture marks. Both methods yielded equivalent rates of complications (infection in 1.3–3.3%, dehiscence in 4.4–5.5%), cosmetic scores, and rates of dysesthesia (at 12 months 4.5–12.9%, p = 0.09) by per-protocol and intention-to-treat analyses. While the authors concluded that interrupted sutures had less dysesthesia and may be preferred, those results were not significant (1b) [41].

In a prospective randomized split-wound trial, 101 patients were sutured with either continuous or interrupted nylon stitches to repair facial Mohs wounds. The cosmetic appearance was assessed with multiple scar scales at 1 week, 8 weeks, and 6 months by the principal investigator, and blinded cosmetic appearance was assessed by a plastic surgeon and general dermatologist at 1 week and 6 months. There was no statistically significant difference in scar outcome at any time point for any assessor. By tabulating the ratings of all three assessors into the overall number of times one method was better, worse, or equivalent, running sutures were equivalent or better than interrupted sutures 72% of the time (1b) [42].

In a prospective single-blinded randomized trial, 50 patients underwent layered closure to one half of the wound and buried sutures with adhesive strip closure for the other half of the wound after removal of cutaneous malignancies on the cheek. Wounds were at least 3 cm in length after Mohs or excision, and all had buried vertical mattress sutures with polyglactin 910. Superficial closure was with 6-0 nylon and adhesive strips to the opposite half. Thirty-eight patients completed the trial (mean age 47–82 years). By blinded evaluation between 1 and 24 months, contour, erythema, and overall cosmetic outcomes were equivalent between sides. Adhesive strips may be a less expensive and time-saving option for cutaneous repairs of the cheek (2b) [43].

Several Studies Comparing Outcomes Based on Varying the Suture Material Only

In a 2017 report of a blinded prospective randomized controlled trial, 520 (95%) patients completed the study comparing subcuticular 3-0 poliglecaprone 25 (n = 263) versus subcuticular 4-0 polyglactin 910 (n = 257) in the closure of Pfannenstiel incisions following cesarean delivery. Subcuticular poliglecaprone 25 was associated with a significantly lower rate of overall wound complications compared to polyglactin 10 (8.8% vs. 14.4%, relative risk 0.61, 95% confidence interval 0.37–0.99; p = 0.04). However, differences between groups were not significant for individual wound complications (surgical site infections which could be superficial, deep, organ, seroma, or separation) making up the overall wound complication outcome (1b) [44].

In a prospective trial reported in 2013, 140 patients completed a study (out of 155 randomized) of bilayered Mohs repairs comparing deep absorbable poliglecaprone 25 versus polyglactin 910 sutures. Epidermal closures (in terms of techniques and materials) were completed according to the discretion of the surgeons. There was sta-

tistically less suture extrusion with poliglecaprone 25 compared to polyglactin 910 (3.1% vs. 11.4%, $p < 0.01$). There were no differences in the percentage of lumps (both 22%) or in 1-week or 3-month overall scar ratings by two blinded dermatologic surgeons on a visual analog scale (1b) [45].

In a randomized trial, interrupted 4-0 nylon ($n = 17$), 4-0 polyglactin 910 ($n = 25$), and 4-0 stainless steel ($n = 19$) sutures were used to close the skin after carpal tunnel surgery in 61 patients (ages 30–83 years). There was no significant difference in pain as recorded on a visual analog scale at any time point. Four blinded reviewers assessed scar photographs at 6 weeks for redness, granuloma, and hypertrophy on a three-value scale (none, mild, severe). Granulomas were scored significantly more often in the Vicryl group ($p < 0.05$); there were no differences for erythema or hypertrophy between groups. Two patients in the Vicryl group developed superficial wound infections (8%) and one developed post-traumatic dystrophy. The authors conclude that absorbable Vicryl sutures should not be used, due to higher incidence of infections and suture granulomas (1b) [46].

In a multicenter prospective randomized controlled trial evaluating 241 patients, dermal closure with barbed versus non-barbed sutures was performed on opposite sides of the body. Overall, 229 patients were treated with barbed and smooth sutures (115 with slow-absorbing barbed sutures and 114 with rapid-absorbing barbed sutures). Deep dermal sutures were mostly or completely eliminated on the barbed side, making the mean dermal closure time significantly quicker for barbed sutures. Rapid-absorbing barbed suture showed no difference in complication rates compared to smooth suture; however, slow-absorbing barbed suture showed a higher incidence of minor suture extrusion (1b) [47].

In a randomized trial, 72 of 88 open-heart surgery fair-skinned patients completed a study comparing skin closure with subcuticular 3-0 chromic catgut ($n = 20$), 3-0 polyglycolic acid ($n = 28$), or 3-0 Prolene removed 8–10 days after surgery ($n = 25$). There was no significant difference in wound infections (0–3%), scar width, or hypertrophy between groups. Scar width increased significantly from top to bottom of the sternum in all groups. The lower third of the scar was significantly more likely to show hypertrophy and the middle third of the scar was significantly more likely to show marked hypertrophy (overall incidence of 37%). Marked hypertrophy occurred more often in females (males 24% vs. females 53%, Fischer's exact test significant at $p = 0.05$) (1b) [48].

In a prospective randomized study, 59 patients completed a trial (out of 62) where Dupuytren's contracture fasciectomy wounds were closed with interrupted irradiated 5-0 polyglactin 910 absorbable sutures ($n = 38$ digits) or interrupted 5-0 nonabsorbable polypropylene sutures ($n = 41$ digits). Outcomes included time spent attending to the wound at the first postoperative visit (day 1014), pain score, and complications. Absorbable sutures fell off after a mean of 3.2 weeks (range 3–5 weeks). Wound care took significantly more time for the nonabsorbable suture group, but there was no significant difference in pain scores or complications between the two groups. There was one case of delayed wound healing in the polyglactin group and one case of a swollen hand; in the polypropylene group, there was one case of wound infection, two of delayed wound healing, and two with retained suture material. Absorbable sutures are recommended to save time and resources compared to nonabsorbable polypropylene sutures (1b) [49].

In a randomized study, Pfannenstiel incisions were closed with continuous subcuticular poliglecaprone 25 ($n = 106$) or polypropylene ($n = 107$). The dropout rate was high with 30% of participants lost to follow-up by week 1 and 64% lost to follow-up by week 4. Nonabsorbable polypropylene was removed at 1 week. The primary outcome showed no difference between methods for patient satisfaction (by visual analog scale) at 1 and 4 weeks. Secondary outcomes assessed by yes or no questions showed a significant difference in wound itch at 4 weeks, favoring polypropylene (0%) over poliglecaprone (8.5%, $p = 0.04$) (2b) [50].

In a randomized trial, 70 of 100 randomized patients completed 5-month questionnaires

(visual analog scale and a 6-point validated scar assessment tool) regarding scar cosmesis. At 6 weeks, no dehiscence, hematomas, or infections were noted. At 6 weeks, no dehiscence, hematomas, or infections were noted. There was no difference in cosmesis 5 months after elective hand and wrist surgeries were repaired with absorbable 3-0 Vicryl compared to nonabsorbable 3-0 nylon interrupted sutures (2b) [51].

Comparing Various Suture Techniques and Materials in Several Studies

In 2001, a prospective randomized study compared intracutaneous 3-0 poliglecaprone ($n = 150$) versus transcutaneous 3-0 polyamid ($n = 150$) sutures in the closure of sternal wounds after cardiac surgery. The subcutis was closed with 2-0 polyglactin in both groups. There was a lower rate of total infection in the transcutaneous group (3% vs. 5%, $p = 0.007$) compared to the intracutaneous group. This was due to a lower rate of superficial infections in the transcutaneous group (2% vs. 6.7%, $p = 0.01$), with no difference in the deep infection rate between groups. The 6-week cosmetic results were equivalent on a visual analog scale as judged by the patients (1b) [52].

In a prospective randomized observer-blinded study of 21 patients (ages 40s to 80s) with post-Mohs scalp defects, pulley closure was compared to bilayered closure in terms of closure time and scar cosmesis. Bilayered closure was accomplished with buried vertical mattress 4-0 polyglactin 910 sutures with running 5-0 fast absorbable plain gut. The pulley closure was accomplished by placing interrupted pulley 3-0 monofilament nylon sutures at the center until tension was decreased, along with horizontal mattress along the ends. The Patient and Observer Scar Assessment Scale was completed at 2 weeks, 2 months, and 6 months. A blinded observer assessed before and after photographs on a visual analog scale. The pulley technique resulted in significantly shorter closure times (4.6 ± 1.5 versus 10 ± 1.5 min, $p < 0.001$). Blinded observer scores of cosmesis were similar in both groups, but overall scores were superior in the pulley group by patient scores at 2 weeks and observer scores at 6 months (1b) [53].

In a split-scar prospective randomized controlled trial, deep barbed 3-0 sutures versus deep 3-0 Maxon and subcuticular sutures (both polyglyconate monofilament synthetic absorbable sutures) were compared in 33 elective plastic surgery cases with long wounds. Patients' ages ranged from 34 to 74 years. Photographs at 2 years were assessed by 9 blinded plastic surgeons and specialist registrars using the modified Hollander cosmesis score in 24 patients. Wound closure time and number of suture packets used were significantly less with barbed sutures ($p < 0.001$). Complication rates were equivalent with both methods. Cosmesis at 2 years was superior with barbed sutures ($p = 0.0075$). Patient pain ratings on a 10-point visual analog scale were equivalent between groups. Barbed sutures distribute wound tension evenly and eliminate the need to tie knots which may decrease the risk of needle-stick injuries (1b) [54].

A prospective randomized study of 113 patients compared 4 methods of leg wound closure after coronary artery bypass grafting: (1) a continuous vertical mattress suture of 2-0 nylon ($n = 27$ patients); (2) a continuous subcuticular suture of 2-0 polyglycolic acid ($n = 29$ patients); (3) disposable metal skin staples ($n = 27$); or (4) "Op-site" transparent adhesive sutureless skin closure. Wounds were examined by two independent observers at 5, 10, and 45 days. The overall infection rate was 4.5%. Continuous subcuticular sutures led to significantly less discharge at 5 days; significantly better healing at 10 days in terms of wound overlap, inflammation, dehiscence; and final cosmesis significantly better than metal staples or vertical mattress nylon sutures but equivalent to closure with "Op-site" sutureless closure. The authors conclude continuous subcuticular polyglycolic acid is superior in all criteria except speed of insertion and cost and recommend it for standard use (1b) [55].

In a prospective randomized trial of 58 hands in 50 patients, subcuticular absorbable 4-0 polyglytone 6211 sutures were compared to interrupted nonabsorbable 5-0 polybutester sutures

for closure after endoscopic release of the carpal tunnel. Overall, 36 females and 14 males with ages ranging from 21 to 70 years entered the trial, and 54 hands of 47 patients completed the study. Pain diaries were completed by patients on a visual analog scale until a nurse visit for suture removal at days 10–14. There was a significant reduction in pain scores on days 1 and 2 in the subcuticular suture group. One patient in each group had inflammation during the first 14 days. There were no infections or suture granulomas. There was no significant difference in terms of inflammation, infection, or 3-month cosmesis assessed by the surgeon (a nonsignificant trend toward better cosmesis with subcuticular polyglytone was noted) (1b) [56].

Intracutaneous or transcutaneous sutures were compared in 100 sternal closures (50 per group) after median sternotomy for open-heart surgery. Cosmetic results were similar between groups, no deep infections occurred, and superficial infections occurred in one patient or 2% of the transcutaneous group (4-0 polypropylene) and eight patients or 16% of the intracutaneous group (4-0 polycaprolate). One patient in the transcutaneous group was diabetic, and six patients in the intracutaneous group were diabetic. Transcutaneous sutures may decrease the risk of superficial infection, particularly in diabetics (1b) [57].

In a rater-blind randomized controlled trial, superficial simple running 5-0 polypropylene sutures were compared to subcuticular running 5-0 polypropylene sutures removed after 14 days, subcuticular running 5-0 polypropylene sutures left in place, and subcuticular running 5-0 polyglactin 910 sutures left in place. Deep dermal closure was accomplished with simple interrupted polyglactin 910 sutures (size 3-0 for the back and 4-0 for all other sites) in all cases. The trial included 72 wounds in 36 adult patients (ages 19–65 years) needing concurrent elliptical excision of at least 2 clinically atypical nevi of the trunk and/or extremity with an expected suture line of at least 2 cm in length. At 3 months and 9 months, scar width, a blinded assessment of overall scar appearance on an ordinal scale, the Vancouver Scar Scale, the Hollander Scar Scale, and pruritus were recorded. Results showed that immediately after closure all methods appeared similar. At 3 months, vascularity was significantly less, and overall appearance was superior with subcuticular polyglactin 910 suture left in place compared to all other groups. By 9 months, both subcuticular polyglactin 910 suture and subcuticular polypropylene suture left in place were significantly superior in overall appearance compared to the other two groups. At both time points, subcuticular polypropylene suture left in place had a significantly better overall appearance than simple running polypropylene removed after 14 days. Subcuticular polypropylene left in place had significantly more contour irregularities at 3 months than all other groups and also significantly less inversion at 3 months compared to simple running Prolene removed after 14 days. Simple running Prolene also led to significantly greater vascularity at 3 months than in all other groups. In post hoc analysis, back wounds resulted in significantly greater width than non-back locations. At 3 months, two cases of erosion and partial dehiscence were reported with running subcuticular polypropylene left in place. No differences in pruritus were noted. Vascularity was the only parameter that differed across surgeons. In conclusion, superficial subcuticular sutures left in place appear to be superior for bilayered closures of the trunk and extremities. This could decrease closure costs by half if the same caliber sutures were used for deep and superficial sutures, and even if different caliber polyglactin 910 sutures were used, this would be less expensive than using polypropylene superficial sutures (1b) [58].

In a prospective randomized trial of 40 hand surgery defects, continuous subcuticular absorbable 3-0 polyglactin 910 sutures were compared to nonabsorbable 3-0 polypropylene sutures in the closure of open carpal tunnel release. A total of 36 hands completed the study. No significant differences between groups were found in terms of pillar pain, scar tenderness, wound inflammation, and overall surgical outcomes at 2, 6, and 12 weeks after evaluation by an independent observer (1b) [59].

Fifty consecutive saphenous vein coronary artery bypass graft patients aged 33–71 were

randomized to leg closure with subcutaneous 2-0 Dexon and 2-0 Prolene subcuticular ($n = 25$) versus a single layer of interrupted 2-0 Ethilon sutures ($n = 25$). Sensory perception was assessed at 48 h, 7 days, and 6–8 weeks in all patients. Sensory recovery was significantly better in the group closed with interrupted Ethilon sutures at 7 days and 6 weeks. No wound infections or hematomas were reported. In 37 patients, no difference was reported in cosmetic results (rated excellent, good, or average) at 14–18 months. There was a higher incidence of sensory abnormality in the subcutaneous Dexon and Prolene group at 14–18 months, but this was not assessed for significance (2b) [60].

In a randomized trial of 43 hernia repairs or cholecystectomies, closure with interrupted 3-0 nylon mattresses was compared to 3-0 polyglactin 910 for interrupted inverted subcuticular sutures. Assignment was by lot drawing; there was no mention of dropout rate. After 12 weeks, no objective or subjective differences in scar appearance or adverse events were reported. Subcuticular sutures took twice as long but saved the patient the need for a suture removal visit (2b) [61].

Twenty of 30 patients completed a prospective upper eyelid blepharoplasty trial and were treated with both 5-0 running subcuticular polypropylene and 6-0 running superficial fast absorbing catgut in a randomized fashion. Results were comparable in terms of operative time, minor complications, senior author and patient aesthetic preferences, and postoperative discomfort. Patients and the senior author rated the scar slightly superior with running catgut after 1 month (0.3–0.7 points higher on a scale of 1–10). No statistical comparisons were performed (2b) [62].

In one study, single-layer versus double-layer closure was compared. The suture materials used were not specified. In the double-blind randomized study of excisions of atypical nevi on the upper back, 50 patients were treated with conventional bilayered closures (with simple interrupted buried and surface sutures) and 50 patients were treated with buried vertical mattress sutures alone. The modified technique showed less hypertrophic scarring and keloid formation (2% vs. 16%, $p < 0.031$), less wound scar spread >3 mm (6% vs. 24%, $p < 0.02$), and no difference in infection rates, dehiscence, suture reactions, or patient satisfaction (96% vs. 88% in conventional closure, nonsignificant). The authors conclude it produces excellent cosmetic results (statistically superior in terms of hypertrophy and wound spread) for the closure of elliptical excisions in anatomic locations with thickened dermal skin under moderate to severe wound tension and obviates the need for suture removal (1b) [63].

Evaluation of Several Nonrandomized Studies Representing Mostly Level 3 Evidence

Study Comparing Suturing Techniques

In a blind, nonrandomized, prospective, longitudinal, comparative study, 90-day esthetic results were compared after excision of benign facial growths and closure with simple interrupted ($n = 47$) versus running intradermal 5-0 polypropylene sutures ($n = 46$). Most lesions were intradermal nevi (86%) with a mean size of 9 or 10 mm, and all were removed by a single surgeon. Suture removal and inspection for erythema, edema, dehiscence, and infection occurred on day 5. The surgeon assessed the scars at 30 days. Two independent dermatologist observers made blinded esthetic assessments of pictures of the wounds before and after 90 days. Of 100 procedures (on patients aged 2 months to 70 years), 93 scars were assessed in patients completing the study. Five patients were lost to follow-up and two were excluded due to wound infection within the first 10 days. Suture marks and tracks present at 30 days in 28% of scars after simple interrupted sutures had disappeared by 90 days. Hypertrophic scars occurred more frequently at 30 days ($n = 16$ overall); however, by 90 days only two scars in each group were hypertrophic. Erythema decreased in both groups from 30 days to 90 days but was more frequent in the inter-

rupted suture group at both time points. A similar proportion of 90-day esthetic results were rated by the patients and blinded observers as fair/poor, good, or excellent (45–75% excellent) with both methods. Patients were more benevolent in their ratings than the blinded observers (75% excellent). No statistical analyses were performed (2b if cohort 3b if case control) [64].

Several Studies Comparing Suture Materials

In a prospective clinical study, intradermal closures for 80 patients undergoing facial rhytidectomy were compared using 6-0 polydioxanone versus 6-0 polyglactin 910. The superficial skin was closed with 6-0 catgut in all cases. There were no statistically significant differences between intradermal suture material groups in double-blind evaluations of erythema, induration, scar spread <1 mm, infection, and hypertrophic scarring at 5 months and 1 year (3b) [65].

In a follow-up survey study, 1 year after 876 operations and histologic study of 60 scars at 20–100 days postoperatively, polydioxanone (n = 486) and polyglactin 910 (n = 399) were compared using buried, butterfly-shaped, interrupted sutures for Mohs wounds with tension. By histology, nonsignificant trends noted that polydioxanone showed less thread reaction and granulocytes; however, milder tissue reaction for polyglactin 910 could be expected when buried deeper than 1.6 mm as opposed to 0.8 mm. Polydioxanone showed slighter better overall patient-rated cosmesis, more hypertrophic scars, fewer dehiscent scars, and less inflammation, suture reaction, and suture perforation, but no statistical differences were reported. Operator experience was reported to affect cosmetic results independent of suture material used (3b) [66].

In a prospective study of 28 patients undergoing upper eyelid blepharoplasty, healing with 6-0 absorbable fast-absorbing catgut was equal to healing with nonabsorbable 6-0 nylon suture in terms of patient satisfaction 1 year or more after surgery, pain, and scarring on a visual analog scale (3b) [67].

In a nonrandomized prospective split-wound study, 44 skin cancers were removed from the head and neck area in 41 adults. Defects were repaired with rotational flaps using absorbable simple interrupted 5-0 Vicryl Rapide sutures and the other half of the wound with 5-0 Prolene sutures. Closure lengths ranged from 3.5 to 12.0 cm (average 7.5 cm) and were mostly facial in location (n = 37). The deep layer was closed with poliglecaprone 25. Prolene was removed at 7 days, and photographs were evaluated at 3 and 6 months for observer evaluation. Railroad tracking occurred in 3 cases with Prolene and in 2 cases with Vicryl Rapide, all located between the mandible and the neck. Overall, no significant difference was noted between the areas closed with Prolene and those closed with Vicryl Rapide. Wound infection did not occur (3b) [68].

A nonrandomized prospective split-wound study compared simple running sutures using absorbable 5-0 poliglecaprone 25 with nonabsorbable 6-0 Prolene in the superficial layer of primary closure of 48 facial Mohs defects. Rosenzweig et al. found no significant difference in blinded cosmetic outcomes at 1 week and 4 months postoperatively. At 4 months, there was no difference in 85% of cases; poliglecaprone 25 was better in 4%, and polypropylene was better in 10%. No complications of infection, hematoma, or dehiscence occurred (3b) [69].

It is possible that single-layer closure may be sufficient. A follow-up study of 149 excision procedures evaluated whether buried absorbable monofilament vertical mattress sutures alone could be used safely without superficial suturing. Wounds were located on the face (43%), trunk (29.5%), upper extremities (13.4%), head/neck (10.7%), anogenital area (2.7%), and lower extremities (0.7%). Patient ages ranged from 1 to 89 years. Wounds were evaluated for color, dehiscence, hypertrophy, granulomas, and keloid at 13–64 weeks. Buried interrupted vertical mattress sutures were placed with the arc coming as close to the epidermis as possible for perfect apposition of skin edges. Single superficial sutures were needed in 14.7% of cases. Wound closure tapes were applied to the wounds and removed after 5 days along with any single sutures. The over-

all outcome was excellent (< 5% dehiscence and no hypertrophy, granuloma, or keloid) to good (5–10% dehiscence and no hypertrophy, granuloma, or keloid) in 78.5% of cases, satisfactory in 19.5%, and poor in 2%. Wound dehiscence expressed as a percentage of wound length was <5% in 68.5%, 5–10% in 20.8%, 10–20% in 9.3%, and > 20% in only 1.4%. Hypertrophic scarring was present in 10.1%, keloid formation in 1.3%, and granulomas in 3.4%. No suture marks or infections were recorded. Hypertrophic scarring was significantly more frequent with polyglactin (31%) than polydioxanone (8%) ($p < 0.0001$). The mean overall score for scars in facial locations was significantly better than all non-facial locations (excellent in 78.1%, even with a mean wound length of 5.9 cm). Increased length of the wound was significantly correlated with scar dehiscence; however, the overall cosmetic result was not significantly affected by wound length. The authors conclude the technique is safe, easy to use, and prevents suture marks as long as exact skin edge apposition can be achieved with intradermal sutures alone (3b) [70].

Several Studies Comparing Combinations of Sutures and Techniques

In order to identify patient and technique factors relating to early (up to 2 weeks) complications, a nonrandomized study of 1000 consecutive outpatient primary closures of small (<3 cm) defects was designed. In multivariate analysis, older age, male sex (for bilayered wounds), and longer wound length were significant risk factors for tissue reactivity. Suture materials had little effect, with silk having the highest, though not significant, risk of tissue reactivity. In terms of dehiscence, male sex, surgeon experience (for one-layer wounds), and patient age ≤50 years (for two-layer wounds) were significant risk factors in multivariate analyses. Smaller caliber external sutures were associated with a borderline risk of dehiscence. In terms of infection, male sex and age >50 years were significant risk factors in multivariate analyses for the combination of one-layer and bilayered closures (2b or 3b) [71].

In a large prospective study of 866 sequential blepharoplasties over 5 years, 6-week complication rates and 3-month satisfaction rates were compared between repairs using different suture materials and techniques. Four techniques were compared: (1) 5-0 running subcuticular polypropylene (n = 198), (2) 5-0 running cutaneous locked polypropylene (n = 45), (3) running 6-0 plain gut suture (n = 177), and (4) running 6-0 fast-absorbing gut suture and two simple interrupted 5-0 polypropylene (n = 466). Nonabsorbable sutures were removed at 5 days. Groups 1 and 4 had significantly lower rates of milia (2.5% and 2%) and groups 2 and 3 had higher rates (17% and 6.7%). Group 4 had significantly less scarring than expected (0%) and Group 3 had significantly more scarring than expected (2.8%) (Groups 1 and 2 also had 0% scarring). Group 3 had statistically more erythema (9%) than all other groups (2%). There were no differences in standing cone deformities between groups 1 and 2. There were no differences between groups 3 and 4 in terms of suture marks. There was no difference between groups 1, 3, and 4 in terms of minor hematoma. There were no infections or cases of dehiscence. Of 568 patients surveyed at 3 months, 74% were highly satisfied, 21% were satisfied, and 5% were unsatisfied with their results (2b or 3b) [72].

Blood supply is a factor in closure site healing. In a nonrandomized study of 63 patients, cutaneous blood flow was evaluated on the first and fifth postoperative day in relation to 3 suturing techniques (n = 21 per group). Infrared laser Doppler flowmeter on either side of abdominal incisions with uninjured adjacent skin as a control showed statistically higher blood flow with subcuticular sutures compared to mattress sutures and staples (3b) [73].

In a nonrandomized split-wound study of five patients, fast absorbing gut suture placed in a running subcuticular technique was compared to simple interrupted nylon sutures for layered facial Mohs closures under minimal tension. No complications or differences in cosmetic outcome were noted at 1 week and 3 months (3b) [74].

Among a group of boys aged 14 months to 18 years, 146 orchidopexies were closed with subcuticular 4-0 polyglycolic acid and 27 were closed with interrupted 3-0 silk. Follow-ups occurred 12–37 months after surgery. Hypertrophic scars were raised above the surrounding skin and measured more than 1 mm in width. No hypertrophy was noted in 94.5% of wounds sutured with subcuticular polyglycolic acid. With interrupted black silk sutures, 18.5% of the scars developed medial hypertrophy. Hypertrophy was found to be dependent on location rather than suture material (3b) [75].

In a prospective study of 60 patients, postoperative pain assessments for the first 5 days were compared when hernia repairs or upper abdominal closures were completed with either simple full-thickness 2-0 nylon interrupted sutures or 3-0 polydioxanone subcuticular interrupted sutures. In the hernia group, the subcuticular method resulted in significantly less pain. Both groups were equivalent in terms of wound healing, sepsis, and cosmetic outcome (3b) [76].

In a retrospective nonrandomized case-control study, 186 consecutive patients with primary closure of 188 full-thickness lower eyelid defects with single or bilayered closure techniques were compared. Single-layer closures (n = 82) were with nonabsorbable polypropylene. Bilayer closures (n = 106) were with absorbable polyglactin. Single-layer closure of full-thickness eyelid defects is equally as safe and effective as bilayer closure with no differences in terms of notching, dehiscence, or other complications (3b) [77].

In a retrospective cohort study of 142 patients undergoing breast reconstruction, half were closed with standard suture material while the other half were closed with barbed sutures. The standard suture group closed Scarpa's fascia with interrupted 2-0 Vicryl, deep dermis with 3-0 Monocryl, and subcuticular closure with 4-0 Monocryl. In the barbed group, fascia was closed with 2-0 V-Loc 180 unidirectional barbed sutures, deep dermis with fewer 3-0 Monocryls, and subcuticular closure with 3-0 V-Loc 180. There was no significant difference in operation times, seroma, infection, or wound dehiscence; however, less hematomas were observed in the barbed suture group (3b) [23].

In a prospective case-control study, 117 craniotomy scalp closures with continuous 2-0 nylon sutures were compared with intradermal 2-0 Monocryl sutures. Intradermal suture was performed in 44 cases, and continuous suture was performed in 56 cases; 17 patients died and were excluded from the study. Equivalent rates of wound infection were observed with one case (2.2%) of wound infection in the intradermal group and three cases (5.3%) of wound infection in the continuous suture group (P = 0.73). There were no cases of wound dehiscence in either group (3b) [78].

Review of Studies Consisting of Level 4 Evidence

In a small case series of three patients, Wong (1993) described successful use of a running locked intradermal suture in elliptical facial excisions that accomplished the following goals: to close dermal dead space under light tension, to allow for good wound edge apposition, to make superficial sutures unnecessary (avoiding suture marks and giving good cosmesis), and to reduce the need for wound care and suture removal (4) [79].

In a case series where barbed sutures were used for wound closure on 11 ft in 8 patients undergoing hallux valgus correction or revision correction, 5 (45%) had delayed wound healing with irritation or dehiscence due to prominent barbs, and 4 (36%) required open suture excision and formal scar excision due to adverse reaction at around 4 weeks (4) [80].

A limited cost analysis by Fosko et al. calculated an average savings of US$ 3.36 per dermatologic reconstruction by using polyglactin 910 only instead of an additional package of nylon. This results in saving US$ 336 per 100 repairs (4) [81].

There is a report of two cases of allergy to poliglecaprone 25 sutures confirmed by patch testing (4) [82].

Evidence-Based Review: Tissue Adhesives and Glue

1. *Three systematic reviews and meta-analyses on the topics of tissue adhesives or surgical glue were reviewed; one was downgraded due to quality of the included studies and heterogeneity for some outcomes.*

A systematic review and meta-analysis performed by Gkegkes et al. included 12 randomized controlled trials. A total of 1317 incisions were compared using adhesive strips for wound closure versus conventional wound closure methods such as sutures. Eight of these studies showed that there was no significant difference in infection rates between closure with surgical strips and sutures (odds ratio = 0.47; 95% confidence interval = 0.12–1.85). Of nine studies that provided data regarding cosmetic outcome, only five studies provided data that was eligible for statistical synthesis by the authors, which showed no significant difference in the cosmetic outcome when using surgical strips (standardized mean difference = 0.01; 95% confidence interval = −0.19–0.20), though a variety of scoring techniques were used. The authors also showed no significant difference with regard to wound dehiscence (odds ratio = 1.22; 95% confidence interval = 0.32–4.64). More studies are needed to determine the distance between wound edges where use of surgical strips is still an effective means of wound closure to gauge how much tension can be allowed, the need for resuturing, patient satisfaction with this method of wound closure, and whether surgical strips offer any time-saving benefits (1a) [83].

A meta-analysis investigating the early cosmetic outcomes with the use of skin adhesives conducted a search through PubMed, Medline, and the Cochrane Central Register of Controlled Trials for randomized controlled trials published between January 1990 and December 2011. The limitations of the study included differing techniques for tissue adhesives between studies, only 3 months of follow-up for cosmesis leading to significantly heterogeneity, and small sample sizes of the studies. To be included, a study was required to compare skin incision closure with tissue adhesive versus traditional wound-closure methods, and a visual analogue scale (VAS) must be mentioned. A total of 9 publications were included in the meta-analysis. There was significant heterogeneity between studies regarding overall effect on the incision's cosmetic appearance 3 months postoperatively. No significant differences in overall cosmetic outcomes were found between the use of tissue adhesives and staples or when using sutures (P = 0.54, P = 0.99). There was no significant difference for facial wounds (P = 0.79), body wounds (P = 0.46), older patients (P = 0.07), or selective surgery (P = 0.78). However, the VAS results between the use of sutures and tissue adhesives were significant, and there was no heterogeneity of studies. The evidence indicated that the cosmetic results of incisions closed by tissue adhesives were worse when dermal sutures were not used (P = 0.04) or when a laceration wound was involved (P = 0.03). Study authors concluded that dermal suture is required to decrease wound tension and prevent dehiscence in laceration wounds, and therefore any tissue adhesive used must also include dermal sutures (1b) [84].

Another meta-analysis investigated the use of tissue glue for surgical incision closure. A literature search for randomized controlled trials was performed using PubMed, the Cochrane Database, Ovid, Medline, Google Scholar, Ovid, Embase, and Medline. To be included, studies had to compare surgical skin closure with tissue adhesive and another type of standard closure method. A total of 26 studies were included. There was no significant difference in wound infection rates between the two groups (I^2 = 0%, risk ratio [RR] = 1.10; 95% CI, 0.71–1.69). This included subgroup analysis between tissue glue and sutures, tissue glue and monofilament sutures, tissue glue and interrupted sutures, and tissue glue and subcuticular sutures. Similarly, no significant difference was identified in wound infection rates between tissue glue and staples (skin clips) (I^2 = 0%, RR = 1.05; 95% CI, 0.41–2.65). Of the 26 studies, 19 included data on time for wound closure. Of these 19 studies, 14 found closure to be significantly faster using

tissue glue compared with sutures, with 1 more finding tissue glue faster but included no tests for significance. One study found no significant difference in times between tissue glue and sutures. Four studies compared the use of tissue glue with staples (skin clips), and three of these found staples (skin clips) to be considerably faster for skin closure, while one study found no significant difference between the groups. A study comparing tissue glue with adhesive tape found no significant difference between groups. Twenty studies analyzed wound dehiscence after skin closure by tissue glue, and a statically significantly increased wound dehiscence rate was found when using tissue glue (I^2 = 14%, RR = 3.29; 95% CI, 1.77–6.15). Further subgroup analysis between tissue glue and skin sutures also demonstrated statistically significant increases in dehiscence for tissue glue (I^2 = 33%, RR = 3.31; 95% CI, 1.73–6.34), as well as tissue glue versus monofilament sutures (I^2 = 5%, RR = 4.61; 95% CI, 2.17–9.79), and tissue glue versus subcuticular sutures (I^2 = 34%, RR = 7.39; 95% CI, 2.49–21.94). Cosmetic results were included in 21 studies, but due to heterogeneity in scoring, these results were not included. However, of note is that 15 studies found no significant difference in cosmetic outcome in wounds closed with tissue glue versus standard wound closure, while 2 studies reported that tissue glue produced better cosmetic outcomes. With regard to patient satisfaction, eight studies stated that patients were more satisfied with the use of tissue glue, while another two studies stated that standard wound closure increased patient satisfaction. Equivalent patient satisfaction for standard wound closure and tissue glue was reported in two other studies. Finally, nine studies assessing the material cost of tissue glue in comparison with standard closure methods reported tissue glue as more expensive. However, two studies that included time savings in addition to material costs found tissue glue was less expensive. In summary, tissue adhesives/glue have the advantages of reduced closure time, reduced pain, and no follow-up for removal as compared to standard wound closure methods. These traits make tissue glue/adhesives particularly useful in pediatrics. However, there is a small increase in risk of wound dehiscence for wounds closed with tissue glue and no definitive evidence of improved cosmetic outcome (1a) [85].

2. *Review of several randomized controlled trials studying tissue glue*

In this randomized control trial, subjects undergoing total knee arthroplasty (TKA) were randomly assigned into one of four cohorts based on wound closure method with any one of n-butyl-2-cyanoacrylate tissue adhesive, 2-octyl tissue adhesive, Visistat 35W Stapler, or Monocryl suture (control). Of the 90 subjects recruited, a total of 75 subjects completed the study. Staple-based closure was deemed the fastest and least-expensive TKA wound closure technique in the operating room, but was associated with a statistically significant longer hospital stay in comparison with tissue adhesives and suturing. Of the 4 closure methods, tissue adhesives and staples were faster than sutures. The 2-ocytl and n-butyl-2 tissue adhesives required an average of 2.5 and 2.6 s/cm, whereas staples required 1.8 s/cm, and subcuticular Monocryl 4-0 suturing required an average 26 s/cm ($P < 0.0007$). However, the intraoperative efficiency of staples may be offset by lengthened hospital stay, thereby making tissue adhesives an efficient, viable alternative to TKA closure. Further study is needed to determine if the relationship between hospital stay and staple closure may be causal. The successful use of tissue adhesives for high tensile strength knee replacement in this study was believed to be due to added underlying reinforcement with 50% higher frequency (7.5 mm for adhesives vs. 10-mm staples, 8-mm suture) interrupted subcutaneous sutures. The adhesive and staple cohorts experienced an average 17% greater occurrence of peripheral edema with respect to subcuticular suturing ($P < 0.03$). However, there were no statistically significant differences in infection, dehiscence, cosmesis (patient-assessed visual analog scale), general health (SF 12v2), and functional and clinical assessments (extension, flexion, ROM, Knee Society knee score, and pain visual analog scale) (1b) [86].

In a blind randomized controlled trial, differences in operating time, wound complications, and cosmetic outcomes were assessed in wounds of 29 patients closed using either octyl-2-cyanoacrylate (2-OCA) tissue adhesive or conventional subcuticular skin sutures. A total of 15 patients (20 incisions total) received closure by 2-OCA and 14 patients (20 incisions total) received closure by subcuticular sutures. On days 5–10 postoperatively, the wound was evaluated for healing. A total of 3 months postoperatively, wounds were assessed for cosmetic outcome by a plastic surgeon (independent of the study) using a Hollander Wound Evaluation Scale (HWES) and a visual analog scale (VAS). Patient satisfaction was also evaluated using a VAS. There were no significant differences between treatments with regard to adverse outcomes. At the 3-month follow-up, there was no significant difference in the frequency of an optimal HWES score between the two closure groups ($P = 0.835$). The surgeon's VAS scores had no significant differences ($P = 0.332$) between treatment groups, as did the patients' VAS scores ($P = 0.129$). The results indicate that 2-OCA significantly reduced time required for wound closure, as compared with the time required for sutures (2-OCA at 69.50 ± 33.39 s vs. 379.00 ± 75.39 s for sutures) ($P < 0.005$). 2-OCA proved to be a verified alternative to sutures for an effective and faster method of maxillofacial incision closure. However, the authors noted that 2-OCA has a maximum tensile strength equivalent to that of 5-0 suture, and should not be used for high tension wounds that would require 3-0 or 4-0 sutures. In addition, no analysis of cost-effectiveness was included in this study, but one can deduce that tissue adhesives are more economical (1b) [87].

In this randomized controlled trial investigating optimal closure materials for upper lid blepharoplasty, 36 patients underwent a split-eyelid study to compare the efficacy of polypropylene, fast-absorbing gut, and ECA (Dermabond). Patients were randomized for treatment into 1 of 3 groups: (1) fast-absorbing gut suture versus ECA, (2) ECA versus polypropylene suture, and (3) polypropylene versus fast-absorbing gut suture. All surgeries were conducted by the same surgeon, and in all groups the lateral third of the defects were standardized for wound tension via one deep dermal suture with 5-0 Vicryl. At the 1-month follow-up, a blinded-physician evaluation scored ECA with a statistically significant better cosmetic outcome than fast-absorbing gut suture and nonsignificantly better outcome than polypropylene. Polypropylene was nonsignificantly better than fast-absorbing gut suture. At the 3-month follow-up, a statistically significant better cosmetic outcome was demonstrated for group 1, in which ECA had superior cosmetic outcomes than fast-absorbing gut ($p = 0.03$). Overall, the study concluded that the use of ECA resulted in speedier application and cosmetic results equivalent if not superior to that of sutured wounds. Tissue adhesive is recommended for closure of low-tension wounds during cosmetic surgery, especially for the eyelid. However, patients should be warned about potential for irritation and pruritus with the use of ECA (1b) [88].

In this single-blind RCT, Bartenstein et al. reported that cyanoacrylate tissue adhesives produce equivalent cosmetic outcomes to that of sutures, in addition to increased ease of use, patient satisfaction, and speed of application. After completing skin cancer removal (via Mohs or excision) and following placement of deep absorbable sutures, patients were randomized to receive wound closure by Prolene suture, LiquiBand (butyl-cyanoacrylate), or Dermabond (octyl-cyanoacrylate). Upon surgery completion and until the 2-week follow-up, patients were asked to write a daily record on the amount of time needed to care for their wound and how much the wound interfered with daily activities (VAS 0–10). At 3 months, subjects rated satisfaction with their wound and evaluated wound cosmetic outcome (VAS 0–10). A photograph was taken at the 3-month follow-up and was used by an independent, method-blinded panel of three dermatologists and three plastic surgeons. Wound closure with either tissue adhesive was found to be significantly faster than sutures (median 256.0 s, range 172.0–530.0 s; $p < 0.0001$ for LiquiBand vs. suture, $p < 0.0001$ for Dermabond vs. suture). At the 2-week follow-up, nurses required significantly more time ($p = 0.01012$) with the subjects

who had sutures than they did with subjects who had either type of tissue adhesive. At the time of wound closure, the surgeon found it significantly easier to close wounds with either tissue adhesive as compared to sutures ($p < 0.001$ for both Dermabond vs. sutures and LiquiBand vs. sutures). However, the surgeon reported more initial satisfaction with the wounds closed by sutures compared with adhesives ($p = 0.0004$ for LiquiBand vs. sutures and $p = 0.0001$ for Dermabond vs. sutures). It is worth noting that 24 subjects underwent past surgery with wound closure by traditional suturing but in this study were randomized to closure by tissue adhesive. When these patients were asked to rank their satisfaction with tissue adhesive as compared to suture, the ratings were statistically significantly for an increase in satisfaction for tissue adhesives (LiquiBand: $p = 0.0039$, Dermabond: $p = 0.002$) as compared to suture (1b) [89].

3. *Review of several randomized controlled trials studying adhesive strips*

In a prospective randomized split-wound controlled trial, researchers investigated if addition of adhesive strips to a wound closed with subcuticular sutures improved cosmetic outcomes. Study subjects were adults with postoperative defects of at least 3 cm resulting from either Mohs surgery ($n = 35$, 73%) or surgical excision ($n = 13$, 27%) located anywhere on the body. Buried vertical mattress subcuticular sutures were used to close the wound. Following closure by the surgeon, the wound was divided in half, and one side was randomly chosen to receive adhesive strips applied by a nurse (with supplemental tissue adhesive, Mastisol). At 3-month follow-up, two blind observers and the patient evaluated the scar using the Patient and Observer Scar Assessment Scale (POSAS). No significant difference in mean POSAS scores was found between the two closure techniques regarding vascularity, pigmentation, thickness, relief, pliability, surface area, and overall opinion. Additionally, there was no significant difference for scar width between the sides of the scars with or without adhesive strips. The mean width of both scar sides was 1.1 mm (SD = 0.8, $P = 0.89$). Any adverse events (suture abscess, wound dehiscence) that occurred were not statistically significant with regards to either closure group. Therefore, it was concluded that adhesive strips did not improve the appearance of scars from cutaneous surgical procedures using subcuticular sutures. Equivalent outcomes were observed on both wound sides with no changes by addition of tissue adhesive (1b) [28].

In a prospective randomized study, Steri-Strips were compared to running absorbable subcuticular sutures for skin closure following median sternotomy in 36 patients. There were no significant differences in closure times between the groups. Steri-Strips led to significantly less erythema ($p = 0.003$) and edema ($p < 0.001$) with no difference in pain or cosmesis on day 7. At 21 days, the only difference remaining was less erythema ($p = 0.01$) in the adhesive group. The suture technique used about two packets of Vicryl sutures per patient (US$ 4.36 per patient), whereas about three packets of adhesive strips were required per patient (US$ 32.91 per patient). The strips are safe and effective but not clearly superior for the average patient (1b) [90]. They may be of potential benefit for patients where it may be desirable to avoid additional inflammation from superficial sutures such as in the case of diabetics, or patients with immunosuppressive or inflammatory disorders (5) [90].

A prospective randomized study of 113 patients compared 4 methods of leg wound closure after coronary artery bypass grafting: (1) a continuous vertical mattress suture of 2-0 nylon ($n = 27$ patients), (2) a continuous subcuticular suture of 2-0 polyglycolic acid ($n = 29$ patients), (3) disposable metal skin staples ($n = 27$), or (4) "Op-site" transparent adhesive sutureless skin closure. Wounds were examined by two independent observers at 5, 10, and 45 days. The overall infection rate was 4.5%. Continuous subcuticular sutures led to significantly less discharge at 5 days; significantly better healing at 10 days in terms of wound overlap, inflammation, and dehiscence; and final cosmesis significantly better than metal staples or vertical mattress nylon sutures but equivalent to closure with "Op-site" sutureless closure. The authors conclude continu-

ous subcuticular polyglycolic acid is superior in all criteria except speed of insertion and cost and recommend it for standard use (1b) [55].

In a randomized controlled trial of 169 patients (ages 15–78 years) undergoing acute appendectomy, inguinal herniorrhaphy, or saphenofemoral ligation, traditional interrupted 2-0 Prolene sutures were compared to subcuticular 2-0 Prolene sutures and sterile porous adhesive tape (Micropore Surgical Tape). All sutures were removed at 7 days, and the micropore tape was left for 2 weeks. Scars were graded at 4 weeks by the patients, surgeon, and a blinded assessor. The combination closure resulted in significantly higher percentages of "excellent" grading by surgeons for herniorrhaphy and by all raters for appendectomies. No differences in "excellent" gradings were noted for saphenofemoral ligation. The appendectomy group had the highest number of patients, and it is possible the sample sizes for the other two groups were too small to show more significant differences. Seven cases of wound infection were reported (four in the traditional group and three in the combination group) (1b) [91].

Op-site sutureless skin closures of at least 7 cm were compared to continuous nylon sutures in a randomized controlled trial in 55 orthopedic surgery patients. Sutures were removed at 10–12 days, and Op-site was removed at 2 weeks. Op-site gave better cosmesis, comfort, and less wound inflammation but problems were identified in terms of safety, accuracy of wound edge apposition, and ease of use. The sutureless system could not close the skin due to oozing in one case, skin could not be apposed perfectly in two cases, indented scars formed in four cases, and there was dehiscence in one case (2b) [92].

A polyurethane membrane coated with firm adhesive skin closure method (Op-site) was compared to skin closure by interrupted silk sutures and subcuticular nylon. Wound closure by Op-site proved statically significant for reduced erythema ($P = 0.0457$) and tenderness ($P = 0.0464$) compared to suture closure (2b) [93].

This randomized controlled trial compared skin closure time using either subcuticular Monocryl sutures or coaptive film (Steri-strip) in eight children undergoing bilateral soft tissue releases. Cosmetic outcome was scored by a blinded plastic surgeon using a visual analog scale (1–10). Both methods resulted in similar cosmetic results with no statistically significant differences ($P = 0.44$). No complications occurred. Incisions closed with coaptive film required less time as compared with suture closure of the corresponding incision on the contralateral limb ($P < 0.0001$). Average time saved for skin closure using coaptive film was 87.68 s per incision (1b) [94].

Closures of 102 breast biopsies were randomized to either subcuticular Prolene, subcuticular Dexon, or Op-site adhesive. One subcutaneous fat stitch was used to approximate wound edges before Op-site closure. Fourteen patients were withdrawn from the study due to malignancy being diagnosed and one Dexon patient was lost to follow-up. After follow-up at 1 week, 3 months, 6 months, and 12 months or more, no difference in wound appearance (by an independent assessor) or patient preference was found for any method. One hematoma developed in the nylon group and one hypertrophic scar developed in the Dexon group (2b) [95].

One Study Using both Tissue Glue and Adhesive Strips

Ten patients undergoing excision of a single benign or malignant lesion on the back were recruited to participate in this split-scar randomized controlled trial. All patients were Caucasian with Fitzpatrick skin types I–III, all lesions were removed by elliptical excisions, and the subcutaneous layer was closed by buried vertical mattress 4-0 polyglactin 910 sutures in all wounds. The wound was divided in half as Side 1 or Side 2. Side 1 of the wound was closed with running 4-0 polypropylene sutures. Following application of liquid adhesive (Mastisol), Side 2 was closed with 1/4" Steri-Strips spaced approximately 3–5 mm apart. Wound closure was timed for each method. Scar cosmetic outcome was assessed by the Patient and Observer Scar Assessment Scale (POSAS) at a minimum of 2 weeks, 14 weeks,

and 26 weeks postoperatively. The adhesive Steri-Strips required significantly less time than the sutures ($p = 0.0002$), resulting in an average of 3 min of time savings. At 26 weeks, patient and observer POSAS scores of scar appearance were not significantly different. In summary, Steri-Strips resulted in equivalent scar cosmetic outcomes in comparison to sutures but reduced the time necessary for wound closure for surgical excisions on the back (1b) [96].

4. *Review of a number of nonrandomized studies of adhesive strips*

In a prospective nonrandomized controlled study of 300 patients undergoing elective colorectal resection, 150 patients each underwent clean-contaminated wound closure with adhesive paper tape or interrupted sutures. The paper tape group (Micropore Hypoallergenic Surgical Tape) took significantly less time for wound closure than the silk interrupted suture group (116 ± 23 versus 457 ± 64 s, $p < 0.01$). Paper tape was retained for 7–10 days, and sutures were removed at 7 days. The overall wound complication rate (infection + separation, in 3.3% per group) and infection rate were equivalent in both groups. There were three cases of wound infection and two cases of skin wound separation in the paper tape group and five cases of wound infection in the suture group. However, peeling of the paper tape due to wound secretion requiring replacement was noted in 14 cases (9.3%), blistering was noted in 1 case, and a mild allergic reaction was noted in 1 case. No differences in scar width were found at 6 months. In the paper tape group 95% of patients were satisfied with their scar compared to 92% in the suture group ($p = 0.03$) (3b) [97].

As mentioned in the suture review section, there has been a follow-up study of 149 procedures, where buried vertical mattress sutures were only covered by wound closure tapes, removed at 5 days. The technique was concluded to be safe, easy to use, and prevented suture marks as long as wound edges could be exactly opposed. Wound length was correlated with scar dehiscence and facial locations healed best (3b) [70].

In a trial of 120 patients (ages 14–63 years), sutureless skin closure with a new adhesive polyurethane membrane (op-site) was compared to standard skin closure with interrupted 2-0 silk sutures for various surgeries (e.g., appendectomies, laparotomies, thyroidectomies, herniorrhaphies). Wounds closed with sutures were also covered with the membrane to standardize the healing environment. Patients were matched for age and sex. Results after 1 month were comparable in both cases; however, the membrane group experienced higher rates of uneventful recovery, no risk of suture marks, and a higher percentage of patient satisfaction with cosmetic appearance (no statistical comparisons made) **(3b)** [98].

5. *Review of several nonrandomized studies of tissue glue*

In a retrospective analysis of 60 patients (ages 4–40 months) with unilateral ($n = 59$) or bilateral ($n = 1$) cleft lip, skin closure with 6-0 Prolene was compared to closure with medical-grade cyanoacrylate glue. Glue closure took significantly less time than closure with Prolene ($p < 0.01$). One wound infection occurred in the Prolene group. Three of five blinded observers favored cyanoacrylate in terms of cosmesis by visual analog scale ($p = 0.05$). Patients were significantly more satisfied with the healed scars in the glue group (3b) [99].

In a prospective study of 46 wound closures in patients ages 5–85 years, a less costly cyanoacrylate, 2-etil-cyanoacrylate, was investigated. Excisions (97.8%) and traumatic wounds (2.2%) were closed by this method. Complications recorded over 3 months included unsatisfactory scars (22%), infection (2.1%), dehiscence (2.1%), and allergic contact dermatitis (2.1%). Patients were satisfied with the results in over 97% of the cases (3b) [100]. Study authors concluded that the use of ECA achieved satisfactory cosmetic outcomes, while reducing cost and rates of complication. However, ECA use is contraindicated in contaminated, bleeding, or infected wounds,

wounds in tight skin or mucosa, areas subject to friction and/or moisture, or when allergy to ECA is indicated (5) [100].

The use of cyanoacrylate in skin closure was studied in 30 patients undergoing planned surgery from September to March 1984, and compared to 25 patients undergoing similar procedures whose skin was closed with 4-0 monofilament (nylon) polyamide sutures. Closure of the wound required less time when using cyanoacrylate. Infection occurred in 1 of the 28 (7.14%) cyanoacrylate patients versus 3 of the 25 (12%) suture patients. A single linear scar was observed upon use of cyanoacrylate, while a linear scar with cross-hatch marks was observed for wounds closed by suture (3b) [101].

Two cases of allergic contact dermatitis to 2-octyl cyanoacrylate (Dermabond) were confirmed by patch testing (4) [102].

In this case series, Tayebi et al. present a novel technique for primary wound closure as used in six patients with atrophic skin undergoing Mohs surgery on the upper and lower limbs (defect size 1.5–3.0 cm). Adhesive glue was used to fortify the edges of atrophic, sun-damaged skin so that the sutures held better. An additional layer of adhesive was applied along the suture line, and sterile adhesive strips were placed over epidermal sutures to further decrease wound tension. No adverse events were reported (4) [103].

Evidence-Based Review: Staples

1. *Review of four meta-analyses after removal of duplicates, with the downgrading of one based on quality*

In a 2015 meta-analysis of randomized controlled trials of cesarean skin closure by subcuticular absorbable sutures versus staples, data were gathered regarding cosmesis, pain, patient satisfaction, wound complications, and operating time. The results from 12 randomized trials including 3112 women showed that suture closures were less likely to result in overall wound complications than staple closures (risk ratio, 0.49; 95% confidence interval, 0.28–0.87). This was largely due to a 71% lower chance of wound separation in the suture group and the effect remained significant even after stratifying by obesity. The two methods performed equally with respect to pain perception, patient satisfaction, and cosmesis; however, operating time was approximately 7 min longer with suture closure (95% CI, 3.10–11.31) (1a) [104].

This meta-analysis searched PubMed, Scopus, and Cochrane Central Register of Controlled Trials for randomized controlled trials comparing sutures with staples for surgical wound closure. A total of 20 studies were included, involving a total of 2111 patients. Specifically, 1233 patients underwent suture closure, whereas 878 patients underwent staple closure. Among the 20 included studies, 5 studies referred to obstetrics and gynecological operations, 7 to general surgery, 4 to emergency care treatment (2 involving pediatric patients), 3 to head/neck operations, and 1 to vascular surgery. Studies referring to orthopedic operations were not included. The follow-up period ranged from 7 days to 11 months among the included studies. Wound infections occurred significantly less in the staples group in comparison with the sutures groups (12 studies, 1529 patients; odds ratio [OR], 2.06; 95% CI, 1.20–3.51). Regarding time needed to close the wound, staples were found to be superior to sutures in 5 studies. The mean difference observed between the sutures and staples groups was 5.56 min per wound (95% confidence intervals [CI], 0.05–11.07). The majority of the included studies reported nonsignificant differences regarding the cosmetic outcome using sutures versus staples, yet in four studies, use of sutures was significantly associated with a superior cosmetic outcome compared with staples. This meta-analysis suggests that staples are better than sutures regarding the development of wound infections in obstetrics/gynecology, abdominal, head/ neck, and vascular operations in addition to emergency care surgical procedures. However, in five of the studies, staples were associated with significantly more pain compared with sutures. With regard to patient satisfaction, the majority of the included studies reported nonsignificant differences between the sutures and staples groups.

Considering that use of staples is quicker than suturing and that the majority of the studies reported analogous results for these two methods with regard to patient's satisfaction and cosmetic result, surgeons may consider using staples for wound closure for the mentioned procedures. More trials of higher methodological quality, incorporating more objective assessments of pain perception, patient satisfaction, and cosmetic outcome, are required to better answer this question (1a) [105].

In this systematic review of systematic reviews with panoramic meta-analysis of pooled estimates, 11 systematic reviews, including 13,661 observations, were analyzed. The authors note that there was wide variation in method preference between specialties, some finding a statistically significant benefit to sutures, others to staples. In orthopedic surgery, sutures were preferred, as staples were associated with a statistically significant increase in surgical site infection (OR 4.27 95% CI 1.00, 19.08). Staples were found to increase postsurgical complications in caesarean sections. However, staples were found protective against leak in ileocolic anastomosis. For all other surgery types, there was no consistent evidence that staples or sutures outperform the other. While there was some indication that staples resulted in increased odds of postsurgical complications, the 95% confidence interval was wide, indicating considerable uncertainty (OR 2.02 95% CI 0.69, 5.86). Evidence across surgical specialties indicated that staples reduced mean wound closure time. In conclusion, despite including several thousand observations, there was no clear evidence of an advantage for either staples or sutures with respect to length of stay, postsurgical complications, or surgical site infection incidence (1a) [106].

A systematic review and meta-analysis of sutures versus staples in orthopedic surgeries were conducted using Review Manager V 5.0 and included 13 studies published between 1990 and 2015. The cumulative sample size of all studies was 563 patients within the suture group and 692 patients within the staple group. Ten studies were randomized controlled trials and three were observational studies. The primary outcome was the incidence of surgical site infection. There was no significant difference in infection comparing sutures to staples. The cumulative infection relative risk of sutures versus staples was 1.06 (0.46–2.44). In addition, there was no difference in infection comparing sutures to staples in hip and knee surgery, respectively. Secondary outcomes included closure time, inflammation, length of stay, pain, abscess formation, necrosis, discharge, wound dehiscence, allergic reaction, and health-related quality of life. This meta-analysis found no significant difference in superficial infection and secondary outcomes comparing sutures to staples. Based on qualitative analysis, there seems to be a trend that staples cause more pain on removal than sutures, and this trend is consistent with non-orthopedic surgeries. However, the results from studies reporting pain data could not be combined quantitatively. Regarding closure time, the mean difference (MD) of closure time was significant in favor of staples, with a MD of 5.84 min (4.52–7.15) comparing suture and staple groups. Two other included studies also noted faster closure times with staples, but the data could not be used in the cumulative MD assessment. It was concluded that there may be no difference in effect between the two skin closure methods, and due to the methodological limitations of the included studies, the authors should begin to consider the economic and logistic implications of using staples or sutures for skin closure. Future studies should focus on conducting high-quality randomized control trials that include detailed baseline characteristics, and in addition a detailed patient recruitment flow chart should be presented. Poor quality of evidence and significant heterogeneity was found across included studies (2a) [107].

2. *Review of several randomized controlled trials*

As mentioned in the adhesives section, in a randomized control trial, subjects undergoing TKA were randomly assigned into one of four cohorts based on wound closure method with either n-butyl-2-cyanoacrylate tissue adhesive, 2-octyl tissue adhesive, Visistat 35W Stapler, or

Monocryl suture (control). Of the 90 subjects recruited, a total of 75 subjects completed the study. Staple-based closure was deemed the fastest and least-expensive TKA wound closure technique in the operating room but was associated with a statistically significant longer hospital stay in comparison with tissue adhesives and suturing. Of the four closure methods, tissue adhesives and staples were faster than sutures. The 2-ocytl and n-butyl-2 tissue adhesives required an average of 2.5 and 2.6 s/cm, whereas staples required 1.8 s/cm, and subcuticular Monocryl 4-0 suturing required an average 26 s/cm ($P < 0.0007$). However, the intraoperative efficiency of staples may be offset by lengthened hospital stay, thereby making tissue adhesives an efficient, viable alternative to TKA closure. Further study is needed to determine if the relationship between hospital stay and staple closure may be causal. The successful use of tissue adhesives for high tensile strength knee replacement in this study was believed to be due to added underlying reinforcement with 50% higher-frequency (7.5 mm for adhesives vs. 10-mm staples, 8-mm suture) interrupted subcutaneous sutures. The adhesive and staple cohorts experienced an average 17% greater occurrence of peripheral edema with respect to subcuticular suturing ($P < 0.03$). However, there were no statistically significant differences in infection, dehiscence, cosmesis (patient-assessed visual analog scale), general health (SF 12v2), and functional and clinical assessments (extension, flexion, ROM, Knee Society knee score, and pain visual analog scale) (1b) [86].

A blinded randomized controlled trial compared skin closure using subcuticular suture, staples, and OCA (Dermabond) in patients undergoing total knee or hip replacement. The primary outcome measure was the development of complications in the wound, either as an inpatient or after discharge. The absence of blood strike-through onto the dressing was assessed at 24 h as a measure of how well the wound was sealed. OCA was proved significantly better than staples or suture for both hip and knee replacements. There were significantly more cases without strike-through indicating that more wounds were sealed completely with OCA in both the THR (Fisher's exact = 15.77; $p = 0.0004$) and TKR (Fisher's exact = 12.68; $p = 0.002$) groups. The Mann–Whitney U test indicated that wound closure with skin staples was significantly faster than with OCA (Mann–Whitney U test = 8; $p < 0.0001$) which was significantly faster than with suture (Mann–Whitney U test = 174; $p < 0.0007$). There was no significant difference in the median length of stay in hospital, the Hollander wound evaluation score and patient satisfaction for the three groups in both THR and TKR. There were no reported adverse events or side effects. For subjects undergoing total knee replacement, there was a trend toward a longer stay in hospital with OCA compared with suture ($p = 0.09$), but no significant difference compared with staples ($p = 0.50$). The studies' results suggest that there is little difference between the three techniques of closure following replacement of the hip. However, the increased tensile forces associated with total knee replacement makes OCA inappropriate as increased wound discharge occurred upon early rehabilitation. Study authors now use staples routinely for the wounds following arthroplasty of the hip and knee (1b) [108].

In a blind prospective randomized control study, patients undergoing bilateral breast reconstruction with tissue expanders received wound closure on one breast using INSORB absorbable dermal staples and on the contralateral breast using 3-0 braided polyglactin 910 suture. Each patient's left or right breast was randomly assigned a closure method, and a randomly selected surgeon completed closure on both sides for each patient. The wound was examined objectively by a blinded attending plastic surgeon at each follow-up visit. The dermal stapler was four times faster than standard suture closure, reducing closure time by 10.5 min ($p < 0.001$). No wound complications or infections were documented in any patients. Early preoperative wound assessment was initially 1.13 points higher (Vancouver Scar Scale) for wounds closed by INSORB dermal stapler due to improved skin edge eversion ($p = 0.048$). However, after 136 days postoperatively, wounds closed by dermal stapler or dermal suture became statistically equivalent, indicating

a comparable cosmetic result between the two methods. At 6 months, histological analysis of scars indicated decreased inflammatory cell division in scars closed by the INSORB dermal stapler method. Overall, cost savings with the dermal stapler was US$ 220 per case. This study supports the beneficial qualities of the dermal staple device for surgical wound closure, as the INSORB dermal staple was significantly faster than standard suture closure techniques with equivalent cosmetic outcomes and reduced cost. However, the authors note that the small size of the stapler head, reduced tensile strength of the staple in settings of edema or tension, and the learning curve required to operate the technology must be considered (1b) [109].

One study evaluated the safety, efficacy, and cosmesis of wound closure using an absorbable subcuticular stapling system (INSORB) compared to wound closure by conventional percutaneous metal staples in 16 female patients requesting aesthetic facial rejuvenation (endoscopic eyebrow-lift or rhytidectomy). The mean age was 59 years, ranging from 48 to 76. Skin incisions for both procedures were placed in bilateral temporal and postauricular hair-bearing scalp. Each patient had 50% of incisions closed by one method, with the other 50% closed by the second method, resulting in one side of the head closed with absorbable subcuticular staples and the contralateral side closed with percutaneous metal staples. Use of a particular method on right or left side of head was assigned randomly. Both staple types were placed at ~7-mm intervals. Incisions closed with subcuticular staples were oversewn with running 5-0 plain gut suture. During the early postoperative period, metal staples produced more incisional erythema and crusting. In contrast, subcuticular staples produced better tissue eversion, less erythema, and less crusting. Both systems were deemed easy to use intraoperatively; however, it was noted that the thin skin of the scalp created difficulty with accurate subcuticular staple placement. One year postoperatively, incisions closed with either stapling method showed no significant differences in cosmesis or quality of healing. However, two patients reported greater comfort and improved cosmesis with subcuticular staples. Untoward bleeding and dehiscence were absent with both techniques. The INSORB Stapler is more expensive than percutaneous metal stapler, but theoretically faster incision closure times with INSORB system would result in reduced operative room times with future device modifications (such as improved ability to properly engage dermis in thin skin) (1b) [110].

In a randomized controlled trial of closure of groin incisions after cardiac bypass surgery, 114 patients were randomly assigned 1 of 4 skin closure methods: subcuticular Maxon, interrupted nylon, continuous nylon, or clips (staples) following a 2-layer closure of subcutaneous tissue using 3-0 Maxon. No correlation was demonstrated regarding skin closure method and subsequent infection. Staples were found to be the most expensive method, followed by subcuticular Maxon or interrupted nylon, whereas continuous nylon was the least expensive. Thus since the results fail to prove superiority of one closure method in terms of infection rate, skin closure method should depend on surgeon preference or financial considerations (1b) [111].

In a randomized controlled trial involving 106 Black-skinned subjects undergoing Caesarean section, wound/scar appearance, pain, and operation time/costs were compared. Of the 106 participants, 53 were randomly allocated to receive subcuticular suture (2-0 polyglycolic acid) and 53 were allocated to receive metal skin staples (B/Braun Manipler AZ-35W). The patients, surgeons, and nurse were not blinded to the types of skin closure techniques used. Use of staples resulted in a statistically significant shorter mean operating time (40.26 min.) compared to the suture group (47.55 min.) ($P = 0.025$). The mean estimated blood loss and wound length for the participants in both groups were similar. There was no significant difference in mean pain score for participants in either group. The mean VAS by participants in suture and staple groups was similar on day 5 ($P = 1.00$); however, at 6 weeks, the score was slightly higher for participants in staple group than in suture group but was not statistically significant. Mean patient satisfaction scores for the two groups were similar ($P = 0.0452$). The

VAS by the nurse and independent observers in the staple group was better than the mean VAS for the suture group on the fifth postoperative day ($P = 0.023$). However, the mean VAS score at 6 weeks was not significant ($P = 0.566$). In conclusion, the use of staples was better than subcuticular suture in terms of scar appearance and wound closure time and resulted in no difference in pain. However, staple use was significantly more expensive ($P < 0.001$). The perceived benefit of subcuticular suture versus skin staples was not observed and participants were satisfied with both wound closure techniques **(1b)** [112].

3. *Review of several cohort or case-control level studies*

In a nonrandomized observational prospective study, 100 patients undergoing abdominal dermolipectomy or surgery for breast hypertrophy received skin closure using either INSORB absorbable subcuticular staples or sutures. Operators from seven different centers were requested not to modify usual procedure, except for replacement of absorbable thread with INSORB staples during subcutaneous closure. For each patient, length of suture, time for closure, and operator ease of use was assessed. The results for average speed of closure per site and method were statistically significant and demonstrated that the use of staples reduced skin closure time by an average of fivefold. All operators considered the stapler easy to handle (mean 4.3, range 4–5). At 1-year follow-up, healing quality was evaluated by the surgeon depending on swelling, inflammation, and hypertrophy on a scale from 0 (very poor) to 5 (excellent result), as well as by the patient (scale of 0–10). Of the 95 patients (5 lost to follow-up), overall results were not different for the 2 methods as assessed by the surgeons and patients (Wilcoxon signed rank test, $P < 0.05$). Thus, the INSORB stapler was found easy to use and saved time while ensuring healing quality equivalent to that observed for conventional sutures. However, the authors noted that in some cases staples do not appear preferable, such as when there is marked tension between the two skin edges that cannot be controlled as it could be with a slipknot or when the skin is too thin to allow proper positioning of the stapler. Overall, the study's analysis would benefit from the inclusion of a larger number of patients (2b) [113].

A retrospective review of 511 patients receiving sarcoma resections of the buttock, thigh, and femur from 2003 to 2010 assessed outcomes following wound closure by staples or sutures. Surgical protocols were standardized across the cohorts, and only two surgeons were used who preferred use of either sutures or staples. Of the 511 patients reviewed, 376 had closure with sutures and 135 had closure with staples. Wound closure by staples was an average of 5.3 min faster than by sutures, resulting in a mean savings of 2.1% of total operating time. No significant difference was found in wound complications upon closure with either sutures or staples. Study authors noted that obesity and radiation treatment appeared to affect outcome and that future investigation of wound closure specific to orthopedic oncology with respect to specific patient variables is needed. In conclusion, closure by staples may be preferred due to speed and time savings, but preoperative clinical evaluation of patients is most important in determining closure method (2b) [114].

A total of 90 patients undergoing total knee arthroplasty (TKA) were evaluated to determine the pain score, cosmetic score, and wound complication rate of a zip-type skin closing device compared to conventional staple devices for wound closure. All TKAs were performed by the same surgeon. Pain evaluation was assessed using a visual analog scale (VAS) on postoperative days 1, 3, 14, 42, and 90. Cosmetic wound evaluation was conducted using the Vancouver Scar score 90 days postoperatively. The mean VAS of the zip group was significantly lower compared to that of the staple group on postoperative days 1, 3, and 14 ($P < 0.01$). The Vancouver Scar score for cosmetic outcome on postoperative day 90 was significantly better in the zip group versus the staple group ($P < 0.05$). There was no significant wound complication rate between the two groups. In conclusion, the zip-type skin closing device showed less pain and better cosmetic outcome. However, the authors noted that

3 of the 45 zip-type closure patients experienced a mild allergic reaction to the adhesive tape area, so this should be taken into account before use in patients with sensitive skin. In addition, the zip-type closure device has a medical cost twice that of conventional staples (3b) [115].

In this study, patients received wound closure by either staples or discontinuous nylon sutures (20 per group). The closure time was recorded for each patient. Patients were assessed postoperatively and then followed up 30, 60, 90, 120, 180, and 360 days after surgery. Each return visit was conducted by the same physician who was blinded as to which group the patient belonged to. Complications were recorded and wound appearance was rated (good, moderate, or poor). There was no statistically significant difference between the two groups regarding complications according to Fisher's exact test ($P = 0.6945$). Cosmetic scar results in the two groups were statistically the same (Fisher's $P = 1.000$). The time needed for wound closure in bilateral neck dissection for the staple group (5 min) was significantly faster than nylon suture group (25 min) (Mann–Whitney U test, $P < 0.0001$). According to this study, staples are more expensive than nylon sutures; however, the time saved during wound closure was not included in the cost assessment. The authors suggest that the use of staplers for skin closures should be considered mainly for closure of large or multiple incisions when saving time is an important factor. The use of staples will not affect the final cosmetic result or increase incidence of complications (3b) [116].

Evidence-Based Review: Other Closure Devices

1. *Review of one meta-analysis and several randomized trials*

In a meta-analysis of four randomized controlled trials of moderate risk of bias including 678 patients, the surgical zipper technique ($n = 333$) was compared to traditional intracutaneous sutures ($n = 354$) in various surgical procedures (open-heart surgery, orthopedic surgery, spinal fusion surgery, and saphenous vein harvesting). The zipper technique resulted in equivalent rates of wound infection and dehiscence, significantly less time for closure (although there was significant heterogeneity for this result), and no need for suture removal. Cosmesis was reported to be better in the zipper group in two of the trials and no different in the remaining two trials. The authors report that excellent cosmesis can be expected with the exception of areas of substantial curvature, with wound secretion, when patients are obese, or when wounds are under high tension (1a) [117].

In a randomized controlled split-wound trial, a new adhesive skin closure system (Prineo Skin Closure System) was compared to standard intradermal sutures in 83 patients undergoing elective plastic surgery closures. The Prineo system consists of pressure sensitive mesh tape with octyl-2-cyanoacrylate placed overtop. Approximation of wounds was equivalent between groups, and mean wound length was about 22 cm in both groups. Closure was about 5 min faster with the Prineo system ($p < 0.0001$). Both groups had equivalent cosmesis and healing over 90 days, 6 months, and 12 months by the modified Hollander Cosmesis Scale and at 6 and 12 months by the Patient and Observer Scar Assessment Scale. There were no differences in wound infection, inflammatory response, or adverse cosmetic outcome rates between groups. Blistering was present in 2 (2.4%) of 83 patients at day 7 and days 12–25 with the new closure system. Overall, the two methods are concluded to be equivalent for closure of full-thickness surgical incisions (1b) [118].

In a prospective randomized controlled trial, the novel "zipper" device for skin closure was used in 203 of the 610 cases of abdominal surgery. The device consists of a zipper between two adhesive strips of Polyamide with an elastic band on both ends that is pulled to close the skin. There were 205 patients closed with staples and 202 patients closed with sutures. Sutures and staples were removed on days 7–11, and the zipper was removed on days 7–9. Six patients in the zipper group developed complications such

as hematoma, lymphorrhea, wound infection, and reintervention, necessitating second intention healing or an alternative to the zipper closure (2b) [119].

In a prospective randomized controlled trial of 20 patients (mean age 51.17), a novel closure device called the Zipline 3 system (Zipline Medical) was assessed by blinded evaluators. The device is a single-use, sterile adhesive with a releasable ratcheting device that tightens the wound edges, and it is applied after deep sutures. The two treatment arms ($n = 9$) included Zipline with or without dermal suturing versus a control arm of nylon interrupted sutures ($n = 8$) for closure after excisions of skin cancers or nevi on the trunk or extremities. The treatment arm without dermal sutures using the Zipline device was dropped after the first case resulted in dehiscence. After 3 months of follow-up, three patients withdrew. Mean wound length was 3.06 cm ± 0.38 cm. There was no significant difference in aesthetics based on high-resolution photographs which were assessed by averaging the scores of three blinded evaluators on a 10-point visual analog scale. Time to both place and remove the device was significantly shorter than time to place and remove sutures. It took about 2 min to place and 8 s to remove the device, versus taking about 4 min to place and 1 min to remove sutures (to place $P = 0.001$; to remove $p < 0.001$). The cost of the device was about US$ 40 (3b) [120].

2. *Review of several nonrandomized studies*

As mentioned in the staples section, a total of 90 patients undergoing TKA were evaluated to determine the pain score, cosmetic score, and wound complication rate of a zip-type skin closing device compared to conventional staple devices for wound closure. All TKAs were performed by the same surgeon. Pain evaluation was assessed using a VAS on postoperative days 1, 3, 14, 42, and 90. Cosmetic wound evaluation was conducted using the Vancouver Scar score 90 days postoperatively. The mean VAS of the zip group was significantly lower compared to that of the staple group on postoperative days 1, 3, and 14 ($P < 0.01$). The Vancouver Scar score for cosmetic outcome on postoperative day 90 was significantly better in the zip group versus the staple group ($P < 0.05$). There was no significant wound complication rate between the two groups. In conclusion, the zip-type skin closing device showed less pain and better cosmetic outcome. However, the authors noted that 3 of the 45 zip-type closure patients experienced a mild allergic reaction to the adhesive tape area, so this should be taken into account before use in patients with sensitive skin. In addition, the zip-type closure device has a medical cost twice that of conventional staples (3b) [115].

In a prospective study, MEDIZIP closure system was used for 45 immunocompromised patients (ages 12–73) undergoing median sternotomy. The device was kept in place on average 9.98 days (range, 8–13 days). The average time taken for inspection was 70.00 ± 2.48 s. No wound infections occurred. In five patients, blood obstructed the device and it had to be replaced (11%). On a 3-level scale, cosmetic results were very good in 39 patients (87%) and satisfactory in 6 (13%) after 8 months (4) [121].

In 14 cases, a novel wound closure device, the Zip Surgical Skin Closure device, was evaluated. The device consists of two strips coated with hypoallergenic adhesive with plastic locks and straps that bridge the incision. The straps are pulled to bring the skin edges closer together. The device was removed after 10 days. The investigators used a 6-point wound evaluation score accounting for wound edge step-off, contour irregularity, scar width over 2 mm, edge inversion, inflammation, and poor cosmetic result. A 100-point VAS was also rated at 2–3 months. Ease of application, patient comfort with placement, patient pain with removal, and ease of removal by the investigators were all favorable. Wound scores, cosmetic scores, and patient satisfaction with the device were also reported as favorable. One subject experienced minor dehiscence in the setting of postoperative trauma. Limitations include inability to place on hair bearing or excessively oily areas and contraindication for high-tension wounds (4) [122].

In a prospective study of 96 patients with 103 lesions <3 cm in diameter, a sutureless foil flip-over system (Opti-Close System) was evaluated. The foil keeps the excision area sterile and the flip over system provides fast and easy skin closure. Deep 3-0 or 4-0 monofilament sutures were placed under the device, which remained in place for 10–14 days. Most lesions were on the back (44%) or chest (26%). No wound infections occurred, 96% of wounds were scored excellent or good in terms of healing by the surgeon, and 92% of the patients reported comfort with device removal based on a 100-point VAS. Seven cases (7%) of allergic reactions were found; one was severe with bulla; the system should not be used in those with a history of tape or adhesive allergy. Itching or discomfort was significantly more common on the back. Patient satisfaction with the scar was significantly lower on the chest. The cost of the system is similar to one polypropylene suture (3b) [123].

In a prospective nonrandomized study, 22 wounds not suitable for primary closure were closed with a novel skin and soft-tissue stretching device, Wisebands. The device has a tension feedback control mechanism (force is limited to 1 kg/cm^2), a flat plastic band, and a metal needle that is passed through the wound edges. The device was used to gradually close defects until the edges could be approximated for primary closure in 18 patients (90%). The calf (59%) and forearm (18%) were the most common defect locations; trauma and surgery were the most common causes followed by tumors and burns. The mean defect size was 12.5 × 5.5 cm. One to four devices were applied per wound, and the treatment time ranged from 1 h to 7 days. Major wound complications necessitating removal occurred in two patients, one with infection and one with intractable pain with tightening (10%). Two minor complications (10%) occurred with one case of local pain and skin irritation and one case of temporary neurapraxia. By 1 year, acceptable scarring and aesthetics were achieved (only 3 patients or 15% with wide or hypertrophic scars) (3b) [124].

In a series of cases, the initial clinical experience with a new device called the Suture Tension Adjustment Reel is reported. With the steel device, suture loops are passed through the device, and a reel tightens the suture loop incrementally to close the wound. It effectively functions as an adjustable knot that can be loosened or tightened without removing the sutures. The device was used uneventfully for intraoperative tissue stretching without undermining for a basal cell excision site on the knee, preoperative tissue stretching of an excision site of the left arm, intraoperative stretching of an advancement flap on the left lateral forehead, and intraoperative tissue mobilization (replacing an assistant's hands) in a scalp reduction surgery. In cases 1 and 3, three to five tension cycles lasted 3–5 min with rest cycles of 1–2 min (unless blanching occurred, then tension was for <1 min) until no further stretching could be achieved. In case 2, the skin was slowly tensioned over a period of hours. A disposable version of the device may be more useful (4) [125].

In two patients who underwent wide local excision of squamous cell carcinomas on the scalp and feet, an acellular dermal regeneration template (Integra LifeSciences Corp) was successfully combined with split-thickness skin graft and negative-pressure wound therapy to promote the healing of defects when vital structures (tendon, cartilage, bone) were exposed. The template is a scaffold of bovine collagen and choindroitin-6-sulfate which promotes neovascularization and formation of a neodermis. Silicone is added as a temporary epidermis. In these two cases, the template was applied for 10–14 days before a split-thickness graft was applied. The authors cite several randomized controlled trials which have shown negative-pressure wound therapy to improve graft take and appearance compared to traditional bolsters. Negative pressure therapy is contraindicated over ischemic wounds or those with fragile skin or wounds with active malignancy. The authors also cite studies showing synergy between the Integra Template and negative pressure therapy with skin grafts (4) [126].

In a retrospective case series of eight patients (men aged 17–95 years) with resection of nine moderate to large scalp tumors, the TopClosure® device was investigated as an alternative to skin grafts, flaps, or tissue expanders. The device was used to achieve intraoperative cycles of stress relax-

ation without undermining and, in some instances, was followed by additional cycles for mechanical creep and securement of scar. Defects averaged 3.5 cm, and the device enabled primary closure of all wounds. Two wounds were closed within 1 h after stress relaxation. Seven wounds required further stretch by mechanical creep and staged primary closure was completed in the outpatient setting (the device was used to secure the skin for up to 3 weeks postoperatively). The TopClosure® device is both invasively and noninvasively attached to the skin to accomplish skin stretching. Stress relaxation cycles consisted of 2–3 min of high tension (causing blanching or shininess at wound edges) followed by 5 min of relaxation. No complications or device failures occurred (4) [127].

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development, and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
Sutures	
Triclosan-coated sutures do not decrease the rate of surgical site infection	A
There is evidence to suggest barbed sutures decrease operating time without increasing complications. Cost savings are less likely for the dermatologist without operating room costs	A
There is no evidence to suggest differences between the use of absorbable and nonabsorbable sutures for cutaneous closure in terms of complications, cosmesis, or satisfaction; absorbable sutures may be preferable for time and cost savings	A
Continuous subcuticular sutures may reduce risk of wound dehiscence	B
Superficial mattress sutures (horizontal or vertical) give superior scar outcomes compared to simple running sutures	B
Subcuticular poliglecaprone 25 sutures give a lower rate of complications than polyglactin 910	B
Transcutaneous sutures may have a lower risk of superficial infection than intracutaneous sutures	B
A modified vertical mattress technique can result in superior outcomes compared to traditional suturing for moderate to severe tension wounds on thickened dermal skin	B
Dermal suturing alone with wound closure tape or adhesive can be safely used and may perform significantly better on the face compared to other locations	B
Evidence is needed to determine whether eversion achieves superior cosmesis; it may be more important in certain areas (facial) and perhaps not in others (trunk, extremities)	C
Most studies find no difference in outcomes between running subcuticular sutures, interrupted sutures, and simple running sutures for closure	C
Tissue adhesives or surgical glue	
Surgical glue may increase the risk of wound dehiscence, and there is no definitive evidence of improved cosmetic outcomes	A
Adhesive strips or membranes provide no long-term benefits over buried vertical mattress sutures alone or running subcuticular closures	B
Tissue glues or adhesives may save time compared to sutures	B
Concerns with tissue glues or adhesives in place of sutures include peeling or inability to close due to wound secretion, inability to perfectly approximate wound edges, inverted scars, and irritant or allergic reactions	B
Staples	
In orthopedic surgery, sutures give a lower risk of surgical site infection compared to staples	A
In cesarean sections, sutures lower the risk postsurgical complications compared to staples	A
For other surgery types, there is no consistent evidence that either staples or sutures outperform the other	A
Other closure devices	
The surgical zipper technique gives equivalent rates of wound infection and dehiscence compared to intracutaneous suture closure	A

Self-Assessment Questions

1. Compared to nonabsorbable sutures, absorbable sutures have been shown to:
   (a) Result in increased complications
   (b) Result in time and cost savings associated with closure and suture removal
   (c) Result in equivalent cosmetic outcomes
   (d) b and c
   (e) All of the above
2. Superficial mattress sutures have been shown to:
   (a) Result in cosmetically inferior closures compared to superficial running sutures
   (b) Result in equivalent closures compared to interrupted sutures
   (c) Result in increased complications compared to superficial running sutures
   (d) a and c
   (e) None of the above
3. With regard to wound edge eversion, evidence suggests that:
   (a) Eversion results in superior cosmetic outcomes compared to planar closure.
   (b) Eversion prevents inverted scar formation.
   (c) Roughly equal evidence exists showing improved outcomes with eversion and no difference in outcomes for eversion.
   (d) Eversion may improve outcomes in some, but not all locations of the body.
   (e) None of the above.
4. Tissue glue and adhesives have been shown:
   (a) To improve cosmetic outcomes compared to sutures
   (b) To decrease closure time compared to sutures
   (c) To be safe to use without dermal sutures
   (d) To decrease closure costs compared to sutures
   (e) To increase short-term inflammation compared to sutures
5. Meta-analysis has shown that staples:
   (a) Increase complications compared to sutures in orthopedic surgery
   (b) Increase complications compared to sutures in obstetric surgery
   (c) Decrease complications compared to sutures in surgical fields other than obstetrics and orthopedics
   (d) a & b
   (e) All of the above.

Answers

1. d: Choices b and c are correct. Meta-analysis has shown there is no evidence to suggest differences between the use of absorbable and nonabsorbable sutures for cutaneous closure in terms of complications, cosmesis, or satisfaction; absorbable sutures may be preferable for time and cost savings since they are often cheaper than nonabsorbable sutures and they have the potential to obviate the need for suture removal visits.
2. e: None of the above. Two studies have shown horizontal or vertical mattress sutures give superior scar outcomes compared to simple running sutures.
3. c: Roughly equal evidence exists showing improved outcomes with eversion and no difference in outcomes for eversion. To our knowledge, only two studies have directly investigated eversion with regard to scar outcomes and produced conflicting results. Further research is necessary to determine whether eversion may be more important in certain locations (such as facial) compared to others.
4. b: To decrease closure time compared to sutures. While tissue glues and adhesives can save time compared to sutures, most glues and adhesives require the support of dermal sutures, increase the risk of dehiscence, and have not been proven to have superior cosmetic outcomes in most studies. In the short term, less inflammation compared to sutures has been shown in a number of studies. Tissue adhesives, glues, or membranes can be more expensive to use than sutures. While sutureless adhesive membranes can be used, there can be significant rates of complications related to inability to close or approximate wound edges, inversion of scars, issues related to wound oozing, and dehiscence.
5. d: Choices a and b are correct. Staples have been shown to increase the rate of surgical site infection or postoperative complications in the fields of obstetric and orthopedic surgery, but there is no clear evidence regarding the superiority of sutures or staples in other fields of surgery.

Non-invasive Fat Reduction

14

Neil Sadick

Abstract

The field of cosmetic medicine has evolved rapidly in the recent years offering patients and their treating physicians a plethora of non-invasive options for body rejuvenation. Particularly for indications such as fat reduction, innovations in technology and scientific breakthroughs have led to non-invasive strategies validated for their safety and efficacy through several high-evidence-level peer-reviewed studies. Four main types of energy-based devices have dominated the field of fat reduction: radiofrequency, laser, ultrasound, and cryolipolysis. In addition, injectable biologics have been developed with the goal to target localized pockets of fat. In this chapter, our goal is to provide an unbiased overview of the scientific evidence regarding procedure selection, effectiveness, and safety for non-invasive fat reduction.

Keywords

Ultrasound · Radiofrequency · Low-level laser · Cryolipolysis · Injectable biologics

Introduction

Nonsurgical fat reduction is a new frontier in the realm of cosmetic procedures. According to the latest data from the American Society of Plastic Surgery, the percentage of consumers considering a cosmetic medical procedure has almost doubled since 2013, with 15.9 million surgical and minimally invasive cosmetic procedures performed in the United States in 2015, a 2% increase over 2014 [1]. Among the most popular procedures sought were those for non-invasive body reduction, whereas requests for liposuction experienced a 37% reduction from 2000. The rise in popularity for non-invasive fat reduction is indicative of the public's desire for nonsurgical alternatives in lieu of their invasive counterparts. Although procedures such as liposuction are effective at removing large amounts of excess fat, they are accompanied by a significant risk of complications and severe adverse effects, including post-procedural pain, infection, prolonged recovery, scarring, ecchymosis, or edema. Currently, the four leading strategies for non-invasive fat reduction are radiofrequency, laser, ultrasound, and cryolipolysis. Additionally, minimally invasive strategies for fat removal using injectable biologics that target localized fat pockets have been recently approved by the FDA, and several other candidate drugs that target fat are in the R&D pipeline. All of these strategies target the subcutaneous fat layer with the goal to destroy adipocytes either through necrosis or apoptosis.

Pregnancy/nursing

Patient Selection

Success in non-invasive fat reduction relies on suitable patient selection that can be achieved through a thorough medical consultation (Table 14.1). Non-invasive fat reduction treatments are ideal for nonobese patients (body mass index (BMI) < 30) with mild/moderate skin laxity. With a BMI of more than 30, patients often have visceral fat, which increases cardiovascular and other health risks. These patients need to be referred to internists that can aid them achieve a global weight reduction with careful medical monitoring. Qualified patients are healthy individuals who have mild to moderate areas of stubborn fat that seem resistant to diet and exercise. When selecting patients, it is important to thoroughly discuss their motivations for treatment and gain an appreciation of their social and psychological well-being during the consultation. The treating physician needs to understand the patient's concerns and expectations and relay to the patient all available options, side effects, and anticipated results. The need for maintenance follow-up treatments should also be discussed as many non-invasive fat reducing approaches require multiple sessions and additional sessions to maintain the clinical results. Psychosocial assessment is important, and specific questions regarding psychiatric history and medical treatment should be posed. Signs of body dysmorphic disorder and eating disorder should warrant a full psychiatric assessment. It is reported that as much as 15% of patients requesting fat reduction procedures suffer from mental illness [2, 3]. Pregnant or breastfeeding women should defer treatment until after delivery or when they have stopped nursing. Finally, although these treatments are safe for all skin types, patients should be evaluated for any open sores, infections, or hernias in the treatment area, and treatment must be delayed until issues resolve.

Radiofrequency

Radiofrequency-based devices harness energy from the emission of focused electromagnetic waves that generate heat upon meeting tissue impedance [4, 5]. The subsequent cascade of collagen contracture and neocollagenesis stimulates fibroblast activation resulting in increased dermal thickness without affecting the epidermis, while heating of the subcutaneous layer results in adipocyte necrosis and release of triglycerides. Thus, radiofrequency (RF) devices can mitigate both skin tightening and non-invasive fat removal [6, 7]. Depending on the number of electrodes, RF devices can be classified into unipolar, bipolar, and multipolar devices; the latest generation of RF devices also commonly combines other treatment modalities such as broadband light, lasers, ultrasound, pulsed electromagnetic fields, and vacuum devices, allowing enhanced efficacy and reduced adverse effects. Treatments with RF are typically customized depending on the parameters set by the manufacturer, but for most devices an average of four to six treatments is necessary spaced out weekly or biweekly. The average treatment duration is 30–40 min, and no side effects are reported other than self-resolving erythema.

For the indication of fat reduction, there is both a time and temperature dependence for internal temperatures at the adipose layer to remain at ~45–46 °C for at least 1 min to stimulate lipolysis. Since not all RF devices meet these requirements, it is important to highlight the select RF technologies shown through peer-reviewed studies to safely and effectively result in fat reduction.

In a study using a bipolar radiofrequency, infrared, vacuum, and mechanical massage device, 19

subjects underwent 5 weekly treatments of the upper arms, and 10 subjects underwent 4 weekly treatments of the abdomen and flanks. Circumference measurements, photographs, and subject weights were performed prior to treatment and at 1- and 3-month follow-ups. Results showed that the change in arm circumference at the fifth treatment was statistically significant with a mean loss of 0.625 cm. At 1- and 3-month follow-ups, mean loss was 0.71 cm and 0.597 cm, respectively. Reduction of abdominal circumference at the third treatment was statistically significant with a 1.25-cm mean loss. At 1- and 3-month follow-ups, average loss was 1.43 cm and 1.82 cm, respectively. In conclusion, with an average of four to five treatments, statistically significant fat reduction was achieved in the arms and flanks (2b) [8].

In another study evaluating a novel suction-coupled RF device with ultrashort pulse duration, high-voltage electrical pulses for its efficacy and safety on adipose tissue reduction, 21 subjects underwent treatment of their abdominal fat once weekly for 6 weeks. Clinical outcomes including abdominal circumference, adipose tissue thickness (measured by ultrasound), adipose tissue weight, body weight, and clinical photographs were obtained at visits 1 and 3 months after the last treatment. Biopsies from the RF-treated and untreated sides were harvested and measurements of adipocyte size and shape, rate of apoptosis, collagen production, and dermal thickness were determined. Results showed significant clinical improvements for the following clinical outcomes: reduction of abdominal circumference (113.4–110.7 cm), reduction of subcutaneous adipose tissue thickness (40.5–38.5 mm), and reduction in adipose tissue weight (32.2–30.7 kg) at 3-month follow-up visits. Histologically, adipocytes were observed to have decreased size and withered shape, with increased levels of apoptosis; increased collagen synthesis, with compaction and reorganization of the dermis was also observed. Overall, the study demonstrated clinical and histological evidence of the safety and efficacy of the RF device in non-invasive fat reduction (2b) [9].

Fat reduction has also been demonstrated using a non-contact radiofrequency device in a series of clinical studies (5, 2b) [10–13]. This device features a selective RF applicator that shapes the energy field to optimize the penetration and maximize the treatment area. It automatically tunes the tissue-applicator-generator circuitry to selectively deliver the energy to tissue layers with the specific impedance such as adipose tissue layers with minimizing the risk of overheating of the skin, muscles, or internal organs. In a study of 40 subjects with a significant volume of subcutaneous fat tissue on the abdomen and waistline, four once-a-week sessions were performed, and abdominal circumference was measured at the baseline and after the last treatment. The average decrease in abdominal circumference at the end of the study was 4.93 cm, demonstrating the selective RF system designed for contactless deep tissue heating as a painless, safe, and effective treatment for nonsurgical body contouring and circumferential fat reduction.

Finally, a recent study using a high-powered monopolar radiofrequency with a real-time temperature feedback system evaluated its efficacy in 21 subjects with submental fat accumulation. Subjects were treated twice at 1-month intervals, and submental fat thickness and circumference were evaluated with ultrasonography and a tape measure, respectively, at baseline followed at 1 and 6 months after the last treatment (0, 2, and 7 months). The submental circumference and thickness showed a statistically significant reduction after treatments, and physician's assessment showed that 82.3 and 52.9% of patients demonstrated above mild improvement at 2 and 7 months (2b) [14].

Overall, multiple treatments with radiofrequency devices were shown to be safe and effective for reducing localized fat in several anatomical areas including the trunk, abdomen, arms, and chin. Although new RF devices keep entering the clinical arena, it is important to validate their efficacy toward this indication through clinical studies.

Laser

External low-level laser devices represent another category of energy-based devices employed for adipose tissue reduction [15, 16]. Although the

mechanism of action remains controversial, it is postulated that low-level laser therapy activates the cytochrome-C-mediated mitochondrial pathways that ultimately leads to the formation of pores in adipose cell membranes through which lipids are released [17]. Wavelengths for laser treatments range from 630 nm to 640 nm as these have been shown to be optimum for biomodulation. Treatment may involve six to eight sessions lasting approximately 20–30 min, and adverse effects are limited to erythema and transient pain at the site of treatment.

In a randomized, placebo-controlled trial of 67 patients, six laser treatments over a period of 2 weeks were associated with a mean reduction of 2.6 cm in waist circumference versus baseline value (1b) [16]. In a second randomized, placebo-controlled trial of 40 healthy men and women, laser therapy administered twice weekly for 4 weeks resulted in a 0.87-cm reduction in waist circumference after eight treatments compared with an increase of 0.47 cm in the placebo group, but this difference was not statistically significant (2b) [15].

Although there are no peer-reviewed published studies to date, a new laser device for body contouring was recently cleared by the FDA for non-invasive lipolysis of the flanks and abdomen. The device emits laser energy at a 1060-nm wavelength that penetrates to the level of subcutaneous fat inducing lipolysis and stimulating dermal remodeling (1b) [18]. Treatments can be performed in various anatomic areas and can last an average of 25 min; no adverse side effects have been reported so far.

Ultrasound

High-intensity focused ultrasound (HIFU) devices have also been used effectively for non-invasive body sculpting to either tighten skin by contracting collagen fibers or remove adipose tissue stores via ablation. Ultrasound is unique in that the penetration depth can be freely selected with the choice of frequency, and precise focusing can be easily achieved with a small handheld transducer. HIFU can target a specific volume within the body cavity without harming surrounding tissues via two major mechanisms: hyperthermia and cavitation. By concentrating energy, HIFU causes temperatures to exceed the upper limit of protein denaturation (43 °C), and can reach as high as 80 °C, causing instant coagulative necrosis of targeted cells without damage to surrounding areas. Moreover, at high energy levels, alternating compression and expansion of sound waves create gas cavities that implode and subsequently cause mechanical damage to the target tissues (e.g., adipose) through the release of high levels of pressure and heat in the microenvironment. Average treatment times using HIFU for fat reductions are at 45–60 min with minimal to no recovery time. The procedure typically involves two or three passes over the treatment area, with each pass taking 15–20 min, and during treatment, patients report feeling localized tingling/prickling sensations along with mild warmth and pain. Commonly reported adverse effects include discomfort, ecchymosis, paresthesias, and edema that are temporary and mild in intensity, with the vast majority resolving within 12 weeks [19, 20].

Preclinical and clinical studies of HIFU devices have shown that when treating the fat tissue, macrophages ingest the lipids contained in adipocytes ablated by HIFU in a mild local inflammatory response; thus they do not become liberated systemically, raise serum lipid levels, alter the lipid profile, or provoke prolonged or diffuse inflammation.

A pivotal study on 180 patients using a HIFU system with an internally focused transducer and a pattern generator to ensure that the HIFU waves are directed evenly and at a predetermined depth within the treatment area showed that the treatment was well tolerated and resulted in reduced waist circumference. In the study, subjects with subcutaneous abdominal fat ≥2.5 cm thick received high-intensity focused ultrasound treatment of the anterior abdomen and flanks at energy levels (a total of three passes each) of 47 J/cm (141 J/cm total), 59 J/cm (177 J/cm), or 0 J/cm (no energy applied, sham control). The primary endpoint was changed from baseline waist circumference at the iliac crest level at posttreatment week 12.

For the primary endpoint, in the intent-to-treat population, statistical significance versus sham was achieved for the 59-J/cm but not the 47-J/cm treatment group. In a per-protocol population, statistical significance versus sham was achieved for both the 59-J/cm and the 47-J/cm treatment groups. Investigator subjective measures of global aesthetic improvement and patient satisfaction also favored each active treatment versus sham, while adverse events included mild to moderate discomfort, bruising, and edema (1b) [21].

A subsequent study using the HIFU device assessed the effectiveness and tolerability of treatment using high- and low-fluence settings with either grid repeat (GR) or site repeat (SR). Subjects underwent one HIFU treatment with one of five treatment protocols (150–180 J/cm), and endpoints were changed from baseline in waist circumference at 4, 8, and 12 weeks. All subjects had a statistically significant mean circumferential reduction of −2.3 ± 2.9 cm from baseline at 12 weeks, with no significant differences among the five treatment groups. The study concluded that high-intensity focused ultrasound treatment using either a low or high fluence setting in a GR or SR method is effective for circumferential waist reduction, resulting in statistically significant results in all treatment groups (1b) [22].

Cryolipolysis

Cryolipolysis involves controlled application of cold to subcutaneous tissue to reduce adipose tissue [23, 24]. Although the mechanism of action is not completely understood, preclinical studies suggest that an inflammatory process culminating in necrotic cell death is initiated when fat cells are cooled to temperatures between −2 and 7 °C. This process begins within 3 days after treatment and peaks within 14 days, and from day 14 to day 30, macrophages and phagocytes engulf dead lipid cells and inflammation declines, and the lipids are safely metabolized within 90 days [25].

When cryolipolysis is performed, suction is used to draw the target tissue into a cup-shaped applicator, in which contact is established between the treatment area and two opposing cooling panels. Treatment duration using the first-generation applicators is 45–60 min per treatment site, with most patients receiving treatment at multiple sites. With the use of a novel contoured cup and medium-sized applicator, however, which increases tissue contact and reduces skin tension, treatment times have been reduced to almost 25 min (2b) [26]. Cryolipolysis side effects include pain, bruising, erythema, and numbness, and treatment may also cause mild to moderate short-term dysesthesia in peripheral nerves, but no long-term damage has been reported [27]. The destruction of adipocytes does not significantly affect serum lipid levels or liver function tests [23]. One of the most serious side effects associated with cryolipolysis is paradoxical adipose hyperplasia in which patients develop painless, firm, and well-demarcated tissue masses in the treatment areas approximately 3–6 months following cryolipolysis (4) [28, 29]. Although the pathogenesis is unknown, recent studies have demonstrated factors that increase the risk of paradoxical adipose hyperplasia such as the use of a large applicator and the male gender (5) [30, 31].

Several studies have demonstrated the safety and efficacy of cryolipolysis for fat reduction in several anatomic areas including the abdomen, back, flanks, arms, and submental area (2b) [32, 33]. In a study of 518 subjects treated with cryolipolysis, the procedure was well tolerated, with 89% of respondents reporting a positive perception of treatment duration and caliper measurements demonstrating 23% reduction in fat layer thickness at 3 months (2b) [34]. Aside from being safe and efficacious, cryolipolysis has proven to be a durable treatment with results lasting almost a decade as shown by a longitudinal study of two patients (4) [35].

Since cryolipolysis does not use heat to achieve fat reduction, it does not stimulate dermal remodeling. Thus, although skin tightening after cryolipolysis may occur from the normal elastic recoil properties of skin tightening, a skin-tightening procedure may be required after cryolipolysis.

Injectable Biologics

An emerging trend in the field of non-invasive fat reduction is injectable biologic agents with a lipolytic profile. Extensive preclinical safety testing and rigorous clinical trials demonstrating a favorable product profile using a pharmaceutical-grade formulation are required for regulatory authority approval, and two agents have made the most progress down that line: novel lipolytic (LIPO-102) and adipolytic (ATX-101) agents.

LIPO-102 is a combination of salmeterol xinafoate and fluticasone propionate that targets and stimulates adipocyte (intracellular) lipolysis to produce a nonadipolytic, nonsurgical fat tissue reduction. In clinical testing, 22 weekly abdominal injections of LIPO-102 (0.5 μg salmeterol and 1 μg fluticasone) in 20 subjects for 4–8 weeks produced rapid (within weeks) and significant reductions in abdominal circumference and volume versus placebo (20 subjects). Overall change in waist circumference was statistically significant at 6 weeks postdosing, but at the 12-week follow-up, failed to reach significance. There were no significant hematologic, cardiovascular, or dermatologic adverse effects (i.e., atrophy, pigmentation, nodularity, necrosis) and minimal difference in swelling, redness, irritation, or any other local injection site reactions between LIPO-102 and placebo. According to company press releases, LIPO-202 is currently in phase II trial for the reduction of central abdominal bulging, and a phase II proof-of-concept study of LIPO-202 for the reduction of localized fat deposits under the chin (submental fat) will be initiated by the end of 2016.

Another injectable biologic ATX-101 was approved in 2015 as a first-in-class injectable drug for improvement in the appearance of moderate to severe convexity or fullness associated with submental fat. ATX-101 (deoxycholic acid) physically and preferentially disrupts the cell membrane of adipocytes causing cell death. ATX-101 has been evaluated in a clinical development program that included 18 phase I–III clinical studies to support the current indication. The efficacy of ATX-101 for reducing submental fat was evaluated across all phase III trials, and that showed significant reduction of fat 12 weeks posttreatment. Clinician and patient scale-based assessments of submental fat severity were utilized as well as calipers and MRI as an additional imaging-based objective assessment of the change in submental volume after ATX-101 treatment (5) [36].

Conclusion

Non-invasive techniques such as radiofrequency, laser, ultrasound, cryolipolysis, and injectable biologics have emerged as particularly appropriate options for nonobese patients requiring modest to moderate reduction in fat deposits.

All of these treatments can be administered in an outpatient setting with little or no need for anesthesia or analgesia and typically result in few, transient complications. With the exception of HIFU and cryolipolysis, these procedures require multiple treatments to achieve meaningful results and require maintenance sessions to sustain clinical outcomes. A table comparing the aforementioned strategies for fat reduction is presented in Table 14.2. In summary, non-invasive

Table 14.2 Summary of treatment options for non-invasive fat reduction

Approach	Level of evidence	Number of treatments	Treatment time	Safety/side effects
Radiofrequency	B	4–6	30–40 min	Erythema, pain
Ultrasound	A	1	40 min	Bruising, erythema, pain
Laser	C	4–6	20–40 min	Bruising, erythema, pain
Cryolipolysis	A	1–2	30–60 min	Bruising, erythema, pain, swelling, hyperplasia
Injectable biologics	A	2–6	10 min	Irritation at injection sites

fat removal in the carefully selected candidate is fully safe and attainable. Depending on the site of treatment, patient budget, and time constraints, the treating physician will be able to navigate the patient and recommend the most appropriate non-invasive fat removal strategy.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE).

Findings	GRADE Score: quality of evidence
Available scientific data demonstrate high level of evidence regarding the safety and efficacy of ultrasound and cryolipolysis and ATX-101 for fat reduction	A
Data for safety and efficacy of radiofrequency devices for fat reduction are moderate	B
There is still paucity and low-level evidence for laser devices being effective in reducing fat	C

Self-Assessment Questions

1. Male with excess flank adiposities is requesting non-invasive fat reduction. Male self-reports a low pain threshold. Following the consultation would you recommend:
   (a) Cryolipolysis
   (b) HIFU
   (c) Radiofrequency
   (d) 1060 nm laser
   (e) Low-level laser therapy
2. Female with BMI of 17 is requesting fat removal for the medial arms. She self-reports feeling distress with the look of her extremities. She has previously undergone cellulite and skin tightening treatments. Would you recommend to the patient:
   (a) Cryolipolysis
   (b) Psychiatric evaluation for body dysmorphic disorder
   (c) ATX-101
   (d) HIFU
   (e) Radiofrequency
3. Female that had undergone liposuction 8 months ago is experiencing excess skin laxity with contour irregularities. She does not want to have additional surgery. Recommendation for her would include:
   (a) Cryolipolysis
   (b) Low level laser therapy
   (c) HIFU
   (d) Radiofrequency
   (e) Radiofrequency with vacuum
4. Male requests surgery alternatives to reduce his double chin. He has needle phobia and travels frequently so cannot engage in many treatments.
   (a) ATX-101
   (b) Cryolipolysis with the mini applicator
   (c) HIFU
   (d) Laser
   (e) Low-level laser therapy
5. Female presenting cellulite and excess fat in her inner thighs is requesting the best treatment approach. She has plenty of funds and time at her disposal. Treatment recommendations would be:
   (a) Radiofrequency coupled with IR and vacuum
   (b) Cryolipolysis
   (c) Laser
   (d) ATX-101
   (e) Surgery recommendations.

Correct Answers

1. d: Cryolipolysis in the flanks presents the risk of paradoxical hyperplasia. Low-level laser therapy would not be effective for large areas, and both HIFU and cryolipolysis may be deemed too painful by the patient.
2. b: At a BMI of 17, the patient is dangerously underweight. History of additional treatments and continued dissatisfaction is an indicator of an underlying mental health problem.
3. e: Both HIFU and cryolipolysis would treat the contour irregularities but not the laxity issue. Radiofrequency with vacuum would be the best choice to treat both the adiposities and the skin laxity.
4. b: ATX-101 would be effective, but since the patient has time constraints and needle phobia, this would not be a suitable treatment approach for him. Cryolipolysis would require one to two treatments without subjecting the patient to needles.
5. a: Cryolipolysis or laser would treat the excess fat but not the cellulite. Radiofrequency coupled with IR and vacuum would improve the appearance of cellulite and reduce the adipose tissue layer.

Noninvasive Skin Tightening

15

Eric C. Wilkerson and David J. Goldberg

Abstract

Nonsurgical techniques for rejuvenation have dramatically expanded in recent years and, with this, so have noninvasive techniques, technologies, and devices specifically directed toward tightening the skin. In general, the two technologies primarily utilized for skin tightening are ultrasound and radiofrequency. This chapter seeks to review the available literature discussing the indications, effectiveness, preoperative and postoperative considerations, treatment techniques, and safety of the presently available technologies and methods for noninvasive skin tightening. The available literature suggests noninvasive tightening modalities are generally safe and effective with little downtime and minimal side effects. However, of paramount importance are appropriate patient selection and managing patient expectations preoperatively.

Indications for Noninvasive Skin Tightening

As the demand for nonsurgical skin rejuvenation continues to grow, it is no surprise that the available technology continues to increase and improve, including in the realm of skin tightening. Noninvasive skin tightening can be achieved via a variety of modalities to treat nearly every area of the body. Most commonly, tightening has focused on the face, neck, and abdomen, but, more recently, the décolletage, hands, flanks, thighs, buttocks, knees, and arms have increasingly become targets for tightening therapies. Transdermal radiofrequency (RF) and focused ultrasound (US) are two of the major technologies used primarily for skin tightening. Some laser and light modalities, fractionated and microneedle radiofrequency, and cryolipolysis have also been shown to promote skin tightening, but, since it is not their primary function, these will not be discussed in detail.

While minimal evidence exists to determine truly evidence-based treatment indications, across the spectrum, noninvasive skin tightening treatments are generally indicated for mild-to-moderate skin laxity with some specific variations for certain devices (4, 4, 5, 5) [1–4]. Otherwise, the US Food and Drug Administration (FDA)-approved indications can be mentioned for individual devices, although this is typically not the limit of a device's clinical potential or

common uses. As each device or modality is introduced, its FDA-approved indications, as well as other off-label clinical applications, will be reported.

Effectiveness of Noninvasive Skin Tightening

In some cases, myriad reports and clinical trials exist in the literature on the modalities reviewed, so it would be impossible to discuss them all meaningfully. For some newer devices or treatments, significant studies are lacking. This review will focus on the best available literature; however, it is important to note that there are not many studies in this field with a high level of evidence. Finally, focus is given to trials specifically reporting on "tightening" or improvements in "laxity" rather than surrogates for tightening such as improvements in rhytids, elasticity, or skin quality.

Microfocused Ultrasound

Microfocused ultrasound (MFUS), or microfocused ultrasound with visualization (MFU-V), can target deep to superficial subcutaneous and dermal tissues depending on the transducer used. Ultherapy (Ulthera, Inc., Merz Device Innovation Center, Mesa, Arizona) is the major MFUS system available in the United States and has indications for brow lifting, lifting of the submental and neck tissue, and improving the rhytids of the décolletage. It was the first device to receive a noninvasive lifting indication from the FDA.

For skin tightening, microfocused ultrasound uses specially designed transducers to deliver focused intense ultrasound energy to varying depths in the dermis, subcutaneous tissue, and muscular fascia up to 4.5 mm without affecting other structures including the epidermis. Ultrasound energy is delivered by a selection of transducers operating at 4 or 7 MHz and at fixed depths of 1.5 mm, 3.0 mm, or 4.5 mm. Each transducer delivers a "line" up to 25-mm long of multiple intense, focused points of energy, each of which creates an ~1-mm^3 zone of thermal injury. Energy ranges from 0.75 to 1.2 J. This allows heating of this tissue to >60 °C, which is optimal for immediate collagen fibril contraction and denaturation and long-term neocollagenesis to induce skin lifting and tightening (5, 5, 4) [1, 5–7].

In the initial clinical trial examining MFUS treatment for brow lifting, investigators used the 7-MHz, 3.0-mm or the 7-MHz, 4.5-mm transducer on the neck, the 7-MHz, 4.5-mm transducer on the forehead and temple, and the 4-MHz, 4.5-mm transducer on the cheeks. On average, 110 lines were delivered to the face and neck. Photographs taken 90 days after the treatment of 30 patients were judged by blinded evaluators as having clinically significant improvement in brow lift, and there was a mean brow elevation of 1.7 mm above the pre-treatment baseline. The authors admit that the treatment was performed conservatively and that more aggressive treatment may or may not have yielded greater improvements (4) [8].

In a retrospective study, 45 women were treated on the face and upper neck using both the 4-MHz, 4.5-mm transducer and the 7-MHz, 3.0-mm transducer. On average, 370–420 treatment lines were delivered at the highest energy setting, and subjects were followed at 90 and/or 180 days after treatment. Blinded investigator assessment of improvement from baseline in the primary endpoint of skin laxity at 180 days determined 67% of subjects were improved. Global assessment of improvement by subjects and physician evaluators demonstrated 75% or more of the subjects were improved at 90 and 180 days [1].

Suh and colleagues treated 22 patients on the face and submentum with a single treatment involving multiple transducer depths and energies and an average of 200 treatment lines. Ninety-one percent showed improvement in two objective laxity scores, and the remaining subjects showed improvement in one objective score. Subjectively, 77% and 73% of subjects reported much improvement in the nasolabial folds and jawline, respectively. Histologic analysis showed increased dermal collagen and dermal thickness and straightening of elastic fibers [7].

In the largest trial of MFUS for lower face laxity, 93 patients treated with an average of 293 treatments lines were evaluated, and blinded reviewers reported improvement in 58% of the subjects at 90 days. Using quantitative measures, 64% of the subjects were found to be improved at 90 days. Subjectively, 66% of patients perceived improvement [2].

With proven efficacy on the face, MFUS was then investigated on other body areas. After a pilot study prospectively treating the décolletage of 24 patients showed promising results, Fabi and colleagues completed a prospective multicenter study treating 125 women to assess the treatment's ability to lift and tighten as well as improve lines and wrinkles. The treatment was administered with three different depth transducers (4.5 mm, 3.0 mm, and 1.5 mm) with approximately 280 treatment lines. Blinded assessments revealed 66% achieved improvement at 180 days. 45% of subjects noticed less sagging at 180 days. At 90 days and 180 days, 66% and 63% of subjects, respectively, were overall satisfied or very satisfied (4) [9, 10].

MFUS for lifting of the arms, thighs, and knees was examined in 18 women chosen to receive the treatments in one of these areas. Both sides were treated with the 4.5-mm depth transducer, and one side was randomized to receive a second treatment with the 3.0-mm depth transducer for a dual plane treatment. An average of 160 lines was delivered to the arms, 142 to the knees, and 157 to the thighs with the 4.5-mm transducer. An average of 153 lines was delivered to the arms, 136 to the knees, and 152 to the thighs with the 3.0-mm transducer. There was improvement in all areas by global assessment scores, and the knees and arms had better lifting/tightening than did the thighs on the dual-plane side but without significant difference on the single-plane side (2b) [11].

For the buttocks, a trial of dual plane treatment with the 4.5-mm depth and 3.0-mm depth transducers was conducted with an average of 973 lines delivered to a standardized square area of the left buttock of 30 patients. In assessing laxity, at 180 days, of 19 subjects available for evaluation, the physician global assessment was improved in 89.5% of patients, compared to 81.5% at 90 days. Subject global assessment was improved in 74.1% of the subjects at 90 days and in 89.5% of them at 180 days (2b) [12].

Radiofrequency

Radiofrequency treatments have been shown to induce skin tightening by effecting changes in the dermal collagen and elastin via heating to target temperatures of 40–45 °C. In general, radiofrequency technology produces energy in the electromagnetic spectrum at various frequencies to produce an electric current, with some variations (5, 2b, 4) [13–15]. Immediately, there is a thermally mediated collagen fiber thickening and denaturation with associated collagen fiber contraction, but the effect is temporary. Subsequently, more tightening occurs over time as the wound healing process initiates an inflammatory cascade leading to increased fibroblast activity and, thus, neocollagenesis and neoelastogenesis (5, 4) [4, 13, 16–20]. Many RF devices exist in the cosmetic market today, but only a few devices, which have been represented in the literature, will be discussed here (Table 15.1).

Monopolar RF

Monopolar RF (MRF) passes an electric current through the target tissues from the treatment electrode to a grounding electrode. The dermal and subcutaneous tissues have inherent resistance to the electric current, which creates heat, leading to volumetric heating of the dermal and subdermal tissues, including the fat and fibrous septae. The depth of treatment is typically greater for monopolar RF than other RF technologies and increases with the diameter of the electrode, and some have suggested the depth is approximately half of the electrode diameter [4, 13, 16–19].

Most clinical data, including efficacy, safety, and side effects, that exists for monopolar RF was obtained using the ThermaCool TC™ (Thermage Corp., Solta Medical, Hayward, CA) monopolar RF system since this device was the first of its kind. This system uses a stamping treatment technique with epidermal cooling. The device has

Table 15.1 Comparison of radiofrequency technologies

Type of RF	Electrode configuration	Energy type	Grounding requirement	Depth	Method of energy delivery	Cooling	Notes	Example devices
Monopolar	Single treatment electrode; one grounding electrode	Uses electric current	Requires grounding electrode	Generally deep; depth depends on size of electrode	Pulse or continuous motion	Some require cryogen cooling, topical cooling gel, or no epidermal cooling		ThermaCool, ThermiSmooth 250, Pellevé, Exilis, TruSculpt
Unipolar	Single electrode	Uses electromagnetic radiation	None	Generally deep; depth can be controlled	Continuous motion	None		VShape, Accent
Bipolar	One positive and one negative electrode on treatment probe	Uses electric current	None	Superficial; depth depends on distance between electrodes	Continuous motion	None	Variations include multipolar, fractionated, and microneedle fractionated	Innumerable
Multipolar	Multiple electrodes on the treatment probe	Uses electric current	None	Intermediate depth; depends on energy level and distance between electrodes	Continuous motion	None	Variation of bipolar	3Deep
Fractionated	Multiple electrodes on the treatment probe	Uses electric current	None	Depth depends on energy level	Pulse	None	Form of bipolar	eMatrix, Fractora
Microneedle RF	Multiple penetrating needle electrodes on the treatment probe	Uses electric current	None	Depth depends on penetrating depth of needles and energy level	Pulse	None	Form of bipolar	Infini, Intensif, Profound

FDA indications for the noninvasive treatment of periorbital wrinkles and rhytids including the upper and lower eyelids, noninvasive treatment of wrinkles and rhytids, and temporary improvement in the appearance of cellulite.

Fitzpatrick and colleagues treated 86 patients with the ThermaCool TC™ system at high fluence to determine brow lifting capacity and evaluated results at 6 months. Of 62 evaluable photographs, 61.5% of the brows were lifted at least 0.5 mm, while the average lift was 1.30–1.49 mm. In addition to tightening and lifting, 83.2% of treated periorbital areas had objective blinded wrinkle score improvements. At 6 months, 92.8% of treated areas had improved or remained the same, and improvement of at least one point on the Fitzpatrick Wrinkle Scale was noted in 28.9% of them. A total of 50% of the patients were satisfied with the results (4) [21]. Later, it was noted that this high fluence treatment resulted in scars and other textural adverse effects [17]. A subsequent study with lower fluence and more treatments decreased these effects (4) [22]. Details are discussed in the safety section.

A study examining the ThermaCool TC™ for neck and cheek laxity followed 50 patients with mild-to-moderate laxity. In 28 (93%) of the 30 patients whose cheeks were treated, objective clinical improvement on blinded assessment was noted in the nasolabial and mesolabial folds. On a four-point scale, at 6 months after treatment, the average improvement score was 1.53, where 1 = 25–50% improvement and 2 = 51–75% improvement. Seventeen (85%) of the 20 patients treated on the neck experienced objective improvement in submandibular and neck laxity with a score of 1.27 at 6 months (4) [23]. In another prospective study treating the lower face, 85 Japanese females were treated, and objective improvement in laxity was recorded with results better at 6 months than at 3 months. At 3 months, 50% or better improvement was observed in 70–78% of the subjects for jowls, nasolabial folds and marionette lines, and other facial folds. At 6 months, 84–89% of the subjects were improved by 50% or more (4) [24].

One of the newest monopolar RF devices is the ThermiSmooth® 250 (Thermi™, Irving, TX). It is indicated for the temporary reduction in the appearance of cellulite and used for tightening of the face and neck as well as various other body locations such as the abdomen, thighs, and arms. This system uses a probe in constant contact with the skin in constant motion and provides real-time cutaneous temperature feedback. In a preliminary study of efficacy and safety, 14 women with abdominal laxity received up to four treatments. Blinded objective evaluators found statistically significant improvement over baseline in the subset of 10 of 14 patients that the blinded evaluators correctly identified the before-and-after photos. A patient survey found that patients experienced an average tightening of 2.14 points on a four-point scale with 0 = lowest tightening and 4 = highest. Of 14 subjects, 8 would recommend it to a friend and 3 noticed looser clothing, indicating a slimming effect. This device can be used to treat the face, neck, and, potentially, any other body area, but further studies of efficacy are needed (4) [25].

In an initial study of the device that eventually became the Pellevé MRF system (Pellevé S5 Wrinkle Treatment Generator; Ellman International Inc., Oceanside, NY), 93 patients were treated, and patients noted subjective improvement in laxity and were quite satisfied. This device, indicated for nonablative treatment of mild to moderate facial wrinkles and rhytids, uses a generator and a handpiece in constant motion contacting the skin with topical cooling gel (4) [26]. Chipps and colleagues then examined the device for the treatment of rhytids and laxity of the face and neck. In general, they found objective improvement in global assessment scores by blinded investigators and subjective improvement in laxity by subjects (4) [27]. Another MRF device, (Exilis Elite, BTL Aesthetics, CITY), with FDA approval for the noninvasive treatment of wrinkles and rhytids, also has demonstrated efficacy in reducing skin laxity (4) [28].

Unipolar RF

Unipolar RF differs from other RF technologies in that it uses high-frequency electromagnetic radiation rather than an electric current to produce heat and does not require a grounding pad. The electromagnetic radiation produced causes

oscillations in water molecules that result in heat that can penetrate up to 20 mm in depth [13, 14].

A unipolar RF device (Accent™, Alma Lasers, Buffalo Grove, IL), indicated for the noninvasive treatment of wrinkles and rhytids, was used to treat 30 subjects with grades 3–4 upper thigh cellulite. Significant clinical skin tightening resulting in improvement of the cellulite as well as a decrease in thigh circumference of 2.45 cm on average with histologic evidence of dermal fibrosis after treatment was observed (4) [29].

Bipolar RF

Bipolar RF uses both a positive and negative electrode, which are both on the treatment probe. The current passes between these two electrodes, so these devices cannot penetrate to the depths of monopolar RF technology. There has been some suggestion that the depth of penetration is approximately half of the distance between the electrodes up to approximately 4 mm in depth. With such devices, energy distribution and heating are more controlled, and they require less energy and produce less discomfort [13, 14, 18, 19].

The Accent™ device has a bipolar handpiece in addition to the unipolar and has been studied for efficacy in treating 20 female subjects with mild-to-moderate laxity of the posterior thighs/buttocks. There was statistically significant improvement in laxity (up to 19% from baseline) and tightening (up to 15% from baseline) noted at week 4 and week 8 (2b) [30].

Bipolar devices are often combined with other laser and light-based devices such as an intense-pulsed light (IPL), an infrared light, or a diode laser or even with suction or mechanical massage (4, 3a-, 5) [31–33]. One example of such a device is the bipolar RF combined with IPL in the Aurora SR™ (Syneron Medical Ltd., Yokneam, Israel), which was used for facial rejuvenation treatments in 108 patients every 3 weeks for 5 treatments. Overall improvement was 75%, and laxity improved by 63%. Overall patient satisfaction was 92% (4) [34].

Multipolar RF

Multipolar radiofrequency is a variation of bipolar in which three or more electrodes are used, one of which acts as a positive electrode while the others act as negative electrodes (3a-) [35]. The Apollo™ device, FDA approved for the noninvasive treatment of mild-to-moderate facial wrinkles and rhytids (Pollogen Ltd., Tel Aviv, Israel) using TriPollar™ technology, is in this category and was used to treat 37 patients on the body and face. Weekly treatments, 7 on average (range 2–15), resulted in immediate and long-term skin tightening on the body and face as well as a reduction in body circumference and cellulite and improvement in facial rhytids (4) [36].

The 3DEEP™ technology on the EndyMed Pro (EndyMed Medical Ltd., Caesarea, Israel) is a proprietary multisource RF system indicated for the noninvasive treatment of mild-to-moderate facial wrinkles and rhytids. In one study, investigators examined the results of a series of treatments on 33 subjects with abdominal skin laxity. After six treatment sessions to the abdomen, patients returned for evaluation at 6, 9, and 12 months. Two clinical evaluators rated improvement in laxity on a five-point scale, where 5 = "significant change," with resulting values of 3.2–3.5 after the last treatment and 2.9–3.2 at 12 months, indicating an observed improvement of "visible change" or "slightly better." Patients rated efficacy and satisfaction on a five-point scale, where 5 = "highly satisfied, significant change." Immediately after the last treatment, the score given was 3.4 and then 3.1 at 12 months, corresponding to "somewhat satisfied, visible change." Results were better, on average, when higher final temperatures were achieved as well as when higher temperatures at 20 minutes were achieved. Subject weight was not significantly changed during the study (4) [37]. The same device has shown efficacy in treating facial laxity as well as clinical benefit treating the abdomen and thighs, achieving improvement in laxity, cellulite, and circumference (2b, 4) [38, 39].

Preoperative Evaluation

Evidence-based conclusions regarding the optimal patient for treatment and various other pretreatment considerations are nearly nonexistent.

Most recommendations are based on experience, common sense, common practice, and other "expert" opinion. The limited available evidence and some common practices will be discussed.

Microfocused Ultrasound

Patient Selection

In regards to patient selection, specifically considering lifestyle and patient characteristics, Fabi and colleagues found no evidence that age, skin type, alcohol intake, or major illness had any impact on treatment efficacy. However, for undetermined reasons, subjects reporting high levels of stress had higher physician assessment scores of aesthetic improvement. Subjects with lower BMI ($\leq$25 kg/m^2) had higher self-assessment improvement scores [1].

Along the same lines, Oni and colleagues found that subjects with BMI > 30 kg/m^2 had less subjective and objective improvement after treatment of the lower face than those with lower BMI. They surmised this may be due to excess fat or excessive laxity in the higher-BMI patients [2].

Fabi notes absolute contraindications include broken skin, severe or cystic acne, and implants such as pacemakers and defibrillators. Other situations requiring caution include treatment over keloids, implants, permanent dental fillers, and any other situation that could affect wound healing. These common practice elements have not specifically been tested in any clinical trials (5) [40].

Analgesia

Microfocused ultrasound treatments can be variably uncomfortable. Some clinicians routinely provide patients with an analgesic regimen. Though there is no evidence basis, in Baumann's study, 89% of the subjects received a combination of 2–3 analgesic medications: hydrocodone/acetaminophen, ketorolac, acetaminophen, naproxen, tramadol, and any of several benzodiazepines (4) [41]. In another study, most patients received a combination of a topical anesthetic, oral diazepam, and intramuscular meperidine and hydroxyzine [1].

Monopolar RF

Patient Selection

In Abraham's study, the opinion was given that the ThermaCool RF procedure is best for patients with earlier signs of aging, lacking significant underlying structural insufficiency. Therefore, patients with mild-to-moderate rhytids and laxity in their mid-30s to early 50s or older patients with a prior facelift procedure are likely to be ideal candidates. Those with significant laxity and redundancy are likely to have limited results [3]. Sukal expands this assessment to include benefit in patients even in the mid-60s as well as any patients who could benefit from a degree of brow and forehead lifting [4].

Abraham's report also discussed contraindications to the procedure, which can likely be generalized to all RF procedures. Specifically, any patient with an implanted device such as a pacemaker, defibrillator, or neurological stimulator may not be a candidate or may need clearance to have the device temporally deactivated if they are not completely dependent on it. Additionally, patients with acute or chronic active dermatologic conditions, collagen-vascular disorders, or autoimmune conditions should undergo directed screening and thorough consideration to ensure candidacy for the procedure. Valacyclovir should be used when needed for herpes prophylaxis [3].

Further evidence-based preoperative considerations are lacking in the literature.

Best Techniques and Performance

While each study in the literature uses specific and, typically, unique treatment parameters and techniques, studies directly comparing the efficacy of those parameters and techniques are rare. Therefore, it is difficult to provide an evidence basis for the use of any specific settings, passes, or other parameters being superior to other variations. In most cases, it can only be stated that the results in any given study were achieved with the particular treatment as it was executed in that study. Furthermore, it is important to note that treatment parameters, outcomes, and side effects

are often device specific rather than modality specific, and there can also be significant variability even with the same device based on how treatments are performed. The limited available comparative evidence will be discussed.

Microfocused Ultrasound

Investigating a multi-depth approach, in a study treating 64 patients, Baumann and Zelickson randomized subjects to one of three different treatment groups for treatment of the neck. Efficacy and patient satisfaction were greater in the group treated with both a deep (4.5-mm depth) and superficial (3.0-mm depth) pass versus a single deep pass [41]. Alster and colleagues found slightly higher clinical improvement scores at all sites (upper arms, medial thighs, and knees) treated on the dual-plane side compared to the single-plane (deep) side, but differences were not statistically significant [11]. Sasaki and Tevez determined from their prospective study that areas treated with more lines, higher energies, and at dual depths demonstrated greater lifting (2b) [42].

Based on clinical experience, but without objective prospective or retrospective analysis, Brobst and colleagues suggest that more treatment lines result in better results as does a multi-depth approach (5) [43].

Based on experience, Fabi suggests a treatment algorithm for the treatment of the full face and upper neck based on degree of laxity: 500–600 lines for mild laxity, 600–700 lines for moderate laxity, and 800 lines for severe laxity [40].

Radiofrequency

Initially, the ThermaCool device treatment algorithm involved a single pass at high energy. This resulted, at times, in inconsistent results and significant treatment pain [33]. The first step to improve the treatment algorithm was a small histologic study of three patients treated with one or multiple passes and low or high energies. Multiple-pass algorithms produced ultrastructural collagen changes similar to the more painful single-pass high-energy treatment (5) [44]. This, then, spawned several clinical investigations.

Analyzing a survey of physicians performing 5700 treatments with the ThermaCool device, Dover and a 14-physician consensus panel determined a low-energy, multi-pass technique yielded "substantial and consistent results." Compared to the initial single-pass treatment, the new multiple-pass algorithm resulted in greater immediate tightening, greater tightening at 6 months, much less pain, and an increased frequency of meeting patient expectations. Furthermore, the panel established "patient feedback on heat sensation is a valid and preferred method for optimal energy selection" and visible tightening is a valid clinical endpoint, predictive of results (5) [45]. Similarly, as Dover reports, Geronemus and Koch found a multiple-pass technique (thus using a higher number of pulses) yielded superior results when they treated 45 patients with varying pulse number ranges [45]. Though not directly comparing to the former single-pass technique, Bogle and colleagues also found a multiple-pass, lower-energy technique effective in the treatment of 66 subjects. They concluded this method is ideal to achieve results with the fewest side effects and that the endpoint in treatment is visible tightening (4) [46].

Fritz, Counters, and Zelickson randomized 20 subjects to receive either one or two treatment sessions using the same device and concluded that improvement was significantly greater in those treated with two sessions. Both groups had greater improvement 4 months after treatment than at 1 month after, and both had relatively high patient satisfaction (4) [47].

In a study of the EndyMed multisource RF device, it was determined that there is a greater degree of clinical improvement in subjects when surface temperatures increased more than 11.5 °C by the end of the procedure and remained increased greater than 4.5 °C 20 minutes after the procedure [37].

Further studies are lacking to provide evidence for specific treatment parameters with other devices and modalities.

Safety

A review of the available literature suggests that noninvasive skin-tightening treatments are vastly safe procedures.

Microfocused Ultrasound

No long-term side effects from MFUS treatments have been reported in the literature to date.

Hitchcock and Dobke performed an exhaustive literature review of MFUS (Ulthera) safety encompassing all available studies and trials in the literature as well as postmarket reports to the manufacturer (3a-) [48]. At the time of the review, an estimated 350,000 treatments had been performed worldwide. The most commonly reported side effects include transient erythema (which commonly occurs in all or nearly all patients treated), tenderness, and edema. Ecchymoses, numbness/tingling, and welts/wheals/striations (most likely due to inadequate transducer contact) are less common. Rare events include postinflammatory pigment changes and paresis. All side effects and rare adverse events have been temporary and resolved without sequelae. In a summary of 769 treated subjects in 22 clinical trials, tenderness/soreness occurred in 1.6%, welts/lines in 1.2%, and bruising in 0.4%. Other effects beyond the typical common adverse events occurring in less than 0.4% included moderate pain, nerve irritation, numbness/paresthesia, lumps, swelling, tingling, itchiness, redness, hives/rash, headaches, and swollen throat during treatment. All were mild except the moderate pain, hives/rash, and swollen throat which were moderate. All were temporary [48].

In a large European review of 318 treatments, beyond the expected, known adverse events as discussed, there were four unexpected side effects attributed to or possibly attributed to a poor treatment technique. These were a moderate submental burn leaving a "very small scar" (22 days to resolution), a severe mentalis nerve irritation (47 days to resolution), a 2 × 1-cm firm lump on the neck (91 days to resolution), and a moderate motor nerve deficit of the depressor angulis oris muscle (90 days to resolution) [48].

Another large European systematic survey examined side effects treating 233 patients. Transient erythema (<1 h) occurred in 100%. Other erythema (12–24 h), eyelid edema (<3 days), superficial ecchymosis (duration not specified), and moderate continuous pain (<3 weeks) occurred in 2.2–3% of patients. Vesicles and papules lasting <8 days occurred in 9.4%, and transient numbness occurred in 2.6%. Hitchcock and Dobke concluded that the treatment is safe and effective typically with only mild and transient side effects. Unexpected and rare adverse events are often attributed to poor technique and most can be avoided. Generally, all side effects have resolved [48]. No significant differences in safety have been reported since their review in 2014.

A 2015 study of the treatment of 52 patients with Fitzpatrick III to VI revealed a similar safety profile with only three adverse events: mild edema or welts in two subjects and severe prolonged erythema with mild scabbing in one subject. All resolved within 90 days, and the authors concluded the treatment is safe in all skin types (4) [49].

Radiofrequency

Monopolar RF

In the initial study using monopolar RF, Fitzpatrick and colleagues reported data on pain and adverse events. Of 86 subjects, 22 of whom received nerve blocks and all of whom received topical anesthesia, 3% reported no pain, 45% reported mild pain, 35% reported moderate pain, 13% reported severe pain, and 3% reported intolerable pain. The treatment energy was reduced when needed per patient's pain tolerance. The most frequent side effects were erythema (present immediately in 36% and present in 17% within 72 h) and edema (14% immediately and 6.4% within 72 h). Scabbing occurred in 7.7% within 72 h but was not present immediately. Other events occurring with an incidence of 5% or less included abrasion, blistering, blanching,

bruising, crusting, hyperpigmentation, oozing, purpura, and ulcer. Scarring had an incidence of 6.3% by 4 months and 3.6% by 6 months. Textural changes were noted to reach an incidence of 2.4% by 6 months without data beyond that point. Other than scarring and textural changes, most events resolved by 1 month, still others by 4 months, and all others by 6 months. There were 15 subjects with at least 1 area of second-degree burn for a total of 21 second-degree burns out of 5858 RF exposures, resulting in an incidence of 0.36%. They noted the overall high level of safety with this device to be "impressive" and that burns were likely due to user technique as well as some correlation between higher energies resulting in more burns [21].

Alster's study of 50 treated patients also found the procedure to be safe with limited adverse effects. Subjects described the procedure as moderately uncomfortable. All had erythema lasing 2–12 h. 56% reported soreness in the treated area. Erythematous papules that resolved in 24 h occurred in 6%, and one patient described dysesthesia along the mandible that resolved within 5 days. There were no pigmentary changes, blistering, or scarring [23].

Narins and colleagues investigated overtreatment with the ThermaCool RF device causing "delayed contour irregularities." Although most adverse reactions with this monopolar RF device are limited to superficial burns and these delayed contour irregularities are, overall, quite rare, with an incidence lower than that of the adverse events of many other surgical and nonsurgical treatments, they are thought to occur secondary to deeper tissue overheating. Using data tabulated from all contour irregularities reported by clinicians to the manufacturer, it was determined that this occurred with an incidence of 0.23% during the 18 months prior to a modification in the manufacturer's treatment guidelines to address this concern. After modification, the incidence declined to <0.04% during the subsequent 6 months. Furthermore, 70% of the cases prior to the treatment modification occurred when nerve blocks, tumescent anesthesia, and/or intravenous sedation impeded the patient pain perception and reporting. By following a modified treatment algorithm consisting of multiple passes at lower energies, patient feedback as a guide, and a delay between passes to allow tissue cooling, complications should be fewer [22].

In the prospective trial treating 49 subjects with the Pellevé system, there were no adverse events reported and no post-procedure recovery time or pain [27]. Vega's group also reported only mild-to-moderate discomfort during the treatment and no adverse events in their prospective trial using this system to treat the hands of 28 patients (4) [50].

The newer ThermiSmooth 250 monopolar RF system uses a probe with constant motion in constant contact with the skin that provides real-time surface temperature feedback to control energy delivery and does not require a cooling mechanism. In the preliminary prospective study treating 14 subjects, Key did not report any adverse events [25].

Overall, microfocused US and monopolar RF treatments present an excellent safety profile (B).

Unipolar, Bipolar, and Multipolar RF

Many studies using various systems have consistently reported a post-treatment transient erythema typically lasting 15–30 min up to 120 min in all or nearly all patients. None found any other significant adverse events such as blistering, scarring, or pigmentary changes (4) [14, 29, 30, 36–39, 51, 52].

Postoperative Care and Follow-Up

There are no specific evidence-based recommendations for particular follow-up intervals or monitoring. Anecdotal recommendations exist suggesting follow-up treatments at anywhere between 6 and 24 months. It should be noted that they are not at all evidence based.

Alternative Procedures and Modifications

Noninvasive skin tightening techniques can serve as the structural backbone for a comprehensive, multiple-modality approach to rejuvenation to

correct rhytids, photodamage, volume loss, and contour irregularities. Once the skin has been tightened and lifted, fillers, neurotoxins, superficial and deep resurfacing, as well as other vascular and pigment targeting lasers and intense-pulsed light can be combined as needed for correction of the aging skin.

Alternatively, more profound lifting from minimally invasive techniques such as absorbable suture lifts or even invasive lifting such as facelifts can be initially performed. Then, the results can be improved, maintained, and finessed with noninvasive tightening techniques as discussed.

A couple of minimally invasive energy-based techniques exist as alternatives to the tightening provided by the external tightening modalities reviewed: laser lipolysis and subdermal monopolar radiofrequency treatments.

Laser lipolysis has been shown in multiple studies to achieve skin tightening. Two large studies >40 patients, for example, showed tightening at all body areas treated including the neck and extremities in addition to the abdomen. While one study used measurements of circumference as proof of tightening, the other used skin caliper measurements (4) [53, 54]. Circumference measurements could be confounded by the volume loss from the lipolysis procedure. Complications were minimal to none. When present, they consisted of only prolonged edema in some patients [53, 54]. It is unclear if common and expected side effects occurred but were not reported.

In a study of subsurface monopolar radiofrequency treatment, 35 subjects were treated in the submental region. Subject graded improvement scores showed improvement in 84% at 90 days and 77% at 180 days. At 90 days, 68% of subjects were satisfied, and 64% of subjects were satisfied at 180 days. Adverse events included tenderness, edema, bruising, numbness, and nodules and induration. Two subjects experienced temporary marginal mandibular nerve palsy resolving within 14 days. One had a transient burn (4) [55].

While not discussed in detail, other radiofrequency technologies, devices, and techniques have also been shown to induce skin tightening. While they tend to be used primarily for other indications, fractionated bipolar RF and microneedle fractionated bipolar RF have been shown to induce skin tightening (5 [56], 4 [57–64]) [13, 35, 56–64]. Thus, skin tightening can be a secondary benefit to the use of these devices, or these treatments can be employed primarily for their tightening effect, usually on the face and neck.

Other noninvasive devices and treatment modalities have been shown to produce tightening effects as well. While used more commonly for resurfacing and photodamage, fully ablative lasers, fractional ablative lasers, fractional nonablative lasers, various nonablative laser wavelengths, infrared devices, and intense-pulsed light have all been shown to produce some degree of skin tightening, as has cryolipolysis. (4 [65–73], 2b [74–78], 5 [79, 80]) [17, 65–80]. Picosecond systems with nonablative laser wavelengths are being studied for photorejuvenation including skin tightening as well. These modalities can be employed in place of or in addition to the other tightening technologies discussed as needed for each patient.

Other body contouring procedures and noninvasive fat reduction procedures can be complementary to skin tightening procedures. These include other contouring lasers such as the 1060-nm body sculpting laser, the multipolar contactless RF field treatment, intense-focused ultrasound devices, and acoustic pulse therapy devices.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development, and Evaluation (GRADE).

Findings	GRADE score: quality of evidence
The noninvasive skin tightening techniques, modalities, and devices as discussed are generally safe and effective means for achieving nonsurgical tightening results with minimal downtime and minimal side effects	B
Careful patient selection matching severity of laxity and goals of treatment with the appropriate device and referring for invasive treatments when necessary are both important	D
Of paramount importance is ensuring patients completely understand the expectations of the treatment and potential results	D
Microfocused ultrasound, various radiofrequency technologies, ablative fractional and full-field resurfacing, nonablative fractional resurfacing, various laser wavelengths, and cryolipolysis have shown evidence of various degrees of skin tightening. Often this may be dependent upon treatment technique, patient characteristics, and the modality employed, but studies affirming optimal treatment parameters are generally lacking	B-C
Microfocused ultrasound, various radiofrequency technologies, ablative fractional and full field resurfacing, nonablative fractional resurfacing, various laser wavelengths, and cryolipolysis have shown evidence of various degrees of skin tightening	B-C
Radiofrequency, microfocused ultrasound, and nonablative laser wavelengths in the infrared spectrum are generally safe for the treatment of all Fitzpatrick skin types when used appropriately	B
Younger patients with mild-to-moderate laxity are likely to see more improvement than older patients or those with significant redundancy, particularly as studied for radiofrequency modalities	C
This may be generalizable to the other noninvasive tightening modalities	D
As studied in microfocused ultrasound, subjects with BMI ≤ 25 kg/m^2 are likely to see better results compared to those with higher BMI	C
Additionally, studies suggested a dual-plane treatment algorithm likely improves results	C
It seems a greater number of treatment lines might as well	D

Self-Assessment Questions

1. Which of the following types of radiofrequency technology does not use an electric current to create heat in the skin?
   (a) Bipolar RF
   (b) Fractionated RF
   (c) Monopolar RF
   (d) Multipolar RF
   (e) Unipolar RF
2. Which of the following lifestyle or patient characteristics has been shown to affect the final outcome from microfocused ultrasound treatments?
   (a) Age
   (b) Alcohol consumption
   (c) BMI
   (d) Illness
   (e) Skin type
3. Which of the following treatment algorithms was determined best to avoid delayed contour irregularities from the original monopolar RF treatment device:
   (a) Single pass, higher energy
   (b) Single pass, higher energy with tumescent anesthesia of the entire treatment area.
   (c) Single pass, lower energy
   (d) Multiple passes, higher energy
   (e) Multiple passes, lower energy
4. A device of which of the following technologies has an FDA indication for brow lifting?
   (a) 1550-nm fractional laser
   (b) Bipolar RF
   (c) Microfocused ultrasound
   (d) Monopolar RF
   (e) Multisource RF
5. Which of the following is true of bipolar RF compared to monopolar RF?
   (a) In bipolar RF, one electrode is located in the treatment probe, and the other is a grounding pad.
   (b) In bipolar RF, the presence of both the negative and positive electrode in the treatment probe results in a generally deeper treatment.
   (c) In bipolar RF, the presence of both the negative and positive electrode in the treatment probe results in a generally more superficial treatment.
   (d) Monopolar RF is typically delivered in a fractionated pattern.
   (e) Monopolar RF uses high-frequency electromagnetic radiation instead of an electric current to produce a thermal effect.

Correct Answers

1. e: Unipolar RF uses a single electrode to deliver electromagnetic radiation to the skin, which results in oscillation of water molecules to produce heat. Other forms of RF use two electrodes to deliver an electric current. Fractionated RF and multipolar RF are a form and variation of bipolar RF, respectively.
2. c: BMI $\leq$ 25 kg/m^2 was shown to result in higher self-improvement scores, and BMI > 30 kg/m^2 was shown to have lower subjective and objective improvement scores when using microfocused ultrasound [1, 2].
3. e: After the initial treatment protocol using the first monopolar RF treatment device with epidermal cooling and a "stamp" treatment technique called for a single high-energy pass, there was a small incidence of delayed contour irregularities. A multiple-pass, low-energy algorithm was determined to be safest to avoid contour irregularities as well as to yield superior results. Additionally, upon review, it was determined that local anesthesia prevented appropriate patient feedback for safety [22, 45].
4. c: A microfocused ultrasound device has an FDA indication for brow lifting.
5. c: The short distance between electrodes in bipolar RF limits the depth of treatment.

16 Vascular Laser and Light Treatments

Brent C. Martin and Kristen M. Kelly

Abstract

This chapter provides an overview of vascular targeting light treatments applied to treatment of commonly encountered cutaneous vascular lesions, specifically port wine birthmarks (PWBs), infantile hemangiomas (IHs), and telangiectasias. Evidence-based recommendations are provided regarding light-based treatment effectiveness, preoperative evaluation, treatment techniques, safety, and postoperative management. We also discuss device and drug combinations which have been utilized including photodynamic therapy or laser in combination with antiangiogenic agents for PWBs and beta-blockers with lasers for IHs. This chapter provides a practical, concise, and evidence-based guide for the utilization of vascular-specific laser treatments available today.

Introduction

One of the first applications of lasers in dermatology was the treatment of port wine birthmarks (PWBs). Vascular-specific lasers such as argon lasers were used in the 1960s and improved PWBs but caused an unacceptably high incidence of scarring, due to the relatively non-specific heating of skin. Anderson and Parrish published their landmark paper on selective photothermolysis [1] in 1983, which proposed a way to confine thermal injury to the target of interest, while minimizing damage to surrounding tissue, reducing scarring and pigmentary change. Three laser parameters are important to selective photothermolysis: laser wavelength, pulse duration, and fluence. The wavelength should have preferential absorption for the targeted chromophore. In the case of vascular lesions, this is oxyhemoglobin, which has the greatest absorption peaks at 418, 542, and 577 nm (Fig. 16.1). Pulse duration should be matched to the target size with short durations for smaller targets and longer pulse durations for longer targets. In the case of vascular lesions, blood vessels are relatively large targets, and millisecond pulse durations are used. Fluence is the energy per unit area and must be adequate to cause damage to the target, but not excessive, which could result in nonselective injury.

The pulsed dye laser (PDL) (577–600 nm) was developed in the 1960s and provided the

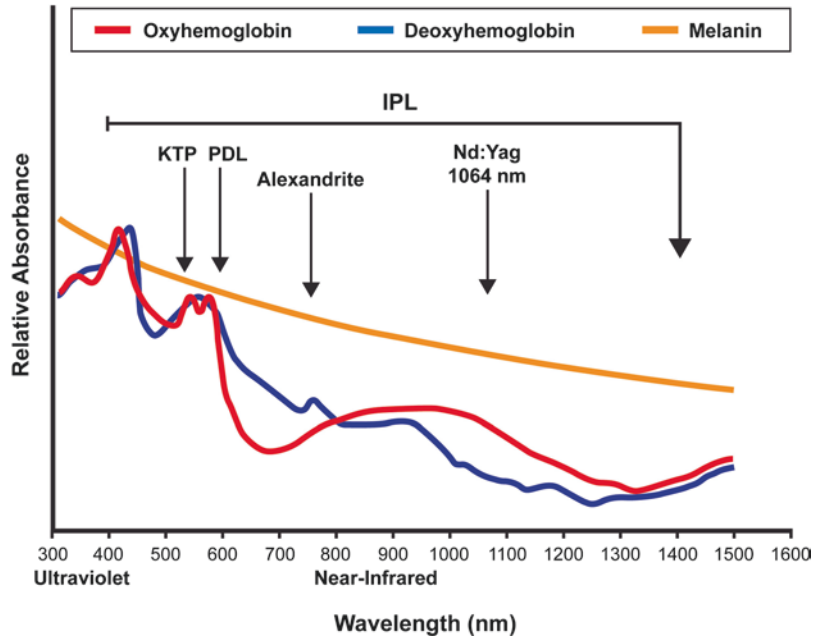

Fig. 16.1 Relative absorbance curves of vascular lasers and light

necessary components for selective photothermolysis to target vascular lesions. Several advancements were made in this device over subsequent decades. PDLs with longer wavelengths (585 and 595 nm compared to the original 577 nm) allow for slighter greater depths of penetration. The ability to use longer pulse durations (3–40 ms as compared to 1.5 ms or less) allows treatment for some lesions such as telangiectasias with minimal purpura, which is advantageous for cosmetic treatments [2 (2b)].

Epidermal cooling was introduced in the 1990s to protect the skin surface and to minimize pigmentary change and scarring, while reducing patient discomfort. Use of epidermal cooling is especially advantageous in patients with dark skin types, where increased epidermal melanin prevents penetration of light to targeted dermal tissues. Epidermal cooling also allows the use of higher fluences to improve tissue effect. The three types of epidermal cooling used are cryogen spray cooling, contact cooling, and air cooling.

Other devices have also been used for vascular lesion treatment. Potassium titanyl phosphate (KTP) lasers use a neodymium:yttrium aluminum garnet (Nd:YAG) crystal frequency doubled with a KTP crystal to emit a wavelength of 532 nm. The depth of penetration is slightly less than that of PDLs given the shorter wavelength. There is also increased melanin absorption at the 532 nm wavelength. Longer wavelength lasers can penetrate up to 50–75% deeper into the skin and can be used to treat deeper lesions. The alexandrite laser at 755 nm is a good choice to treat deeper, more resistant venous lesions, as its wavelength is close to the deoxyhemoglobin absorption peak (Fig. 16.1). Near-infrared diode (800–810 nm, 940 nm) devices are also used successfully for vascular targeting. The Nd:YAG laser can be used to treat vascular lesions by targeting the secondary, lower peak for the absorption of light by oxyhemoglobin (Fig. 16.1). It is important to note that the absolute absorption of hemoglobin is lower, requiring the use of higher fluences, which increases the risk of tissue damage and scarring. As such, these devices should be used with caution and are best used by clinicians with extensive experience. Intense pulsed light (IPL) devices emit polychromatic noncoherent broadband light from 420 to 1400 nm with varying pulse durations. Filters are implemented to remove unwanted shorter wavelengths to treat

vascular lesions with blue-green to yellow wavelengths. Dual wavelength or energy devices such as PDL combined with Nd:YAG (595 and 1064 nm) and PDL combined with radiofrequency energy are also available.

When selecting a device and treatment parameters, the user should keep in mind the type of lesion, the depth of the lesion, and the patient characteristics such as skin type. As an example, since the PDL penetrates 0.5–1.2 mm into the skin, it is efficacious for treating vascular lesions in the superficial dermis [3] and is most easily used in patients with lighter skin types, although settings can be adjusted (e.g., lower energies and longer pulse durations) for patients with dark skin types. Near-infrared and infrared wavelengths can be used to treat deeper lesions; however, as noted above, there is increased risk.

Indications for Vascular Lasers and Light Treatments

A diverse range of cutaneous vascular lesions can be treated with light-based devices. We describe some specific indications below.

Port Wine Birthmarks

Port wine birthmarks (PWBs) are congenital capillary malformations characterized by erythematous to violaceous patches. PWB vessels vary in size from 7 to 300 μm, with older patients tending to have larger vessels. PWBs are found in approximately 0.3% of newborns. They are commonly found on the head or neck, but can occur anywhere throughout the body. Over decades, lesions may thicken and develop papules and nodules [4, 5 (4, 4)]. Tissue hypertrophy, which can occasionally occur at birth, has been associated with 60–70% of lesions by the fifth decade of life. PWBs can be associated with various syndromes such as Sturge–Weber syndrome, which involves a facial PWB with associated ophthalmologic and/or neurologic abnormalities including glaucoma, seizures, and developmental delay. PWBs can also occur in association with arteriovenous malformations in Klippel–Trénaunay–Weber and Parkes Weber syndromes as well as in capillary malformation–arteriovenous malformation syndrome. Many patients seek treatment for these lesions due to the psychosocial or functional impact. Laser therapy is the standard of care treatment for PWBs.

Infantile Hemangiomas

Infantile hemangiomas (IHs) are the most common benign vascular tumors in children, occurring in 4–10% of infants. IHs are three times more common in females. Lesions are present at birth or become evident during the first several weeks of life. Sixty percent of lesions arise on the head and neck. Hemangiomas are characterized as localized or segmental, and as superficial (red papules or plaques), deep (blue or skin colored nodules), or mixed [6 (2a)]. Associated syndromes need to be considered when evaluating patients with IHs. PHACES syndrome needs to be considered in large segmental facial IH and involves posterior fossa malformations, IH, arterial anomalies, coarctation of the aorta, eye abnormalities, and sternal or supraumbilical raphe. LUMBAR syndrome includes **l**ower body infantile hemangiomas with **u**rogenital anomalies and **u**lceration, **m**yelopathy, **b**ony deformities, along with **a**norectal, **a**rterial, and **r**enal anomalies. Diffuse neonatal hemangiomatosis involves multiple skin hemangiomas and an associated risk of visceral hemangiomas.

Most IHs proliferate, often rapidly, until 6–9 months of life. Lesions then stabilize and begin to regress, with the majority of lesions regressing by 9 years of age, although recent studies suggest this may occur sooner [7 (1a)]. Some IHs leave behind residual fibrofatty tissue, atrophy, or telangiectasias. Small, non-ulcerated lesions in a non-cosmetically sensitive area may not require treatment. Treatment is needed for lesions that affect an important function (vision, feeding etc.), ulcerated lesions (as these are very painful), and for lesions that are in cosmetically sensitive areas and are likely to

result in scarring. Common locations of IHs that are indicated for treatment include lesions on the face or in the anogenital region. Treatment should be aimed at stopping progression of lesions early on to minimize tissue damage and therefore avoiding the need for long-term treatment in the future. Topical therapies (such as topical timolol), systemic medications (especially beta-blockers such as propranolol), and occasionally surgical intervention are used for lesions that ulcerate or impact functionality, such as feeding or vision. Beta-blockers are currently the standard of care for IHs, for which treatment is recommended. Laser therapy may be beneficial, especially for superficial or ulcerated lesions. Laser therapy is often used in combination with topical or systemic medications. Vascular targeting and fractioned lasers are commonly used to remove residual skin changes after involution.

Telangiectasias

Telangiectasias are common lesions that present as 0.1–1-mm diameter vascular dilatations that are visible on the skin anywhere on the body but especially on the face, around the nose, the cheeks, and the chin. They may occur in an acquired fashion in the setting of other conditions including cutaneous photodamage, rosacea, connective tissue or liver disease, radiation dermatitis, and post-long-term topical corticosteroid therapy [8 (2a)]. Numerous congenital conditions are associated with telangiectasias including hereditary hemorrhagic telangiectasia (HHT), Osler-Weber-Rendu syndrome, and ataxia-telangiectasia. Facial redness is a common complaint in patients with many telangiectasias.

Telangiectasias and resultant facial redness often do not require treatment from a medical standpoint, but some lesions, especially those associated with syndromes, may bleed. Telangiectasias can be treated for cosmetic purposes. Lasers provide quick and effective therapy. New telangiectasias often develop with time, and repeat treatments are often beneficial.

Effectiveness of Vascular Laser and Light Treatments

Port Wine Birthmarks

PDLs are commonly used to treat PWBs, with many studies demonstrating efficacy [9–14 (2b, 2b, 3b, 2b, 2b, 4)]. Multiple treatments are required to achieve maximum lightening of PWBs (15–20 or more are not uncommon), and complete clearance is uncommon [9–11 (2b, 2b, 3b)]. In 1 study of 76 patients, 79% clinical improvement was reported over an average of 9 PDL treatments [12 (2b)]. Factors that lead to improved response to PDL treatments of PWBs include small size (<20 cm^2), a location directly above a bony area (particularly the central forehead), and treatment at a young age [13 (2b)]. One study on 49 infants, all of whom started laser treatment before the age of 6 months, found an average clearance of nearly 90% after 1 year [14 (4)]. Additional studies have also indicated that earlier treatment of PWBs might allow for better results with fewer total treatments [15–18 (2b, 2b, 2b, 3b)]. Greater efficacy of treatment in young children may be related to increased hemoglobin concentration in the first 6–12 months of life and the presence of thinner skin and smaller lesion vessels in infants as compared to older individuals. Studies have shown that PWBs located on the trunk, extremities [19 (2a)], and central face (medial cheek, upper lip, nose) [20], and those lesions that are violaceous or nodular [21 (2b)], are more difficult to treat.

Lesions may recur after treatment. In a 10-year follow-up study of 51 patients treated with PDLs for PWBs, lesions were found to be significantly darker at follow-up than at the time of the last treatment. Lesions did remain significantly lighter than prior to initial therapy [22 (4)].

Infantile Hemangiomas

As noted above, beta-blockers are currently the standard-of-care treatment for IHs. When lasers are used, PDLs are a common laser used for the treatment of infantile hemangiomas. Study results

vary on the efficacy of treatment. Variability in study results is likely due to the natural course of these lesions (regression with time) and the range of laser parameters that have been used. Recent studies that suggest early treatment with PDLs can halt further growth and facilitate a transition to the involution phase, with minimal risk of adverse effects, when appropriate settings are used and patients are selected correctly. In a retrospective study of 90 patients, treatment with a 595-nm PDL with cooling led to 85% clearance of color and 64% resolution of thickness [23 (2a)]. Superficial IHs, as compared to deeper lesions, respond better. This is due to the limited depth of penetration of PDL light. A prospective study of 165 patients showed complete clearance of superficial IHs, while no mixed superficial-deep lesions exhibited complete clearance [24 (2b)].

PDL is also beneficial for treatment of ulcerated hemangiomas, especially in the anogenital area. A study on 78 patients with ulcerated hemangiomas showed that 91% improved after a mean of 2 PDL treatments [25 (2b)].

Propranolol can be used in combination with PDL. A retrospective study showed that complete clearance occurred more commonly when IHs were treated with propranolol and PDLs concurrently compared with IHs treated with propranolol followed by PDLs and IHs treated with propranolol alone [26 (2a)]. The same study also showed that clearance occurred at 92 days with combined therapy as opposed to 288 days for propranolol alone.

Telangiectasias

Many different light sources are effective in treating telangiectasias including PDLs, long-pulsed 532-nm lasers and intense pulsed light. PDL treatment with shorter pulse durations generally results in temporary purpura. Longer pulse durations, greater than 6 ms, can decrease resultant purpura, but more treatment sessions are usually needed. Two studies involving patients with facial telangiectasias and erythema showed that fluences that induce purpura were more effective at reducing the appearance of telangiectasias, although subpurpuric fluences did reduce surrounding erythema [27, 28 (3b, 2b)]. Vessels around the nasal ala are more difficult to treat. One study showed that cautious stacking of non-purpuric PDL settings resulted in successful resolution after PDL alone [29 (3b)]. Follow-up treatments are often required as telangiectasias can recur or new lesions develop with time.

Preoperative Evaluation

An initial consultation is important to determine the correct diagnosis, to assess if additional work-up is needed, and to discuss treatment options. If laser therapy is planned, expectations for treatment, the need for multiple sessions, and risks of treatment as well as benefits should be discussed. It also needs to be determined whether anesthesia will be used for the procedure, and if so, anesthesia options should also be discussed. Expected post-treatment effects including erythema, purpura, and swelling should be described and aftercare, including sun protection and avoidance of trauma should be addressed. Photos should be taken prior to each treatment to check and assess improvement.

As mentioned earlier, associated syndromes need to be considered when evaluating patients with PWBs, infantile hemangiomas, and telangiectasias. For PWBs, if Sturge-Weber syndrome is suspected, then ophthalmology and neurology referrals may be appropriate. Imaging studies including ultrasound (in the first year of life) or magnetic resonance imaging (MRI) may also be appropriate to assess central nervous system involvement. For large facial IH, features of PHACES syndrome should be assessed through utilization of imaging studies including echocardiogram and brain MRI/MR angiogram. An eye exam by an ophthalmologist may be warranted. If hemangiomas of the beard area (mandibular innervation area of the trigeminal nerve) are seen, referral to an otolaryngologist is warranted to assess for upper airway hemangiomas, which can cause airway obstruction. Urologic workup including imaging (ultrasound, MRI) of the pelvis and perineum to assess for abnormalities in the kidney, urinary tract, and genitalia should be considered if

LUMBAR syndrome is suspected. Work up is not generally required for telangiectasias unless a genetic syndrome such as HHT is suspected.

Prior to treatment, the question of whether to use local/general anesthesia or pain medications should be addressed. Non-steroidal anti-inflammatory drugs (NSAIDs) should be avoided as they inhibit clotting and can minimize treatment effects. Topical anesthetics can be used, but vasoconstriction and lesion blanching may occur with some topicals, which could potentially decrease the efficacy of treatments. Injected anesthesia, nerve blocks, and local injections can be considered [30 (2a)]. One study showed that complete nerve block, when utilized for laser treatment of cutaneous lesions, led to excellent pain control in 96% of cases, while complications, including vasovagal syncope, swelling, and neurapraxia occurred in only 1.1% of cases and were generally mild and transient [31 (2b)]. Early treatment of PWBs and IHs is often beneficial, and general anesthesia may be considered for treatment of infants and young children as treatments are uncomfortable and require eye protection and limited movement of the patient. In our clinic, general anesthesia is used in some children over 6 months of age; it offers the advantage of minimizing fear and pain in children who will need lengthy and/or multiple procedures for large lesions. One study reported no serious adverse events in 881 dermatologic procedures performed on children with an age range of 2 months to 18 years [32 (2b)]. Other studies have shown little risk during the procedure if general anesthesia is performed with pediatric anesthesiologists [33, 34 (2b, 2b)]. In recent years, the risk of developmental delay when general anesthesia is used in children less than 3 years of age has been a concern. Some of the concerns were based on animal studies. The US Food and Drug Administration (FDA) recently released a warning [35] as these animal research studies have shown that there may be risks, including neurodegenerative changes in the developing brain, with general anesthesia in the first few months to a year of life. At the current time, the FDA states that there is insufficient data to determine the clinical relevance of these findings and further studies are needed to assess the long-term effects. There have been some recent large clinical studies, which did not find significant increased risk of development delay associated with general anesthesia procedures in young children [36, 37 (2b, 1b)], but additional studies are pending. However, all potential risks should be discussed with parents, so informed decisions can be made.

Immediately following laser treatment for vascular lesions, local swelling and pain similar to a sunburn is common. Aftercare including elevation, ice application, over-the-counter oral analgesics (if not contraindicated acetaminophen is preferable to NSAIDs as the latter could affect treatment effects and increase bruising), mild topical emollients (such as petrolatum), sun avoidance/protection, and avoidance of trauma all are beneficial for decreasing the likelihood of patient discomfort, hyperpigmentation, and scarring [38 (2a)].

Best Techniques and Performance

Use of lasers always requires appropriate eye protection. All present in the room must wear appropriate goggles. Patients can wear goggles if non-facial areas are treated, if goggles of the correct size are available, and if the patient is unlikely to remove them. Young children often require more secure eye protection, such as laser safe eye pads (adhesive pads with metal to protect the eyes) and gauze or securely placed overlying metal eye shields. If the skin inside the orbital rim is to be treated, corneal shields are needed. These can be placed using anesthetic drops approved for ophthalmologic indications and lubricant. Use of lubricant may cause post-procedure blurriness, so patients should have an accompanying driver or make sure lubricant is rinsed out prior to driving. There is a small risk of corneal eye injury with placement of these shields, so this should be done with care.

Laser parameters vary based on type of lesion, lesion characteristics and location, and patient skin type. Large spot sizes offer the advantage of minimizing light scatter and allows for increased penetration of light. It may be advisable to use

lower fluences and longer pulse durations in those with darker skin types. Epidermal cooling techniques are used concurrently for all laser treatments of vascular lesions.

Port Wine Birthmarks

PDLs are commonly used for PWBs. An example of parameters include [39 (2a)]:

- Wavelength: 585–595 nm
- Pulse duration: 0.45–10 ms
- Fluence: 4.5–12 J/cm^2 (settings need to be individualized for each device; lower energies are generally used with larger spot sizes)
- Spot size: at least 7 mm
- Appropriate epidermal cooling

Treatment parameters for PWBs with PDLs vary to some degree with each specific device. Appropriate initial PDL fluence settings vary largely due to individual patient characteristics including skin color, lesion morphology, and lesion location. Lower initial fluences are typically used for young children, individuals with dark skin (due to risks of hyper/hypopigmentation), and lesions in areas at higher risk for cutaneous damage, such as the neck or eyelid. Fluences can be increased by 0.5 J/cm^2 during subsequent treatment visits, if adequate response has not been obtained and there are no adverse effects [38 (2a)]. It is important to know desired treatment end points for all laser treatments. For PDL treatment of PWBs, purpura without cutaneous whitening or graying is the desired endpoint.

Other devices can also be used. The 532-nm frequency-doubled Nd:YAG is one option. In one study, the 532-nm Nd:YAG (9.5–20 J/cm^2, pulse duration 15–50 ms, 2–6 mm spot size, unspecified integrated cooling system utilized) generated 50% improvement from baseline in PWBs resistant to other laser treatments [40 (2b)]. Another study found that lesion color improved at least 25% in 53% of patients after treatment with a 532-nm frequency-doubled Nd:YAG (5–50 J/cm^2, pulse duration 1–50 ms, variable spot sizes, cooling method unspecified) [41 (2b)].

Near-infrared lasers including the alexandrite and 1064-nm Nd:YAG lasers are helpful for violaceous, nodular, or hypertrophic lesions [42, 43 (3b, 4)]. Scarring is more likely to occur, as higher fluences are needed to target the vasculature. This is especially true of the Nd:YAG laser which preferentially targets arterial blood, as opposed to the venous blood which is present in PWBs. Studies of the Alexandrite 755-nm laser have demonstrated good efficacy for hypertrophic PWBs resistant to PDLs, with clinical observations showing mild-to-moderate PWB lightening (40–100 J/cm^2, pulse duration 1.5 ms, 8 mm spot size, dynamic cooling device utilized), (35–100 J/cm^2, pulse duration 3 ms, 8–12 mm spot size, forced cold-air cooling) [44, 43 (5, 4)]. One study demonstrated good to excellent improvement with only a few treatments using the long-pulsed 1064-nm Nd:YAG laser in most patients treated for hypertrophic PWBs (100–240 J/cm^2, pulse duration 30 ms, 5 mm spot size, liquid cooling via stainless steel hand piece). Lesion hypertrophy responded better than color, and authors recommended combining with PDL treatment to further improve coloration of lesions [45 (2b)].

IPLs can also be utilized to treat PWBs. A study by Faurschou et al. found that both PDLs and IPLs lightened PWBs and could be used safely without adverse events (595-nm PDL, 7–14 J/cm^2, pulse duration 0.45–1.5 ms, 7–10 mm spot size; dynamic cooling device at 30-ms spray duration and 20-ms delay; IPL, 500–1400 nm, 22–46 J/cm^2, pulse duration 5–10 ms; handpiece equipped with sapphire contact cooling). In this study, more patients experienced better clearance rates with PDL (75%) as compared to IPL (30%) [46 (1b)]. Another study showed that in a group of 15 patients with PDL-resistant PWBs, 40% achieved more than 75% clearance with IPL (555–950 nm, 13–22 J/cm^2, pulse duration 8–30 ms, optical coupling gel utilized) [47, (3b)]. IPL was found to be safe and efficient in the treatment of PDL-resistant PWBs, except for those located in the V2 type distribution of the face as these lesions in the central part of the face are located deeper in the skin, and thus insufficient energy may have reached these areas. Furthermore, shorter pulse durations may be ben-

eficial for these lesions given the average size of vessels.

PWB treatment sessions are typically scheduled at 4–6-week intervals, and ten or more treatment sessions are often required. Shorter intervals can be considered as described in a retrospective study of 24 infants with facial PWBs where treatment intervals of 2, 3, or 4 weeks were effective and were well-tolerated [48 (3b)]. Darker skin types or lesions in the extremities may require longer intervals between treatments, ranging from 6 to 8 weeks.

Pulses can be overlapped by 10% [38 (2a)]. Multiple passes during the same treatment session may benefit PWBs [49] but should be approached with caution as this approach can increase the risk of adverse effects including pigmentary change (which can be permanent) and scarring.

Infantile Hemangiomas

As noted above, PDLs are the most common lasers used for the treatment of IHs. Commonly used parameters include (parameters vary by device):

- Wavelength: 585–595 nm
- Fluence: 5–7.5 J/cm^2
- Pulse duration: 0.45–6 ms
- Spot size: 5–10 mm

The growth phase of the IH must be taken into account. Proliferating lesions have a higher risk of ulceration and lower fluences must be used during this period. Lower fluences are also advisable in darker skin types and areas of thin skin, such as the eyelids. As mentioned earlier, skin cooling techniques are vital as they allow for higher fluences while minimizing the risks of epidermal damage. Multiple treatments are usually required and may be done at 2–4-week intervals for rapidly proliferating/ulcerated lesions or 4–6-week intervals for stable/involuting lesions.

Other laser options that have also been implemented to successfully treat IHs include frequency-doubled Nd:YAG. A retrospective study of 50 infants were treated with a 585 nm PDL (5.3–6.8 J/cm^2, pulse duration 0.3–0.45 ms, 7 mm spot size, chilled tip cooling utilized) or a 532-nm frequency-doubled Nd:YAG (20 J/cm^2, pulse duration 1–50 ms, 5 mm spot size, chilled tip cooling utilized). PDL was found to be more effective, where cessation of growth or improvement occurred in 93% (average of 3 treatments) of lesions compared to 70% (average of 2.6 treatments) of lesions using the 532-nm Nd:YAG laser [50 (2b)]. The 1064-nm Nd:YAG has been suggested for use with thicker hemangiomas given its greater depth of penetration. An uncontrolled study showed that sequential 595-nm PDL (7–15 J/cm^2, 10–40 ms pulse duration, variable spot sizes, unknown if cooling utilized) with 1064-nm Nd:YAG (50–100 J/cm^2, 10–40 ms pulse duration, variable spot sizes, cooling not described) treatments led to excellent improvement in the majority of hemangiomas involving the head and neck [51 (3b)]. There is a high risk of scarring with the 1064-nm Nd:YAG, and the authors never use this device for IHs and would recommend that use of this device only be considered by experienced users. For IHs with a superficial and deep component, beta-blockers in combination with PDLs may be a good option.

After involution, IHs can leave behind telangiectasias or residual fibrofatty tissue. Telangiectasias can be treated with PDL, and texture changes have been shown to improve with ablative or non-ablative fractional resurfacing (NAFR). A case report showed excellent skin texture improvement along with a substantial decrease of residual tissue bulk using NAFR (fractionated 1440-nm erbium-doped fiber laser, 25 J/cm^2, 15 mm spot size, forced air device cooling utilized) [52 (5)]. A series of case reports have shown that ablative fractional CO_2 lasers have promise in the flattening of fibrofatty residual tissue with 50–75% improvement in color, texture, and overall appearance (ablative fractional CO_2 laser, 20–40 J/cm^2, 15 mm spot size) [53 (5)].

Telangiectasias

Lasers are the most common treatment for multiple or large areas of telangiectasias and can also

be used when other modalities, such as electrocautery, have failed. Multiple treatments (2–4) are often required to achieve the best results, especially when non–purpuric settings are utilized [27, 28 (3b, 3b)].

Commonly used parameters for PDL include (parameters vary by device):

- Wavelength: 595 nm
- Fluence: varies depending on spot size and pulse duration
- Pulse duration: 1.5–20 ms
- Spot size: 7–12 mm
- Appropriate epidermal cooling

Multiple passes or pulse stacking can be considered when longer pulse durations are used [49, 54 (3b, 2b)]. Telangiectasias respond in fewer treatment sessions when purpuric settings are used, but cosmetic patients often prefer to avoid purpura. Vessel clearance and purpura indicate appropriate end points of therapy. Follow-up treatments are usually necessary.

The 532-nm frequency-doubled Nd:YAG laser is also commonly used and effective. The 532-nm laser can be used to treat facial telangiectasias with minimal to no purpura. In a study of 66 patients with facial telangiectasias, a 532-nm Nd:YAG laser (16–22.5 J/cm^2, pulse duration 15–30 ms, 5–7 mm spot size, cooling not specified) resulted in 75–100% clearance of telangiectasias in >90% of subjects after one treatment [55 (2b)]. A disadvantage of this laser is increased melanin absorption, resulting in a greater risk for adverse effects in darker skin types.

IPL can also be used very successfully for telangiectasias. One study showed that IPL-treated telangiectasias (570 nm cut-off filter, 40–43 J/cm^2, 4 ms pulse duration, ice application for 10 min following procedure) achieved 75–100% clearance with minimal purpura. Results correlated with operator experience [56 (2b)].

The long pulsed 1064 nm Nd:YAG laser can also be used for facial telangiectasias. One study demonstrated 95–100% clearing of facial telangiectasias after only one treatment (100 J/cm^2, 10 ms pulse duration, 2.5–7 mm spot sizes, external epidermal cooling device utilized) [57 (2b)]. Again there is an increased risk of scarring with the device, and it should be used cautiously by operators experienced with 1064-nm Nd:YAG use and end points.

Safety

Lasers are safe for use in patients of all ages, including young infants. Knowledge about desired end points and careful monitoring of the skin during and after the procedure are the best ways to avoid undesired adverse effects [58 (4)]. When using the PDL, temporary purpura is expected when treating PWBs and IHs. Purpura usually resolves within 7–14 days [39 (2a)]. A gray color may indicate epidermal damage, and treatment should be stopped or settings adjusted. The 755-nm alexandrite laser has a treatment end point of a transient gray discoloration of the skin followed by purpura. Persistent gray discoloration is not desired and may result in adverse effects including scarring.

Potential adverse effects of laser therapy include blistering, erosions or ulcerations, scarring, and hyper- or hypopigmentation. There is low risk of pigment changes and scarring with yellow wavelength lasers, particularly if appropriate cooling and longer pulse durations are implemented as mentioned above [59 (2b)]. Darkly pigmented skin and extremity lesions have a higher risk of adverse effects. As noted above, proliferating IHs are at increased risk for ulceration, which often results in scarring, and treatment at this stage needs to be approached with caution [60 (4)]. Laser treatment of vascular lesions with longer wavelengths, especially the 1064-nm Nd:YAG, carries increased risk of ulceration and scarring and should be considered only by more experienced laser surgeons.

Hair loss can occur with any millisecond laser or IPL, especially in patients with darker hair, and as such, hair-bearing areas are generally avoided. Applying aloe vera gel or Vaseline to the eyebrows and eyelashes when treating near these areas can help protect the superficial follicles that are most susceptible to hair loss during laser treatment.

Appropriate eye protection as described above is essential and allows avoidance of eye injury.

Postoperative Care and Follow-Up

Laser treatment sessions for PWBs are typically scheduled at 4–6 week intervals, and many treatments are often required [38 (2a)]. Multiple treatments are also required for IHs and may be done at 2–4 week intervals for rapidly proliferating/ulcerated lesions or 4–6-week intervals for stable/involuting lesions. Multiple treatments may also be required to achieve the best results for telangiectasias and can be performed at 4–6-week intervals.

During follow-up visits, patients or their parents should be asked about bruising or blistering, and the skin should be evaluated for scarring, atrophy, and dyspigmentation. As previously noted, patients with darker skin tones are at greater risk for pigmentary change and scarring. Daily application of a bleaching cream, such as hydroquinone 4%, after the resolution of any purpura and between treatment sessions can be used to decrease this risk or to treat post-inflammatory hyperpigmentation. Sun protection for treatment areas before and after treatment can decrease melanin and improve treatment results (greater efficacy with diminished risk of adverse effects).

Alternative Procedures and Modifications

Port Wine Birthmarks

Lasers and light-based devices are clearly the standard of care for PWBs in the United States and Europe. Photodynamic therapy (PDT) has also been used to treat PWBs. It is most commonly used in China. One study found PDT to be at least as effective as PDL in terms of blanching rate and side effects for the treatment of neck and upper arm lesions [61 (3b)]. Another study determined that fewer treatment sessions were required using PDT for PWBs compared to PDL for the successful treatment of superficial lesions and improvement of thick lesions [62 (3b)]. PDT has rarely been used in the United States as the administration of systemic photosensitizers results in prolonged photosensitivity for weeks after the procedure, and there is a risk of multiple side effects including deep vascular injury, which can result in significant scarring [62 (3b)]. Optimization of the parameters of PDT or its combination with PDL may improve the utility of PDT for PWBs [63–65 (2b, 3b, 3a)].

Angiogenesis inhibitors, such as rapamycin, in combination with PDL, have also been evaluated. This is an off-label use of rapamycin. Topical and oral formulations of rapamycin have been studied; use of topically applied medication has the benefit of minimal systemic absorption and few side effects. Multiple studies have demonstrated that topical rapamycin can suppress angiogenesis pathways induced by PDL [66, 67 (1b, 5)] and that the combination of topical rapamycin and PDL can, at least in some cases, provide improved treatment results. Further studies are necessary to determine the effectiveness of combined device/antiangiogenic agents and to find an optimal combination and protocol.

Infantile Hemangiomas

Oral propranolol has been established as a safe and effective treatment and is the first-line therapy for IHs. Clinicians treating IHs must be familiar with and consider the option of beta-blockers for IHs. In a meta-analysis, propranolol showed superior reduction in IH size compared to observation, placebo, and oral corticosteroids [68 (2a)]. A recent randomized, controlled trial on 460 infants showed propranolol to be effective in doses up to 3 mg/kg/day for 6 months [69 (1b)]. Side effects of nonselective beta-blockers include dizziness, weakness, trouble breathing, shortness of breath, chest pain, changes in heart rate, and seizures. Beta-blockers are generally well tolerated in infants for which there are no contraindica-

tions for treatment. Topical beta-blockers are another option and have also been demonstrated to provide benefit in treatment of IHs. A randomized controlled trial using topical timolol gel on superficial hemangiomas on 41 infants aged 5–24 weeks showed significant color change and reduction in size after 24 weeks of treatment with minimal variation in blood pressure or heart rate [70 (1b)]. Another randomized controlled trial using atenolol, a cardio-selective beta-blocker with less respiratory comorbidities than propranolol, showed that oral atenolol was at least as effective as oral propranolol in the treatment of IH [71 (2b)].

Combining beta-blockers with laser may achieve enhanced results compared to either treatment option alone. A study by Reddy et al. showed that facial IH treated with both oral propranolol and PDL showed more complete resolution with propranolol treatment needed for a shorter period of time (595-nm PDL, 8.5–12 J/cm^2, pulse duration 0.45–1.5 ms, 7 mm spot size, dynamic cooling device spray duration of 30 ms and delay of 30 ms) [72 (2b)]. In another randomized, controlled trial, timolol plus PDL was superior to PDL alone in effecting resolution of IHs (585-nm PDL, 9 J/cm^2, pulse duration 0.45 ms, 5 mm spot size, no cooling) described [73 (1b)].

Telangiectasias

Telangiectasias often do not require treatment. Laser therapy is a quick and effective treatment, when desired. Electrocautery can be considered as an alternative when there are a small number of superficial lesions and/or a laser is not available.

Observations and Recommendations (Table 16.1)

Table 16.1 Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
Vascular lesions including PWBs, IHs, and telangiectasias are among the most common indications for laser treatments	B
Epidermal cooling techniques minimize pigmentary changes and scarring and are important to use during laser treatment of cutaneous vascular lesions	B
The risk of scarring and pigmentary change is increased in patients with darker skin tones and when using deeper penetrating lasers	C
Port wine birthmarks	
PDLs are commonly used for PWBs, but multiple vascular targeting devices can be used	B
Resistant, nodular and/or hypertrophic lesions can be treated with deeper penetrating lasers but should be used cautiously by experienced clinicians due to increased risk of adverse effects	C
Multiple treatments are required and some recurrence is common	C
Treatment at an early age may enhance response	C
Infantile hemangiomas	
Infantile hemangiomas that are superficial are the best candidates for laser therapy	C
PDL is the most common laser used for treatment	C
Combining beta-blockers with laser therapy should be considered and may achieve quicker and more complete response	B
Telangiectasias	
Laser therapy is an effective, and when performed correctly, safe treatment for telangiectasias	B
Multiple devices can be used including PDL, 532-nm lasers, and IPL	B
Development of new lesions is common	B

Self-Assessment Questions

1. Which of the following increases the potential for side effects including discoloration, ulceration, or scarring when treating vascular lesions?
   (a) Use of longer wavelength lasers (such as 1064 nm)
   (b) Use of small spot size with high fluences
   (c) Turning off epidermal cooling
   (d) Treatment of patients with darker skin types
   (e) All of the above
2. All are factors that portend to an improved response to PDL treatment of PWBs except:
   (a) Small size (<20 cm^2)
   (b) Nodular lesions
   (c) Treatment at a young age
   (d) Lesion above a bony area
   (e) Lesion near the peripheral face
3. Which of the following statements regarding laser treatment of PWBs is false?
   (a) A desired end point is purpura without cutaneous whitening/graying.
   (b) The 755-nm alexandrite laser can be used for hypertrophic lesions resistant to PDL treatment.
   (c) Both PDL and IPL treatments have been shown to produce good clearance rates of PWBs.
   (d) Lesions may recur after treatment.
   (e) None; all of the above statements are true.
4. All of the following are indications to treat IHs early except for:
   (a) Lesions in the anogenital region
   (b) Lesions near the mouth
   (c) Non-ulcerated lesions near an extremity
   (d) Ulcerating lesions
   (e) Lesions near an eye
5. Which of the following is/are false regarding the treatment of IHs?
   (a) Propranolol used in combination with PDL for IH has been shown to be as efficacious as propranolol alone.
   (b) It has been shown that topical timolol plus PDL is superior to PDL alone.
   (c) PDL is the first-line therapy for IH.
   (d) Mixed superficial–deep lesions treated with PDL have not been shown to exhibit complete clearance.
   (e) a and c.
6. Which of the following devices can be used to treat telangiectasias?
   (a) PDL
   (b) Long-pulsed 532-nm laser
   (c) IPL
   (d) Long-pulsed 1064-nm laser
   (e) All of the above

Correct Answers

1. e: Risks of discoloration and scarring are higher with longer wavelengths such as the 1064-nm Nd:YAG and 755-nm alexandrite lasers. The use of large spot sizes, low fluences, and epidermal cooling techniques helps to minimize the risk of ulceration and scarring. Patients with darker skin types have increased melanin and are at higher risk of adverse effects.
2. b: Factors that lead to improved response to PDL treatments of PWBs include small size (<20 cm^2), a location directly above a bony area (particularly the central forehead), and treatment at a young age. Studies have shown that PWBs located on the trunk, extremities, central face (medial cheek, upper lip, nose) rather than on other facial areas, and those lesions that are violaceous or nodular are more difficult to treat.
3. e: For PDL treatment of PWBs, purpura without cutaneous whitening or graying is the desired end point. Other laser therapies can be utilized in patients who fail to improve with PDL therapy alone. Near-infrared lasers including the 1064-nm Nd:YAG and 755-nm alexandrite lasers have been shown to improve the appearance of hypertrophic PWBs, particularly lesions resistant to other laser treatments. More patients have experienced better clearance rates with PDL compared to IPL, but clearance rates following both treatments have shown good results. Lesions may recur after treatment. In a 10-year follow-up study of 51 patients treated with PDLs for PWBs, lesions were found to be significantly darker at follow-up than at the time of the last treatment, although the lesions did remain significantly lighter than prior to initial therapy.
4. c: Treatment of IH should be aimed at stopping progression of lesions early on to minimize tissue damage and therefore avoiding the need for long-term treatment in the future. Intervention is recommended for lesions that ulcerate or impact functionality, such as feeding or vision.
5. e: Propranolol can be used in combination with PDL. A retrospective study showed that complete clearance occurred more commonly when IHs were treated with propranolol and PDLs concurrently compared with IHs treated with propranolol followed by PDLs and IHs treated with propranolol alone. In a randomized, controlled trial, timolol plus PDL was superior to PDL alone in effecting resolution of IHs. Oral propranolol has been established as a safe and effective treatment and is the first-line therapy for IH (not PDL). In a meta-analysis, propranolol showed superior reduction in IH size compared to observation, placebo, and oral corticosteroids. Superficial IH, as compared to deeper lesions, responds better to PDL treatment. This is due to the limited depth of penetration of PDL light. Studies have shown complete clearance of superficial IH, while mixed superficial-deep lesions exhibited less complete clearance.
6. e: All of the above devices can be used to treat telangiectasias. Lasers are the most common treatment for multiple or large areas of telangiectasias and can also be used when other modalities, such as electrocautery, have failed. Treatment/device selection and settings should be individualized to conform to patient's skin type, vessel characteristics, and healing time tolerance.

17 Pigment Lasers and Light Treatments

Daniel A. Belkin and Roy G. Geronemus

Abstract

Altered or uneven pigmentation is a common reason to present to a dermatologist or laser surgeon. Modalities available for treating pigmentary alterations include medication, destruction, excision, resurfacing lasers, and lasers specifically targeted to pigment. The last modality will be the focus of this chapter.

Keywords

Hyperpigmentation · Q-switched lasers · Picosecond lasers · Tattoo lasers · Light treatments

Introduction

Altered or uneven pigmentation is a common reason to present to a dermatologist or laser surgeon. Modalities available for treating pigmentary alterations include medication, destruction, excision, resurfacing lasers, and lasers specifically targeted to pigment. The last modality will be the focus of this chapter.

The principle of treatment with pigment lasers involves the photothermolysis of pigment, whereby absorption of light energy by the chromophore produces heat, fragmentation, and destruction. In most cases, the chromophore is melanin. In cases of exogenous sources of pigmentation, such as a tattoo, other pigments are targeted. Melanin is one of the main endogenous chromophores of the skin and is most concentrated at the basal layer [1]. It has a broad absorption spectrum, from 250 to 1200 nanometers (nm) [1], absorbing light avidly in ultraviolet wavelengths, less so in visible light wavelengths, and still less in the infrared range (Fig. 17.1). Conversely, depth of penetration of laser light into the skin increases with increasing wavelengths in this range. In general, the appropriate wavelength for the condition at hand should balance the avidity of melanin absorption with the depth of penetration of light.

Laser media used for the purpose of treating pigments produce light that falls in the visible and near-infrared spectra. Lasers include the ruby (producing light at 694 nm), alexandrite (755 nm), neodymium-doped yttrium aluminum garnet (Nd:YAG; 1064 nm), and the Nd:YAG that is frequency-doubled with a potassium titanyl phosphate (KTP) crystal (532 nm). These lasers can be used in their "long-pulsed" forms, which produce pulses in the millisecond range,

and in their "quality-switched" (Q-switched) forms, which traditionally produce pulses in the nanosecond range. More recently, picosecond devices are available that produce extremely short pulse widths in the picosecond range. Because melanosomes and tattoo pigments are small targets with short thermal relaxation times, short pulse durations are required, so Q-switched and picosecond lasers are most frequently used. Long-pulsed lasers with pulses in the millisecond range are used for larger chromophores that require wider heat damage, such as the hair bulb in laser hair removal or vessels in vascular lesions.

Although this chapter will attempt to organize and synthesize the current evidence regarding the use of pigment lasers and light therapies, it is important to remember that evidence is limited in this area. In large part, this field has relied on expert opinion, case reports, and case series. Furthermore, laser surgeons have techniques that are non-standardized, and laser devices, settings, and protocols vary across available studies. However, reviewing the available evidence should give the reader a general sense of the current state of the art.

Q-switched Pigment Lasers

Melanosomes have a thermal relaxation time that ranges from 50 to 500 ns [2]. Q-switched lasers, traditionally with nanosecond pulse widths, can selectively target melanosomes with minimal diffusion of heat and thermal damage [3]. These are therefore the "go-to" lasers for pigmentary disorders. Vejjabhinanta and colleagues treated freckles with Q-switched 532-nm light, with 10-ns pulse width, and long-pulsed 532-nm light, with 10-ms pulse width; they found that the Q-switched laser produced immediate whitening and good efficacy, while the long-pulsed setting did not (4) [1]. Since they are targeted toward the pigment, Q-switched lasers also tend to be more effective than nonspecific resurfacing. Schoenewolf and colleagues compared Q-switched ruby laser with fractional ablative carbon dioxide (CO_2) laser for the treatment of solar lentigines on the dorsal

hands of 11 patients and found the Q-switched ruby laser significantly more effective (4) [4].

Conditions that may respond to Q-switched lasers include those of increased epidermal or dermal melanin, such as solar lentigo, lentigo simplex, café au lait macule (CALM), dermal melanocytosis (including nevus of Ota, nevus of Ito, and Hori's nevus), and post-inflammatory hyperpigmentation (PIH). Besides the condition to be treated, the most important variable in determining the appropriate treatment settings is the Fitzpatrick skin type (FST) of the patient. Darker skin types are more challenging to treat, because higher pigment content in background skin competitively absorbs laser energy [5]. Not only is there increased epidermal melanin in darker skin, but there are larger and more widely distributed melanosomes and a more labile melanocytic and fibroblast response [6]. Due to these features, there is both an increased prevalence of pigmentary disorders in nonwhite individuals and a greater risk of post-procedure pigmentary alteration [6]. Among individuals with skin of color, those with Asian type IV skin are well-represented in the literature. There are few studies in those of African ancestry or type V and VI skin [6].

Q-switched Ruby and Alexandrite

The red lasers ruby, at 694 nm, and alexandrite, at 755 nm, are highly effective for disorders of hyperpigmentation. Red light can penetrate relatively deep in the dermis compared to the green light of 532 nm and is absorbed by melanin with high avidity compared with the near-infrared light of 1064 nm.

Ruby has been used for multiple disorders in both white skin and skin of color, though it tends to produce more pigmentary side effects in the latter. Multiple case series report success in treating lentigines, CALMs, and nevus of Ota. Sadighha and colleagues ran a controlled comparison study in 91 patients with FST II-IV with solar lentigines and found that one or two treatments with Q-switched ruby laser cleared all lesions (2b) [7]. It caused post-inflammatory pigmentary alteration, mainly hyperpigmentation, in 7.8% of FST II patients, 9.8% of FST III patients, and 16.6% in FST IV patients, all of whom improved over 6 months [7]. Mucosal pigmented lesions respond very well to ruby laser as well (5) [8].

Treatment of nevus of Ota is frequent in the literature given it is relatively common, cosmetically disfiguring, and challenging to treat. It is characterized by excess dermal pigment, and it tends to occur in FST IV or higher; this combination makes safe treatment more difficult, and hyper- and hypopigmentation are common side effects. Kang et al. reported PIH in 55% of Asian patients treated with Q-switched alexandrite for nevus of Ota, though all were resolved within 4 months (4) [9]. Suh reported hyper- or hypopigmentation in about 25% of 87 Asian patients with nevus of Ota treated with alexandrite, though all cases were mild and transient (4) [10]. In 81 Korean patients, most patients achieved at least 50% clearance, though 40% had transient hyperpigmentation lasting for 2–6 months (4) [11]. In a study of 102 Japanese patients with nevus of Ota treated 12 months prior with Q-switched ruby laser, 16.8% had persistent hypopigmentation and 5.9% had persistent hyperpigmentation, suggesting that though ruby is effective, pigmentary alterations can be permanent (4) [12].

Despite higher incidences of pigmentary side effects in skin of color, many have reported good results with ruby and alexandrite. A large retrospective study in China with 602 patients confirmed good efficacy of Q-switched alexandrite laser for nevus of Ota, with only seven cases (1%) of transient hypopigmentation and only five cases (1%) of hyperpigmentation (2b) [13]. In 114 Japanese patients, ruby was safe and effective for lightening nevus of Ota, generally by more than 70% in patients who had four to five treatments, with only eight patients (7%) having transient PIH [14]. In one of our early studies using Q-switched ruby to treat nevus of Ota in mostly skin of color, all patients had at least 50% clearance with two of 15 (13%) having pigmentary alteration post-procedure (4) [15]. Alster and Williams reported seven patients with skin of color, five of which had 100% clear-

ance of nevus of Ota, with no incidence of pigmentary complications with Q-switched alexandrite (4) [16]. One case report showed effective treatment with no post-procedure pigmentary alteration in the treatment of facial lentigines in an Afro-Caribbean woman with inherited patterned lentiginosis after four sessions of the Q-switched ruby laser (4) [17]. Treating with Q-switched laser earlier in childhood seems to reduce risk of complications. In a study of 46 children and 107 adults who had achieved 75% clearance or more, complications were only 4.8% in the younger group compared with 22.4% in the older age group (2b) [18]. Unfortunately, it is likely that even after complete clearance of nevus of Ota, recurrence can occur (4) [19].

Alternatives have been tried in skin of color in hopes of producing fewer side effects, such as the Q-switched Nd:YAG, intense pulsed light (IPL), and picosecond devices. Because the Q-switched Nd:YAG at 1064 nm penetrates deeper and is absorbed by melanin less avidly, it provides some inherent epidermal protection. However, Q-switched ruby seems to produce better results. Chang and colleagues performed a retrospective review of 94 patients of Asian descent with nevus of Ota treated with Q-switched ruby laser or Q-switched Nd:YAG and found that clearing and fading was clinically and statistically significantly better in subjects treated with ruby [20]. Post-inflammatory hyperpigmentation (PIH) was comparable in both groups and transient [20]. Chan et al. compared the efficacy of Q-switched alexandrite and Q-switched Nd:YAG in Asian patients with nevus of Ota and though there was a trend toward lower efficacy and more complications with alexandrite, the difference was clinically minimal (4) [21]. In our work in nevus of Ota, we have seen good efficacy and safety using Q-switched ruby in FST IV and Q-switched 1064 nm in FST V and FST VI. In 24 children with skin of color and nevus of Ota treated in this way, there was over 50% improvement in 86% of patients with minimal lasting pigmentary alteration [22]. In a comparison between Q-switched alexandrite and intense pulsed light (IPL) for ephelides and lentigines in Asian patients, results differed based on the lesion type (2b) [23]. Alexandrite was superior to IPL for both ephelides and lentigines, but while safe in ephelides, it caused PIH in nearly half of patients with lentigines. The authors concluded that Q-switched alexandrite was better for ephelides but that because of safety, IPL should be used for lentigines. Finally, in comparison with picosecond devices, our group found that while Q-switched lasers seemed to fare better than picosecond in the clearance of pigmentary disorders in FST III–VI, they caused a high rate of side effects in darker-skinned groups (4) [24]. Sixteen percent of patients treated with Q-switched laser had lasting dyspigmentation, and all were FST V or FST VI [24]. Pigmentary side effects with 755 nm picosecond laser, on the other hand, were temporary and resolved with no intervention [24].

One of the most challenging conditions in dermatology to manage is melasma. Though our group favors low-density low-energy nonablative resurfacing for this condition, others have tried Q-switched laser with variable outcome. Jang et al. showed mild efficacy of low-dose Q-switched ruby laser in 15 Korean patients with melasma (4) [25]. Q-switched ruby combined with intense pulsed light (IPL) was used by Park et al. in treating Asian patients with a variety of types of complex dyspigmentation, including melasma, solar lentigines, ephelides, and Hori's nevus (4) [3]. Sixty percent of patients achieved 76–100% improvement with minimal side effects. Three patients had transient PIH (12%) and one patient (4%) had hypopigmentation. Our group frequently uses low-density low-energy 1927 nm fractional resurfacing for the treatment of melasma in all skin types. In a series of 23 patients treated with this method, 10 of which had melasma and the rest with PIH or other photo-induced pigmentation, we found an increase in improvement with each treatment session, with an average of moderate to marked improvement seen after the sixth visit [26]. There was transient PIH in one (4%) patient. In clinical practice, we tend to combine laser therapy with adjunctive topical depigmenting agents or oral tranexamic acid.

An important pigmentary abnormality in Asian patients is Hori's nevus, also known as acquired bilateral nevus of Ota-like macules. It is notoriously difficult to treat, and laser treatment frequently leaves PIH. Lee and colleagues treated 82 patients with either Hori's nevus or nevus of Ota with Q-switched alexandrite laser and found more post-procedure erythema and PIH in the Hori's nevus group (2b) [27]. Interestingly, they found that the rate of complications seemed to correlate with the extent to which dermal melanocytes resided in a perivascular distribution on histologic examination, which was more often the case in Hori's nevus. In contrast, in nevus of Ota, dermal melanocytes were more frequently scattered throughout [27]. In another study by Lam et al., Q-switched alexandrite, though achieving decent clearance, produced high numbers of pigmentary alteration in 32 Chinese women (4) [28]. Though more than 80% of patients had more than 50% clearance, 12.5% had hyperpigmentation and 50% had hypopigmentation [28]. Some feel that in this condition and perhaps in other conditions of complex dyspigmentation, it is helpful to remove epidermal pigment before treating dermal pigment with laser. Two studies combining Q-switched ruby laser with topical bleaching agents (tretinoin and hydroquinone) achieved successful results with less PIH than is often seen when treating Hori's nevus (4) [29, 30]. Similarly, epidermal ablation prior to Q-switched ruby laser with one pass of a scanned carbon dioxide laser was significantly more successful in 13 Thai women with Hori's nevus (2b) [31].

Q-switched Nd:YAG

Q-switched Nd:YAG at 1064 nm is frequently used to treat pigmented lesions in darker skin types, because the longer wavelength is associated with less epidermal absorption and greater safety. Melasma, nevus of Ota, Hori's nevus, and PIH are four pigmentary disorders that are particularly problematic in darker-skinned individuals and where this laser has frequently been used. Alexis has the following recommendations for treating darker skin types: (1) use longer wavelengths; (2) use lower fluences and longer pulse durations; (3) emphasize pre- and post-treatment sun protection; (4) consider pre- and post-treatment bleaching agents; (5) optimize epidermal cooling; and (6) consider topical steroids post-procedure (5) [6].

Reports of treating melasma with this laser are conflicting [2, 32]. In a study of 22 Asian patients with melasma treated with low-fluence 1064 nm Nd:YAG, all patients had recurrence of melasma despite temporary improvement, three (14%) developed hypopigmentation, and four (18%) developed rebound hyperpigmentation (4) [2]. The authors therefore concluded that Q-switched Nd:YAG treatment for melasma in Asians was not worth doing. In another study of 25 Asian patients with melasma, 72% had at least 50% improvement with low-fluence Q-switched 1064 nm laser, with only two patients suffering from post-treatment pigmentary alteration. The authors here felt that the treatment is effective (4) [32]. Vachiramon et al. studied this laser in 12 Asian men with melasma, randomized to five sessions of Q-switched Nd:YAG plus 30% glycolic acid peel on one side and the laser alone on the other (2b) [33]. The adjunctive glycolic acid peel was intended to allow lower fluence and lesser frequency of laser treatments. While there was a significant improvement in the combined group (and none in the monotherapy group), there were two cases of hyperpigmentation and one case of guttate hypopigmentation that did improve in the study period. The authors did not feel the risk of side effects was worth the short-lived benefits of this treatment [33]. The same group also studied 20 women with melasma, comparing laser plus IPL with laser alone in the same split-face method, with better improvement on the combined side and without pigmentary complications (2b) [34]. The authors emphasize the importance of low fluence; here it was 2.6–2.8 J/cm [2]. Low-dose Q-switched 1064-nm Nd:YAG may fragment melanosomes without being strong enough to destroy cells [2]. Still others have shown that low-flu-

ence Q-switched Nd:YAG is of benefit (4) [35, 36]. Choi et al. combined Q-switched Nd:YAG with long-pulsed Nd:YAG in 30 patients with melasma aggravated from prior laser treatment with very good results (4) [37]. Eighty percent had 76–100% improvement, and the rest had over 50% improvement. The authors note that the addition of the long-pulsed Nd:YAG may prevent rebound hyperpigmentation, and the combination is a safe and effective salvage treatment for those whose melasma has worsened from prior laser treatments.

In nevus of Ota, Q-switched Nd:YAG is somewhat less efficacious but may reduce risk. In our practice, we use this laser for FST V and FST VI while using ruby for most FST IV as described above. In a large series of 171 patients with nevus of Ota by Chan et al., there was no significant difference in the complication rate between Q-switched Nd:YAG and Q-switched alexandrite, but there was a significantly higher incidence of complications, mainly hypopigmentation, in patients who had received both treatments (4) [38]. In Hori's nevus, Q-switched Nd:YAG was modestly effective with 50% of patients achieving good to excellent results in a series of 66 patients (4) [39]. The authors noted better clearance is seen when this laser is used for nevus of Ota. Ee et al. showed that Q-switched 1064-nm treatment alone is not as effective for Hori's nevus than when combined with Q-switched 532 nm (2b) [40]. Though combined treatment produced higher incidence of mild PIH, it was resolved at 2 months and felt by the authors to be worth the increased efficacy.

PIH can be challenging to treat. In our practice, similar to melasma, we use low-energy low-density 1927 nm fractional nonablative resurfacing along with topical bleaching agents. A prospective randomized controlled trial by Kim and Cho found that low-fluence Q-switched Nd:YAG was clinically and statistically significantly more effective in reducing PIH in type IV and type V Korean patients than acne surgery with intralesional corticosteroids (2b) [41]. Interestingly, it was also more effective at reducing inflammatory acne. In our group, we have also noticed the benefit of Q-switched 1064 nm, together with long-pulsed Nd:YAG, for inflammatory acne.

Q-switched Frequency-Doubled Nd:YAG

In our practice, we use the Q-switched frequency-doubled 532 nm Nd:YAG for superficial pigmentary abnormalities, such as solar lentigines, in skin of color (Fig. 17.2). Though this wavelength is absorbed avidly by melanin, it penetrates superficially. Furthermore, the shape of the beam is flat-topped, rather than Gaussian, which minimizes nonspecific heat injury (from personal conversations; 5). Others have used 532 nm

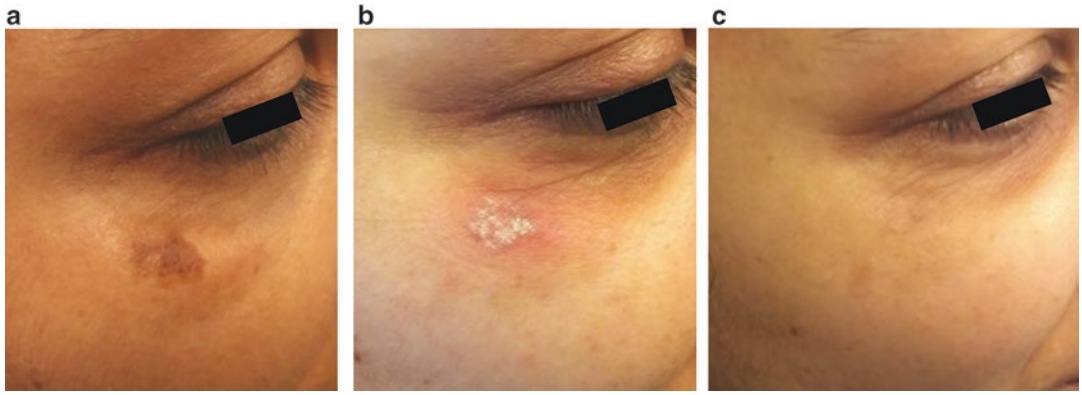

Fig. 17.2 A solar lentigo in a patient with Fitzpatrick type V skin at baseline (**a**), immediately after a subsequent treatment with appropriate whitening response (**b**), and 1 month after three treatments with a Q-switched 532-nm laser (**c**)

for Asian patients with good efficacy, though with some sacrifice in efficacy compared to the ruby. Noh et al. ran a randomized, split-face, double-blinded comparative study to assess a Q-switched 532 nm Nd:YAG against a Q-switched 660 nm ruby-like laser for solar lentigines in Asian women and found similar improvement with both lasers (2b) [42]. However, there was a trend toward better efficacy of the 660 nm laser, and the improvement was longer lasting with 660 nm. The authors proposed that this was perhaps due to slightly more PIH in the 532 nm group due to superficial vascular damage caused by absorption of 532 nm light by hemoglobin [42]. We have not noticed this phenomenon in our practice. Tse et al. noticed similar findings when comparing ruby to Q-switched 532 nm in 20 patients with several types of pigmented lesions including lentigines, CALMs, and nevus of Ota; both achieved significant lightening but with a slightly better response with the ruby (4) [43]. Hereditary lentigines such as those associated with Peutz-Jeghers syndrome have also been treated with Q-switched frequency-doubled Nd:YAG. Ge et al. found excellent response with more than 75% lesion clearance in 8 of the 11 patients and at least 50% clearance in the rest after 2–6 treatments (4) [44].

Several investigators have added adjunctive treatments to further improve efficacy or safety. Park et al. investigated whether a cream containing epidermal growth factor (Easydew Repair Control, Daewoong Pharmaceutical Co, Seoul, Korea) twice daily postoperatively could prevent PIH after treatment with Q-switched 532 nm for lentigines in 25 Asian patients (2b) [45]. They found that PIH was significantly less in those who applied the cream, with 7.7% incidence, compared with those who applied a control cream, with 50% incidence [45]. Another group ran a split-face controlled study on Q-switched 532 nm laser alone for solar lentigines in Asian patients versus laser plus an Erbium-doped YAG "micropeel" (2b) [46]. They found that though both techniques reduced pigment, adding the epidermal ablation significantly increased PIH and should not be used.

Picosecond Lasers

For Pigmentary Disorders

All the benefits of the picosecond devices are still being elucidated. Our group evaluated 755 nm picosecond laser as part of a chart review of 42 patients with skin types III through VI treated with pigment lasers (4) [24]. Though clearance was generally better with Q-switched lasers, the picosecond laser was safer, with only transient post-procedure dyspigmentation compared with some in Q-switched lasers that was not seen to resolve. Among conditions treated, picosecond seemed to be most consistently effective for nevus of Ota, with similar efficacy to Q-switched lasers. It is likely that with picosecond devices, photomechanical effects enhance clearance of melanin beyond classic photothermal effects, decreasing adverse effects [24]. Interestingly, some of the picosecond subjects had initial apparent exacerbation at 1 month with subsequent improvement at about 3 months. This may be due to aggregation of melanin particles after rupture of melanosomes and then delayed clearance by dermal macrophages and fibroblasts [24]. Chan also found the 755 nm picosecond laser to be highly effective for benign pigmented lesions in Chinese patients, especially nevus of Ota, with lower risk of PIH than Q-switched technology (4) [47]. CALMs responded fairly well, but Hori's nevus was fairly resistant. There was no PIH and only transient hypopigmentation in 2 of 13 (15%) patients [47]. Our group has also studied 532 nm picosecond laser for lentigines on the dorsal hands in Caucasian skin types, with slow but excellent results; this modality seems to be highly effective and extremely safe (unpublished results; Fig. 17.3).

Our group also showed that the picosecond laser with the diffractive lens array ("Focus" handpiece) is safe in skin of color [48]. A retrospective review identified 56 patients with skin types IV to VI who had undergone treatment for various conditions, about 10% of which were pigmentary abnormalities. Six patients reported hyperpigmentation that resolved within a few days to 2 weeks, and two patients reported hyperpigmentation that took 1 month to resolve (4) [48].

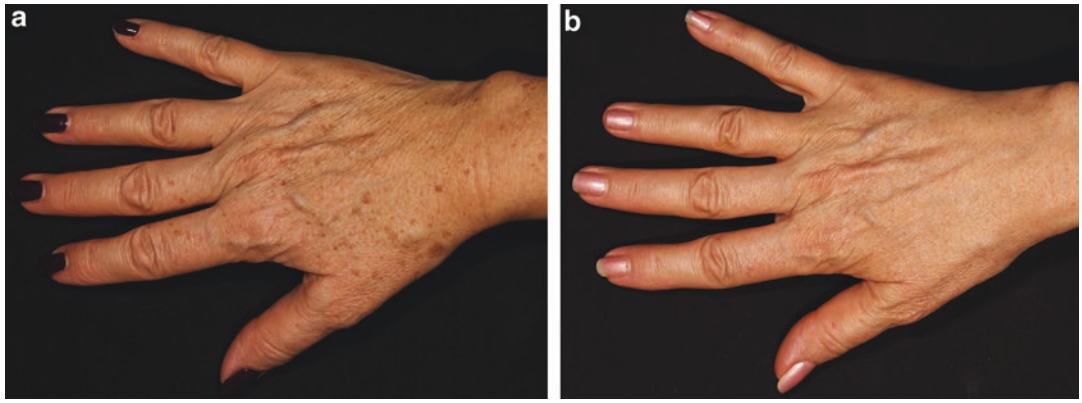

Fig. 17.3 Solar lentigines in a patient with Fitzpatrick type II skin at baseline (**a**) and 3 months after four treatments with a 532-nm picosecond laser (**b**)

Fig. 17.4 A large predominantly black tattoo at baseline (**a**) and after 12 treatments with a 755-nm picosecond laser (**b**)

Tattoo Lasers

It is generally agreed that picosecond lasers are superior to Q-switched lasers for tattoo removal (Fig. 17.4). Q-switched lasers rely on photothermal damage as the main mechanism of pigment destruction, so adverse reactions from thermal damage can occur, especially in darker skin types. This manifests as pigmentary alteration, textural change, and scarring. Hypopigmentation has been reported in up to 50% of patients treated with Q-switched alexandrite and textural changes reported in up to 12% (3a) [49].

With picosecond devices, photoacoustic fragmentation enhances photothermal effect, which increases efficacy while reducing nonspecific heat damage. The extremely short pulse durations create acoustic waves that further fracture pigment particles. Computer simulations support this [50]. Studies have shown that tattoo particles are more effectively cleared with picosecond pulses compared to nanosecond (2b) [51, 52]. Saedi et al. found that in 12 patients, a 755-nm picosecond device was able to achieve 75% clearance in all patients with black or blue tattoos at an average of 4.25 treatments with most having near-complete

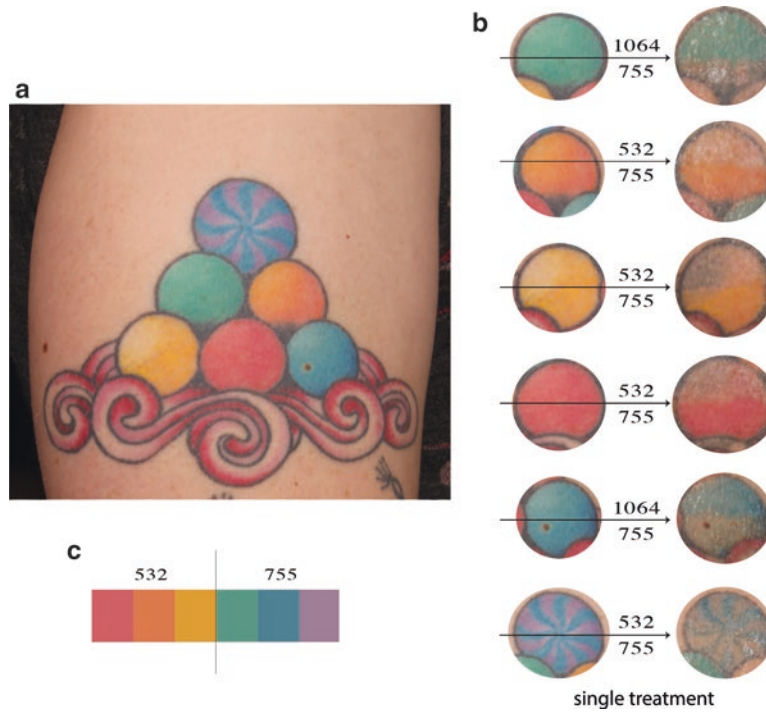

Fig. 17.5 A multi-colored tattoo (**a**) demonstrates variable efficacy of picosecond laser by color. For green and blue, 755 nm and 1064 nm were compared, and for orange, yellow, red, and purple, 532 nm and 755 nm were compared (**b**). In a single treatment, red, orange, and yellow responded best to 532 nm whereas green, blue, and purple responded best to 755 nm (**c**)

clearance (4) [53]. Compared to historical controls, picosecond treatments appear to be more rapid with Q-switched devices taking on average 8–9 treatments for 95% clearance [53].

The type of laser used for tattoo removal depends on the color of the targeted pigment. Our group demonstrated successful treatment of green and blue tattoos using the picosecond alexandrite [54]. Clearance of at least 75%, and in most cases near-complete clearance, was achieved after only one or two treatments (4) [54]. In practice, we have found picosecond technology to be a major game-changer when it comes to green and blue tattoos, which were previously quite difficult to remove. Our group also showed that yellow tattoos can be cleared relatively easily with picosecond technology, in this case a frequency-doubled Nd:YAG at 532-nm wavelength (4) [55]. Six patients achieved over 75% clearance of yellow tattoos with two to four treatments [55]. We are currently running a trial using a 1064 nm picosecond device to clear black tattoos in FST V and FST VI. In our experience, 755 nm is the most effective device for blue, green, purple, and black ink, and 532 nm is the most effective device for red, yellow, and orange ink (Fig. 17.5).

Other Treatments

IPL and pulsed dye laser (PDL), though not generally considered pigment lasers, have been used for pigmented lesions. IPL is not a laser, as it uses a polychromatic light with a broad band of wavelengths. Filters allow the exclusion of lower wavelengths to restrict output and to some extent mimic laser therapy. PDL is a laser comprised of yellow light at 585 nm or 595 nm, which corresponds with a peak in the absorption spectrum of oxyhemoglobin and is therefore used most commonly for vascular lesions. Because melanin does avidly absorb light at this wavelength, epidermal protection is built into these devices with either dynamic or contact cooling.

IPL with a cut-off filter of 560 nm in 3–5 treatments was used for solar lentigines and ephelides in 18 Japanese patients (4) [56]. There was modest efficacy, with 28% of patients "markedly improved" and the rest with no to slight improvement. There

were no side effects. In another study in 60 Japanese patients with the same protocol, there was modest efficacy, with only about half achieving 50% improvement, though with no side effects. Interestingly, when broken down, those with ephelides did much better with 70–75% of patients achieving 50% improvement (4) [57]. Though these studies showed no pigmentary side effects, IPL should be used cautiously in skin of color and perhaps avoided altogether in FST V and FST VI, due to the risk of hyperpigmentation (5) [6].

PDL has also been studied for treating lentigines in Asian skin. In 18 patients, treatment was compared between Q-switched ruby laser and PDL with diascopy to prevent absorption by oxyhemoglobin (4) [58]. PDL was safer and more effective, with 83% clearance compared with 70% and with no side effects compared with four cases of PIH with Q-switched ruby. A larger series in 54 patients using PDL with diascopy to prevent oxyhemoglobin absorption showed excellent response in 70% and good response in 26%, with PIH occurring in only one (2%) patient (4) [59]. Ho and colleagues compared four lasers for the treatment of lentigines and ephelides in 40 Asian patients, the 595 nm PDL, the 755 nm long-pulsed alexandrite, the 532 nm long-pulsed Nd:YAG, and the Q-switched 532 nm Nd:YAG (4) [60]. All but the long-pulsed alexandrite produced improvement, and though there was 10% incidence of PIH with the Q-switched Nd:YAG, there was none with PDL. They concluded that long-pulsed lasers may be safer in darker skin types.

Conclusion

Treating pigment with laser technology is powerful, but technique- and operator-dependent, and the evidence reflects this. There is a large number of case series, but they use different devices, settings, and treatment protocols, and most lack controls. However, general themes do emerge from the data and give laser practitioners a good idea of what is available and useful.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE).

Findings	GRADE score: quality of evidence
Q-switched lasers, with nanosecond pulse widths, are the preferred modality for treating disorders of basal layer hyperpigmentation	B
Q-switched ruby is safe and effective for epidermal pigmented lesions, such as solar lentigines, in Caucasian skin	C
Q-switched ruby is effective for nevus of Ota in Asian skin, but the incidence of post-procedure hyper- or hypopigmentation is relatively high	B
Q-switched 694 nm, 1064 nm, and 532 nm appear to be safer than Q-switched alexandrite for treating lentigines in Asian skin	C
Picosecond laser is generally less effective than Q-switched lasers for disorders of endogenous hyperpigmentation but appear to be safer for skin of color	C
Picosecond laser may approach efficacy of Q-switched lasers with nevus of Ota	C
Hori's nevus is more effectively treated with the Q-switched ruby laser when it is combined with either adjunctive bleaching agents or light epidermal ablation	C
If Q-switched lasers are to be used on melasma, low-energy Q-switched 1064 nm appears to be the safest but still with unpredictable results	B
Adding a cream containing epidermal growth factor twice daily post-procedure may help prevent PIH when treating lentigines in type IV skin with Q-switched 532 nm	C
Picosecond laser with diffractive lens array is safe in skin of color	C
Picosecond devices are safer and more effective for tattoo removal than Q-switched devices	B
Yellow, green, and blue tattoos, which were traditionally very difficult to remove, are highly responsive to picosecond lasers	C
Long-pulsed PDL and cautious use of IPL may be useful for lentigines and ephelides in Asian patients	C

Self-Assessment Questions

1. Why are quality-switched (Q-switched) lasers frequently used for pigmented lesions?
   (a) Because they are higher quality than other laser devices
   (b) Because they produce light in the ultraviolet range
   (c) Because they penetrate deeper than other types of lasers
   (d) Because the thermal relaxation time of melanosomes is in the nanosecond range
   (e) Because the thermal relaxation time of melanosomes is in the millisecond range
2. The following laser does *not* fall in the visible light spectrum:
   (a) Nd:YAG (1064 nm)
   (b) Frequency-doubled Nd:YAG (532 nm)
   (c) Pulsed dye laser (595 nm)
   (d) Ruby (694 nm)
   (e) Alexandrite (755 nm)
3. All of these are benefits of picosecond lasers *except*:
   (a) They produce more rapid clearance of tattoos than Q-switched lasers
   (b) They produce more rapid clearance of pigmented lesions than Q-switched lasers
   (c) They seem to be safer in skin of color than Q-switched lasers
   (d) Photoacoustic effect of short pulse width enhances fragmentation of pigment
   (e) Tattoo colors previously difficult to treat such as green and yellow are now much easier to remove
4. The following are general strategies to increase safety in skin of color *except*:
   (a) Use longer wavelengths
   (b) Use higher fluences
   (c) Use longer pulse widths
   (d) Treat slower
   (e) Consider perioperative bleaching agents
5. Nevus of Ota is treated with all of the following *except*:
   (a) Q-switched ruby laser
   (b) Q-switched alexandrite
   (c) Q-switched 1064-nm Nd:YAG
   (d) Picosecond 755 nm
   (e) Q-switched 532 nm frequency-doubled Nd:YAG

Correct Answers

1. d: Q-switched lasers create pulse widths in the nanosecond range, which corresponds to the thermal relaxation time of melanosomes. They are not necessarily higher quality than other devices, and they generally produce light in the visible and near-infrared spectra. Depth of penetration is more a function of wavelength and fluence.
2. a: Nd:YAG produces laser light at 1064 nm, which falls in the infrared spectrum and cannot be seen by the human eye. Frequency-doubled Nd:YAG produces light at 532 nm, which is a green light. Dye laser produces light at 585 or 595 nm, which is yellow. Ruby and alexandrite produce light at 694 nm and 755 nm, respectively, which are red lights.
3. b: Picosecond technology allows for extremely short pulse durations, which cause fragmentation via photoacoustic effect in addition to photothermal effect. They have changed the treatment of tattoos, allowing for more rapid treatment and treatment of previously difficult colors. For pigmented lesions, case series suggest that though picosecond lasers cause less post-procedure pigmentary alteration, Q-switched lasers still have better efficacy.
4. b: There are several strategies to decrease risk of post-treatment pigmentary alteration in skin of color. Longer wavelengths penetrate more deeply and are absorbed by melanin relatively less, thereby providing some epidermal protection. Longer pulse widths deliver the same energy over more time and can avoid unwanted destruction of melanosomes, which have short thermal relaxation times. Treating slower prevents bulk heating and allows for effective epidermal cooling. Perioperative bleaching agents can help prevent PIH. Lower fluences, not higher fluences, should be used in darker skin types, to prevent nonspecific thermal damage.
5. e: Because nevus of Ota is a disorder characterized by dermal melanocytes, laser light must be able to penetrate into the dermis. The green light of 532 nm will not penetrate far beyond the epidermis. However, the red and near-infrared light of the other options penetrate well into the dermis and will have efficacy for dermal disease.

18 Nonablative Fractional Energy Treatments

Stephanie D. Gan and Jeffrey S. Orringer

Abstract

Nonablative lasers heat but do not vaporize the skin. Many nonablative devices emit light in the infrared portion of the electromagnetic spectrum, including traditional intense pulsed light (IPL, 500–1200 nm) devices, neodymium/yttrium-aluminum-garnet (Nd/YAG, 1064 and 1320 nm), and diode lasers (980 and 1450 nm). The fractionated nonablative resurfacing lasers include the 1550-nm erbium-doped, 1540-nm erbium glass (Er/glass) lasers, and several others. The energy emitted by these nonablative lasers is absorbed by dermal water, leading to tissue heating and subsequent dermal remodeling. In contrast, the ablative devices, such as the carbon dioxide (CO_2) and Erbium/YAG (Er/YAG) lasers, remove the epidermis and dermis during treatment (see Chap. 19). While the results of ablative treatments may be impressive, there is a significant degree of associated postoperative morbidity. By completely preserving the stratum corneum and precisely confining epidermal and dermal coagulation, nonablative fractionated laser (NAFL) treatments often offer satisfactory clinical results with much less postoperative morbidity (roughly 3 days of downtime versus 7) as compared to their ablative counterparts (5) (Hantash and Mahmood, Dermatol Surg 33(5):525–534, 2007). Results from an individual NAFL treatment, as expected, are less dramatic than those from traditional resurfacing lasers, but the side effect profile is significantly more favorable. Due to these advantages, the nonablative methods for skin resurfacing have become a mainstay treatment.

ers. The energy emitted by these nonablative lasers is absorbed by dermal water, leading to tissue heating and subsequent dermal remodeling. In contrast, the ablative devices, such as the carbon dioxide (CO_2) and Erbium:YAG (Er:YAG) lasers, remove the epidermis and dermis during treatment (see Chap. 19). While the results of ablative treatments may be impressive, there is a significant degree of associated postoperative morbidity. By completely preserving the stratum corneum and precisely confining epidermal and dermal coagulation, nonablative fractionated laser (NAFL) treatments often offer satisfactory clinical results with much less postoperative morbidity (roughly 3 days of downtime versus 7) as compared to their ablative counterparts (5) [1]. Results from an individual NAFL treatment, as expected, are less dramatic than those from traditional resurfacing lasers, but the side effect profile is significantly more favorable. Due to these advantages, the nonablative methods for skin resurfacing have become a mainstay treatment.

The first fractional laser device was the Fraxel SR750 Laser™ (Solta, Hayward, CA), a 1550-nm erbium-doped fiber laser system that could be adjusted to vary both depth of laser penetration and the percentage of skin surface area coverage. This allowed for the safe treatment of various skin types. A later model, the Fraxel Re:Store™ (formerly called the SR1500™), was capable of delivering higher fluences (up to 40 J/cm^2), along with the production of wider and deeper zones of thermal injury (up to 40% of surface area coverage and a depth of 1.114 mm). Since then, several companies have produced fractional lasers, such as the Fraxel Re:fine™, an erbium fiber that delivers a 1410-nm wavelength; Fraxel Re:Store Dual,™ combining the 1550-nm erbium-doped fiber laser with a more superficial thulium of 1927-nm wavelength; the Palomar Lux 1540™ (Cynosure, Westford, MA) with an erbium/glass laser; Sciton Halo™ (Sciton, Palo Alto, CA), a hybrid fractional laser combining the 1470-nm diode with the 2940-nm ablative Er/YAG laser; and the ResurFX™ module of the M22 platform (Lumenis, San Jose, CA) with a 1565-nm wavelength, among other devices. These devices deliver energy either via a stamping scanner or a rolling scanner handpiece.

In contrast to traditional full-field lasers that cover 100% of the skin surface, fractional photothermolysis (FP) creates numerous discrete epidermal and dermal microscopic treatment zones (MTZs) that cover a fraction (generally 20–35%) of the skin surface while sparing adjacent skin (5) [2]. The intervening surrounding normal skin acts as a structural reservoir facilitating rapid wound healing through migration of untreated viable tissue. These findings correlate with short-lived post-procedure erythema and edema and limited social downtime.

Histologic examination demonstrates well-defined cylindrical zones of necrosis in the papillary and reticular dermis with an intact stratum corneum, termed microscopic epidermal necrotic debris (MEND). These MENDs contain substantial pigment and epidermal dyskeratotic cells that act as a "melanin shuttle," promoting extrusion of pigment within 1 week after FP. Cellular markers of dermal wound healing and neocollagenesis such as heat shock protein (HSP) 70, matrix metalloproteinase-1, collagen I and III, and procollagen I are expressed within the treatment areas. HSP 47 is required for collagen remodeling and maturation. It becomes generalized throughout the dermis at 1 month and may persist for up to 3 months, indicating ongoing tissue remodeling (5) [1, 3–5]. Given their frequently excellent cosmetic outcomes, favorable safety profile, and shortened recovery time, the NAFL has become a workhorse technology in skin resurfacing.

Indications for Nonablative Fractional Energy Treatments

NAFL technologies have successfully improved photodamage, dyspigmentation, skin texture, rhytides, striae distensae, and scars (5) [6]. Table 18.1 summarizes the main indications of the NAFL and their efficacy. Due to the preservation of the epidermis which facilitates rapid wound healing, NAFL treatments have a favorable safety profile in all skin types, ages, and

Table 18.1 Clinical indications for nonablative fractional energy devices

Indication	Efficacy
Acne scars	Excellent
Surgical, traumatic, and hypertrophic scars	Excellent
Dyschromia or photodamage, facial	Good
Dyschromia or photodamage, non-facial	Good
Melasma	Mixed
Striae distensae	Mixed
Deep or perioral rhytides	Poor

anatomic sites (1a) [7]. Commonly treated areas for photorejuvenation include the face, neck (5) [8], décolletage (5) [9], and dorsal hands (5) [10].

Multiple studies have demonstrated relatively consistent results in the treatment of a variety of scars, including acne, surgical (1a) [11], traumatic, burn, and hypertrophic scars. The 1540-nm laser improves atrophic acne scars (1b) [12–14]. Specifically, boxcar scars reportedly respond better than rolling and ice-pick scars after six treatments with the 1540-nm device (2b) [15].

Treatment of melasma using NAFL devices must be done cautiously with conservative settings, as there is a propensity for developing a rebound effect (4) [16–22].

Less commonly, granulomatous conditions such as lupus miliaris disseminatus faciei are treatable with the 1565-nm NAFL, when other topical therapies, oral medications, and laser devices have failed (4) [23].

Effectiveness of Nonablative Fractional Energy Treatments

In general, the results of NAFL treatments for some indications are often difficult to assess and even more challenging to quantify, although attempts have been made to do so. Correction of photodamage is one of the most common aesthetic indications for the NAFL. Improvements in texture, rhytides, and dyspigmentation are safe even in darker Fitzpatrick skin types (III–IV) (1b) [24–26]. Off-face applications of the NAFL, including addressing poikiloderma of Civatte (5) [27] and dyschromia of the hands and chest, are notable areas that are otherwise treated with caution with the fractionated ablative device due to concerns of scarring. When treating non-facial locations, post-treatment redness usually persists longer, approximately 1 week (5) [28]. The NAFL is not a first-line treatment for deeper rhytides that may be better addressed with a fractionated ablative laser. Similarly, perioral laxity and rhytids commonly demonstrate only mild-to-moderate improvement after NAFL and often require a multimodal approach in conjunction with neuromodulators, soft tissue filler, and ablative fractional laser therapy.

The thulium 1927-nm laser is ideal for treating superficial lesions, including lentigines, actinic keratoses (AKs), macular seborrheic keratoses (4) [29], and some syringomas (4) [30]. Its higher absorption coefficient of water allows for more superficial penetration compared to that of other NAFL wavelengths. The 1927-nm laser reverses clinical photodamage as demonstrated by an 86.8% clearance of actinic keratoses 6 months following four monthly treatments (2b) [31]. In contrast, the deeper penetrating 1550-nm fractionated laser is not an adequate single-treatment modality for actinic keratoses. Six months after a series of five 1550-nm laser treatments, histologic evidence of AKs persisted even though clinically apparent facial AKs were reduced by an average of 55% (2b) [32].

Outcomes with NAFL treatments for melasma have been mixed, with the risk of exacerbation an ongoing concern (4) [16–22]. Formation of MENDs and subsequent pigment extrusion via the "melanin shuttle" is the most likely mechanism for clinically apparent lightening of lentigines and melasma (5) [33]. Despite significant short-term improvement, recurrence rates of melasma are high. In particular, darker skin type patients tend not to respond as favorably. Patients currently taking an oral contraceptive pill should be advised to switch to a low-estrogen type, as this could be contributing to the melasma. A paradoxical exacerbation of melasma diffusely throughout the face after NAFL is possible and patients should be counseled about this potential side effect. In general, a gentle treatment approach (e.g., low laser fluence/energy density,

fewer passes) is recommended. Lastly, a Consensus Group recommends decreasing cooling levels to avoid overcooling the skin. This could increase dermal-epidermal junction inflammation and consequently result in post-inflammatory hyperpigmentation (PIH) (5) [28]. Treatment success rates for treating melasma patients with skin phototypes V–VI are low given the higher risk of PIH. Physicians should be cautious when treating melasma in this select patient population.

Repigmentation in areas of post-inflammatory hypopigmentation may also reportedly be induced following serial 1540- and 1550-nm laser treatments alone or in combination with topical bimatoprost and tretinoin or pimecrolimus (4) [34–36]. In a prospective case series, seven patients with hypopigmented facial scars received 2–4 treatments every 4 weeks with the 1550-nm NAFL. Treatment settings ranged from 7 to 20 mJ and density of 1000–2500 MTZ/cm^2. Independent physician assessment 1 month after the final treatment demonstrated a 51–75% improvement in hypopigmentation in six of seven patients (2b) [36]. The mechanism of repigmentation may rely on melanocyte recruitment from the periphery of the hypopigmented scar.

The NAFR is a first-line treatment for noninvasive scar revision. A randomized, prospective, split-lesion study of hypertrophic scars treated with four monthly treatments using the 1540-nm fractional laser demonstrated a statistically significant improvement in patient scar assessment after 1 ($p = 0.006$) and 3 ($p = 0.02$) months; however, physician global assessments could not confirm clinical efficacy (1b) [37]. Second- and third-degree burn scars demonstrated improvements in skin texture, dyschromia, and degree of hypertrophy/atrophy 3 months after five 1550-nm NAFL treatments according to independent investigators. Patients' self-reports revealed moderate-to-excellent improvements in burn scar areas and significant improvement in self-esteem ($p = 0.03$) (2b) [38]. Uniquely, NAFL can lead to improvement in cosmesis and functionality in contracted scars. A 28-year-old woman with a 1-year-old traumatic scar of her right lower extremity received two treatments with the 1927-nm laser (10 mJ, 30% density, 8 passes) and four treatments with the 1550-nm laser (40 mJ, 17–26% density, 8 passes) spaced 4–8 weeks apart. There was objective improvement in range-of-motion measurements for plantar flexion (15°), inversion (10°), eversion (6°), and dorsiflexion (5°) as well as a 60–75% patient- and clinical-rated improvement in both texture and pigmentation (3b) [39]. NAFL treatments address a variety of scar types from both an aesthetic and functional perspective by inducing collagen turnover and remodeling.

In addition to hypertrophic and contracted scars, patients with atrophic scars may also benefit from a series of NAFL treatments (5) [11]. A series of laser treatments are often followed by injection of soft tissue fillers directly into the atrophic scars to provide additional volume. Atrophic acne scars have shown significant improvement (50% or greater) after a series of treatments using either the fractionated diode (1410-nm) laser, the 1550-nm laser, or the 1540-nm laser (1b) [40–44], and these devices are safe to use in patients with Fitzpatrick skin types IV–VI (1b) [45]. Interestingly, post-inflammatory erythema within acne scars also demonstrated statistically significant improvement that is comparable to that of the pulsed dye laser (PDL) (1b) [46].

The fractional 1540- and 1550-nm laser has been shown to safely and effectively improve the appearance of striae rubra and alba in Fitzpatrick skin types II–IV (1b) [47–51]. Before the patient commits to a series of treatments, a test spot treatment may be performed first. After several weeks, if there is improvement, the patient can proceed with a series of roughly five treatments. Striae rubra, in particular, may benefit from a combination of both PDL and NAFL treatments in order to address the underlying hypervascularity component (5) [28].

Preoperative Evaluation

The ideal candidate for nonablative skin resurfacing is relatively young (25–65 years of age) and has minimal facial skin sagging. Patients who

want to minimize treatment discomfort and downtime tend to favor nonablative over ablative treatments. They should be made aware that skin texture irregularities and fine lines will improve but will not be completely eliminated. Furthermore, since the effects of treatment are cumulative, it is important to reiterate that multiple treatments, typically from three to six or more, will be more beneficial than a single treatment. Since changes occur gradually, patients should not expect immediate results and they should understand that final results may take months to develop following the final treatment session (5) [52].

All patients should be screened for a history of prior facial herpes simplex virus (HSV). The energy from the procedure can cause a reactivation of dormant HSV with the potential for scarring. If the patient has a known strong history of HSV, the authors prophylactically treat with a 5-day course of valacyclovir 500 mg orally every 12 h starting the day before the procedure. Despite adequate prophylaxis, HSV reactivation may still occur. In a large retrospective chart review of 961 successive 1550-nm laser treatments, 6 of 86 treatments (7%) preceded with adequate antiviral prophylaxis still resulted in an HSV outbreak (2b) [53]. Widespread use of antiviral prophylaxis regardless of HSV history, however, is not recommended.

Historically, it is believed that laser procedures should not be performed until 6–12 months after completion of a course of isotretinoin (13-*cis*-retinoid acid; 4) [54]. This rationale is extrapolated from data on keloids induced after dermabrasion or argon laser treatment when carried out during or within 6–12 months of isotretinoin treatment (4) [55–57]. Isotretinoin may impair wound healing through alterations in pilosebaceous units and inhibition of collagenase, thus increasing the risk for scarring (5) [58]. However, recent evidence suggests that wound healing after laser treatments sooner than 6 months after completion of a course of isotretinoin does not necessarily lead to adverse events (2b) [59–62]. A patient on high-dose isotretinoin was treated with the nonablative fractional 1540-nm laser, ablative fractional 2940-nm laser, and fully ablative 2940-nm laser. At 6-month follow-up, both the fractional nonablative and ablative treatment sites did not develop scarring. Therefore, the authors concluded that at least the fractional lasers may be relatively safe to use during isotretinoin therapy (5) [63]. A retrospective study evaluated 20 patients who received fractional ablative CO_2 laser therapy for facial acne scars and had completed isotretinoin (10–60 mg/d) within 1–3 months of laser treatment (2c) [64]. Six-month follow-up evaluations showed normal reepithelialization in all patients. No side effects, such as prolonged, persistent, and intense erythema, or development of hypertrophic scars, or keloids occurred. Conservative management with a minimum 6-month wait after completing isotretinoin therapy before any NAFL treatments is advisable, although shorter periods prior to initial laser treatment may not lead to any long-term adverse events.

For all patients, a topical pretreatment regimen should include a broad-spectrum sunscreen with a minimum SPF of 30 as well as strict sun avoidance. Although there is no consensus regarding a specific topical pretreatment regimen for preventing PIH in skin types IV–VI, a review panel recommends prescribing topical tretinoin and hydroquinone (HQ) for several months before treatment. Tretinoin should be discontinued 1 week before laser treatment and HQ discontinued 3 or 4 days before (5). [28] A specific protocol described by Clark et al. recommends topical HQ 4% to the entire face or treatment area 2 weeks prior to the laser treatment, followed by transient discontinuation for 7 days post-laser and then subsequent topical HQ 4% for 4 weeks thereafter (5) [65]. Adequate pre-procedure prophylaxis with sunscreens and lightening agents may reduce the risk of PIH, particularly in those with darker skin types.

Pretreatment photographs using a high-resolution, reproducible digital photography system such as the Visia (VISIA GmbH, Stuttgart, Germany) or Canfield (Canfield Scientific Inc., Fairfield, NJ) systems allow for more precise monitoring of results.

Due to the nonablative nature of this type of laser and light-based technology with only

minimal risk and downtime, only a few contraindications exist for this treatment. Patients on chronic systemic corticosteroids or those with serious underlying illnesses should be evaluated by their primary care physician before undergoing this procedure. Contraindications include unrealistic expectations, active or latent HSV infection, and isotretinoin use within 6 months. Relative contraindications include an active collagen vascular disease, poor wound healing, a history of drug reactions to or use of medications that may interact with topical anesthetics, and intolerance to the intraoperative discomfort associated with nonablative resurfacing. Moreover, those with a predisposition for excessive scarring, pigmentary changes, and/or keloid formation may be at an increased risk of developing these changes after therapy and should be made aware of these possibilities beforehand (5) [28]. Finally, there are no studies available on the safety and efficacy of treatment in pregnant or lactating women; therefore, treatment of these individuals should generally be avoided.

Best Techniques and Performance

Topical anesthesia may be used to provide intraoperative comfort. Topical anesthetic agents are often applied from 20 min to 1 h prior to the procedure and then removed immediately before treatment. There are several preparations available, including 5% lidocaine, 7% lidocaine/7% tetracaine, 23% lidocaine/7% tetracaine, and 30% lidocaine. Although only 5% lidocaine and 7% lidocaine/7% tetracaine have FDA-approved preparations, stronger preparations are available through compounding pharmacies. Limiting the treatment area to 300–400 cm^2 and using the lowest dose of lidocaine that will achieve adequate anesthesia are important to minimize the risk of lidocaine toxicity from the topical anesthesia. Symptoms of lidocaine toxicity include perioral paresthesias, lightheadedness, dizziness, tinnitus, and at higher doses, slurred speech and seizures. If patients are still uncomfortable despite topical anesthesia, regional nerve blocks may be helpful. To further reduce discomfort, 800 mg of ibuprofen can be taken orally 45 min prior to the procedure. Anxiolytics are generally not required.

Concomitant application of handheld forced cool air or direct contact cooling has been demonstrated to significantly reduce pain and increase patient comfort during fractional laser treatments. Fisher et al. conducted a study of 20 patients to rate their pain level with and without cooling; 19 of 20 noted a mean improvement of 2.8 +/− 1.8 on a pain scale of 1–10 with the addition of handheld forced air cooling (4) [66]. Moreover, forced cool air is recommended to prevent bulk heating of the skin, thereby reducing the risk of hyperpigmentation and blistering. However, Laubach and colleagues found that cooling decreases the size of the MTZ and may interfere with treatment efficacy [33]. In the authors' experience, alternating treatment sides with intervening chilled ice pack applications also aids in patient comfort. Adjuvant direct cooling is important for improving patient comfort and reducing side effects, such as hyperpigmentation and scarring.

Fractionated laser treatments are delivered using either a stamping or rolling scanner handpiece. The procedure requires multiple, generally 3–8, passes. Treatment zones using the stamping method should be overlapped and laid down in the same direction. When treating the entire face, sequential treatment by cosmetic subunits—forehead, temples, cheeks, upper cutaneous lip, chin, and nose—is an organized approach to reduce application technique error. To minimize bulk heating and reduce pain, passes should be applied in a proximal-to-distal format for two passes and then lateral to medial for two passes. Brief pauses between passes allow for adequate cooling. Simply rolling the handpiece back and forth without changing planes does not allow for sufficient cooling and risks significant pain, blistering, and potentially scarring [28]. Ice packs should be applied for at least 15 min post-procedure followed by a broad-spectrum sunscreen SPF 30+. Table 18.2 reviews a proposed treatment protocol for the NAFL.

Tissue effect for a given laser is determined by the laser wavelength, the fluence or energy per focal spot area, the density or fixed percentage of surface

Table 18.2 Proposed treatment protocol for patients undergoing fractional laser resurfacing

1. Pretreatment in those predisposed to post-inflammatory hyperpigmentation with topical hydroquinone and/or tretinoin to the entire treatment area for at least 2 weeks prior to laser treatment, followed by discontinuation for 7 days post-laser therapy. Restart topical therapy for 4 weeks thereafter
2. Patients with a history of herpes labialis should be prophylaxed with a 5-day course of valacyclovir 500 mg twice daily starting the day prior to the procedure
3. Photographs and written consent prior to each treatment
4. Topical anesthetic (23% lidocaine, 7% tetracaine cream) applied to the treatment area 60 min before each treatment
5. Continuous forced air chiller use intraoperatively
6. Post-procedure cooling with ice packs to the treatment area for approximately 15 min
7. Post-procedure application of a broad-spectrum SPF 30+ sunscreen and written posttreatment handout given to patient

area of coverage, and the number of passes delivered. Increasing fluence produces a greater depth of dermal penetration and tissue effect, while increasing density also serves to increase clinical effect (5) [67]. Increasing these treatment parameters may produce more patient discomfort and pain. Slowing down the handpiece speed, increasing the handheld cooling device level, or decreasing the density or MTZs/cm^2 in each pass can optimize patient comfort at higher treatment levels.

To define optimal NAFL parameters to treat photoaged skin, Orringer et al. examined molecular changes in expression of selected genes and proteins after high (70 mJ) and low (15 mJ) fluence treatments. Photodamaged forearms of subjects were treated with the 1550-nm NAFL, and serial skin biopsies were obtained up to 28 days posttreatment. As expected, the high-fluence NAFL produced a more intense inflammatory response. Interestingly, both treatments produced similar patterns of molecular changes, and only minimal differences were observed between lower- and higher-energy settings (5) [3]. The data suggest that lower-fluence/higher-density settings which are generally better tolerated by patients may yield similar dermal changes to that of higher-energy/lower-density parameters.

Optimal treatment settings for scar management appear to be low-density and high-fluence treatment settings as extrapolated from the fractional ablative laser literature (2b) [68]. Similar comparative studies adjusting the fluence and density variables have not been reported with the NAFL. Lin et al. examined the effect of density settings using the 1550-nm laser in a prospective, randomized split-scar study. Half of 20 linear hypertrophic scars were treated with either a low-density (14% coverage; treatment level 5) or high-density setting (26% coverage; treatment level 9) at a fluence of 40 mJ every 2 weeks for four treatments. Subjects in the low-density treatment arm rated the treated side with higher scores compared to internal controls than those in the high-density arm (p = 0.001; 1b, B) [69]. In lower-density NAFL, significant improvement over control was seen at both 1 and 3 months post-NAFL. Subjects in the high-density treatment arm experienced significantly more side effects, including erythema, exfoliation, and pain (p = 0.05, 0.02, and 0.01, respectively), as compared to those in the low-density treatment arm. The low-density NAFL treatments demonstrated better clinical efficacy with fewer side effects, compared to the high-density NAFL treatments.

The ideal time to first start treating a new scar is still unclear. In one study, younger scars <2 years old responded better to NAFR as compared to scars >6 years old (5, D) [69]. Early intervention may be key in the treatment of scars.

The fractional 1927-nm NAFL is an option for treating photopigmentation. A prospective multicenter study demonstrated moderate-to-significant improvement in facial lentigines and ephelides in 82% of subjects at 1 month and 69% at 3 months after two treatments with the 1927-nm laser. Subjects with skin types I–IV were treated at a fluence of 10 mJ, density of 40%, and 4–6 passes. Independent physician assessment of photos demonstrated a durable response at 3-month follow-up (A) [26]. The fractional thulium laser produced moderate-to-marked improvement in overall appearance and pigmentation with high patient satisfaction.

There are limited comparative trials of the various nonablative fractional devices. A small

trial compared the efficacy and safety of a 1540-nm NAFL and a 1410-nm NAFL for the treatment of abdominal striae distensae. After six treatment sessions, all nine subjects experienced improvement at 3-month follow-up visits both histologically with an increased epidermal and dermal thickness and elevated collagen and elastin density compared to baseline and clinically with blinded photographic evaluation. These differences were not statistically significant (2b) [70]. Clinical experience suggests that when used optimally, results among the nonablative devices appear to be similar (5) [71].

Safety

The biggest advantage of nonablative fractional laser systems is their relatively low incidence of adverse effects and minimal postoperative recovery periods. In a retrospective review of side effects and complications of the NAFL from 961 treatment sessions in 422 patients, 73 (7.6%) complications were documented: 18 acneiform eruptions, 17 herpes simplex outbreaks, 13 erosions, 8 cases of prolonged erythema, 7 cases of PIH, 6 cases of prolonged edema, 2 cases of dermatitis, and 1 case each of impetigo and purpura [53]. Common adverse events include pain during the procedure and posttreatment erythema, edema, crusting, and scaling (2b) [72]. Longer duration of erythema is expected when a higher fluence is used (2b) [73]. Typically, facial erythema lasts for 2–5 days and patients are able to return to work the next day with minimal post-laser skincare (5) [74]. The nonablative lasers are often favored by patients who are unwilling or unable to schedule the requisite time for recovery required by the ablative modalities.

Herpes simplex virus (HSV) infection is the most common infectious complication following NAFL treatment with an incidence of up to 2% (2b) [75]. Antiviral prophylaxis can minimize the rate of reactivation to less than 0.5% and should be administered in patients with a history of facial HSV. In contrast, the incidence of bacterial infection after fractionated laser treatment is extremely low with an incidence of 0.1% in all treated cases (4) [53, 76]. Antibacterial prophylaxis is not typically necessary for nonablative treatment; however, it is sometimes recommended for ablative fractionated laser resurfacing [77].

Transient acneiform eruptions after fractional skin resurfacing occur in 2–10% of patients and are particularly common in those who are acne-prone (2b) [7, 53, 78]. Avoidance of occlusive moisturizers and use of noncomedogenic equivalents are recommended for preventing milia development [78, 79].

Pigmentary alterations including PIH have been observed in 1–32% of patients, depending on the device used, parameters applied, and skin phototype treated (2b) [43, 80–82]. Patients with a darker phototype (Fitzpatrick III–VI) have a greater likelihood of developing PIH. Higher density, rather than higher fluence, has been shown to increase the risk of PIH [80]. To minimize such risk, patients should avoid significant sun exposure at least 2 weeks before and after the resurfacing procedure (5) [80, 83]. Although it often resolves without treatment within 6–12 months, application of topical bleaching and mild peeling agents (e.g., retinoic, azelaic, ascorbic, and glycolic acid) and liberal use of sunblock may hasten its resolution (5) [84]. There have been no reported cases of iatrogenic hypopigmentation following nonablative fractionated laser therapy.

Hypertrophic scarring is a relatively uncommon complication of the NAFL. The use of excessively high treatment densities, lack of adequate cooling during and between passes, and postoperative infection are potential causes for scarring. Furthermore, non-facial sites including the neck and chest are more prone to develop scars. With fewer pilosebaceous units and a less rich vasculature, two factors that greatly impact wound healing (5) [85], these scar-prone anatomic sites and the periorbital area and mandibular ridge, require more conservative laser parameters. Early treatment of hypertrophic scarring may include the use of topical or intralesional steroids and silicone gel products. The KTP or pulsed dye laser is also a helpful adjuvant therapy for treating any underlying erythema (5) [86, 87].

Rarely, development of low-grade malignant skin tumors called keratoacanthomas may follow the 1550-nm laser resurfacing of photodamaged skin of the legs (4c) [88]. Trauma to the follicular unit could be a possible mechanism for keratoacanthoma development.

Other uncommon side effects include a transient and benign heat-induced recall phenomenon (4c) [89]. An irritant contact dermatitis may be induced by topical natural or herbal remedies used in the perioperative treatment regimen [53]. Topical anesthesia-induced toxicity rarely occurs but has been reported after 30% lidocaine gel was not removed before fractional laser treatment (2b) [90].

Postoperative Care and Follow-Up

After treatment, ice packs may be applied for comfort and acetaminophen can be taken for pain. The patient can wash his or her face with a gentle cleanser and lukewarm water. A noncomedogenic moisturizer should be used instead of an occlusive ointment, such as petroleum jelly, as the latter may lead to post-treatment acne. Avoidance of prolonged direct exposure to sunlight as well as wearing a broad-spectrum sunscreen with SPF 30 or higher is recommended. Resuming topical bleaching agents in darker skin types may help reduce the risk of PIH.

Mild erythema and edema are expected to occur immediately post-procedure. This typically resolves within 1–5 days. Fine desquamation lasting for 1–3 days is common during the week after treatment. Patients should expect a rough skin texture and dryness during this time period and often require extra moisturizer use. The use of oral corticosteroids posttreatment is controversial. There is evidence that they may speed up recuperation. However, they may also impede the inflammatory response, thus negatively impacting collagen synthesis and reorganization.

Because nonablative lasers have limited thermal tissue effects, a series of three to six treatments performed at 3–6-week intervals may be recommended for optimal results (2) [52, 71, 79, 91]. Significant, long-lasting effects are rarely achievable following a single treatment [28]. Improvements continue to develop months after the final treatment.

Similar to the fractional, infrared-domain millisecond nonablative lasers mentioned previously, laser therapy with the fractional nonablative Qs 1064-nm Nd/YAG laser requires a series of treatments at approximately 2–4-week intervals. Treatments may improve hyperpigmentation, telangiectases, skin laxity, tactile roughness, and actinic keratoses (2b) [92]. The fractional Qs 1064-nm laser demonstrated efficacy in both patient self-assessment and objective melanin index scores when treating melasma in patients with skin types III and IV. No adverse events were reported (4) [93]. With its excellent safety profile even on areas at higher risk of scarring such as the neck and chest, no downtime, and no minimal pain, the fractional nonablative Qs Nd/YAG laser is a reasonable option for treating superficial rhytides and photoaging (2b) [94, 95]. The frequency-doubled Qs Nd/YAG (532 nm) laser has also been reported to successfully treat a café-au-lait macule with less downtime as compared to conventional laser treatments (3b) [96]. Post-procedure care and follow up with these devices are similar to those outlined earlier for more conventional NAFL treatments.

Alternative Procedures and Modifications

Alternative treatments that target wrinkles, acne scars, and pigmented lesions include the fractional ablative devices (Chap. 19) and picosecond lasers with a fractional diffractive lens array (DLA) (4) [97–99]. The picosecond laser delivers short-pulse bursts of energy to the skin in the picosecond range, effectively targeting pigment and melanin. The DLA is an optical attachment composed of 120–130 tightly packed diffractive lenses that evenly distribute energy in high-energy pulses. By redistributing energy, multiple passes may be used to safely treat a specific area. Within each localized zone, Tanghetti et al. described histologically unique intra-epidermal cavities (5) [100].

These cavities result from an electron avalanche breakdown, alternatively termed "laser-induced optical breakdown" (LIOB). The number and size of cavities depend on the amount of melanin in the epidermis (melanin index) and laser energy used. Once formed, LIOBs absorb most of the subsequent incoming laser irradiation. Excessive radiation does not reach the dermoepidermal junction, protecting pigment and minimizing collateral damage. These focal areas of injury form MEND zones that exfoliate over the subsequent 2–4 weeks. LIOBs can directly stimulate an epidermal repair mechanism that results in improvement in dyspigmentation and new collagen, elastin, and mucin formation. The 755-nm picosecond alexandrite laser with DLA was reported to be a safe treatment of atrophic and hypertrophic scars, pigmented lesions, and striae in skin types IV–VI (2b) [101]. The most common side effects in this study were mild swelling, pain, redness, and crusting. Three of 56 patients developed hyperpigmentation that was resolved without any intervention. A total of 2–3-week treatment intervals were found to expedite results without increasing side effects when using the 755-nm picosecond laser with the fractional DLA to treat facial pigmentation and wrinkles (2b) [102].

Dyspigmentation can alternatively be addressed with Quality-switched (Qs) or the newer picosecond lasers (see Chap. 17. "Pigment lasers and light treatments"). Both nanosecond and picosecond lasers have been observed to produce a photomechanical effect that causes fragmentation of tattoo ink or pigment. The latter technology can be used to deliver lower fluences to affect tattoo pigment particles and melanosomes. These very small chromophores or targets have a thermal relaxation time of less than 10 nanoseconds (5) [103]. In a retrospective analysis, the Qs 694-nm ruby, Qs 532-nm KTP, and Qs 1064-nm Nd/YAG nanosecond lasers and the 755-nm alexandrite picosecond laser were noted to be safe and effective modalities for removing lentigines in skin types III–VI if used appropriately (2b) [104]. Notably, the risk of PIH in darker skin types may be decreased with the use of a picosecond laser as compared to the Qs lasers. Evidence of PIH was noted in only 2 of 255 total treated lentigines following laser therapy in patients with skin type IV using the 532-nm picosecond laser. The patient who developed PIH admitted to picking the treated area and potentially confounding results (2b) [105]. Similarly, a 755-nm picosecond laser demonstrated efficacy for the treatment of benign pigmentary lesions in Asians with only 2 of 13 patients developing transient hypopigmentation and none developing hyperpigmentation (4) [106]. The picosecond laser appears to more efficiently clear pigmentation than the Qs lasers with fewer treatments necessary. After only one picosecond laser treatment, 78% of lentigines improved by 75–100% [105]. Split-face studies comparing the picosecond and Qs lasers are needed.

As mentioned previously, melasma is a challenging condition to treat with the NAFL due to the high risk of a rebound effect and potential for exacerbation. Topical skin brighteners including bleaching creams and strict sun protection with a broad-spectrum sunscreen SPF 30 or higher can be used synergistically with the NAFL (4) [28, 79, 107]. Pretreatment for at least 2–4 weeks followed by posttreatment for 2–6 months with a bleaching agent is recommended to prevent hyperpigmentation particularly in skin types III–IV.

Fractional ablative laser therapy is an alternative treatment to address photoaging. In a comparative study using the fractional ablative 2940-nm (Er/YAG) laser versus the 1550-nm nonablative fractional laser to treat photoaging in Asian skin, Moon et al. found that a reduction in pigment, uneven tone, and erythema scores was significantly greater with the use of the Er/YAG ablative laser, while wrinkle score reduction was significantly greater using the 1550-nm NAFL (1b) [108]. Moreover, recalcitrant perioral and deeper rhytides tend to respond better to the fractional ablative lasers than the NAFLs (5) [6].

Scar revision often requires a multimodal approach to address the textural and vascular components of an individual scar. Hypertrophic erythematous scars are best addressed using a combination approach with PDL followed by the 1540-nm or 1550-nm laser (5) [11]. In a meta-analysis of keloidal and hypertrophic scars treated with intralesional steroids alone or in combination with 5-Fluorouracil, the combination treatment arm demonstrated statistically significantly greater efficacy based on patient satisfaction scores, observer assessment, and scar height (1a) [109]. When performed on the same day, intralesional injections should be performed after NAFL to avoid ulceration from bulk heating secondary to an increase in the aqueous target of NAFL (3b) [110].

Microneedling therapy and fractional needle radiofrequency treatments are alternative techniques that may be used for the treatment of scars. The process of microneedling involves the use of small, minimally invasive microneedles that break the collagen bundles in the superficial layer of the dermis that is responsible for scars, leading to a subsequent induction of more collagen immediately below the epidermis (5) [111].

Fractionated radiofrequency devices deliver sub-ablative energy that induces coagulative damage to the dermis. With relative sparing of melanin, the risk of dyspigmentation may be minimized with these devices. Studies in patients with skin types I–IV demonstrated favorable results in treating atrophic acne scars (1b) [112–124], periorbital wrinkles (2b) [125], and photoaging (2b) [126]. The use of fractional needle radiofrequency devices alone or in combination with microneedling has shown promising results in smaller studies in the treatment of scars and photoaging; however, there is still a need for larger comparative trials against the gold standard ablative and nonablative lasers.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
Nonablative fractional energy devices are safe and effective options for the treatment of a variety of conditions	B
Nonablative fractional energy devices offer the advantages of rapid recovery, minimal side effects and complications, and the ability to treat all skin types	B
Disadvantages of nonablative fractional energy devices include the requirement of multiple treatment sessions to achieve a clinical endpoint due to the lower efficacy per treatment compared to ablative resurfacing lasers	B
Nonablative fractional energy devices demonstrate consistent clinical efficacy in treating photoaging, rhytides, and scars on both facial and non-facial anatomic locations, including the neck, chest, and hands	B
Perioperative care includes herpes simplex virus prophylaxis if there is a positive history, photoprotection with a broad-spectrum sunscreen, sun avoidance, and topical hydroquinone and/or tretinoin for those predisposed to developing post-inflammatory hyperpigmentation	D

Self-Assessment Questions

1. Which of the following conditions is NOT ideally treated using a nonablative fractional laser?
   (a) Rhytides
   (b) Dyspigmentation
   (c) Telangiectases
   (d) Striae distensae
   (e) Scars
2. Which of the following is NOT a symptom of lidocaine toxicity?
   (a) Seizures
   (b) Perioral paresthesias
   (c) Hearing loss
   (d) Slurred speech
   (e) Lightheadedness and dizziness
3. Which of the following is the most common infectious complication of nonablative fractional laser resurfacing?
   (a) Staphylococcus aureus
   (b) Candida albicans
   (c) Streptococcus
   (d) Human papilloma virus
   (e) Herpes simplex virus
4. Which of the following fractional nonablative lasers is best for treating superficial conditions such as actinic keratoses?
   (a) 1410-nm erbium laser
   (b) 1550-nm erbium-doped laser
   (c) 1540-nm erbium glass laser
   (d) 1927-nm thulium laser
   (e) 10,600-nm CO_2 laser
5. Which of the following patients would be the most ideal candidate for the nonablative fractional 1550-nm/1927-nm laser?
   (a) An 80-year-old woman with deep rhytides and severe photodamage
   (b) A 32-year-old pregnant woman with melasma
   (c) A 16-year-old man with boxcar acne scars on the cheeks who finished a course of isotretinoin 2 months ago
   (d) A 25-year-old man with a traumatic scar on his upper lip who also has on closer inspection grouped vesicles on an erythematous base
   (e) A 45-year-old woman with mild-to-moderate facial rhytides and mild skin laxity

Correct Answers

1. c: Telangiectases. Nonablative fractional lasers target the chromophore water. Vertical columns of thermal damage induce microscopic epidermal necrotic debris that stimulates collagen formation and produces the melanin shuttle in which pigment is extruded through the epidermis. Therefore, rhytides, dyspigmentation, striae distensae, and scars are treatable with the NAFL. Telangiectases are best treated with lasers targeting the chromophore hemoglobin within red blood cells such as the 532-nm KTP and 585–595-nm-pulsed dye lasers.
2. c: Hearing loss is not a sign of lidocaine toxicity. Symptoms of lidocaine toxicity include perioral paresthesias, lightheadedness, dizziness, tinnitus, and at higher doses, slurred speech and tonic-clonic seizures.
3. e: Herpes simplex virus infection is the most common infectious complication with an incidence of up to 2% [75]. Antiviral prophylaxis can minimize the rate of HSV reactivation to less than 0.5% and should be administered in patients with a history of facial HSV.
4. d: The 1927-nm thulium laser is best for treating superficial lesions such as actinic keratoses. Its high absorption coefficient of water allows for more superficial penetration compared to that of other NAFL wavelengths. The 1927-nm fractional laser produced an 86.8% clearance of actinic keratoses 6 months following four monthly treatments [31]. In contrast, the deeper penetrating 1550-nm fractionated laser is not an adequate single-treatment modality for actinic keratoses. Six months after a series of five 1550-nm laser treatments, histologic evidence of AKs persisted, although clinically apparent facial actinic keratoses (AKs) were reduced by an average of 55% [32]. The 10,600-nm laser is an ablative device.
5. e: The ideal candidate for the nonablative fractional resurfacing procedure is a relatively young (25–65 years of age) patient with minimal facial skin sagging and realistic expectations. Deep rhytides and significant photodamage are better treated with an ablative fractional device. Women who are pregnant or nursing should not be treated with these lasers. A recent history isotretinoin use (</= 6 months) should preclude the laser resurfacing procedure. Laser treatment should be avoided in a patient with an active herpes simplex virus infection. Moreover, this patient should be given antiviral prophylaxis prior to each laser treatment, given his high risk of viral reactivation.

Medium to Deep Chemical Peels

19

Suzan Obagi

Abstract

Prior to the development of laser resurfacing, chemical peels were among the sole methods by which to resurface the skin. For decades, medium and deep peels have been used to treat a number of skin conditions in ethnically diverse patients. Despite the growing popularity of lasers, peels continue to rank among the most popular cosmetic procedures performed today showing a 4% increase to 1.36 million procedures in the USA during 2016. The two most commonly used acids for medium and deep peels are trichloroacetic acid (TCA) and phenol. The most common indications for chemical peels are actinic keratosis, photodamage, ephelides/lentigines, rhytides, post-inflammatory hyperpigmentation, certain types of acne scars, and melasma. By varying the concentration of the solution or the peeling agent, peels can be used to treat the skin of the neck, chest, and upper extremities.

Introduction and Indications for Medium to Deep Chemical Peels

Prior to the development of laser resurfacing, chemical peels were among the sole methods by which to resurface the skin. For decades, medium and deep peels have been used to treat a number of skin conditions in ethnically diverse patients. Despite the growing popularity of lasers, peels continue to rank among the most popular cosmetic procedures performed today [1] showing a 4% increase to 1.36 million procedures in the USA during 2016. The two most commonly used acids for medium and deep peels are trichloroacetic acid (TCA) and phenol. The most common indications for chemical peels are actinic keratosis, photodamage, ephelides/lentigines, rhytides, post-inflammatory hyperpigmentation, certain types of acne scars, and melasma. By varying the concentration of the solution or the peeling agent, peels can be used to treat the skin of the neck, chest, and upper extremities.

Chemical peeling agents can be classified as protein denaturants (TCA, phenol) or as keratolytic agents (glycolic acid, lactic acid, salicylic acid, and low strength phenol). It is the protein

denaturing property that is desired in medium and deep peeling to achieve wounding through the epidermis and into different levels of the dermis. Medium depth peels penetrate through the epidermis and into the papillary dermis level while deep peels penetrate through all the layers of the skin and reach the upper reticular dermis. Extremely deep peels into the mid reticular dermis can be performed but the risk of hypertrophic scarring, hypopigmentation, and permanent textural change make that type of peel very risky.

What Accounts for Chemical Peel Penetration?

A lot of importance is given to acid concentration when it comes to phenol and TCA peels. However, peel depth penetration is determined by more than just acid concentration. TCA is hydrophilic; therefore oily skin would serve as a barrier to peel penetration. Phenol is lipophilic and will penetrate through the skin very quickly. Furthermore, we now understand the important role croton oil plays in driving phenol peels deeper.

The Following Factors Influence Peel Penetration

Concentration

Higher concentration of TCA or phenol will penetrate through the skin to a deeper level than the same volume of a lower concentration TCA or phenol. The higher the acid concentration, the more protein coagulation that occurs. Thus, the acid will reach a deeper depth with each application.

Volume

As TCA and phenol acids penetrate the skin, their effect stops once enough protein coagulation has occurred to negate the acid that was applied. Thus, further peel penetration would require more acid be applied to the skin to drive the peel deeper. Therefore, thicker skin would require more acid volume than thinner skin to achieve a peel to the same depth.

Body Surface Area

Body surface area (BSA) is another factor. A fixed volume and concentration of peel solution will penetrate more deeply if the entire volume is applied over a small area of skin as opposed to the same volume being applied to a larger surface area.

Skin Thickness

Epidermal and dermal thickness varies by patient age, gender, anatomic location, and ethnicity. Chemical peel solutions will reach the dermis more quickly in thinner skin patients than those with thicker skin. Therefore, the physician will need to adjust either the volume or concentration of the peeling solution.

Skin Oiliness

Sebum and thicker, oilier skin is more challenging for TCA penetration. Properly degreasing the skin will allow TCA to penetrate more deeply than it would otherwise. Patients with oily skin will require either more volume of TCA or a higher concentration of TCA to penetrate through the sebum. Alternatively, patients who are very oily may require systemic therapy with isotretinoin for a month or two to reduce sebum production prior to the peel. However, if a patient is treated with isotretinoin, a waiting period of 3 months before peeling of the skin may be suggested to ensure proper wound healing.

Croton Oil Concentration

The most recognized formula for deep phenol peeling is the Baker & Gordon formula in which patients were peeled to the mid reticular dermis. While the results were dramatic, the risk of scarring and permanent hypopigmentation greatly reduced the number of patients that could or would undergo this procedure. Two researchers, Stone (2b) [2] and Hetter(2b) [3], studied the peel depth penetration achievable by varying either the phenol acid or croton oil concentration.

Other Factors Influencing Peel Depth

Pre-peel thinning of the stratum corneum with topical retinoids or fruit acids will help the peel solution penetration more easily. Furthermore, the amount of rubbing or pressure applied to the

skin when performing the peel will also drive the solution deeper.

Effectiveness of Chemical Peels for Treating Melasma

Melasma is one of the most common complaints of patients presenting to the dermatologist. It remains a challenging condition to treat. Many modalities, while giving initial improvement, are associated with a significant relapse rate.

Kumari and Thappa (2b) [4] looked at glycolic acid (GA) versus TCA peels in patients with melasma. Forty patients with epidermal (78%) or mixed melasma (22%) (epidermal and dermal) were randomized into two groups. "Most" patients were phototype IV–VI. All patients had baseline melasma area and severity index (MASI) scores calculated. The GA group received pretreatment with 12% GA cream and a sunscreen SPF 15 to use daily for 2 weeks prior to the peel. The TCA group was given 0.1% tretinoin nightly and sunscreen SPF 15 daily starting 2 weeks before the peels. Patients were then peeled every 2 weeks with escalating concentration or contact time to the peel solutions. Peel 1: 20% GA or 10% TCA left on for 2 min. Peel 2: 20% GA or 10% TCA for 4 min. Peel 3: 35% GA and 20% TCA for 2 min. Peel 4: 35% GA or 20% TCA for 4 min. More peels were performed after these initial four if patients showed slow or inadequate response. At the conclusion of all the peels, patients were treated with 2% hydroquinone cream nightly and an SPF 15 daily to maintain the results. The study showed that the GA group had MASI score reductions from 26.6 to 5.6 (79%) and the TCA group showed a reduction from 29.1 to 8.2 (73%). The difference between the GA and TCA group was not statistically significant. Similarly, the subjective improvement scores showed a good to very good response in 75% of GA patients and 65% of TCA patients. The difference between the two was not statistically significant. During the recovery periods, the GA patients were able to continue working whereas the TCA patients often had to take time off of work. At 6 months, two of the GA patients showed relapse. There is no mention as to which type of melasma (epidermal or mixed) did better for the TCA group. However, the GA acid group was evaluated for response with statistically significant reduction in MASI for the epidermal melasma patients (79% reduction) but not for the mixed-type melasma (27.8%).

Puri (2b) [5] compared 15% TCA peels ($n = 15$) versus 35% GA peels ($n = 15$) in 30 epidermal melasma patients. Patients were primed for 2 weeks prior to the peels with 2% Kojic acid or 0.25% tretinoin. There is no mention of SPF use. MASI scores were calculated at baseline and after each peel. Peels were performed at 3-week intervals for six sessions or once the melasma was clear (whichever occurred first). Subjectively, patients noted a good or very good response in 70% of the GA group and 64% of the TCA group. The difference between the two groups was not statistically significant. MASI scores showed a statistically significant improvement from baseline in both groups with the TCA group changing from 22.3 to 5.6 and the GA group changing from 23.6 to 4.25. The difference between the two groups' MASI scores was not statistically significant. Subjects found the GA peel easier to tolerate and that it required no time off from activities. The authors conclude that both peels were equally effective in the treatment of melasma. This study fails to mention the average number of peels needed per group, and there is no mention of the contact time that the GA peel was left on the skin. Furthermore, patient phototypes were not mentioned.

Safoury et al. (2c) [6] compared 15% TCA peels to a modified Jessner's Peel + 15% TCA peel in patients with phototypes III or IV. A modified Jessner's solution has salicylic acid, lactic acid, and citric acid (in place of resorcinol). Twenty patients with epidermal melasma were treated in a split-face, single-blinded manner. Prior to the peels, patients were primed for 2 weeks with a 10% zinc oxide sunblock daily and adapalene 0.1% gel nightly. The treating physician was not blinded. The left malar area was treated with the modified Jessner's solution until erythema appeared. Then a 15% TCA solution was in a uniform coat to the whole face

including the left malar "until frosting." Peels were repeated every 10 days until the melasma cleared or until a maximum of eight peels. MASI scores decreased from 4.46 to 2.04 on the TCA side (54.26%) and from 4.35 to 1.23 on the combination Jessner/TCA side (71.72%). Follow-up at 8 weeks showed a slight worsening of MASI scores to 2.27 (TCA) and 1.67 (Jessner/TCA), but these scores remained statistically significantly lower than the baseline. No comparison of scores were made between the two sides. No mention was made of the average number of peels performed. The authors conclude that the combination peel is superior to TCA alone.

Abdel-Meguid et al. (2b) [7] performed a single-blinded, split-face trial of 20–25% TCA peels versus Jessner + 20–25% TCA peels in 24 patients with phototypes IV–V. Patients were primed with 2% hydroquinone cream nightly and sunscreen daily for 2 weeks prior to the peels. Peels were performed six times at 2-week intervals. Patients were randomized to left or right cheek treatments with Jessner+TCA and TCA alone. The first three peels were with 20% TCA, and the last three peels were with 25% TCA. MASI scores were calculated at baseline and at the conclusion of the peels. Fourteen patients had epidermal melasma, and ten had mixed-type (epidermal and dermal) melasma. Four patients were dropped for non-compliance. Results showed a statistically significant decrease in MASI scores with either modality: Jessner + TCA (67.75% improvement) and TCA alone (48.60% improvement). Furthermore, the difference in improvements between the two modalities was statistically significant ($p < .05$). There is no mention of long-term follow up to evaluate relapse. Furthermore, there is no breakdown of response by melasma type. The authors conclude that both modalities are effective in improving melasma but that the Jessner + TCA combination is more efficacious.

Soliman et al. (2b) [8] evaluated 20% TCA peels versus 20% TCA peels + topical ascorbic acid cream in 30 patients with epidermal melasma with skin phototypes III or IV. Patients were randomized into two groups: group A 15% TCA peels and group B 15% TCA peels with home use of a topical ascorbic acid cream. All patients were primed with 2 weeks of 0.05% tretinoin gel daily and 4% hydroquinone daily and SPF > 15. In addition to these agents, group B received a 5% ascorbic acid cream to apply daily as well. MASI scores were calculated at the baseline, after peels were concluded, and at a 16-week follow-up. Peels were performed with 20% TCA weekly until melasma cleared or for a maximum of 6 sessions. Results for group A showed a MASI score reduction of 34.4% (15.31–10.107). This increased to an overall reduction of 20.06% by week 16. Results for group B showed a MASI score reduction of 61.75% (13.753–5.260). This increased by week 16 to reflect an overall reduction of 43.79% in group B. Comparing both groups showed a statistically significant reduction in MASI in group B over group A ($p < .001$). Patients rated themselves as good, marked, or moderate improvement in 13 of 15 patients (86.66%) in group B and 10 of 15 patients (66.66%) in group A. By week 16, group A showed that results maintained in 48%, worsened in 33%, and continued to improve in 19% of the cases. By week 16, group B showed results maintained in 60%, worsened in 13%, and continued to improve in 27% of the cases. All but two patients in group B required all six peel sessions.

Moubasher et al. (2b) [9] evaluated different concentrations of TCA peels versus 2 different Q-switched neodymium-doped yttrium-aluminum-garnet laser (Qs-Nd:YAG) laser treatments on 65 female patients, phototypes III to V. Patients were assigned to four groups. There was no special priming of the skin before or after treatments, only the use of topical sunscreen with an SPF > 50. MASI scores were calculated at baseline and after the treatments were completed. Group 1: 15 patients with epidermal melasma treated with 20% TCA. Group 2: 20 patients with epidermal, dermal, or mixed melasma were treated with 30% TCA. Group 3: 15 patients with dermal and mixed melasma were treated with 30% TCA. All peels were repeated at 2 week intervals up to eight sessions or until melasma clearance was achieved. Group 4: 15 patients were treated with Qs-Nd:YAG for epidermal melasma (7 patients treated with 532-nm) and dermal or mixed melasma (8 patients

treated with 1064-nm). All laser treatments were monthly for up to six sessions or until clearance was achieved. Patients were monitored for 3 months after treatment to evaluate for recurrence. Results showed the greatest reduction in MASI scores (64.7% improvement) in group 2 compared to group 1 (39.9%), group 3 (24.7%), and group 4. Group 4 showed worsening of MASI scores in the 532-nm group (−83.6%) and the 1064-nm group (−19.1%). Epidermal melasma (52% MASI reduction) improved more than the dermal type (12.1% MASI reduction) ($p = .0029$), whereas epidermal versus mixed-type melasma (49.5% MASI reduction) showed similar amounts of improvement ($p = .77$). Patients were "very satisfied" in group 2 (50%) followed by group 1 (40%), and then group 3 (6.7%). All patients (100%) in group 4 were "unsatisfied" followed by group 3 (46.7%), group 1 (6.7%), and group 2 (5%). By 3 months, there was a 32% recurrence rate. The authors conclude that 25% TCA peels were the most effective for melasma and that Qs-Nd:YAG should be avoided. However, it is noteworthy that the settings for the laser used in this study are much higher than those used in other melasma studies.

Conclusion on Peels for Melasma

The literature supports the use of low-concentration TCA peels (up to 25%) for the treatment of epidermal melasma and mixed-type melasma more so than dermal melasma. Phenol peels were not studied for melasma. Studies on dermal melasma are lacking. What is needed are more split-face studies to address melasma in the same patient using two different modalities including split-face peel and laser studies.

Effectiveness of Chemical Peels for Treating Lentigines and Actinic Keratosis

Many patients present for the treatment of lentigines and ephelides. These lesions can be seen across a wide range of ethnicities. Lasers and peels are commonly used modalities.

Li and Yang (2b) [10] evaluated a Qs-Nd:YAG laser versus 35% TCA for the treatment of lentigines in an Asian population. This was a split-lesion study of 20 patients with 37 lentigines in which the medial half of the lesion was treated with a Qs-Nd:YAG laser, 532-nm, 2.4–2.6 J/cm^2, 10 ns, 2 mm spot size and the lateral half was treated with 35% TCA until an even frost developed. Results were evaluated photographically by four investigators, and scored on a 5-point scale (1–5 with 5 being the best), comparing baseline photos to photos taken 6 months posttreatment. Results showed improvement with both modalities (4.16 for laser and 3.67 for TCA). However, 65% of lentigines responded better to Q-switched neodymium-doped yttrium-aluminum-garnet laser (Qs-Nd:YAG), 14% did better with TCA, and 21% were equal.

Raziee et al. (2b) [11] looked at cryotherapy versus 33% TCA in the treatment of lentigines on the dorsal surface of the hands in patients with phototypes II to IV. Thirty-three patients (2 men and 31 women) with at least 5 lentigines on each dorsal hand were treated with cryotherapy to lesions on one hand (cotton-tipped applicator for 3–5 s) versus 33% TCA to lentigines on the other hand (cotton-tipped applicator to a fine white frost). Patients were evaluated photographically at baseline and at 2 months. Eight patients did not complete the study. Results were judged by one attending dermatologist and two residents on a 4-point scale. No patient showed marked improvement (>75% change). Results of cryotherapy showed moderate (50–75%) improvement in phototype II (100%), phototype III (44%), and phototype IV (0). Results for the TCA group showed moderate (50–75%) improvement in phototype II (33%), phototype III (11%), and phototype IV (0). The main complication was post-inflammatory hyperpigmentation (PIH) seen in 40% of cryotherapy- and 44% of TCA-treated hands. The difference in PIH between the two groups was not statistically significant. Pain and length of healing was greater in the cryotherapy group with 84% of patients saying cryotherapy was more painful and 76% saying that TCA healed faster.

Holzer et al. (2c) [12] compared aminolevulinic acid + photodynamic therapy to 35% TCA in a split-face blinded study on patients with at least

five actinic keratosis (AKs) per treatment side. Patients were enrolled and randomized to left- and right-sided treatments on identical anatomic areas such as the forehead or midface or scalp. Twenty-eight patients were enrolled, but 23 completed the study. Aminolevulinic acid (ALA) + photodynamic therapy (PDT) was performed by applying 5% ALA to the anatomic area being treated, occluded for 4 h, and then activated by red light (Waldman PDT 1200), 600–740 nm, 75 J/cm^2 at an irradiance of 75 mW/cm^2. The TCA group had a topical anesthetic applied for 30 min, degreased with 95% alcohol followed by TCA 35% to an end point of an "even pink white frosting." Results showed a reduction in AKs with ALA+PDT (58%) compared to TCA (31.9%). At 12 months, the ALA+PDT group showed 73.7% complete clearance compared to the TCA group with 48.8% ($p = 0.011$). Pain was notably higher in the PDT group (7.5 on visual analog score) compared to TCA (5.1). However, non-permanent scarring was seen in the TCA group in 6 patients (21.4%).

Hantash BM et al. (2b) [13] performed a prospective study of three groups of patients with extensive sun damage or a history of non-melanoma skin cancer (NMSC). Patients were phototypes I to III, had extensive AKs, and no history of prior skin resurfacing within 5 years of the study. They were primed and post treated with tretinoin 0.05% cream and a sunscreen. Patients were randomized to a 5-fluorouracil (5-FU) group ($n = 9$), 30% TCA peel ($n = 10$), ablative carbon dioxide skin resurfacing ($n = 8$). The 5-FU group had to apply the 5-FU cream twice a day for 3 weeks, the TCA group had one peel at 30% TCA performed to the level of an even frost, and the ablative CO_2 laser group underwent two passes of fully ablative laser resurfacing. Patients were followed up every 3 months for 24 months. Actinic keratosis recurrence was measured and the development of any NMSC was noted. Of note, all but three patients in this study had a history of a face or scalp NMSC. Results showed that all three groups had a statistically significant reduction in AKs, 5-FU (83%), TCA (89%), and CO_2 (92%), with no adverse scarring or pigment alterations. While it was a small study size, the TCA group exhibited a greater reduction in NMSC risk (3.75–5.25-fold) compared to the other two groups ($p < .001$).

Conclusion on Peels for Photodamage and Actinic Keratosis

Comparing Qs-Nd:YAG to 35% TCA for lentigines showed almost equal results. For areas that did not resolve, retreating with TCA or laser is an acceptable option. However, the cost-effectiveness of the TCA exceeds that of the laser. Similarly, the cost of cryotherapy or TCA peels are both very low. The improvement seen in cryotherapy over TCA for lentigines may suggest that the TCA peel was not performed deep enough. However, it is a fine balance between eliminating the lentigo and risking permanent hypopigmentation with any modality.

The use of ALA+PDT for AKs warrants a large study to truly draw conclusions on outcome. Studies need to be done with the same concentration of TCA but applied to a slightly deeper level. The authors mention "descaling" AKs before applying the ALA but did not do the same prior to applying the TCA. Furthermore, a slightly deeper peel may have resulted in more impressive AK reduction.

Reduction in AKs was seen as being substantial in 3 groups using 5-FU, TCA, or CO_2 laser resurfacing. Large studies should be conducted to see if the reduced risk of NMSC with TCA peels carries forward. However, patients found the TCA recovery to be easier than 5-FU and CO_2. That makes TCA a very cost-effective tool.

Effectiveness of Chemical Peels for Treating Acne Scars

In 2002, Lee et al. (2b) [14] described the CROSS technique now widely utilized for the treatment of icepick scars in which high-concentration TCA is applied focally to isolated scars to create wounding and subsequent improvement. This is performed by using a sharpened wooden applicator stick or other similar tool to focally apply TCA to the scar including the deep track of scar tissue associated with icepick scars.

Dalpizzol et al. (2b) [15] looked at the treatment of icepick and boxcar scars in a split-face,

non-randomized, single-blinded study of 15 patients, phototypes IV or lighter, using the CROSS technique with TCA or phenol. The skin was primed with 0.3% adapalene gel nightly for 15 days prior to the start of the peels. The left hemiface was treated with 88% phenol and the right hemiface with 90% TCA using the standard CROSS technique. The peels were repeated every 21 days for 4 sessions. Patients were assessed photographically and were asked to rate healing time and pain for each side. Prior to treatment, both sides showed similar scar scores on an acne scar grading scale (ECCA). After the treatments, both sides showed statistically significant improvement in scars compared to baseline (ECCA) but again, there was no statistically significant difference between the TCA or the phenol sides in regard to the degree of improvement. Patients rated the phenol side as more painful during the procedure. There was no significant difference in healing time between the two acids. The DLQI (dermatological quality of life index) score improved from a score of 6.7 to 3.3 ($p < .05$) after the treatments. Four patients developed hyperpigmentation (two with TCA, two with phenol), two patients developed hypochromia (TCA group), and two developed widening of the scars (TCA group).

Ramadan et al. (2b) [16] evaluated 20 patients, phototypes III and IV, in a split-face trial of 100% TCA CROSS technique to subcision in patients with rolling scars. Acne scar severity was measured on a 4-point scale from 1 (macular), 2 (mild atrophy), 3 (moderate) to 4 (severe). Patients were treated with CROSS 100% TCA on the left side of the face and subcision on the right (needle gauge was not mentioned). Patients were treated 1–3 times at 1–4-month intervals. All scars improved with both techniques but improved more with subcision than TCA ($p = 0.001$). Of note, there was a large difference in baseline scar sizes between the right (0.416 cm^2) and left (0.182 cm^2) sides of subjects.

Leheta et al. (2b) [17] compared percutaneous collagen induction (PCI) microneedling (1.5 mm) with 100% TCA CROSS technique in acne scars (rolling, boxcar, icepick), in 30 patients (27 completed the study), phototypes II to IV. Patients were randomized to either the PCI (five passes in four directions) or the TCA groups, primed with a topical retinoid and 4% hydroquinone for 2 weeks prior to treatment, and received four treatments at 4-week intervals. Results showed an improvement in the severity of acne scars in both groups ($p < .001$ for each group) but no statistically significant difference in improvement between the two groups. However, when looking at scar morphology, rolling scars did better with PCI while boxcar and icepick scars did better in the TCA group.

Nofal et al. (2b) [18] compared three modalities in patients with rolling, boxcar, and icepick scars. Patients were divided into 3 groups of 15 patients: intradermal platelet-rich plasma (PRP), 100% TCA CROSS, and topical PRP + microneedling (PCI, 2 mm, 6 passes in 4 directions). Three sessions were performed at 2-week intervals. All patients had an improvement in their scars with no statistically significant difference between the groups as graded by the patients, a quartile grading system, and photographic assessment (blinded evaluation). The authors did not breakdown responses by scar morphology.

Agarwal et al. (2b) [19] looked at 70% TCA CROSS in rolling, icepick, and boxcar scars in 62 patients (53 completed the study). Patients received four sessions at 2-week intervals. Blinded reviewers evaluated photographs, and patients performed a self-assessment and patient satisfaction survey. Physician assessment showed that 66% of patients had >50% improvement (22.6% excellent and 43.4% good). Patients reported excellent improvement (11.3%) and good improvement (54.7%). No patient reported a poor response. Boxcar scars showed the most improvement as rated by physicians and patients.

Conclusion on Peels for Acne Scars

The CROSS technique, utilizing 88% phenol or 90% TCA, has been shown to be effective in the treatment of boxcar and icepick scars. The treatment of choice for rolling or valley scars remains subcision or PCI. Rolling scars tend to be wider and deep, requiring a treatment that promotes

collagen building while not altering surface color or texture.

The shortcoming of these studies is the lack of a standardized acne scar scale across studies to allow for better comparisons of outcomes. Furthermore, larger studies are needed to look at scar morphology and treatment outcomes to better decipher which scars do better with different treatments.

Preoperative Evaluation

Since skin resurfacing procedures create controlled wounds in the skin, there are precautions taken with regard to selecting the correct patient, preparing the skin, and minimizing complications by obtaining a good medical and social history. Preoperatively, patients should be screened for medications, allergies, smoking, infections, and a history of any psychological or behavioral issues that may make them have unreasonable expectations or may make them less prone to following postoperative care. Patients that are pickers, for example, may pick at the unhealed skin and create infections or scars. Many studies talk about performing the procedure, but there have not been studies that objectively evaluate preresurfacing skin care, postoperative skin care, or the best regimen for viral and bacterial prophylaxis. Therefore, each study's patient cohort is based on protocols selected by the investigators according to their personal experiences rather than being firmly grounded in science.

Most investigators suggest a pretreatment regimen of a topical retinoid (retinol, retinoic acid, retinaldehyde), a topical hydroquinone cream (2% or 4% applied daily or twice daily), and a sunblock. The pretreatment routine is usually started 2–6 weeks prior to the peel and resumed upon healing of the skin.

Antiviral Therapy

When the perioral area is being treated, physicians usually start an antiviral regimen starting the day before and continuing until fully healed, 7–14 days. The dosing of the antiviral regimen is physician dependent and may be adjusted if a patient has a strong history of herpes simplex virus (HSV) outbreaks. There is general agreement that antiviral therapy is mandatory for all patients undergoing perioral resurfacing since the risk of HSV becoming disseminated and causing scarring is catastrophic.

Antibacterial Therapy

There is no consensus on the use of antibiotics to prophylactically prevent infection. The infection rate with skin resurfacing is not high to begin with, but should an infection occur, the risk of scarring goes up. For this reason, care is taken to monitor these patients postoperatively in order to detect and treat infections early. No studies have been done to look at the rate of infection in patients treated or not treated with prophylactic antibiotics. The author has anecdotally found that mupirocin ointment applied to the opening of the nostrils three times a day starting 1 week prior to the peel and for 1 week afterwards results in a lower rate of postoperative bacterial infections.

Best Techniques and Performance

There is no consensus statement on properly performing this procedure. Most physicians will degrease the skin with acetone or 70% alcohol prior to the peel. The peel solution is applied with cotton-tipped applicator (CTA) sticks (TCA or phenol), a triangular makeup sponge (TCA), or two to three CTAs (phenol).

TCA Peels

Most physicians will degrease the skin with acetone or 70% alcohol prior to the peel. The peel solution is applied with cotton-tipped applicator (CTA) sticks (TCA or phenol) or a triangular shaped makeup sponge (TCA). About 2 min is allowed between applications to be able to see the full frost as it develops. If more depth of pen-

etration is needed, more TCA is applied, and then the frost is re-evaluated. Frost is evaluated as mentioned earlier based on a level 1 to level 3 frost. As TCA is first applied, a light non-organized frost begins to form. This is a level 1 frost and signifies an epidermal level peel. Further application results in the frost being solid but with a diffuse pink background to become a level 2 frost. This marks a peel just reaching the papillary dermis level. Continued TCA application results in more solid white frost with a loss of the pink background indicating coagulation of the papillary dermis vascular plexus (level 3 frost). This is the deepest suggested level of application of TCA peels. Beyond this level, risk of scarring and hypopigmentation increases greatly.

Phenol Peel

Depending on the solution used and the extent of the peel, cardiac monitoring and intravenous (IV) hydration may be required. In instances of a half-face or full-face peel, the peel is performed in quadrants with a 15-min waiting time between application and lots of IV hydration to allow the body to metabolize and excrete any absorbed phenol. Great caution is indicated when performing a phenol peel on patients with impaired cardiac, hepatic, or renal function.

The skin is degreased with acetone. The phenol mixture must be swirled before dipping the CTA into it as the oil and water components have a tendency to separate. The solution is applied with 1–3 CTA (held like a fan). The skin quickly frosts when the solution is applied. The end point of a phenol peel is an even white frost. The frost quickly begins to dissipate so the physician must pay close attention to the treated area to avoid reapplying the solution and exceeding the desired depth of penetration.

Safety

There are no randomized clinical trials or large case series publications on the complications of chemical peels. Most publications report complications as they relate to the peels described in their study. In general, most peel complications stem from the depth of the peel and not from the actual solution used. Minor complications include post-procedure irritant or contact dermatitis to a product used for wound healing, acne flare up, swelling, erythema, sterile pustules, and PIH. Major complications include infection (viral, bacterial, fungal/yeast), hypertrophic/keloidal scarring, prolonged erythema, texture change, ocular injury from the solution, ectropion, and hypopigmentation. Early recognition and intervention is key to mitigating these complications.

Any suspected infection warrants a bacterial culture and sensitivity (aerobic, anaerobic, possibly mycobacterial) to identify the organism and to tailor antibiotics to the organism. The use of preoperative antibiotics that cover gram-positive bacteria may allow the growth of gram-negative bacteria by eliminating the normal flora balance. Infections typically are staphylococcus, but atypical mycobacteria, *Enterobacter*, *Pseudomonas aeruginosa*, and *Escherichia coli* have been reported.

Viral infections can present as areas that were healing and then began to regress. The virus can be herpes simplex or varicella zoster virus. Either of these can spread quickly on denuded skin and cause deep erosions and possible scarring. These viruses can erupt anywhere during the healing process until the skin is fully re-epithelialized. Cultures or direct immunofluorescence characterization of the virus should be performed, and high-dose (zoster dosing) antiviral medications should be implemented for 10 days and adjusted to clinical response.

With the occlusive dressings and use of antibiotics, patients can sometimes develop pruritic papules that show budding yeast on KOH prep. These usually develop by postoperative days 4 or 5. Oral anti-yeast agents can be helpful in treating this.

Postoperative Care and Follow-Up

There is no consensus on postoperative management. The extent of postoperative follow-up usually relates to procedure depth. “Lunchtime” peels

may not require a follow-up necessarily. However, medium and deep peels should be followed up at day 3 or 4, again at day 7, and further out until the patient is fully re-epithelialized. Patients should be brought in at anytime if they call with any symptoms that portend scarring or infection.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
Chemical peels remain a very important tool in treating dyschromia, photodamage, and certain types of scars	D
With appropriate knowledge and training, physicians may find that they are able to treat a wider diversity of patients with peels as compared to laser resurfacing	D
Until larger studies are performed to standardize preoperative skin preparation, procedure performance, patient selection, postoperative management of complications, and indications, it behooves the physician to start slowly and gradually work his/her way up to deep peels	D

Self-Assessment Questions

1. A 53-year-old female, Fitzpatrick type III, Glogau type III, undergoes combination 30% TCA peel resurfacing of her face to a level 2 frost. She is at increased risk for all of the following *except:*
   (a) Post-inflammatory hyperpigmentation
   (b) Bacterial infection
   (c) Acne flare up
   (d) Textural abnormalities
   (e) Melasma flare up
2. On day 4, post-resurfacing, the patient presents with purulent drainage from the wound, some thick, honey-colored crusting, and a low-grade fever. The most likely infectious etiology is:
   (a) *Staphylococcus aureus*
   (b) *Candida albicans*
   (c) *Pseudomonas aeruginosa*
   (d) Herpes simplex virus
   (e) Contact dermatitis
3. In an attempt to minimize or avoid post-inflammatory hyperpigmentation (PIH) after a resurfacing procedure, it is appropriate to:
   (a) Begin hydroquinone in the immediate postoperative period
   (b) Wait until re-epithelialization is complete to begin hydroquinone
   (c) Wait until evidence of PIH manifests itself
   (d) Begin hydroquinone therapy 5–6 weeks postoperatively
4. A 40-year-old male, Fitzpatrick type II, is seeking treatment of shallow, small atrophic acne scars. All of the following would be appropriate treatment modalities *except*:
   (a) TCA peel to the level of the reticular dermis
   (b) A 1 min 70% glycolic acid peel
   (c) CROSS TCA technique
   (d) Fractionated CO_2 laser resurfacing
5. When evaluating a patient for chemical skin resurfacing, many factors must be assessed. Which of the following is the *least* important:
   (a) the patient's expectations of improvement
   (b) medical history
   (c) family history
   (d) pre-existing skin disease
   (e) history of keloids

Correct Answers

1. d: A level 2 frost should not reach the reticular dermis thus the risk of scarring or textural change with a level 2 frost peel is low.
2. a: The most common bacterial infection is staphylococcus aureus. However, on the setting of an infection while a patient is on an antibiotic that covers gram-positive bacteria, a gram-negative infection should be suspected.
3. b: Once the skin heals, reinstituting hydroquinone may help reduce PIH rather than if one were to start HQ once PIH has set in.
4. b: A 1 min 70% glycolic acid will not reach the dermis to a degree that will build collagen in shallow, atrophic, boxcar scars.
5. c: While everything is important in medical, social, and family history, the family history would yield the least helpful information. It is better to understand the patient's state of mind, health history, tendency to scar, and the history of skin diseases that may worsen or affect wound healing.

Superficial Chemical Peels and Microdermabrasion

20

Rachel Miest

Abstract

Superficial skin resurfacing is a process causing controlled injury to the epidermis. Processes can be chemical or mechanical and classified as laser or nonlaser. Although our armamentarium for skin resurfacing ranges from topical medicaments to ablative lasers, superficial skin resurfacing with chemical peels and microdermabrasion (MDA) has maintained its popularity. These well-established therapies have proven safe and effective, offer minimal risk, low cost, and are well-tolerated by patients often with little to no post-procedure downtime. Potential benefits extend to all Fitzpatrick skin types and if done appropriately are highly unlikely to cause significant dyspigmentation or scarring. Indications for treatment are acne vulgaris, rosacea, post-inflammatory hyperpigmentation, melasma, and photodamage including lentigines, fine rhytides, and actinic keratoses. Superficial resurfacing with chemical peels or MDA can be used in combination with other therapies (e.g., laser) and may enhance the efficacy of other topical treatments. A superficial depth of penetration may be of significant benefit to the patient but does have limitations. It is important for patients to understand the likely need for a series of treatments, the importance of pre- and post-care regimens, and expected outcomes.

MDA can be used in combination with other therapies (e.g., laser) and may enhance the efficacy of other topical treatments. A superficial depth of penetration may be of significant benefit to the patient but does have limitations. It is important for patients to understand the likely need for a series of treatments, the importance of pre- and post-care regimens, and expected outcomes.

Chemical Peels

Chemical peels are the application of a chemical peeling agent to the skin that causes controlled destruction of the epidermis and/or dermis. A number of factors determine the depth of injury induced by the peeling agent including the specific chemical(s) and concentrations used, the preparation of the skin, application technique, duration of contact, and skin characteristics. Superficial chemical peels primarily affect the epidermis and so are indicated in the management of acne and its post-inflammatory erythema/hyperpigmentation, mild photoaging including fine rhytides and lentigines, and melasma. Peels may increase penetration of topical therapies (e.g., transdermal drug delivery) and may be used as an adjunct to topical or systemic therapies [1, 2]. Commonly used superficial peeling agents are alpha hydroxy acids (AHAs), salicylic acid (SA), and Jessner's solution (JS). These superficial peeling agents produce their effects by decreasing corneocyte adhesion in the epidermis and inducing neocollagenesis in the dermis [3–6]. Superficial chemical peels generally require four to six applications at 2–4-week intervals for desired clinical response. They are typically associated with mild burning or stinging with application and limited post-procedure downtime. Pre- and post-treatment regimens are integral to successful outcomes. Pre-treatment with a retinoid or an AHA 2–4 weeks prior to the procedure prepares the skin for the peeling process ensuring more homogenous penetration and consistent results and can hasten post-treatment healing. Post-treatment care including diligent photoprotection, and particularly in darker Fitzpatrick skin types, hydroquinone preparations or other bleaching agents are also important to prevent post-treatment dyschromia [6–10]. Complications of superficial chemical peels are rare but may include prolonged erythema, pigmentary changes including hyper/hypopigmentation, infection, and scarring [11, 12]. Superficial chemical peels are a useful tool to treat many skin conditions and may work synergistically with other treatment modalities to achieve optimal results.

Alpha Hydroxy Acid Peels

Alpha hydroxy acids (AHAs) are nontoxic organic acids found in foods and may be naturally occurring or synthetically produced [13]. AHAs include glycolic acid, lactic acid, malic acid, mandelic acid, oxalic acid, citric acid, pyruvic acid, and tartaric acid [5, 14]. Glycolic acid (GA) is the lowest molecular weight AHA and penetrates the skin readily making it a commonly used agent for chemical peeling. GA peels are commercially available as free acids, partially neutralized, or buffered solutions ranging from concentrations of 20% to 70% [11, 15]. Low concentrations decrease the cohesion of corneocytes, while higher concentrations may lead to complete epidermolysis [2, 14, 16]. AHAs have been associated with increased epidermal thickness, decreased melanin deposits in the epidermis, and increased fibroblast proliferation and collagen production [17–19]. A study of the effects of multiple peeling agents on mini-pig skin found minimal inflammation and a disproportionate increase in collagen deposition with GA, suggesting a stimulatory mechanism rather than damage and subsequent repair [20]. And in a study by Usuki et al., GA was shown to suppress melanin formation by direct inhibition of tyrosinase [21]. In another study, GA was found to have moderate growth inhibitory and bactericidal effects of *P. acnes* [22]. With these properties, AHAs are therefore beneficial for many cutaneous conditions including photodamage, melasma, and acne [8]. Application is often painless although may be associated with mild burning or stinging. GA is hydrophilic and has a low pH. The pH varies depending on the concentration of the

acid, with higher concentrations resulting in lower pH and increased peeling capacity. GA peels typically require neutralization to avoid excess acidification and subsequent burning of the skin. As with other superficial peeling agents, multiple treatments are typically required to achieve desired results. Concentration of the acid used and application time may be increased with serial treatments as tolerated [6, 23].

Photodamage

Early studies demonstrated reduced corneocyte cohesion with subsequent epidermal thinning and significant therapeutic benefit with application of AHAs to the skin of patients with disorders of keratinization [16, 24]. Subsequent studies focused the effects of AHA peels on photodamaged skin (Table 20.1). Ditre et al. demonstrated that application of GA, lactic acid (LA), or citric acid (25% lotion) to photoaged skin of the forearm resulted in histologic evidence of increased epidermal thickness and dermal changes including increased synthesis of glycosaminoglycans and collagen [25] (2b). A study examining the effect of GA 50% chemical peeling on photoaged skin using Skh:HR-1 hairless mice demonstrated an increase in dermal collagen on biochemical analysis that was not statistically significant [26] (5). In a double-blind, vehicle-controlled study of weekly GA 50% peels, Newman et al. demonstrated clinical improvement of photoaged skin including a decrease in rough texture and fine rhytides, a reduction of actinic keratosis, and lightening of lentigines. Histopathology was consistent with previous studies showing a thinning of the stratum corneum but overall increase in epidermal thickness [27] (3b). A randomized controlled trial comparing low-intensity MDA and low-intensity GA peels (20%) showed that while GA peels were preferred by patients, no significant clinical improvement from baseline was noted with either treatment [28] (2b). This finding supports the hypothesis that maximum efficacy is best achieved by a series of peels at the highest tolerated concentrations.

Melasma

The efficacy of AHA peels in the treatment of melasma has also been studied (Table 20.2). In a single-blind, right/left comparison study of glycolic acid peels with GA 10% and hydroquinone 2% gel, there was subjective improvement of melasma and fine rhytides when both treatments were utilized compared to the hydroquinone gel alone. This improvement was not statistically significant [29] (3b). A split-face study from Lawrence et al. comparing GA 70% and JS demonstrated equal efficacy in the treatment of melasma and a more rapid response than topical therapies alone [30] (3b). Similarly, a randomized controlled study of Kligman's formula (hydroquinone 5%, tretinoin 0.05%, and hydrocortisone acetate 1%) alone or in combination with GA 30–40% demonstrated a greater overall response and more rapid results with combination therapy [31] (3b). In a study from Hurley et al. of GA 20–30% peels added to a topical regimen of hydroquinone 4%, the addition of GA did not sig-

Table 20.1 Alpha hydroxy acid chemical peels in the treatment of photodamage

Reference	Study design	N	Clinical/histopathologic outcomes	Evidence level
Ditre et al. [25]	Randomized controlled	17	Increased epidermal thickness and dermal changes including increased synthesis of glycosaminoglyans and collagen	2b
Butler et al. [26]	Animal	20 (mice)	Non-statistically significant increase in dermal collagen	5
Newman et al. [27]	Controlled cohort	41	Improved skin texture; decreased fine rhytides, actinic keratosis, and lentigines Thinning of stratum corneum but overall increased epidermal thickness	3b
Alam et al. [28]	Randomized controlled	10	No significant improvement from baseline	2b

Table 20.2 Alpha hydroxy acid chemical peels in the treatment of melasma

Reference	Study design	N	Clinical/histopathologic outcomes	Evidence level
Lim and Tham [29]	Controlled cohort; GA 20%	10	Subjective improvement but not statistically significant	3b
Lawrence et al. [30]	Controlled cohort; GA 70% vs. JS	11	Statistically significant decrease in MASI score for both treatment groups, no statistically significant difference between treatment groups	3b
Sarkar et al. [31]	Controlled cohort; GA 30–40%	40	Statistically significant decrease in MASI score; trend toward greater and more rapid improvement	3b
Hurley et al. [32]	Controlled cohort; GA 20–30%	18	No significant difference when GA 20–30% added to topical regimen	3b
Coleman and Brody [33]	Expert clinical opinion	n/a	Improvement with GA 50–70% peels without adjunct topical therapy	5
Erbil et al. [18]	Randomized controlled; GA 20–70%	28	Statistically significant decrease in MASI score	2b
Sharquie et al. [34]	Case series; LA 92%	12	Statistically significant decrease in MASI score	4
Sharquie et al. [35]	Comparative cohort; LA 92% vs. JS	24	Statistically significant decrease in MASI score for both treatment groups, no statistically significant difference between treatment groups	3b
Sarkar et al. [36]	Randomized comparative; GA 35% vs. SMA (SA 20%/MA 10%) vs phytic acid combination	72	Statistically significant decrease in MASI scores for GA and SMA treatment groups, no statistically significant difference between the two groups	2b

nificantly enhance the effects of hydroquinone monotherapy [32] (3b). Subsequently, Coleman and Brody highlighted the low-strength GA used by Hurley et al. and cited their own experience with improvement of melasma following monthly higher concentration GA 50–70% peels without adjunctive topical therapies [33] (5). A prospective, randomized controlled trial examining serial GA 20–70% peels in combination with azaleic acid 20% cream two times a day and adapalene 0.1% gel nightly showed statistically significant improvement with the addition of GA peels. The statistical significance in treatment response between the control group and chemical peel group was most pronounced at week 12 and persisted through the end of the study at week 20, corresponding with higher concentrations of glycolic acid (50% at weeks 8 and 10, 70% at weeks 12 and 14), supporting the opinion that higher concentrations of glycolic acid are required for optimal clinical outcomes. The authors suggest that glycolic acid 50% acid may be ideal for treatment of melasma, noting diminishing returns with higher concentrations and increased risk for complications such as post-inflammatory hyperpigmentation [18] (2b).

Although the literature for GA in the treatment of melasma is more robust, alternative AHAs and superficial peeling agents have demonstrated efficacy. Lactic acid (LA) demonstrated statistically significant reductions in Melasma Area and Severity Index (MASI) scores in a study by Sharquie et al. [34] (4) A subsequent study again showed significant response and found LA to be as effective as JS in the treatment of melasma [35] (3b). In a recent study, Sarkar et al. compared the efficacy and tolerability of GA 35%, salicylic mandelic acid (SMA; SA 20%/mandelic acid (MA) 10%), and phytic acid combination peels in the treatment of melasma. Patients were primed with hydroquinone 4% and tretinoin 0.05% 4 weeks prior to the initiation of treatment. Peels were performed every 2 weeks for a total of 12 weeks. A decrease in MASI score was seen in all three treatment groups, but was statistically significantly lower in patients receiving GA and SMA peels. Although there was no statistically significant difference noted between these two treatment groups,

SMA has a larger molecular weight than GA and is associated with less procedural discomfort and increased tolerance by patients [36] (2b). Overall, superficial chemical peels are safe and efficacious for the treatment of melasma and are often used in combination with topical therapies to optimize results and reduce potential side effects [9].

Acne

AHAs have proven efficacious in the treatment of acne (Table 20.3). GA has been the most studied for treatment of comedonal and inflammatory acne and its sequelae including post-inflammatory hyperpigmentation and scarring. A 1997 study of the effect of GA 35% and 50% peels in addition to GA home care products on the treatment of acne in Asian patients showed significant improvement of skin texture including pore refinement, "brighter and lighter" looking skin, and resolution of comedones, papules, and pustules. Subtle improvement of acne scars was also noted [37] (4). Another study evaluating GA 70% peels for treatment of acne found the most rapid response in comedonal acne, although noted improvement of papulopustular and nodulocystic acne with additional applications. And a significant improvement in acne scarring was noted in patients with nodulocystic acne, although an increased number of applications (eight to ten) were required. Peels were performed in conjunction with a home care regimen of a topical antibiotic and GA 15% which may have contributed to the efficacy demonstrated, particularly for inflammatory acneiform lesions [38] (4). Kim et al. compared the effectiveness of GA 70% peels and JS in the treatment of facial acne in a split-face randomized clinical trial and found both treatments effective but no significant difference was seen in treatment effects. JS was associated with increased post-procedure exfoliation which led to patient preference for GA peels [39] (2b). In a split-face, double-blind, randomized controlled study, GA 30% peels were compared to SA 30% peels in the treatment of mild to moderate facial acne. Both chemical peels demonstrated statistically significant effectiveness as measured by a reduction of acne lesions, although patients treated with SA did have sustained

Table 20.3 Alpha hydroxy acid chemical peels in the treatment of acne and its sequelae

Reference	Study design	N	Clinical/histopathologic outcomes	Evidence level
Wang et al. [37]	Case series; GA 35–50%	40	Improvement/resolution of comedones, papules, and pustules; pore refinement Subtle improvement of acne scarring	4
Atzori et al. [38]	Case series; GA 70%	80	Most rapid response in comedonal acne, although improvement noted in papulopustular and nodulocystic acne with additional applications	4
Kim et al. [39]	Randomized comparative; GA 70% vs. JS	26	Improvement in both treatment groups but no statistically significant difference. Increased exfoliation with JS	2b
Kessler et al. [40]	Randomized comparative; GA 30% vs. SA 30%	17	Significant reduction of acne lesions in both treatment groups; sustained benefit in SA treatment group	2b
Lee et al. [41]	Case series; GA 30% vs. JS	38	No significant change in sebum levels in either group	4
Kaminaka et al. [42]	Randomized controlled; GA 40%	26	Significant reduction of acne lesions when compared to placebo	1b
Burns et al. [43]	Randomized controlled; GA ≤68%	16	A trend toward greater and more rapid improvement Increased lightening of unaffected skin noted	2b
Garg et al. [44]	Comparative cohort; GA 35% vs. SMA 20%/10%	44	Significant improvement of acne, acne scarring, and post-inflammatory hyperpigmentation in both treatment groups; SMA showed statistically significant superiority in treatment of active acne and post-inflammatory hyperpigmentation	3b

benefit with fewer lesions 2 months after treatment. Of note, patients in the study remained on topical therapies (e.g., retinoids) and oral antibiotics if using at the time of enrollment [40] (2b). In a study on the effect of GA 30% and JS on sebum secretion in patients with mild to moderate facial acne, Lee et al. found no significant difference in the sebum secretion after two peels performed 2 weeks apart [41] (4). A randomized, double-blind, placebo-controlled, split-face study of GA 40% peels in patients with moderate to severe facial acne demonstrated a statistically significant reduction in acne lesions compared to placebo. This study examined glycolic acid peels without the use of concurrent therapies, requiring a 2-month washout period prior to initial treatment [42] (1b).

The sequelae of acne including post-inflammatory hyperpigmentation and scarring may also benefit from treatment with AHAs. Burns et al. compared GA peels to a topical regimen of hydroquinone 2%/GA 10% gel two times a day and tretinoin 0.05% cream nightly in the treatment of post-inflammatory hyperpigmentation in patients with Fitzpatrick types IV–VI skin. Patients treated with GA peels showed a trend toward more rapid and greater improvement of post-inflammatory hyperpigmention. An increased lightening of unaffected skin was also noted [43] (2b). Garg et al. found both GA 35% and SMA peels to be effective in the treatment of acne, acne scarring, and post-inflammatory hyperpigmentation, but SMA peels showed statistically significant superiority in the treatment of active acne and post-inflammatory hyperpigmentation. The role of MA versus SA in the outcomes of this study is unclear [44] (3b). While the utility of SA in the treatment of acne is well established (Table 20.4), further study is needed to better understand the potential therapeutic efficacy of other chemical peeling agents for acne.

Salicylic Acid Peels

Salicylic acid (SA) is a 2-hydroxybenzoic acid or ortho-hydrobenzoic acid. Previously classified as a beta hydroxy acid, its properties are most consistent with a phenolic aromatic acid [51, 52]. Similar to AHAs, SA comes from natural sources such as willow bark or may be synthetically produced. As an organic acid, SA extracts desmosomal proteins including desmo-

Table 20.4 Salicylic acid chemical peels in the treatment of acne

Reference	Study design	N	Clinical/histopathologic outcomes	Evidence level
Lee and Kim [61]	Case series; SA 30%	35	A decrease in inflammatory and noninflammatory lesions; no post-procedure differences in stratum corneum hydration, skin surface lipid, skin pH, or transepidermal water loss	4
Ahn and Kim [62]	Case series; SA 30%	24	Gradual skin whitening and significant improvement of redness	4
Dainichi et al. [63]	Case series; SA 30%	436 6 (mice)	Reduced development of comedones and inflammatory papules Histopathology (mice): Early changes of decreased epidermal thickness, near complete removal of cornified cells from hair follicles; late change (2 weeks) of new regularly arranged cells of the cornified layer	4
Hashimoto et al. [64]	Case series; SA 30%	16	Significant reduction (mean of 75%) in comedones	4
Bae et al. [65]	Comparative cohort; SA 30% vs. JS	13	Reduction of inflammatory lesions in both treatments; SA more effective for noninflammatory lesions	3b
Dayal et al. [66]	Randomized comparative; JS vs. SA 30%	40	Greater overall improvement of acne severity including significantly reduced comedone counts with SA	2b

gleins, leading to a loss of cohesion of epidermal cells and subsequent exfoliation [52–54]. In a study of the histologic changes in the skin of hairless mice following peeling with SA, Imayama et al. noted a loss of cornified cells with subsequent activation of epidermal basal cells and underlying fibroblasts without degenerative or inflammatory changes [53] (5). SA is lipid-soluble allowing for penetration of the pilosebaceous unit and a unique comedolytic property. As a lipophilic agent, it removes intercellular lipids covalently linked to the cornified envelope in the uppermost layer of the skin [55]. This property in addition to keratolytic and anti-inflammatory effects make SA well-suited to treat acne. Although less well studied, SA can also be used to treat melasma and photodamage. SA peels are commonly performed at a concentration of 20–30% although lower concentrations are available, particularly over-the-counter for home use [56, 57]. SA has been used in ethyl alcohol solutions and a newer formulation in polyethylene glycol [50, 52, 58]. Although the risk of salicylism is very low in the use of SA as a peeling agent, this new formulation is associated with minimal systemic absorption and is thought to further reduce this risk. Application of SA is associated with a mild to moderate stinging or burning sensation but is transient given an inherent anesthetic effect. Unlike AHAs, SA is a self-neutralizing acid [52].

More recently, beta-lipohydroxy acid (LHA), a lipophilic derivative of SA, has become another option for patients. With an additional fatty chain, LHA has greater lipophilicity and keratolytic effect than SA. It also has comedolytic, antimicrobial, and anti-inflammatory properties [7, 59]. LHA targets the corneosome/corneocyte interface leading to detachment of individual corneosomes and even exfoliation mirroring the natural turnover of skin cells. It is worth noting that this unique property differs from AHAs and SA which may cause only partial detachment and uneven exfoliation. LHA is used in 5% and 10% concentrations. It has a pH similar to normal skin and does not require neutralization [6, 7]. Although the literature on LHA is limited, its efficacy in the treatment of acne and photoaging has been demonstrated in small studies and often in concentrations and vehicles suited for frequent home use [4, 59, 60].

Photodamage and Disorders of Pigmentation

Salicylic acid (SA) may be used to treat a variety of dermatologic conditions including acne, post-inflammatory hyperpigmentation, photodamage, melasma, and fine rhytides (Table 20.5). A pilot study of the safety and efficacy of SA 20–30% peels in the treatment of acne, post-inflammatory hyperpigmentation, melasma, and textural changes in patients with Fitzpatrick type V and VI skin showed moderate (51–75% clearance) to significant (>75% clearance) improvement in 88% of patients. Patients applied hydroquinone 4% for 2 weeks prior to initiation of five salicylic acid peels [45] (4). A prospective, randomized, split-face controlled trial of SA 20–30% peels in the treatment of melasma failed to demonstrate a significant difference when SA was added to hydroquinone 4% [46] (1b). In a double blind, randomized interventional comparative study of JS with SA 30% peels for epidermal melasma, Ejaz et al. demonstrated a statistically significant decrease in MASI scores for both treatment groups, but no significant difference between the groups [47] (2b). And as shown by Joshi et al. in a prospective, randomized controlled, split-face study, SA 20–30% peels for treatment of post-inflammatory hyperpigmentation were rated as clinically effective by patients and approached but did not reach statistical significance according to blinded dermatologist evaluators [48] (1b). Kligman and Kligman described improved texture and a reduction of hyperpigmentation and fine rhytides following treatment with SA 30% peels [49] (4). Furthermore, a study evaluating the effects of SA 30% on tumor formation using hairless SKH/hr1 mice demonstrated a reduction of ultraviolet B-induced skin tumors [50] (5).

Acne

SA has anti-inflammatory, keratolytic, and comedolytic properties that make it a particularly useful treatment for acne. In a study of salicylic acid

30% peels for the treatment of acne in Fitzpatrick type III and IV skin, a decrease in both inflammatory and noninflammatory acne lesions was achieved. No post-procedure differences in stratum corneum hydration, skin surface lipid, skin pH, or transepidermal water loss were seen [61] (4). A subsequent study from the same institution showed a gradual but continual skin whitening effect and a statistically significant improvement in redness following the application of SA 30% peels to acne patients at 2-week intervals for 12 weeks [62] (4). Dainchi et al. demonstrated a reduction of comedones and inflammatory papules with SA 30% peels. Histopathology performed on mice showed early epidermal thinning and dissolution of cornified cells from hair follicles, while late change showed new, regularly arranged cells of the cornified layer [63] (4). As discussed above, Kessler et al. compared GA 30% and SA 30% peels for treatment of acne in a split-face, double-blind, randomized, controlled study and found the peels to be similarly effective [40]. SA peels were associated with a sustained reduction of acne lesions, hypothesized to be secondary to the lipophilicity of SA [40]. This lipophilicity is also responsible for the comedolytic property of SA, and in a study of SA in the treatment of comedonal acne, Hashimoto et al. demonstrated a significant reduction (mean 75%) in comedones [64] (4). This effect was further demonstrated by Bae et al. in a comparative study of SA 30% peels versus JS for acne. Both treatments reduced inflammatory acne lesions, but SA 30% peels were more effective for treating noninflammatory acne [65] (3b). And in a recent comparative study, SA 30% peels were more effective than JS in overall improvement of acne severity including significantly reduced comedone counts [66] (2b).

Jessner's Solution

Jessner's solution (JS) is composed of lactic acid 14%, salicylic acid 14%, and resorcinol 14% in ethyl alcohol. Despite keratolytic properties that have been recognized since the early twentieth century, there is a paucity of literature on its efficacy as a therapeutic agent. Thought to disrupt the epidermal barrier, it is often used to enhance the penetration of additional peeling agents such as trichloroacetic acid (TCA). When used as monotherapy, it has been shown to be effective for many hyperkeratotic skin conditions as well as for acne and melasma [39, 47, 67, 68]. As above, JS has shown equal efficacy to AHAs in the treatment of melasma [30, 47] and acne [39] (2b–3b). And when compared to SA, JS demon-

Table 20.5 Salicylic acid chemical peels in the treatment of photodamage and disorders of pigmentation

Reference	Study design	N	Clinical/histopathologic outcomes	Evidence level
Grimes et al. [45]	Case series; SA 20–30%	25	Moderate (51–75%) to significant (>75%) clearance in 88% of patients treated for acne, post-inflammatory hyperpigmentation, photodamage, melasma, and fine rhytides	4
Kodali et al. [46]	Randomized controlled; SA 20–30%	18	No significant difference when SA added to topical regimen for melasma	1b
Ejaz et al. [47]	Randomized comparative; SA 30% vs. JS	60	Statistically significant decrease in MASI score for both treatment groups, no statistically significant difference between treatment groups	2b
Joshi et al. [48]	Randomized controlled; SA 20–30%	10	Subjective improvement of post-inflammatory hyperpigmentation but not statistically significant when evaluated by blinded dermatologists	1b
Kligman and Kligman [49]	Case series; SA 30%	50	Improved skin texture and a reduction of hyperpigmentation and fine rhytides	4
Dainichi et al. [50]	Animal; SA 30%	10 (mice)	Reduction of UVB-induced skin tumors	5

strates similar effectiveness for treatment of inflammatory acne, but not noninflammatory acne [65, 66] (2b–3b).

Microdermabrasion

Developed in Italy in 1985, microdermabrasion (MDA) is an effective method of superficial skin resurfacing [69]. It is appealing to providers and patients given its safety and tolerability. No local anesthesia or preoperative medications are required, and post-procedure recovery is minimal. MDA has been classified by the US Food and Drug Administration as a Class 1 device (low risk) and is therefore subject to little regulatory control [70]. Many MDA units are closed-loop negative pressure systems that pass aluminum oxide microcrystals over the skin while simultaneously vacuuming used crystals and skin debris. Other microcrystals used include magnesium oxide, sodium bicarbonate, and sodium chloride. Some systems are crystal-free utilizing a handpiece with an abrasive diamond-studded tip [71, 72]. MDA has shown to be effective for treatment of photodamage, acne and post-procedure scars, striae distensae, and superficial rhytides [73]. The number of passes performed depends on desired effect and patient tolerability although typically a minimum of 2–3 passes is required [57, 73]. Mild to moderate erythema without significant abrasion, petechiae, or purpura is the desired post-procedure end point. As with superficial chemical peels, a series of treatments (usually four to eight) is recommended. Treatments may be performed weekly to every other week. Complications include petechiae or purpura and may be indicative of prolonged dwell time or excessive vacuum suction. This may also be seen in patients with severely photodamaged skin or on anti-coagulation. Treatment may induce or exacerbate erythema or telangiectasia, so it should be used with extreme caution or perhaps contraindicated in patients with rosacea [73].

Indications for treatment are varied and data on efficacy is limited for MDA but growing (Table 20.6). In an early study of microdermabrasion, Tsai et al. demonstrated good to excellent

Table 20.6 Microdermabrasion in the treatment of multiple cutaneous conditions

Reference	Study design	N	Clinical/histopathologic outcomes	Evidence level
Tsai et al. [74]	Case series	41	Good to excellent clinical improvement of scarring related to acne, surgery, burns, and varicella zoster infection	4
Shim et al. [73]	Case series	14	Statistically significant improvement in roughness/textural irregularities, mottled pigmentation, and complexion but not in rhytides, comedones, or milia Acute histopathology: Thinning of the stratum corneum with focal compaction and homogenization Chronic histopathology: Thickened epidermis, decreased melanization, increased elastin	4
Tan et. Al [75]	Case series	10	Mild improvement of photodamage Histopathology: Slight orthokeratosis and flattening of rete ridges; perivascular infiltrate, edema, and vascular ectasia	4
Lloyd et al. [76]	Case series	25	Good to excellent improvement of acne	4
Hernandez-Perez and Ibiett [77]	Case series	7	Improvement of skin, dilated pores, thick skin, and fine rhytides Histopathology: Increased epidermal thickness; decreased atrophy, horny plugs, and basal cell liquefaction; increased epidermal polarity Dermal changes included decreased elastosis, edema, telangiectasias, and inflammation	4
Coimbra et al. [78]	Case series	25	Improvement of hyperchromatic discoloration with subjective improvement of fine rhytides Histopathology: Increase in organized collagen and epidermal thickness	4

(continued)

Table 20.6 (continued)

Reference	Study design	N	Clinical/histopathologic outcomes	Evidence level
Bhalla and Thami [79]	Randomized comparative	30	Mild improvement in post-acne scarring, melasma, and facial rejuvenation	2b
El-Domyati et al. [80]	Case series	38	Majority of patients with mild to moderate clinical improvement in melasma, acne scars, and striae distensae; mild in photoaging Histopathology: Decreased melanization and regular distribution of melanosomes in the epidermis in the melasma treatment group; increased density of collagen fibers with more regular arrangement in collagen bundles in the melasma, acne scars, and striae distensae treatment groups	4
Abdel-Latif and Elbendary [81]	Controlled cohort	20	Good to excellent results (greater than 50% improvement of appearance) in 50% of the patients; more marked improvement was noted of striae rubra compared to striae alba Upregulation of type I procollagen mRNA expression was increased in treated skin	3b
Freedman et al. [82]	Case series	10	Histopathology: Epidermal and papillary dermal thickening, increased dermal inflammation, and increased collagen and elastic fibers	4
Hussein et al. [83]	Comparative cohort	45	Histopathology: Increases in epidermal thickness, fibroblast count, dermal vascular ectasia, patchy and perivascular inflammation, and densely arranged thick collagen fibers	3b
Karimipour et al. [84]	Case series	49	Elevation of transcription factors, primary cytokines, matrix metalloproteinases, type I procollagen mRNA and protein levels	4
Karimipour et al. [85]	Comparative cohort	10	Negative pressure: Increased gene expression of MMP-1 and MMP-3 Negative pressure + abrasion: Increased c-Jun component of activator protein-1, interleukin 1β, tumor necrosis factor-α, MMP-1, 3, 9	3b
Rajan and Grimes [86]	Comparative cohort	8	Aluminum oxide and sodium chloride MDA associated with a statistically significant initial increase in transepidermal water loss followed by return to less than baseline at day 7 Statistically significant increase in stratum corneum hydration observed at day 7 with sodium chloride MDA, similar trend with aluminum oxide MDA	3b

clinical improvement of scarring related to acne, surgery, burns, and varicella zoster infection. A pressure between 1 and 4 bar (76 mmHg) was used and multiple treatments (mean 9.1) were required for the 41 patients studied, highlighting the need for more aggressive MDA in the treatment of acne scars in particular (mean treatments 15.19) [74] (4). Further supporting the possible benefit of more aggressive treatment, Alam et al. compared low-intensity glycolic acid peels to low-intensity MDA for facial skin rejuvenation and found no significant clinical improvement from baseline with either treatment (Table 20.1) [28] (2b). A study looking at the clinical improvement of photoaging by patient assessment following MDA every 2 weeks for a total of six to seven treatments over 12–14 weeks showed statistically significant improvement in roughness/textural irregularities, mottled pigmentation, and complexion, but not in rhytides, comedones, or milia. And consistent with previous studies, acne scarring did occasionally improve but required deeper ablation [73] (4). Tan et al. also evaluated the effect of MDA on photodamaged skin. Of nine patients that completed at least five weekly treatments, five patients had mild (1–25%) improvement and one patient had moderate (26–75%) improvement as determined by physician review of post-treatment photographs. Skin thermography showed increased skin temperature, consistent with increased blood flow, while transient decreases in surface sebum post-procedure were also noted. Analysis of cheek skin demon-

strated a statistically significant decrease in skin stiffness and an increase in skin compliance [75] (4). A pilot study on the use of MDA for grade II-III acne in 24 patients demonstrated excellent results in 9 patients, good results in 8 patients, fair results in 4 patients, and poor results in 3 patients. Notably, 23 of 24 patients were happy with their results [76] (4). MDA has also been reported to improve oily skin, dilated pores, thick skin, and fine rhytides [77] (III/B). Using blinded observers (plastic surgeons and laypersons), Coimbra et al. demonstrated subjective improvement in hyperchromatic discoloration (both groups) and fine rhytides (laypersons only) after patients had received eight MDA treatments at 1-week intervals [78] (IV/B). A study of MDA in post-acne scarring, melasma, and facial rejuvenation demonstrated mild improvement that increased when used with a topical retinoid [79] (II/A). And in a recent study by El-Domyati et al., 38 patients with melasma, acne scars, striae distensae, or photoaging were treated with eight microdermabrasion treatments performed at 1-week intervals. A majority of patients had mild to moderate clinical improvement in melasma, acne scars, and striae distensae, while mild improvement was most common in photoaging. Histopathology demonstrated decreased melanization and regular distribution of melanosomes in the epidermis in the melasma treatment group and an increased density of collagen fibers with more regular arrangement in collagen bundles in the melasma, acne scars, and striae distensae treatment groups [80] (III/B). In a clinical and molecular study of MDA on striae distensae in 20 patients receiving five MDA treatments at weekly intervals to one side of the body with the other side of the body used as a matched control, good to excellent results (greater than 50% improvement of appearance) were achieved in 10 patients, with mild to moderate results (up to 50% improvement of appearance) in the remaining 10 patients. More marked improvement was noted of striae rubra compared to striae alba. Using real-time reverse transcriptional polymerase chain reaction for assay in patient biopsies, upregulation of type I procollagen mRNA expression was increased in treated skin [81] (III/B). The effectiveness of MDA in treating disorders of collagen appears to be proportional to the overall aggressiveness of the treatments including level of ablation and total number of treatments [73, 74]. The histopathologic changes in the skin following MDA have been studied in an effort to better understand the mechanism behind improvement of disorders of collagen. Shim et al. found that acute histopathologic change included thinning of the stratum corneum with focal compaction and homogenization. The chronic effects of MDA treatment included a thickened epidermis without a change in the stratum corneum from baseline, a more regular distribution of melanosomes and decreased melanization, and increased elastin. Papillary mucin and collagen content were not consistently elevated [73] (III/B). Hernandez-Perez et al. evaluated atrophy, horny plugs, loss of polarity, and basal cell liquefaction of the epidermis after five weekly MDA treatments and saw microscopic improvement in all parameters. The most marked change was in epidermal thickness with statistically significant post-treatment changes ranging from 0.01 mm to 0.1 mm. Dermal changes included decreased elastosis, edema, telangiectasias, and inflammation [77] (4). Another study found epidermal and papillary dermal thickening, increased dermal inflammation, and increased collagen and elastic fibers [82] (4). It has been noted that the inflammation seen after repetitive epidermal and dermal injury following a series of MDA treatments resembles a reparative process with increases in fibroblasts and collagen and is ultimately responsible for the clinical effects of MDA [77, 83]. Coimbra et al. also demonstrated an increase in organized collagen and epidermal thickness [78] (4). An immunohistological and ultrastructural study confirmed increases in epidermal thickness, fibroblast count, dermal vascular ectasia, patchy and perivascular inflammation, and densely arranged thick collagen fibers [83] (3b). Karimipour et al. examined the molecular effects of a single MDA treatment in 49 patients. Elevation of transcription factors, primary cytokines, matrix metalloproteinases, type I procollagen mRNA, and protein levels was noted.[84] (4). A subsequent study concluded that abrasion is required for stimulating the expression of genes involved in dermal remodeling [85] (3b). Rajan

and Grimes evaluated skin barrier changes following MDA in a split-face study of aluminum oxide and sodium chloride MDA. Both treatments were associated with a statistically significant initial increase in transepidermal water loss followed by return to less than baseline at day 7. A statistically significant increase in stratum corneum hydration was seen with sodium chloride MDA at day 7. The authors note that these findings suggest enhanced lipid barrier function and are likely responsible for improved clinical appearance following MDA [86] (3b). This barrier disruption also increases skin permeability and can serve to enhance transdermal drug delivery [87, 88].

The risks associated with MDA are limited. Mild abrasion and petechiae may occur. Scarring may be possible with aggressive treatment but has not been reported. Post-treatment pigmentary aberrations are rare, but MDA should be used cautiously in darker Fitzpatrick skin types. Ocular complications can be seen in crystal-based systems. Infections, including reactivation of herpes simplex virus can occur [79, 89].

Conclusion

Superficial chemical peels and microdermabrasion have proven to be safe and efficacious for many skin disorders. Often best performed in a series, they are an acceptable alternative to more aggressive procedures for patients seeking mild to moderate results, limited downtime, and with a willingness to undergo a series of treatments with diligent pre- and post-treatment regimens. These procedures have the added benefit of safety for patients with darker Fitzpatrick types. Serving to enhance the effects of other therapies, they play an important role in the armamentarium available to clinicians.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE
Commonly used nonlaser superficial resurfacing procedures include chemical peels (alpha hydroxy acids, salicylic acid, Jessner's solution) and microdermabrasion	N/A
Alpha hydroxy acids are effective in disorders of keratinization and photodamage	B
Alpha hydroxy acids are effective in the treatment of melasma, particularly as an adjunct to topical therapy	B
Alpha hydroxy acids are effective in the treatment of acne and its sequalae	B
Alpha hydroxy acids induce histopathologic changes including thinning of the stratum corneum and thickening of the epidermis	B
Salicylic acid is effective in the treatment of acne	B
Salicylic acid is effective in the treatment of photodamage and pigmentary changes	B
Salicylic acid has been shown to induce the following histopathologic changes: loss of cornified cells and cornified material within hair follicles, activation of epidermal basal cells and underlying fibroblasts without degenerative or inflammatory changes	D
Microdermabrasion has shown efficacy in the treatment of photodamage, acne, acne scarring, melasma, and striae distensae	B
Microdermabrasion has been shown to induce the following histopathologic changes of the epidermis: increased epidermal thickness, a more regular distribution of melanosomes and decreased melanization, decreased basal cell liquefaction, normalization of epidermal polarity	C
Microdermabrasion has been shown to induce the following histopathologic changes of the dermis: papillary dermal thickening, increased collagen and elastic fibers, decreased elastosis	C
Microdermabrasion has been shown to activate a dermal remodeling cascade including cytokines, transcription factors, and matrix metalloproteinases.	C
Microdermabrasion has been shown to decrease transepidermal water loss and increase stratum corneum hydration	C

Self-Assessment Questions

1. Which of the following is NOT a superficial resurfacing technique?
   (a) Jessner's solution
   (b) Jessner's-trichloroacetic acid peel
   (c) Salicylic acid peel
   (d) Glycolic acid peel
   (e) Microdermabrasion
2. Alpha hydroxy acids are effective in the treatment of which of the following?
   (a) Disorders of keratinization
   (b) Acne
   (c) Melasma
   (d) Photodamage
   (e) All of the above
3. Salicylic acid is a particularly effective treatment for acne due to which properties?
   (a) Anti-inflammatory
   (b) Keratolytic
   (c) Lipophilic/comedolytic
   (d) b and c
   (e) All of the above
4. Jessner's solution contains all of the following EXCEPT:
   (a) Glycolic acid
   (b) Resorcinol
   (c) Ethanol
   (d) Salicylic acid
   (e) Lactic acid
5. Which of the following is TRUE regarding microdermabrasion?
   (a) Microcrystals passed over the skin include aluminum oxide, magnesium oxide, sodium bicarbonate, and sodium chloride
   (b) Classified by the US Food and Drug Administration as a Class 1 device (low risk) and is therefore subject to little regulatory control
   (c) Induces epidermal and papillary dermal thickening on histopathology
   (d) Has shown efficacy in the treatment of photodamage, acne, acne scarring, melasma, and striae distensae
   (e) All of the above

Correct Answers

1. b: Jessner's-trichloroacetic acid peel. The Jessner's + trichloroacetic acid (35%) peel is a medium-depth peel (destruction of the epidermis and a portion of or the entire papillary dermis) used for treatment of photodamage, rhytides, and actinic keratoses. Superficial chemical peels primarily affect the epidermis and include alpha hydroxy acids (AHAs), salicylic acid (SA), and Jessner's solution.
2. e: All of the above. Alpha hydroxy acid chemical peels may be an effective treatment for disorders of keratinization, acne, melisma, and photodamage.
3. e: All of the above. Salicylic acid has anti-inflammatory, keratolytic, and comedolytic properties that make it a particularly useful treatment for acne.
4. a: Glycolic acid. Jessner's solution (JS) is composed of lactic acid 14%, salicylic acid 14%, and resorcinol 14% in ethyl alcohol.
5. e: All of the above. All statements are true. Microdermabrasion is an effective method of superficial skin resurfacing and has shown to be effective for treatment of photodamage, acne and post-procedure scars, striae distensae, and superficial rhytides.

Dermabrasion

Ramona Behshad

Abstract

Dermabrasion (DA) has been in the dermatology armamentarium since the early 1900s with both aesthetic and therapeutic indications. DA physically removes the superficial skin layers in a stepwise fashion and allows healing to occur with a more cosmetically acceptable result. There are a variety of abrasive instruments available to perform DA. Mechanical DA uses a rotating diamond fraise or wire brush attached to a motorized hand piece to abrade the epidermis and papillary and/or reticular dermis. The wire brush has numerous small caliber, stainless steel wires that project circumferentially from the curved side of a cylindrical hub, while the diamond fraise consists of a stainless steel cylinder to which industrial-grade diamonds are bonded to create the abrasive surface. Selection of an appropriate end piece for use in the handheld rotary motor is up to the preference of the surgeon, but there has been a slow movement toward the diamond fraise because it is less aggressive and more forgiving than the wire brush (Alt, J Dermatol Surg Oncol 13:618–624, 1987). An alternative to mechanical DA is manual DA, which is performed in an analogous fashion by hand with a variety of coarse surfaces such as sandpaper, drywall screen, electrocautery tip cleaners, the diamond fraise unattached to the electric motor, abrasive pads, tangential planning or scalpel sculpting with a standard #15 surgical blade or razor blade, as well as the standard curette. Regardless of motorized or manual DA selected, depth of injury is controlled by the amount of pressure holding the instrument tip against the skin, the speed of rotation/abrasion, the coarseness of the tip chosen, and the patient's skin type and texture (Orentreich and Orentreich, Dermatol Clin 13:313–327, 1995). The operator has excellent control of the anatomic depth of tissue removed, since the depth of tissue can be visualized sequentially from epidermis and the papillary, superficial, and deep reticular dermis.

stepwise fashion and allows healing to occur with a more cosmetically acceptable result. There are a variety of abrasive instruments available to perform DA. Mechanical DA uses a rotating diamond fraise or wire brush attached to a motorized hand piece to abrade the epidermis and papillary and/or reticular dermis. The wire brush has numerous small caliber, stainless steel wires that project circumferentially from the curved side of a cylindrical hub, while the diamond fraise consists of a stainless steel cylinder to which industrial-grade diamonds are bonded to create the abrasive surface. Selection of an appropriate end piece for use in the handheld rotary motor is up to the preference of the surgeon, but there has been a slow movement toward the diamond fraise because it is less aggressive and more forgiving than the wire brush [1]. An alternative to mechanical DA is manual DA, which is performed in an analogous fashion by hand with a variety of coarse surfaces such as sandpaper, drywall screen, electrocautery tip cleaners, the diamond fraise unattached to the electric motor, abrasive pads, tangential planning or scalpel sculpting with a standard #15 surgical blade or razor blade, as well as the standard curette. Regardless of motorized or manual DA selected, depth of injury is controlled by the amount of pressure holding the instrument tip against the skin, the speed of rotation/abrasion, the coarseness of the tip chosen, and the patient's skin type and texture [2]. The operator has excellent control of the anatomic depth of tissue removed, since the depth of tissue can be visualized sequentially from epidermis and the papillary, superficial, and deep reticular dermis.

Molecular Mechanisms

The ultrastructural and molecular alterations that accompany the clinically visible changes apparent in dermabraded skin have been investigated. Harmon et al. performed an ultrastructural evaluation of scars resulting from a primary closure and those who underwent primary closure with diamond fraise DA 6–8 weeks later [3]. Serial punch biopsies showed organized, unidirectional collagen fiber orientation parallel to the epidermal surface in the DA specimens, whereas the control specimens were found to have sparser and less well-organized collagen fiber orientation. They also observed that DA alters cell–cell and cell–matrix interactions between the epidermis and the dermis by up-regulation of tenascin (an extracellular matrix glycoprotein) expression throughout the papillary dermis, which may promote both epithelial cell migration and fibroblast movement, and of α6 β4 integrin subunit (a transmembrane adhesion receptor) on the keratinocytes throughout the stratum spinosum, which may coincide with an increase in cell migration and may promote re-epithelialization across the scar. Yarborough proposed that DA created a reorientation of collagen fibers parallel to the lines of wound tension, which may account for some of the scar contour smoothing effects noted after the procedure [4]. Similar changes have been seen in photoaging and rhytids. Nelson et al. looked at patients with photoaging who underwent motorized DA before and after treatment [5]. At 12 weeks, when compared to baseline, they showed significant increases in collagen and a sixfold increase in procollagen I mRNA in papillary dermal fibroblasts.

There is a great deal of literature regarding the utility of DA in dermatology, but the bulk of the literature consists of personal experiences, case studies, cohort studies, and randomized controlled trials of varying quality. The fact remains that variable results will always occur when a technically demanding procedure is performed by operators with various levels of skill. This chapter will present the published literature on DA and when available, the level and method of DA is included. To determine whether the evidence is applicable to a specific patient requires physician expertise, an understanding of the patient's preferences, and consideration of the availability, risks, and benefits of the intervention.

Indications for Dermabrasion

DA is most commonly used to improve the appearance of acne scars, but many physicians have successfully used DA to treat skin diseases which previously had no known treatment or as an adjunct in the treatment of dermatologic disorders. Case reports document response to hypertrophic and traumatic scars, actinically damaged and wrinkled skin, pigmentary abnormalities, tattoo removal, adnexal tumors, and Darier's disease, among others. A list of these case studies has been summarized in Table 21.1. A review of these cases, in addition to the literature presented in this chapter, demonstrates that DA has been successfully used in all patient

Table 21.1 Case studies on dermabrasion

Reference	Condition treated	Patient(s) characteristics	Follow-up	Outcomes/comments	Side effects
Agrawal et al. 1995 [6]	Vitiligo	21 patients (10–33 years) with 32 stable vitiligo patches (neck, abdomen, chest, lower limb, upper limb, face)	1–6 years, with 3 patients lost to follow-up	Dermabrasion with thin STSG (0.025–0.03 mm thick) from the posterior arm, posterior thighs, and gluteal region; 100% repigmentation was seen in 27 patches and 90–95% in 10 patches. Time to satisfactory color match was 4–9 months (average 6.3 months)	5 cases of donor site pain, 6 cases of milia at the recipient site, 3 cases of overhanging margin due to the thicker graft, and 2 cases of irregularity over the surface of the graft
Agrawal et al. 1992 [7]	Xeroderma pigmentosum	3 patients (10–22 years, 2 females and 1 male) with xeroderma pigmentosum	18–24 months	Dermabraded areas tumor-free at follow-up	None
Bergfeld et al. 1970 [8]	Granuloma faciale	1 patient (31-year-old African American lady)	6 months	Lesions on malar cheek with sustained flattening, lesions on nose with poor response	None
Clabaugh et al. 1975 [9]	Tattoos	250 patients	Up to 5 years	85% good-to-excellent results, 10% fair results, and 5% poor results	Hyperpigmentation, atrophy, hypopigmentation, hypertrophic scarring in 4 cases
Coleman et al. 1996 [10]	Actinic keratoses	23 patients (33–76 years)	At least from 2 years up to 10 years	96% of patients remained free of new actinic keratoses for 1 year, 83% remained free for 2 years, 70% remained free for 3 years, 64% remained free for 4 years, and 54% remained free for 5 years	None
Diven et al. 1990 [11]	Exogenous ochronosis	53-year-old African American lady	Not mentioned	Improved color and surface contour	None
Drake et al. 1992 [12]	Facial angiofibromas	24-year-old woman	6 months	Cosmetic improvement; no hemorrhage	None

(continued)

Table 21.1 (continued)

Reference	Condition treated	Patient(s) characteristics	Follow-up	Outcomes/comments	Side effects
Dufresne et al. 2008 [13]	Actinic cheilitis	4 patients after Mohs for SCC of the lower lip with intraoperative DA	6 months	No recurrence of SCC or actinic cheilitis	One patient had a small vertical scar
Earhart et al. 1976 [14]	Adenoma sebaceum	15-year-old white girl and 15 –year-old white male	2–4 years	Excellent cosmetic improvement with flattening of lesions and obliteration of telangiectasias	None
Emsen et al. 2007 [15]	Acne scars and burn scars	15 patients with mature acne (8 men and 1 women; average 20.5 years) and acute burn scars (5 men and 1 women; average age 25.5 years) on the head and neck	Not stated	Physician and patients retrospectively rated outcomes after a single treatment as good, very good, and excellent	None
Emsen et al. 2008 [16]	Scars, tattoo	40 patients for burn scars (15 patients), depressed scars (6), acne scars (2), hypertrophic scars (3), trap door scars (9), cellulite (2), periorbital wrinkles (2), and a tattoo (1)	10 months to 6 years	Improvement was seen in 80% of patients at 10-month follow-up (95% CI 60–100%). Ten patients felt that the untreated side looked better	4 patients developed infections that were controlled with antibiotics
English et al. 1971 [17]	Favre-Racouchot syndrome	51-year-old white man	1 month	Dermabrasion with extraction of some cysts during procedure; excellent cosmetic result	None
Epstein et al. 1956 [18]	Actinic keratoses	57-year-old women, 44-year-old white man, 38-year-old white man	N/A	Removal of actinic keratoses in 1 patient on hand, unsuccessful in 1 patient on nose, improvement in number of keratoses posttreatment on lower lip of 1 patient	None

Table 21.1 (continued)

Reference	Condition treated	Patient(s) characteristics	Follow-up	Outcomes/comments	Side effects
Epstein et al. 1966 [19]	Actinic keratosis, leukoplakia, radiodermatitis	10 patients	10 years	4 patients with no recurrences (3 actinic keratoses patients and one leukoplakia patient), 4 cases with recurrences but benefit (one radiodermatitis patient, 2 leukoplakia patients, 1 actinic keratoses patient); 2 patients with fairly early recurrence and/or the development of malignant neoplasia (1 radiodermatitis patient, 1 actinic keratosis patient)	None
Fischer et al. 2001 [20]	Facial angiofibromas	37-year-old African American man	6 months	Shave excision followed by two DA treatments to papillary dermis; smoothing of skin with good cosmetic outcome	No hypopigmentation; no regrowth at follow-up
Fowler et al. 1985 [21]	Non-X histiocytosis on face	22–year-old male	18 months	Excellent cosmetic results with resolution of histiocytic infiltrate on biopsy	None
Fulton et al. 1987 [22]	Osteoma cutis secondary to acne	3 patients (23–48-year white females)	2 months	Dermabrasion followed by punch excision; marked cosmetic improvement	1 keloid that resolved with flurandrenolide tape
Gold et al. 1987 [23]	Hypertrophic psoriasis	65-year-old white male	8 weeks+	8-week clearance possibly due to a temporary reverse Koebner phenomenon; disease recurred shortly thereafter	None
Hamm et al. et al. 1994 [24]	Hailey-Hailey disease	10 patients (36–57 years)	3–79 months (median 42 months)	Treated areas were disease-free, except for major recurrences in 4 sites and minor recurrences in 4 sites; areas were retreated without relapse; punch biopsies up to 59 months later showed no histologic abnormalities beyond scarring	Hypertrophic scarring in 6 patients; 2 patients with hypopigmentation
Hanke et al. 1987 [25]	Multiple facial neurofibromas	3 patients (33–46-year-old women)	5–6 years (one patient lost to follow-up)	Considerable smoothing of the skin for all patients; one patient with moderate recurrence of neurofibromas at 5 years although still more improved than baseline	One patient had postoperative erythema that resolved after 4 months

Table 21.1 (continued)

Reference	Condition treated	Patient(s) characteristics	Follow-up	Outcomes/comments	Side effects
Iverson et al. 1947 [26]	Traumatic tattoos	5 photographic cases	5 weeks	Avoidance of disfigurement and surgical repair	Scarring, including hypertrophic scarring; 8–10 weeks of erythema
Kahn et al. 1995 [27]	Vitiligo	1 patient (35 years old Caucasian man)	14 weeks	Dermabrasion prior to epithelial sheet grafting from thighs; 95% of the operative areas had regained pigmentation	None
Kaufman et al. 1987 [28]	Scleromyxedema	1 patient	4 months	Smoother skin noted	None
Kishi et al. 2007 [29]	Congenital melanocytic nevi	23 patients (from 1 month to 19 years)	At least 3 years	Curettage followed by dermabrasion; 2 patients had recurrence after 1 month thought to be due to extension of nevoid cells around and within hair follicles, sebaceous glands and eccrine apparatus	None
Konrad et al. 2001 [30]	Hailey-Hailey disease	62-year-old lady	12 months	Area pretreated with botulinum toxin A before dermabrasion; remission of disease	None
Lapins 1983 [31]	Telangiectasia on nose	46-year-old white lady	6 months	Good ablation of vessels	None
Lien et al. 1997 [32]	Nodular amyloidosis	1 patient (45-year-old male)	26 months	No recurrence	None
Manchada et al. 1967 [33]	Small pox scar	60 patients (11–40 years)	4 months–4 years	Superficial and discrete scars became fairly imperceptible, moderate scars improved 30–40%, deep scars demonstrated temporary benefit	Hyperpigmentation in 6 patients
Menon 1982 [34]	Facial angiofibromas	17-year-old girl	2 weeks	Considerable flattening and cosmetic improvement	None
Niechajev et al. 1992 [35]	Perioral wrinkles	54 patients (27–73-year-old women)	1–5 years	A long-standing improvement in superficial and deep wrinkles was obtained, and there was only a slight improvement to the nasolabial fold	Permanent hypopigmentation was seen in 67% of patients that was easily coverable with makeup; milia
Notaro 1983 [36]	Traumatic tattoo	1 patient (21-year-old white male)	2 weeks	Acceptable cosmetic results	Mild residual erythema at 2 weeks
O'Neill et al. 2011 [37]	Large congenital melanocytic nevus on the face	4-week-only infant	5 months	Mechanical dermabrasion combined with autologous cell suspension (ReCell®); improved skin texture and normalization of skin color	None

Table 21.1 (continued)

Reference	Condition treated	Patient(s) characteristics	Follow-up	Outcomes/comments	Side effects
Olson 1960 [38]	Psoriasis	17 patients	10 weeks	Patients pleased	2 patients discontinued treatment due to oozing
Olsson et al. 1995 [39]	Vitiligo	100 patients (60 women and 40 men) aged 12–68	5–8 months	90–100% repigmentation were seen in 40 patients, 65–94% in 32 patients, 20–64% in 22 patients, and 0–19% in 6 patients. At 1-year f/u in 50 patients and 2 years in 10 patients, all the repigmented areas seen at the 6-month examination remained pigment	Hypopigmentation around the periphery of the graft
Pepper E et al. 1985 [40]	Giant seborrheic keratosis	71-year-old white male	2 weeks	No recurrence	Mild hypertrophic scarring
Roenigk et al. 1977 [41]	Nevus angiomatosus	1 patient (28 years)	Not provided	Good result	None
	Trichoepithelioma	2 patients (28–42 years)	From 1 month to 3 years	Partial recurrence at 3 years; no recurrence in 1 patient at 1 month	Hypopigmentation that resolved after 3–4 months in a black patient
	Syringoma	1 patient (25-year-old black lady)	6 months	Partial recurrence at 6 months	None
	Adenoma sebaceum	3 patients	3 years	Good cosmetic outcome	None
	Recurrent BCC	1 patient (42-year-old lady)	1 year	No recurrence	None
	Decorative tattoo	1 patient	N/A	Good clearance	None
	Traumatic tattoo	1 patient (28-year-old male)	N/A	Complete clearance	None
	Keloid scar	21-year-old lady	N/A	Significant improvement	None
	Discoid lupus erythematosus	N/A	N/A	Improvement in scarring but not in pigment	Flare of disease
	Darier's disease	N/A	N/A	Good improvement in dermabraded areas	None
	Epidermal nevus	3 patients (8–21 years)	From 6 months to 1 year follow-up	No recurrence in 2 patients; 1 partial recurrence at 6 months	Temporary hyperpigmentation that resolved after 3 months in an Indian patient

Table 21.1 (continued)

Reference	Condition treated	Patient(s) characteristics	Follow-up	Outcomes/comments	Side effects
Rompel et al. 1997 [42]	Congenital nevocellular nevi	215 patients	Median 24 months	Good reduction in pigment in 33.8% and satisfactory removal in 29.7%; improvement showed a significant dependence of the size of the congenital nevus ($p < 0.0001$) and the age at the time of DA ($p < 0.001$) with best results in large nevi treated during newborn age	Hypertrophic scarring in 14.6%, fever without infection in 10.5%, hemoglobin decreased in 2.7%, wound infection in 5.9%, postoperative bleeding in 0.5%
Spencer et al. 1992 [43]	Porokeratosis of Mibelli	79-year-old Pilipino lady	15 months	No evidence of recurrence	Hypertrophic scar that resolved with 20 mg/ml triamcinolone injection
van Lynden-van Nes 2005 [44]	Milia en plaque	60-year-old white lady	9 months	Complete resolution with additional improvement in telangiectasias	None
Vukas 1974 [45]	Small pox scars	3 patients et al. 19–56 (2 women, 1 man)	N/A	Improvement in 2 patients; no change in 1 patient	None
Wee et al. et al. 1990 [46]	Hypertrophic flap (nasalis myocutaneous island flap)	19 patients (11 women, 8 men; 30–76 years)	1 month to 2.5 years	Selected patients, including those younger than 40 years, had scars greatly improved by early dermabrasion 6–8 weeks following surgery	None
Wong et al. et al. 1982 [47]	Lichen amyloidosus	7 patients (7 men, 48–61 years)	5–7 years	Itching disappeared in all cases with satisfactory clinical results with resolution of hyperkeratosis; 3 patients had follow-up biopsies at 3 years with one showing no amyloid and two showing markedly reduced amyloid	Mild hyperpigmentation; infection in one patient that healed with hypertrophic scarring

Table 21.1 (continued)

Reference	Condition treated	Patient(s) characteristics	Follow-up	Outcomes/comments	Side effects
Zachariae et al. et al. 1993 [48]	Vitiligo	3 female patients (12–60 years)	1–3 years	Dermabrasion with epithelial suction blister grafts (3 patients) and autologous cultured melanocytes (1 patient, who had both procedures separately); 1 patient with repigmentation after sheet grafting who later underwent cultured melanocyte transfer with treated areas stable for 1–3 years; 2 patients with incomplete and uneven pigmentation with epidermal grafting alone	Donor sites with slight hyperpigmentation

demographics. Those with dark complexions, however, may experience pigment issues post-treatment that require additional counseling. Yarborough has shown that all skin types can be dermabraded with reasonably predictable pigmentary response with procedure-related dyschromia resolving within 3–4 weeks [49]. Orentreich, in a description of his own experience with DA, reiterates that black patients fare extremely well with DA but Asiatic skin is extremely reactive [2]. Aggressive therapy is associated with a higher complication rate such as hypopigmentation and scarring, and it is best to advise multiple DAs or ancillary techniques such as punch grafting or excisional techniques in patients with darker Fitzpatrick skin types (III–VI). Although a favorable test spot result does not guarantee a positive outcome following DA, an unfavorable test spot result is useful in identifying patients at risk for such complications [50].

Effectiveness of Dermabrasion

The indications for DA include those lesions or skin defects of the epidermis, papillary dermis, and upper reticular dermis that can be partially or completely removed by resurfacing to the level of the reticular dermis. Acne scars, surgical scars, striae, actinic keratosis, and photodamage have all been investigated.

Acne Scars

DA has been particularly successful in treating superficial atrophic acne scars, such as rolling or

boxcar scars [51] (IIB). In a study of 25 patients aged 20–42 years (23 were Fitzpatrick skin types I–III, 2 were Fitzpatrick skin type IV; 18 females and 7 males) treated with diamond fraise DA evaluated with flash photography, case impressions with computer analysis of surface irregularities, and scar counting, there was a statistically significant reduction in the number of superficial scars, but not deep scars, after 1 year ($p < 0.05$). The results were rated by two independent clinicians. This suggests that deeper, ice pick scars are too deep to be effectively treated by DA. Computer analysis showed smoothing in approximately 50% of patients. On the patient satisfaction survey, 21 were satisfied or content, while 4 were unsatisfied. These results are lower than other published studies and may underestimate the true improvement seen with DA given the dry wound care allowing eschars to form, which is contrary to the moist wound care practices of today.

Surgical Scars

DA has been shown to improve the appearance of elevated full-thickness skin grafts [52] (IIB). Two hundred consecutive Mohs surgery patients repaired with a full-thickness skin graft on the nose (105 patients), periorbital skin (57), lips (5), and chin (3) were included in the study. All patients were followed up for 2 years, and eight patients were subsequently excluded because their graft size was too small (lip and chin grafts). The remaining 192 patients were followed up at 6–8 months and sequentially assigned to DA (diamond fraise, endpoint papillary dermis) or to sun protection over a 3-year period. The method of group assignment was not clear. Photographs were taken up to 24 months after grafting, and clinical assessment was made in a blinded fashion. The control group experienced most improvement by 6 months, although 27% continued to improve between 6 and 18 months. The authors suggested cautious waiting for at least 6 months before correcting a graft, given the spontaneous improvement without treatment during this time. Grafts that were depressed at 6 months remained depressed regardless of treatment, suggesting DA is not the treatment for these grafts. The greatest objective improvement is obtained by DA when the grafted skin border is elevated above the surrounding skin. Similar grafts in age-matched control subjects did not spontaneously flatten to the same extent. When taking all grafts in all locations, there was no statistical difference in clinical assessment between the control group and treated group (50% vs. 60%, $p > 0.2$). A patient questionnaire after 18 months that showed fewer patients in the DA group believed they were greatly improved when compared to the control group (40% vs. 12%, $p < 0.001$), possibly due to unmet expectations from treatment.

Manual DA has also been evaluated in improving surgical scars. In a prospective, randomized, split-scar model, facial surgical scars were evaluated in 15 patients after manual DA using sterile 200 grit sandpaper (endpoint pinpoint bleeding) [53] (IIB). Patients who had undergone a surgical procedure on the face within 8 weeks prior to enrollment were enrolled in this prospective study. Follow-up visits were scheduled at 1 month, 3 months, and at least 6 months after treatment when two blinded reviewers evaluated the appearance of the halves. There was 100% follow-up at 6 months, with improvement in the treated half of the scar seen in 12 of 15 (80%) scars (95% CI, 60–100%). Three scars were graded to have a better clinical appearance on the untreated side, which the authors attributed to baseline asymmetries in the scars. A patient questionnaire was distributed and showed that 73% of patients indicated that they would have the procedure again, with the treated side having a better overall appearance.

Striae

Striae rubra may respond to superficial DA based on limited evidence. A randomized, open-label, single-center study of 32 young women (11–24 years) with narrow, early striae rubra (≤6 months old) on the trunk and thighs compared the efficacy of 16 weekly sessions of superficial DA (endpoint no bleeding or pain) to daily application of topical tretinoin 0.05% cream for

16 weeks [54] (IIB). Treatment groups were well matched. Striae length and width were measured and compared between groups for up to 16 weeks with photographs and assessment for side effects. The Global Aesthetic Improvement Scale scores and patient satisfaction scores were also assessed. Three DA patients (one lost to follow-up, one withdrawal of consent, one due to weight gain) and seven tretinoin patients did not complete the study (three due to irritant dermatitis, three withdrawal of consent, and one loss to follow-up). Both treatments demonstrated significant improvement of early striae rubra from baseline, and there was no significant difference in efficacy between the two treatment groups in striae measures (length and width), the Global Aesthetic Improvement Scale, or in subject satisfaction. Adverse events included pruritus, erythema, burning sensation, scaling, crusts, pain and swelling, and papules, although there were no statistically significant differences ($p > 0.05$) between the two treatment groups. All patients were either satisfied or indifferent. Nine patients agreed to biopsy, with eight from the DA group and one from the tretinoin group. No histologic changes were seen in the only tretinoin patient, while the superficial DA group had a reduction in elastolysis, collagen fragmentation, and epidermal atrophy and with collagen formation after treatment.

Actinic Keratoses/Photodamage

Another frequent indications for DA besides acne scarring has been the treatment of actinic keratosis and photodamage. Many of these studies were carried out by the pioneers of DA, and much of the original work is retrospective, nonrandomized, and suffers from selection bias.

Burks et al. completed hemifacial DA (wire brush) on 22 patients (39–77 years) with diffuse photodamage. Only 15 patients were available for review given the high mortality rate in the study population and the patient's request for DA of the untreated side, which disqualified them from the study [55] (IV). He found decreased cancerous and precancerous lesions in two thirds of patients on the treated side that persisted for up to 5 years. Ninety-two percent of observers agreed that the treated side appeared therapeutically improved. Although not the primary objective, cosmetic improvement was also noted by 85% of raters. These subjective changes were supported histologically, with easily identifiable changes between the treated and untreated sides, including the replacement of elastotic material with newly formed collagen. This improvement seems to be achieved when abrasion is carried deep enough to remove and regenerate the epidermal papillary dermal unit even if residual elastotic collagen is left below.

Benedetto et al. prospectively followed up 12 patients with photoaging after full-face wire brush DA with biopsy specimens and clinical exam for various time intervals from 6 months up to 8 years after DA [56] (IIB). All patients had actinic keratoses that were treated regularly prior to DA, and five patients had nonmelanoma skin cancer that was treated prior to DA. Posttreatment, only two patients had one treatment session for actinic keratoses that occurred approximately 4 years later, with no further occurrences for at least 7.5 years. Of the 12 patients in the study, 10 patients had pre-procedure biopsy tissue available for comparison. There was normalization of epidermal morphology demonstrated by lack of dyskeratotic cells and return of rete ridges. In the dermis, there was a widening of the papillary dermal grenz zone with increased collagen bundles and collagen bundle thickness that were more parallel to the skin surface. All patients had repigmentation of their skin to its pre-DA color or only slightly lighter when compared with the adjacent untreated skin.

Spira et al. compared chemical peeling with Baker Gordon peel, DA, and 1% 5-fluorouracil cream twice daily for 3–6 weeks in treating actinic keratosis [57] (IV). Seven patients received phenol solution occluded for 48 h on the entire face or on half the face while the other half was dermabraded, 7 patients received DA (serrated steel wheel to reticular dermis), 1 patient received split-face DA and chemical peeling, and 20 patients received 1% 5-fluorouracil cream twice daily for up to 6 weeks. Pre- and post-photographs and biopsies were taken in most

cases with a follow-up of 4 months to 3 years. Reduction in rhytids and hyperpigmentation was only seen with DA and chemical peeling. Chemical peeling resulted in recurrences as soon as 1 month after treatment, while DA had recurrences at 6 months. The patient who had a split-face application of chemical peeling and DA experienced recurrence on the chemical peel side first. The authors concluded that 5-fluorouracil is far superior to chemical peeling and DA given the longer time to recurrence and the development of fewer new lesions. The results from 5-fluorouracil group were not presented by the authors, however, making their conclusion difficult to accept. Histologic review from all three groups was similar with a thin epidermal layer, a reduced number of rete pegs, and a replacement of a portion of the actinically degenerated basophilic collagen in the papillary layer of the dermis by new collagen.

Winton [58] (IV) retrospectively looked at five patients who received DA (diamond fraise; endpoint papillary dermis) to the bald scalp for actinic keratoses. All patients were white elderly men with skin type II, ranging in age from 61 to 71 years. Two patients who treated themselves with 5-fluorouracil twice daily for 6 weeks were used as a comparison, although their results were never revealed in the study. Using a 6-point scale from 0 (none) to 6+, keratoses improved from 3.2 to 0, dyspigmentation improved from 4.6 to 0.6, and telangiectasias improved from 4.2 to 1.4. Scarring did not occur. Although 5-fluorouracil eradicated actinic keratoses (data not shown) similar to Spira's study [57], it did not improve solar dyspigmentation or telangiectasias.

New Directions

DA as a technique for epidermal skin sampling has been well described. A 2009 study used a modified dermabrader as an epidermal harvesting tool, and the authors were able to obtain representative samples of the epidermis for biomolecular analysis without creating a scar or inducing more than mild pain [59].

Preoperative Evaluation

Patient Expectations

Patient selection is key to obtaining excellent results with any elective procedure, and a thorough history and targeted physical exam is performed at the initial consultation. Patients must have realistic expectations with proper informed consent that discusses common risks such as scarring, infection, redness, and dyspigmentation [60]. Patients with body dysmorphic disorder most frequently seek dermatologic and surgical treatments, including DA [61]. In a retrospective study describing the frequency, types, and outcomes of treatments sought and received by 200 individuals with body dysmorphic disorder, approximately 2% of the dermatologic procedures were DA. Such treatment rarely improved body dysmorphic disorder, with 96% seeing no change in or worsening of their complaint. Care should be taken to identify these patients prior to treatment.

Viral Transmission

Another preoperative consideration is human immunodeficiency virus (HIV) and hepatitis. Since DA results in a great deal of blood accumulating in the field, proper history regarding hepatitis and HIV should be obtained. Wentzell indicated that aerosolized particles produced during DA were of sufficient size to allow access to, and retention by, mucosal and pulmonary surfaces [62]. While no cases of viral transmission have occurred during DA, the studies suggest that commonly used personal protection devices do not prevent inhalation of these particles and that infection can theoretically occur. The room should have proper ventilation, and all persons present in the room need to wear protective gear including 0.1 um filtration face masks, face shields, surgical gowns, and gloves, although there still remains a degree of risk since the seal on masks is rarely perfect. A contained breathing apparatus to isolate the surgeon and his or her assistants from the patient's tissue and body flu-

ids in advisable [63], and a shielded dermabrader with an attached hydration suction apparatus has been described to reduce this risk [64]. Alternatively, manual DA can be used since no aerosol is produced. Similar precautions are recommended when dealing with hepatitis patients.

Isotretinoin

Physicians should obtain medication lists to ensure that patients are not taking drugs that may lead to complications or compromise wound healing. Patients seeking DA for acne scars often have a history of severe acne and may have received isotretinoin therapy.

Clinical Studies

Early reports suggested that DA patients were unaffected by previous treatment with isotretinoin. Roenigk reported nine patients with severe nodulocystic acne who were treated with oral 13-cis-isotretinoin and subsequently received full-face DA without sequelae [65] (IV). Later reports documented patients who were dermabraded after isotretinoin and developed atypical scarring. Rubenstein first reported the occurrence of keloids on the cheeks, chin, and face of six patients (27–48 years) undergoing mechanical DA during (three cases) or within 6 months of treatment (three cases) with isotretinoin [66] (IV). Zachariae reported delayed healing and keloid formation in three patients (25–70 years) treated with DA (two cases) and argon laser treatment (one case) during isotretinoin treatment for acne or rosacea [67] (IV). Katz reported atypical facial scarring after the use of oral isotretinoin in a 30-year-old patient who had just undergone DA for severe cystic acne scarring [68] (IV).

More recent data is once again conflicting, as other surgeons have compiled patients that have been treated with isotretinoin and dermabraded without difficulty [69] (IIB). Picosse et al. prospectively evaluated healing from chemabrasion with 35% trichloroacetic acid (TCA) and manual DA (endpoint pinpoint bleeding) of depressed scars in ten patients who had isotretinoin 1–3 months prior to treatment. Follow-up at 6 months revealed normal healing with neither hypertrophic nor keloid scars, although all patients applied a topical steroid following the procedure. Bagatin performed manual DA on seven patients with atrophic acne scars on the face and neck, all actively taking oral isotretinoin. No topical steroids or oral steroids were given, and there was no abnormal scarring or keloid formation in this study population at 6-month follow-up [70] (IIB). The treatment area, however, was only 1 cm^2 and may not have been large enough to evaluate healing. This conflicting data is difficult to apply in clinical practice because adequate control studies have never been done. Therefore, many advocate for DA to be performed a minimum of 6 months after isotretinoin intake [66]. Guidelines of care for DA have also been published and suggest warning patients of the potential for atypical scarring as well [71] (V).

Herpes Simplex Virus Prophylaxis

Prophylaxis with an antiviral agent prior to DA is prudent in patients known to have a history of herpes simplex virus (HSV); however, significant consideration should also be given to prophylaxis in patients with a negative history of HSV. A retrospective evaluation of 181 consecutive patients undergoing perioral chemical peel or DA from 1983 to 1990 suggests that all patients are at risk for infection regardless of history [72] (IV). Patients with a history of oral HSV were pretreated with oral acyclovir and those without a history were not treated with acyclovir. A subset of 12 patients whose procedures predated acyclovir's commercial availability received no prophylactic treatment despite a positive history, which allowed for a comparison group. This group of patients developed herpetic infections 50% of the time. Interestingly, 6.6% of patients without an HSV history also developed infection within 5–12 days after the procedure. From this, they concluded that all patients should be treated preoperatively with acyclovir regardless of past history, and that treatment should continue for 2 weeks. The treated group with standard doses had an 8.3% infection rate (600 mg/day). No

patient developed herpetic infections if high-dose acyclovir was given (2400 mg/day). Fortunately, although these outbreaks are quite uncomfortable and appear to be severe, the incidences of scarring and long-term poor cosmetic outcomes in this study were low.

Beeson et al. looked at length of treatment and randomized 120 patients to either a 10-day or 14-day course of valacyclovir 500 mg BID starting on the day prior to the procedure [73] (IB). No patient in either group developed an HSV infection. The authors also performed serology and Tzank preparations to determine past exposure to HSV and the presence of virus. Reported histories of herpetic infection were given by 40–60% of patients, but over 80% had serologic evidence of previous infection. This study also found that 70% of patients with negative history did in fact have positive immunoglobulin G antibodies to HSV type 1. This further suggests that prophylaxis based on patient recollection is not reliable.

Opinions vary regarding when to start prophylactic treatment. One study randomly divided 84 resurfacing patients [CO_2 or Er:YAG laser (30 patients), chemical peeling (46), and DA (8)] to start valacyclovir 500 mg BID either the morning before or the morning of the procedure and to continue for 14 days [74] (IB). Patients were followed up for 21 days postoperatively. They found that valacyclovir is 100% effective for preventing herpetic lesions in in both groups with no adverse events reported.

Tretinoin

Prior to the procedure, patients can be pretreated with tretinoin cream to accelerate postoperative healing. In a porcine model, pretreatment with 0.05% tretinoin cream daily for 10 days prior to wounding significantly accelerated wound healing as compared with vehicle ($p = 0.015$) [75] (V). Clinically, Mandy used full-face or half-face DA (wire brush, diamond fraise to depth of scarring) for acne scarring in 123 patients, 88 of whom received pretreatment with 0.05% tretinoin acid cream [76] (IIIB). In the treated group, re-epithelialization occurred in 7 days compared to 11 days in the untreated group. One patient had a split-face treatment, and the pretreated side re-epithelialized in 7 days compared to 9 days for the untreated side. If the tretinoin was restarted 1 week after DA, no milia or post-inflammatory hyperpigmentation was seen, compared to 28% and 20%, respectively in the control group. Based on these findings, many dermatologists prescribed topical retinoids before and after resurfacing to expedite healing and reduce side effects.

Best Techniques and Performance

Describe what is known about optimal methods for this procedure. The standard methodology can be described in just a paragraph or two, but the focus should be on technique elements for which data exists, and these should be discussed in depth (e.g., predetermined number of passes in ablative laser resurfacing due to lack of tissue effect) and the evidence for and against weighed carefully.

Include pertinent negatives. For instance, if there are important elements of technique for which the evidence is lacking or insufficient (e.g., does eversion lead to narrower scars), this should be stated and discussed briefly.

DA is commonly performed in office-based procedure rooms under local anesthesia, although intravenous sedation or general anesthesia is used by some. Regional blocks are effective and additional anesthetic sprays may be used to freeze the skin. Freon-based refrigerants such as Frigiderm (Delasco, Council Bluffs, IA), Fluoro Ethyl (Gebauer Company, Cleveland, OH), and Fluori-Methane (Gebauer Company, Cleveland, OH) were widely used but have limited availability in many countries, including the United States, due to concerns of ozone destruction. Ethyl chloride (Gebauer Company, Cleveland, OH) is flammable but ozone safe, and Instant Cold Spray (HL Moore, New Britain, CT) is ozone safe [77]. Tumescent anesthesia can also be used to stiffen and anesthetize the skin. Goodman reported the 14 patients (average age 31 years) dermabraded with tumescent anes-

thesia and topical anesthesia (EMLA; Astra Pharmaceuticals) using a diamond fraise (endpoint pinpoint bleeding) [78] (IV). Seven patients had full-face DA, four had regional DA, and one had subregional DA. The procedure was found to be effective in producing anesthesia, eliminating the need to freeze the skin, and limiting the necessity for sedatives, narcotics, and other anesthesia. There was also less spatter and therefore less risk for the surgeon. Side effects were limited to one case of transient hyperpigmentation, one case of milia, and one case of irritant dermatitis. Of the 12 patients who completed the patient questionnaire, 8 stated they would go through a subsequent tumescent DA, 11 felt they had an improvement with the technique, and only 1 patient found it painful. All four patients who had DA previously felt that healing was faster with tumescence, and three of four patients felt that the results were better.

When treating scars, the question of timing is important. Katz et al. designed a split-scar study looking at surgical scars in 48 patients aged 25–86 years [79] (IB). Scars were located on the face (19 scars), trunk (20), and extremities (1). The scars were randomly assigned to DA (diamond fraise; pinpoint bleeding) 4, 6, and 8 weeks after surgery. The treated half was not randomized and always assigned to the left half of the scar. Ratings were performed by the physicians, laypersons, and the patients themselves. Photographs and scar measurements were taken at 1 month, 3 months, and 6 months after treatment. There was a statistically significant improvement in the DA portion of the scar compared to no treatment at 8 weeks ($p < 0.05$), but not at 4 weeks and 6 weeks after treatment. Trunk and face and extremities showed comparable improvement. While only 25% of patients responded to the questionnaire, all thought the treated side looked better. They reported mild post-inflammatory hypopigmentation that spontaneously resolved. Four patients agreed to histologic evaluation of each side of the scar at 6 months. Histologically, there were no significant differences between the two groups at 6 months and only scar tissue was seen.

Yarborough similarly showed that post-traumatic scars or scars as a result of excisional surgery could result in a much more acceptable result if DA (wire brush) occurred 6–8 weeks after the skin injury [4] (IIIB). He looked at 97 facial scars (35 surgical and 62 traumatic) on 37 patients between the ages of 15 and 78 who had their scars abraded 4–8 weeks following injury. The comparison group consisted of 64 mature scars from 3 months to 13 years on 24 patients. Evaluations were made for up to 6 months, with 89% of the early group showing no visible scarring at 6 months. In four patients, scars improved but were still visible. Of the 64 mature scars, all were still apparent, essentially unchanged, or modestly improved.

The selection of a dermabrasive device is often determined by surgeon preference. Nelson et al. compared DA with the wire brush and diamond fraise in photoaged skin [80] (IB). Eight photoaged patients (49–80 years) underwent facial dermabrasion to the level of the papillary dermis. Two blinded observers rated photographs at baseline and 12 weeks using a 5-point scale (0 = none, 5 = severe). Side effects were also noted. Biopsies were taken from both halves of the scar and assessed by routine histologic and immunohistologic examinations, Western blot analysis, and radioimmunoassay. Both methods of DA resulted in significant resolution of actinic keratoses, lentigines, and wrinkles at both 3 and 12 weeks postoperatively, although there were no statistically significant differences between the two techniques ($p < 0.01$). Significantly fewer milia occurred with diamond fraise than with wire brush ($p = 0.02$), but no statistically significant differences were found between the two techniques with erythema or hypopigmentation. At 12 weeks, immunohistologic evaluation demonstrated a significant increase in papillary dermal fibroblast staining for type 1 pN-collagen with wire brush and diamond fraise ($p = 0.002$ and 0.008, respectively) and for type 3 pN-collagen with wire brush and diamond fraise ($p = 0.05$ and 0.04, respectively) compared to baseline. A telephone survey 2 years after treatment reached seven patients who were satisfied. Three patients

preferred the diamond fraise, but they did not make any distinction between the two sides in terms of healing.

Gillard et al. compared manual spot DA with diamond fraise DA in patients who had undergone facial skin cancer surgery [81] (IB). Twenty-one patients (34–86 years) with facial scars, including 14 patients with sutured wounds and 7 patients with wounds left to heal by secondary intention, were examined. Scars were divided in half, and each side was randomly assigned to treatment by diamond fraise DA or by manual DA with a medium-grade drywall plaster sanding screen. A blinded observer judged each scar and found no differences between the two methods in quality of contour correction, time for re-epithelialization, camouflage of the scar, hypertrophic scarring, infection, or hyperpigmentation during the 6 months of follow-up ($p > 0.16$). Interestingly, no patient exhibited any perceived difference in correction of contour at any time point between the two treated halves. The authors conclude from this study that manual DA and motorized DA are equally effective in the treatment of facial scars.

Safety

DA remains much more dependent on operative techniques than lasers or chemical peels and is thus more vulnerable to operator error. Scarring, although rare, can occur for many reasons. Cryogenic sprays, which are used to provide a firm base against which to abrade, produce thermal damage that can lead to scarring over boney prominences. Newer freons used to rapidly harden the skin prior to DA can produce their own complications and accelerate the incidence of keloid formation [82–84]. When the skin refrigerants are used for short bursts, little if any dermal damage or impaired healing is seen. Strauss and Kligman found that freezing human cheek skin for up to 6 min with dichlorotetrafluoroethane (Freon 114) resulted in no scarring or clinically significant pigmentary changes [85]. In some subjects, the skin was retreated three times without scarring. Despite this, dermal damage can be seen histologically with prolonged freezing or refreezing [86] and newer refrigerants that can achieve lower temperatures that increase chances of freeze injury [82, 83, 87, 88]. Hanke et al. [84] (IV) reported three patients who were dermabraded with a new potent skin refrigerant mixture. Two patients developed hypertrophic scarring over the mandible (one patient's course was complicated by an infection), and the third had prolonged erythema of the cheeks that was still present (although improved) after 1 year. All three patients received Cryosthesia −30 °C and/or −60 °C (Chemtrex Inc., Hauppauge, NY), which produces a more rapid freeze than Fluoro Ethyl (max cooling temp −42.8 °C) or Frigiderm (−40.6 °C). This was supported by a later study where guinea pig skin was used to compare these three refrigerants. In this study, Cryosthesia both −30 °C (max cooling temp −52 °C) and −60 °C (max cooling temp −66 °C) could cause necrosis and inflammation without subsequent DA, while Frigiderm and Fluro Ethyl produced very little effect on the skin [82].

Infection is uncommon after DA, occurring in less than 4–8% of patients [89]. The most common microorganisms include *Staphylococcus aureus*, HSV, and *Candida* species [90]. Prophylactic antibiotics have been associated with selection for pathogenic organisms and a tendency toward higher infection rates [91]. *Candida* infections are promoted by topical and/or oral antibiotics, and they can manifest up to 2 weeks after the procedure [92] (IV). Nevertheless, many surgeons still prescribe a cephalosporin. Siegle et al. reported three cases (two women and one man, aged 19–38) of facial candidiasis complicating DA. With topical antifungals (two patients) and oral antifungals (one patient), all healed without sequelae. Two patients were on prednisone postoperatively and prophylactic oral antibiotics, and all patients were using topical Polysporin for wound care. The postdermabrasion state was thus strongly conducive to developing a secondary candidosis due to oral and topical antibiotics, which should be used judiciously in DA.

Pigmentary changes are the most common complications after DA and usually take from

weeks to months to resolve [89, 93]. As with any resurfacing method, darker-skinned people are at greater risk of pigmentary changes, but good postoperative skin care and the rigorous use of sunscreen can prevent many of these patients from suffering this complication. Ship et al. looked retrospectively at 63 DA patients (17–63 years; 22 males and 41 females) consisting of 11 Caucasians, 6 Hispanics, 4 blacks, and 1 Oriental [94] (IV). Diamond fraise was used for 21 full-face procedures and 42 spot treatments without refrigerant. Over the follow-up period from 6 months to 15 years, only eight patients had pigmentation changes that resolved (one patient lost to follow-up). Sixty-seven percent (42) of patients reported some pigmentation that resolved before the 6 months. Three patients developed hypopigmentation that also resolved at 1 year plus (two blacks, one Caucasian), and three Caucasian patients developed redness, which was present up to 4 years later in one naturally ruddy patient. As a result, the authors concluded that adverse pigmentation frequently self-resolves.

Fakhouri and Harmon reported subarachnoid hemorrhage during DA in a 69-year-old patient on dabigatran for atrial fibrillation [95] (IV). She complained of gastrointestinal upset prior to the visit and developing chest and shoulder discomfort, diaphoresis, and pallor after the procedure. The authors highlighted the importance of considering all potential complications of a patient's medical history and medication list. It is prudent to have an action plan in place to manage emergent complications of anticoagulant therapy since most patients are maintained on medically necessary anticoagulation during surgery.

Alternative Procedures and Modifications

The preoperative consultation is extremely important. The surgeon should list alternative and adjunctive procedures such as chemical peels, lasers, and surgery.

CO_2 Laser Versus Dermabrasion

Perioral Rhytids

Holmkvist and Rogers compared a pulsed, scanning CO_2 laser with DA in the treatment of perioral rhytides in a split-face manner [96] (IB). Fifteen patients were randomly assigned to DA (eight patients with diamond fraise and seven to manual DA; endpoint pinpoint bleeding) to half the face and a pulsed scanning carbon dioxide laser [LX-20SP Novapulse [(Luxar Corp, Bothell, Wash), 4.24 J/cm^2 with 5–6 W/pass for 2–3 passes)] to the other half of the face. Only skin types 1–3 were included, and all patients were pretreated with 0.025% tretinoin and 4% hydroquinone for 2 weeks. Standardized photographs and clinical exam were assessed by blinded observers for up to 4 months, and all patients were interviewed subjectively throughout the study. Using a 5-point rhytid scale, both treatments resulted in improvement ($p = 0.001$ for DA and $p = 0.002$ for CO_2), and there was no statistically significant difference between the two sides ($p = 0.35$). Subjective opinions regarding superior cosmetic outcomes were similar for patients and blinded observers, with 50% of both groups seeing no difference. Postoperative pain was not significantly different, although crusting was greater with laser ($p = 0.002$) and healing was faster with DA (60% with DA vs. 7% with CO_2 at 6–7 days) with significantly less postoperative erythema at 1 month ($p = 0.003$) but not at 4 months ($p = 0.15$).

Gin et al. used a similar approach to evaluate and compare the scanning CO_2 laser with diamond fraise DA in the treatment of 20 patients (48–76 years, Fitzpatrick skin types I–III) with perioral rhytides [97] (IB). One half of the perioral area was randomly assigned to CO_2 laser (CW 18 W using a 6 mm scan size with a 950 μsec dwell time, three passes) and the remaining half assigned to DA (endpoint pinpoint bleeding or dermal collagen over wrinkles). Rhytides were evaluated by an independent, blinded investigator on a graded scale at baseline and up to 26 weeks after the procedure. Of the 19 patients who completed the study, the mean rhytid score for the laser treated and dermabraded side improved significantly ($p < 0.001$ for both modalities), the

difference between the two techniques being nonsignificant ($p = 0.216$). No major differences were observed in erythema between DA and CO_2 laser, which lasted an average of 2.5 months (range 1–6 months). The authors concluded that DA and CO_2 laser are equally effective in the treatment of perioral rhytides. Side effects were limited. Three patients developed herpes infection that healed without consequence. One patient developed a hypertrophic scar within the dermabraded side, two patients developed dermatitis, and three patients developed milia.

Combined treatments have been shown to decrease downtime and improve efficacy of treatment [98] (IV). Fezza et al. compared the combination of CO_2 laser (details not provided) and manual DA (Silicone carbide 220 grit sandpaper, endpoint pinpoint bleeding) to a historical control of CO_2 laser alone. Ninety patients with perioral wrinkles (Glogau IV wrinkles) underwent treatment and were assessed clinically by the surgeon and staff for wrinkle reduction, healing, and complications. Photographs were also taken at baseline and at 3 months. The combination reduced 95% of heavy perioral wrinkles compared to a historical rate of 75% with laser alone. Healing time for the combination treatment was shorter (9 days) instead of laser alone (12 days). No complications were seen. A subset of 26 patients were followed for a year, and all maintained good results with no additional hypopigmentation.

In 2000, Kitzmiller and colleagues recruited 20 females with moderate-to-severe upper-lip wrinkles to assess the CO_2 laser and DA [99] (IIB). They randomly assigned half the perioral area to DA and half the perioral area to UltraPulse CO_2 laser (2–4 passes, 300 mJ, density 5–6). Photographs at 1 week, 1 month, and 6 months following the procedure were compared by ten blinded plastic surgeons. The laser had higher erythema score at 1 month ($p < 0.001$) but a small, significantly greater improvement in wrinkle score at 6 months ($p = 0.016$). Both treatments reduced facial rhytides by approximately 50%. The participant's overall impression, assessed by a 6-month questionnaire, was that the laser gave a better result tempered with more intraoperative pain and postoperative drainage. Patients reported that they would recommend both procedures equally to a friend. The authors concluded that the pulsed CO_2 laser is slightly more effective at improving perioral rhytides than DA, although they acknowledged that his change may not have been observed if they were more aggressive with their DA technique. As a result, they recommended incorporating operator experience into determining which modality would be optimal for a specific patient.

Surgical Scars

Nehal et al. prospectively compared the clinical effects of DA and high-energy pulsed CO_2 resurfacing (18 W, 6 mm spot, SilkTouch; Sharplan Lasers Inc., Allentown PA) in the revision of surgical scars [100] (IV). They employed a split-scar model in four patients with one half of the scar being dermabraded using a diamond fraise (endpoint reticular dermis) and the other half being resurfaced with the high-energy pulsed CO_2 laser. Three independent investigators compared photos at baseline at 4, 8, and 12 weeks using a four-point scale. Both treatment sites re-epithelialized in 7–10 days with a comparable degree of erythema in both treatment halves at 4–8 weeks. No other complications were observed. Clinical assessments were performed in a non-blinded fashion with photographs, and comparable clinical improvement was seen in all four scars. No statistical analysis was performed given the small sample size. Silicone rubber casts and optical profilometry objectively demonstrated improvement in scar texture following both modalities as well. While both treatment modalities achieved similar clinical improvements, the CO_2 half remained bloodless during treatment, which, the authors commented, allowed greater visibility during the procedure and lowered risk of transmission of blood-borne pathogens to the staff.

For postsurgical scar resurfacing, Christophel et al. compared the safety of fractionated CO_2 laser with DA [101] (IB). A randomized, blinded, split-scar model was used to compare a single treatment of fractionated CO_2 [Fraxel Re:Pair (Solta Medical Inc., Hayward CA), 40 mj, treatment level eight, two passes] with diamond fraise

DA (endpoint punctate bleeding) on postsurgical scars of the face. Six patients (45–64 years, three men and three women) completed the study and were assessed for up to 1 month. They used a four-point scale for safety measures and a visual quartile scale for assessing scar improvement. Secondary endpoint was efficacy at 3 months as measured by blinded evaluation of standardized photographs. Both treatments yielded equivalent scar improvements ($p = 0.77$) at 3 months, although there was less bleeding ($p = 0.001$) and erythema ($p = 0.01$) with fractionated CO_2 laser at day zero and less erythema ($p = 0.01$) and edema ($p = 0.046$) at 1 week; there were no statistically significant differences in safety measures at 1 month.

Chemabrasion (Chemical Peeling Combined with Dermabrasion)

Rhytids

Chemabrasion was first described in 1982 and is the combination of chemical peels and DA. Harris advocated the addition of manual DA to augment a 25% TCA peel and reported his experience with the technique on over 300 patients over 7 years aged 28–66 [102] (V). In his hands, expected results include 70–90% of improvement in wrinkles with less dyschromia. He reported only two cases of hypopigmentation, four cases of hypertrophic scarring along the mandible, and erythema that takes from weeks to months to resolve.

Actinic Keratoses

Cooley et al. looked at 40 patients with actinic damage who were treated split face with manual resurfacing (vigorous pinpoint bleeding) plus 25% TCA on one side and either DA alone or 35%TCA/Jessner's alone on the other side [103] (IV). Four patients underwent sequential biopsies within 1 week and again within 90 days to evaluate the depth of wounding using these techniques. In the chemical peeling group, significant improvements in the epidermis were seen with little change in the elastotic band in the papillary dermis. The DA alone group produced a depth of injury similar to the Jessner's 35% TCA. The combination group revealed a deeper injury histologically, with nearly complete obliteration of the elastotic band, which was replaced with an approximately 0.4 mm wider band of new collagen. Clinically, the combination consistently produced excellent cosmetic results and nearly complete removal of actinic keratoses. The combination treatment resulted in longer healing time by several days and duration of erythema that persisted until day 30 in one patient, as well as occasional pigmentary changes. No scarring was seen. The authors concluded that manual resurfacing combined with TCA is an excellent technique for patients with widespread actinic keratosis and extensive photodamage, although longer healing times can be expected.

Chemical Peeling Versus Dermabrasion

El-Domyati compared microscopic and ultrastructural changes that occur in photoaged facial skin Fitzpatricks type IV and V after treatment with either superficial TCA peeling or DA [104] (IIB). Patients with mild-to-moderate photodamage were treated weekly to biweekly with increasing percentages of TCA (10%, 20%, and 30% TCA), and those with advanced-to-severe photodamage were treated with DA using the diamond fraise until pinpoint bleeding was visible. Punch biopsies were taken at baseline 3 months after treatment for the DA group and within 3 months after the TCA peeling at the sign of clinical improvement, usually after three to five sessions. Both TCA peeling and DA had beneficial effects in improving photoaged facial skin and in revitalization of the skin at histologic and ultrastructural levels, mainly by increasing the amounts of collagen I and collagen III and improving the morphologic appearance of collagen and elastic fibers. While it is difficult to compare the two groups given the baseline differences in photodamage and the variable time of biopsy in the TCA group compared to the standard 3 months in the DA group, the tissue response was more prominent in the patients treated with DA.

Surgical Scar Revision and Dermabrasion

Surgical scar revision prior to DA is an important adjunctive procedure that can improve the ultimate cosmetic outcome. Scar excision, punch elevation, and punch grafting can be used to improve deep scars that are beyond the reach of DA. Whang et al. devised a three-step treatment that combines (1) focal chemical peeling with 50% TCA for 1–3 monthly treatments; (2) excision, punch grafting/elevation, and/or CO_2 laser according to the type of remaining scars; and (3) DA performed 6–8 weeks later for resurfacing the remaining areas [105] (IV). This treatment plan was derived from their published clinical experience, which included 32 patients with acne scars (average age of 26.8 years) who received focal chemical peeling with 50% TCA to their depressed scar for 1–3 treatments. They added CO_2 (3–6 W, 0.05 s/pulse) in six patients, excision in two patients, punch graft/elevation in three patients, and DA in five patients simultaneously or sequentially after chemical peeling. Results were obtained 6–18 months after treatment and were rated from poor to excellent. Seventy-five percent of patients were excellent or good for chemical peeling alone, 70–80% from good to excellent for chemical peeling combined with another modality (CO_2 or DA), and 100% from good to excellent for the patients who underwent all three stages of treatment. Complications arose in six patients and consisted of hyperpigmentation that lasted longer than 3 months in two patients, erythema that persisted longer than 3 months in three patients, and hypertrophic scarring in one patient.

Dermabrasion with Melanocyte Transfer

Vitiligo

DA is also useful for deepithelializing vitiliginous skin recipient sites for epidermal or melanocyte grafts, as part of repigmentation procedures [6, 27, 39, 106]. Although beyond the scope of this chapter, plastic surgeons have combined DA with skin grafts and acellular tissue substitutes as a technique for restoring skin pigmentation after burn injuries in the adult and pediatric populations [107–110].

Vazquez Martinez et al. looked at patients with stable vitiligo over 3 years and compared DA with melanocyte keratinocyte cell suspension transplantation with DA alone on separate achromic macules of the same patient. Lesions were on the trunk (64%), limbs (29%), and face (9%). Blinded dermatologists measured the area of repigmentation in the area treated 3 and 12 months after implantation. At 12 months, the percentage of the treated area that had undergone repigmentation with DA + MKT was not statistically greater than that of the skin treated with DA alone ($p = 0.733$) [111] (IV).

Future Directions

Bacterial Colonization

DA is also used in burn victims as a method for collecting cutaneous samples from the wounds to assess bacterial colonization [112] (IIB). DA of the upper layers of the wound was performed in 12 burn patients using a diamond fraise with the tissue analyzed for bacterial growth in different culture media and compared with biopsy and swab. The abrasion method yielded more bacteria than the swab method and the biopsy method ($p < 0.05$).

Postoperative Care and Follow-Up

Appropriate wound care is vital to success. A moist environment is necessary to promote wound healing, and most practitioners rely on an open technique of treatment with frequent application of ointments. Multiple petroleum-based products are available to maintain a moist environment and prevent crusting. The closed technique involves application of a biosynthetic dressing material and has evidence to support its use after DA. The use of semipermeable dressings reduces the time for re-epithelialization by up to 40% compared to open techniques of

wound care, and this effect is attributed to the ability of these dressings to maintain a critical plane of humidity for epithelial cell migration [113, 114]. These dressings can be left in place for 24–48 h and then changed by the patient every 2–3 days. Following this, ointment dressings can be started. In addition to moist wound care, whether closed or open, patients should minimize sun exposure and/or wear appropriate sunblock for 6–12 months following the procedure to avoid hyperpigmentation. As previously discussed, topical retinoids can be applied 1 week after DA to help prevent hyperpigmentation and milia formation. Residual erythema and edema should be expected to last 1–2 months, and if appropriate, nonallergenic makeup is worn during this time. In the studies reviewed, most patients only required one DA to achieve results, although repeated treatments can also be safely prescribed.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
Dermabrasion is indicated for the treatment of superficial and moderate depth wrinkles in the perioral area	B
All patients should receive appropriate antiviral therapy to prevent and treat possible herpetic outbreaks prior to skin resurfacing	B
Dermabrasion is effective in postsurgical scar treatment	B
Dermabrasion is effective in treating actinic keratoses	B
A short preoperative course of tretinoin cream has the benefit of reducing the time required for re-epithelialization after dermabrasion	C
Patients who have completed isotretinoin therapy within the last 6 months should be counseled on the possibility for atypical scarring	C

Self-Assessment Questions

1. When considering dermabrasion for a full-thickness skin graft, which grafts respond the best?
   (a) Depressed grafts
   (b) Elevated/hypertrophic grafts
   (c) Periocular grafts
   (d) All grafts within the first month of bolster removal
2. A 55-year-old Hispanic lady comes for a 4-week follow-up visit. She had perioral dermabrasion for fine lines and wrinkling. She complains of skin darkening in the treated area. Which of the following statements is true?
   (a) This side effect is usually self-limited and resolves within weeks to months
   (b) Restarting her topical tretinoin 1 week after the procedure caused this side effect
   (c) A laser would not have caused this side effect
   (d) Perioperative acyclovir would have prevented this side effect
3. Which of the following cryoanesthetics is commercially available and ozone safe?
   (a) Frigiderm (Delasco, Council Bluffs, IA)
   (b) Fluoro Ethyl (Gebauer Company, Cleveland, OH)
   (c) Instant Cold Spray (HL Moore, New Britain, CT)
   (d) Fluori-Methane (Gebauer Company, Cleveland, OH)
4. A 35-year-old male comes to the office requesting improvement in a bilobed flap on his nasal supratip that has not responded to corticosteroid injections. He has HIV that is poorly controlled. How do you proceed?
   (a) Tell him that you will not perform HIV status
   (b) Proceed with mechanical dermabrasion and wear protective gear including 0.1 um filtration face masks, face shields, surgical gowns, and gloves
   (c) Proceed with manual dermabrasion and wear protective gear including 0.1 um filtration face masks, face shields, surgical gowns, and gloves
   (d) Proceed with dermabrasion per routine if his CD4 count is above 200
5. A 40-year-old gentleman comes in for a 10-day follow-up. He had dermabrasion to bilateral cheeks for acne scarring. He is a very compliant patient and was prescribed a 10-day course of cephalosporin and acyclovir, was instructed to apply petrolatum ointment to the treated skin postoperatively, and was counseled on strict photoprotection. He complains of new-onset redness and mild itching confined to the cheeks for 1 day. There is no pain, crusting, or drainage. What is the next step in evaluating the cause of his symptoms?
   (a) Prescribe a fluoroquinolone antibiotic for broader bacterial coverage
   (b) Take culture (bacterial, viral, and fungal) culture and add a topical antifungal therapy while awaiting the results of culture
   (c) Prescribe a 2-week course of prednisone for allergic contact dermatitis
   (d) Reassure him that redness and itching is normal after dermabrasion

Correct Answers

1. b: Robinson et al. performed a controlled study looking at the effect of dermabrasion on the appearance of full-thickness skin grafts on the face [52]. When compared to matched controls, the greatest objective improvement was seen in elevated grafts. Depressed grafts and periocular grafts did not improve with dermabrasion. She found that grafts spontaneously improved over the first 6 months, suggesting that patience can prevent an unnecessary procedure.
2. b: This lady has developed post-inflammatory hyperpigmentation, which usually presents several weeks after the procedure. With photoprotection, this condition resolves over weeks to months. The use of post-procedure topical tretinoin does not predispose to post-inflammatory hyperpigmentation. It may, in fact, help prevent it. Any trauma to the skin can predispose to pigment changes, including lasers or chemical peels. Post-inflammatory hyperpigmentation is not prevented by acyclovir.
3. c: Instant Cold Spray (HL Moore, New Britain, CT) is commercially available and ozone safe.
4. c: Unlike mechanical dermabrasion, manual dermabrasion does not create blood spatter and thus reduces the chance of inhaling and/or ingesting aerosolized viral particles. Despite this, proper personal protective gear should still be worn during the procedure. Discriminating against patients based on their HIV status is illegal. A high CD4 count, while good for the patient, will not prevent viral transmission.
5. b: Infection must be ruled out. Since he is already taking an antibiotic and antiviral, bacterial and viral infection are possible but less likely. There have been published reports of candidiasis up to 2 weeks after dermabrasion [92], and antibiotic use is a risk factor. Studies suggest that a 10-day course of an antiviral is adequate length of therapy for HSV prophylaxis [73]. Therefore, taking cultures and prescribing a topical antifungal cream is the best option. Since he is only applying petrolatum, an allergic contact dermatitis is unlikely and a 2-week course of prednisone is a risky treatment for tolerable itching. Without a positive culture to suggest otherwise, adding a fluoroquinolone is not indicated and contrary to antibiotic stewardship. While redness and itching can be a normal part of healing, the new-onset nature warrants investigation.

Subcision (Including Energy and Device-Mediated)

22

Daniel E. Edmondson and Douglas Fife

Abstract

Subcision, short for "subcutaneous incisionless" surgery (Orentreich and Orentreich, Dermatol Surg 21(6):543–549, 1995), is a minor surgical intervention that is useful in the treatment of several types of scars and other contour defects. The procedure involves the insertion of a beveled needle into the skin adjacent to a scar which is advanced forward, backward, and side-to-side to create a pocket underneath the scar, ultimately allowing the skin surface to float up to a more normal level. This procedure is indicated in the treatment of rolling acne scars, depressed scars and contours (due to many causes including skin grafts, surgical wounds, and malar grooves), and wrinkles. While it has also been proposed for treating cellulite dimples, striae, and axillary osmohydrosis, the evidence for improvement in these conditions with subcision is scarce (2b) (Balighi et al., J Eur Acad Dermatol Venereol 22(6):707–711, 2008). Refer to Table 22.1 for a summary of indications.

Indications for Subcision

Subcision, short for "subcutaneous incisionless" surgery [1], is a minor surgical intervention that is useful in the treatment of several types of scars and other contour defects. The procedure involves the insertion of a beveled needle into the skin adjacent to a scar which is advanced forward, backward, and side-to-side to create a pocket underneath the scar, ultimately allowing the skin surface to float up to a more normal level. This procedure is indicated in the treatment of rolling acne scars, depressed scars and contours (due to many causes including skin grafts, surgical wounds, and malar grooves), and wrinkles. While it has also been proposed for treating cellulite dimples, striae, and axillary osmohydrosis, the evidence for improvement in these conditions with subcision is scarce (2b) [2]. Refer to Table 22.1 for a summary of indications.

It is generally agreed that subcision is ineffective for certain other forms of scarring, such as boxcar and ice pick acne scars; however, this has not been rigorously studied. It has been suggested that subcision is notably more effective at treating scars with bases that have normal skin quality

as opposed to those which are hypopigmented or sclerotic (5) [3].

Demographics and Body Areas Appropriate for Subcision

Subcision is used on patients of all ages and skin types and can be performed on any area of the body. While this has not been studied specifically, some authors warn that certain areas of the body, particularly those with increased skin tension, have a greater likelihood of undergoing hyperplasia following subcision. These locations include the periorbital, glabellar, labial commissure, and upper lip areas (4) [1]. In contrast, others have proposed that subcision can be done anywhere on the face (4) [4].

Efficacy of Subcision

Since Orentreich first described subcision in 1995, many studies have been performed to evaluate its effectiveness for acne scars. This has led to an accumulation of data that allows the modern clinician to counsel patients concerning the likelihood of positive outcomes following subcision. While some variability in treatment success has arisen from the utilization of procedural adaptations, studies report percent improvement to be between 25% and 80% (Table 22.2). Several factors may influence the effectiveness of subcision, including the type of needle used, number of treatment sessions performed, the type of postoperative care, the amount of time allowed for follow-up, and the age of the patient. These variables and the evidence supporting them are discussed.

Evidence suggests that multiple subcision sessions on the same scar are more effective than only one session. A case series of 15 patients found that after one session, patients had only 15–30% improvement, while those who completed 3 sessions had improvement of 40–80% (4) [5].

There is lack of uniformity in the follow-up period between studies, and it is likely that subcised scars change over time as post-procedure scar maturation and remodeling occurs. For example, Vaishani et al. found that a 5–10% improvement was seen between the 2- and 6-month follow-up visits. The authors attributed this to the fact that scar remodeling is a continuous process, noting that it takes at least 2 years to reach steady state [5]. Overall, there is mixed evidence on whether longer-term follow-up leads to greater or lesser measured scar improvement (Table 22.3).

The postoperative care may also affect the overall outcome of subcision. A study by Harandi et al. demonstrated the benefit of daily suction after subcision. Even though they had a higher amount of post-subcision bruising and swelling, patients who underwent daily suction with a microdermabrasion device on the skin overlying each scar in the immediate postoperative period had a significantly better overall result (2b) [6].

Another observation regarding subcision that could have clinical implications was made by Ramadan et al. when they found that increasing patient age correlated with a greater degree of scar improvement (2b) [7]. However, since this finding has not been replicated, further investigation is warranted.

Preoperative Evaluation

While studies have not addressed the preoperative evaluation of the patient prior to subcision, it is generally accepted that soft, distensible,

Alam et al. [4]	2005	40	Case series	4	30–90% (50–60%)	51%

Table 22.3 Variability in measured improvement at different points in follow-up timeline

Author, date	Follow-up time	Improvement	Other observations
Alam, 2005 [4]	1 and 6 months	50–60% improvement of appearance	Depth of scar improvement = 52% Visibility of scar improvement = 54% 90% of patients reported that subcision improved their scar appearance
Vaishani, 2008 [5]	2 and 6 months	The visual analog scale improvement ranged from 40% to 80% About 15–30% correction in first sitting	Slightly larger improvement in type-2 rolling scars than in type 1
Ramadan, 2011 [7]	10 months	Mean decrease in size for subcised scars was $0.386 \pm 0.391\ cm^2$	The older the patient, the greater the scar depth improved
Balighi, 2008 [2]	1 and 6 months	Patient assessment was 59.5 +/− 1.57% at 1 month and 53 +/− 1.57% at 6 months	12 cases (60%) had mild improvement 8 cases (40%) showed moderate improvement

rolling acne scars (those which have a gentle, sloped border) are the optimal scars for subcision. It is also important that the quality of skin overlying the depressed scar be normal, without hypopigmentation or fibrosis. Scars which have a sharply angled border such as ice pick and boxcar scars do not improve as much. Notably, subcision appears to be safe in all skin types (5) [3, 8].

While subcision is only minimally invasive and has relatively low risk of causing serious adverse events, there are several contraindications with which the clinician must be familiar (Table 22.4). As with all procedures that disrupt epidermal integrity, it is important that the patient be screened for active infection at or near the site of treatment. Other contraindications include bleeding diathesis, a history of keloid scarring in the area of subcision, and active inflammatory or cystic acne (2b, 4, 5) [6, 8, 9].

Table 22.4 Contraindications to subcision

Contraindications
Absolute
Active infective–at or immediately adjacent to the site to be treated
Deep, ice pick scar–ineffective
Relative
Active acne, especially cystic acne
Bleeding diathesis
History of keloid scarring after trauma or surgery

Overall, the level of evidence supporting the exact indications and contraindications for subcision is poor and consists primarily of clinical experience and expert opinion.

Treatment Technique

Most authors describe a similar technique for performing subcision. Local anesthetic is infiltrated into the treatment area after a sterile surgical preparation of the skin. A needle is then inserted lateral to the scar, which passes forward and backward underneath the scar and is then swept back and forth like a windshield wiper. The back-and-forth and side-to-side movements of the needle sever fibers in the dermis or superficial subcutaneous fat, allowing a space or "pocket" to form. The skin over this space is allowed to float upward to a level that is more consistent with the surrounding skin. In the immediate postoperative period, the pocket created underneath the scar is thought to be filled with serous fluid, a fibrin clot, or a hematoma; however, this has not been studied. The exact mechanism of the long-lasting scar improvement has also not been investigated; however, it is thought to be due to either the production of new collagen or scar tissue underneath the scar or the organization of a hematoma with subsequent fibrosis [3].

The literature does not contain high-quality evidence elucidating an optimal method of subcision. The variables in the subcision technique include the type of needle used, the intensity of sweeping of the needle, and the size of the pocket created under the scar. Some authors recommend small hollow-bore injection needles which are unlikely to create a significant open pocket under the skin, while others recommend more aggressive subdermal undermining with larger needles with large blades, such as the Nokor needle or the cataract blade.

The type of needle that will be utilized is an important decision to be made when preparing to perform subcision. When Orentreich first described subcision, he noted that a number of different needle gauges and lengths could be useful [1]. The paper stated that for larger, more bound-down scars, such as cellulite and surgical scars, 16-gauge needles could be used. Conversely, for smaller, more superficial scars and wrinkles, 25- to 30-gauge needles could be useful. Since that time, numerous studies have been published which have reported successfully using different needle types for subcision (Table 22.5). What it ultimately comes down to is that the needle of choice depends on the scar being treated, and this will require clinical evaluation. The opinion that larger bore needles are useful for larger or bound-down scars and that thinner needles are more useful for smaller, superficial scars is shared by other authors [4–6, 8]. Ayeni described the use of a 20-gauge cataract blade, which is a very sharp, tri-beveled blade that very efficiently creates a pocket underneath the scar (5) [9]. It should be noted however that comparative, prospective studies have not been done to evaluate one needle type against another.

Comparative studies have also not been performed to evaluate differences in treatment techniques such as the number of passes underneath each scar, the size of the pocket created, the optimal depth of injury, or the total number of sessions. However, a number of authors have given recommendations, or treatment pearls, intended to optimize outcomes based on their personal clinical experience. Some of these recommendations address the challenge of maintaining the orientation of the needle once it is inserted into the skin so that the flat, cutting portion is kept parallel to the skin surface. Khunger advised to bend the needle as a way of controlling needle tip orientation and also as a way to maintain a horizontal orientation of the entire needle (5) [10]. Al Ghamdi advised clamping the needle with a needle driver as a way of maintaining orientation (5) [11]. These procedural adaptations may be particularly pertinent, considering the warning made by Alam and colleagues that clinicians take care to keep the needle parallel to the skin surface to avoid injuring deeper structures or potentially even branches of the facial nerve that could be in the treatment area [4]. A few authors recommend multiple sessions over an extended period of time, ranging from three to six sessions [1, 9]; however, the exact number of sessions necessary for optimal improvement has not been studied.

Table 22.5 Types of needles that can be used for subcision

Needle type	Author	Level of evidence	Advantages	Disadvantages
1-inch, 22-G, hypodermic B-D needle [4]	Orentreich	4	Readily available Inexpensive	Small tip not as efficient at cutting dermal/subcutaneous attachments as Nokor or cataract blade
20-G microvitreoretinal (MVR) cataract blade [9]	Ayeni	5	Its diamond shape with a triangular point facilitates lateral sweeping motion Extremely sharp Longer cutting distance because it is sharp along the length of its bevel Has a handle	Significantly more expensive than other needles
18-G 1.5-inch Nokor admix needle [9]	Facts discussed by Ayeni	5	Blade is more efficient at cutting and releasing dermal attachments than standard syringe needles	Not very sharp Can cause significant injury at insertion site No handle, making it difficult to use
24-G needle [5]	Vaishnani	4	Less painful and traumatic, so that unnecessary trauma to normal dermal tissue can be avoided. Smaller hematoma, so chances of post-subcision fibrous nodule are diminished	Small tip not as efficient at cutting dermal/subcutaneous attachments as Nokor or cataract blade
23-G needle [6]	Harandi	4	Accessible for all Does not traumatize the skin at the insertion site	Small tip not as efficient at cutting dermal/subcutaneous attachments than Nokor or cataract blade

Combining Subcision with Other Treatments

Incomplete improvement is a possible outcome of subcision, and investigators have sought ways of making the improvement of scars more substantial or longer lasting by implanting material into the subcision pocket. Materials suggested include the patient's own dermis which is harvested from another site, absorbable plain catgut, and injectable filler substances [2]. No benefit was found in any of the studies evaluating subdermally implanted material over subcision alone, and some cases resulted in long-lasting nodules [2, 3]. Harandi and colleagues evaluated suction onto the skin using a microdermabrasion device in the postoperative period. Patients who received daily or every-other-day suction at subcision sites had a greater degree of improvement than those who had it less frequently; however, suction caused more nodules and bruising [6]. The results of this study have not been replicated. Investigators have also sought to combine subcision with other treatments either on the same day or in the immediate postoperative period. A study of one patient found that a nonablative 1320-nm Nd:YAG laser on scars treated with subcision produced greater improvement than subcision performed alone (4) [12]. It is possible that other treatments could be combined with subcision, such as carbon-dioxide laser, microneedling, and fractional radiofrequency; however, these have not been studied in combination with subcision.

Safety

Overall, subcision appears to be a relatively safe procedure with low risk of major sequelae. Common self-limited complications include pain, swelling, and bruising in the first 1–2 weeks after the procedure (4) [4, 13]. Rare adverse events are infection and hypertrophic scarring [4, 6, 13]. A fairly common, longer-term sequela of subcision is the formation of small to large firm elevations at the treatment site. The composition of the firm subcutaneous elevations has not been described in the literature by histopathology but is thought to be either early fibrosis or organization of a hematoma underneath the scar [13]. These subcutaneous nodules are thought to be responsible for the improvement of the depressed scars and usually resolve by 3 months after the procedure [4]. Goodman describes intralesional corticosteroids as a treatment for those nodules lasting longer than 3 months, which he reports as happening 5–10% of the time. Suction over the lesion in the postoperative period not only increases the amount and duration of bruising, but it also increases the height and the duration of subcutaneous indurations [6]. A final complication described is the formation of acneiform cysts that can result from the disruption of the pilosebaceous unit or subcutaneous sinus tracts (4, 5) [13, 14].

Alternative or Complementary Procedures

The most similar alternative procedure to subcision is the injection of soft tissue augmentation filler material underneath scar tissue. Like subcision, the goal of filler injection is to lift the base of rolling acne scars upward to minimize scar depth and ultimately improve the contour of the skin. The products which have been described include temporary fillers such as naturally sourced porcine collagen and hyaluronic acid, as well as permanent or long-lasting products such as micro-droplet silicone and polymethyl methacrylate microspheres in a bovine collagen matrix (1b, 3b) [15, 16]. The proposed advantages of filler injection include immediate results, minimal to no bruising or swelling, fairly predictable results, and the ability to make corrections at follow-up visits or completely reverse the procedure with hyaluronidase (2b) [3, 8, 17]. Disadvantages of filler injections include the temporary nature of products such as hyaluronic acid and collagen. While other products are longer lasting, they carry the risk of long-term nodules if the scar is overcorrected. These products include PMMA-collagen, calcium hydroxyapatite, poly-L-lactic acid, and autologous fat.

Only one study compared subcision to filler material head-to-head. This was a prospective, randomized, split-face, evaluator-blinded study of 10 patients. The subjects were randomly assigned to undergo subcision one side of the face and to receive injections of a naturally sourced porcine collagen filler on the other. Patients reported a superior result of subcision at 3 months compared to filler ($p = 0.03$); however, at 6 months, subcision was only slightly better ($p = 0.12$). Blinded evaluators scored subcision slightly better at 3 months ($p = 0.12$) and found no difference between the treatments at 6 months ($p = 0.69$) [17].

Some data exists that supports the suggestion that longer-acting or permanent fillers can effectively treat acne scars. A double-blind, randomized, multicenter, split-face, placebo-controlled trial compared saline injections to injections of polymethylmethacrylate microspheres suspended in collagen (PMMA-collagen) for atrophic acne scars in 147 subjects. Subjects received two different sessions of the injections and were evaluated over 6 months with a validated rating scale for each scar. A statistically significant improvement of the PMMA-collagen over saline at 6 months ($p = 0.0005$) was observed. The safety profile was excellent with mild, reversible side effects and no difference noted in different ages, gender, or skin type [15]. Another desirable quality of the PMMA-collagen is its purported permanent or long-lasting effect compared to hyaluronic acid fillers; however, this was not evaluated in this study. Another long-lasting filler is liquid silicone. While it has not been evaluated in a prospective, controlled trial, it has been

reported as being effective and long-lasting for the improvement of acne scars [16].

Finally, surgical and laser procedures are other potential alternatives to treatment. Punch elevation is the surgical procedure that best addresses the same types of scars which are optimal for subcision—rolling acne scars which have good quality skin at the base of the scar (Goodman). The procedure involves performing a punch around the scar and then lifting the scar upwards with either sutures or Steri-Strips. Other surgical procedures such as punch grafts, punch excision, and larger excisions are more appropriate for ice pick, boxcar, or sclerotic scars according to expert opinion article by Jacobs et al. (5) [8, 18]. Resurfacing procedures such as ablative and nonablative fractional lasers also do not address the same types of scars and have not been studied in head-to-head comparative studies with subcision. There is no strong evidence supporting these resurfacing procedures as alternatives to or adjuvants of subcision.

Overall, the evidence is lacking to recommend subcision over any other treatment for rolling, atrophic acne scars. This absence of evidence regarding subcision is consistent with the absence of high-quality evidence in the field of acne scar treatment generally. A Cochrane review made this comment after evaluating 24 randomized controlled studies of various acne scar therapies: "There is lack of high-quality evidence about the effects of different interventions for treating acne scars because of poor methodology, underpowered studies, lack of standardized improvement assessments, and different baseline variables." (1a) [19].

Postoperative Management and Follow-Up

Little has been discovered about the appropriate postoperative management of subcision. Balighi advised that little is required for postoperative care [2]. Alam and colleagues recommended that pressure dressings be placed and removed at 24 h [4]. If suction is to be performed, then daily or every-other-day follow-up visits would be required [6]. Goodman recommended that sun exposure should be minimized for 4 weeks after surgery, especially in olive-skinned patients to minimize the possibility of post-inflammatory hyperpigmentation [13]. Visible elevations and firm nodules can occur in the weeks and months following subcision; however, these resolve on their own. The rare nodule that persists can be treated with intralesional corticosteroid injections [13].

The duration of time required for the skin to achieve its steady state after subcision is also unclear. Vaishani suggested that 2 years is required for scar remodeling to be completed after subcision [5]. Orentreich advised follow-up treatments at 6–12 months for new or recurrent depressions after subcision [1].

Recommendations

- Subcision is effective for treating rolling acne scars on the face (B).
- Subcision is a safe procedure for all skin types, with low risk of serious or long-term complications (B).
- Contraindications for subcision include active infection, history of keloid scars in the area of treatment, bleeding diathesis, and current isotretinoin use (B).
- Various needle types can be used for subcision, depending on the size and depth of the scar to be treated. The needles range from 22- to 30-gauge standard hypodermic needles to Nokor needles or tri-beveled 20-gauge cataract blades (B–C).
- Studies have not demonstrated subcision to be superior or inferior to alternative therapies which treat the same type of scars, such as punch elevation and filler injection (B).

Self-Assessment Questions

1. Subcision is optimal for which types of scars:
   (a) Rolling or atrophic acne scars
   (b) Varicella scars
   (c) Ice-pick acne scars
   (d) Hypertrophic scars
   (e) Subcutaneous sinus tracts
2. What is the level of evidence supporting subcision as an effective treatment for acne scars?
   (a) Primarily level 1A (Systematic review with homogeneity of randomized, controlled trials)
   (b) Primarily level 2A (Systematic reviews with homogeneity of cohort studies)
   (c) Primarily level 3A (Systematic reviews with homogeneity of case-control studies)
   (d) Primarily level 4 and 5 (Case series and expert opinion)
   (e) None of the above
3. What are common postoperative events associated with subcision?
   (a) Bruising
   (b) Swelling
   (c) Self-limited subcutaneous nodules
   (d) Bacterial infection
   (e) All of the above
   (f) a, b, and c
4. Which of the following statements is true?
   (a) Silicone injections have been shown in a randomized, controlled study to be effective for atrophic acne scars.
   (b) Subcision was shown to be superior to polymethacrylate microspheres in collagen (PMMA-collagen) for acne scarring in prospective controlled trial.
   (c) PMMA-collagen was superior to saline injections for atrophic acne scars at 6 months in a prospective, randomized trial.
   (d) CO_2 laser resurfacing was shown to be more effective at treating atrophic acne scars compared to placebo.
5. Comparative studies have determined that the optimal needle to use for subcision is the:
   (a) 18-gauge 1.5-inch Nokor needle.
   (b) 20-G microvitreoretinal (MVR) cataract blade.
   (c) 22–25 gauge hypodermic needle.
   (d) Comparative studies have not been performed to determine the optimal needle to use for subcision.

Correct Answers

1. a: Rolling acne scars with quality skin at the base are considered the optimal scars for subcision. Varicella scars or ice pick scars, which have either sharp borders or poor-quality, scarred skin at the base do not respond as well to subcision. Hypertrophic scars and subcutaneous sinus tracts are not treated by subcision. Subcutaneous sinus tracts can actually be disrupted by subcision.
2. d: The majority of publications supporting subcision are either expert opinion or case series.
3. f: Bruising and swelling are common and expected immediate, self-limited sequelae of subcision. Subcutaneous thickening or nodules are also common, but they resolve over time. Infection is not a common postoperative event.
4. c: A prospective, randomized, placebo-controlled, split-face study demonstrated improvement of atrophic acne scars with PMMA-collagen. Prospective, controlled studies have not been performed comparing injected silicone to placebo, subcision to PMMA-collagen, or CO_2 laser to placebo.
5. d: While specific authors recommend certain blades as being the most effective, comparative studies have not been performed.

Liposuction

23

Ashley Decker and Naomi Lawrence

Abstract

Liposuction is a safe and effective method of subcutaneous fat removal involving aspiration of subcutaneous adipose tissue via cannulas introduced through small skin incisions. In tumescent liposuction, the surgeon utilizes subcutaneous infiltration of dilute lidocaine and epinephrine to provide local anesthesia and hemostasis prior to aspiration of the adipose tissue. In addition to its aesthetic indications, tumescent liposuction is also a safe and effective treatment modality for breast reduction, gynecomastia, lipomas, lipoedema, and hyperhidrosis. Despite the development of newer, noninvasive body-contouring modalities, liposuction remains the gold standard.

Indications for Liposuction

Liposuction is the surgical removal of subcutaneous adipose tissue using aspiration cannulas introduced through small skin incisions. In tumescent liposuction, the surgeon utilizes subcutaneous infiltration of dilute lidocaine and epinephrine to provide local anesthesia and hemostasis prior to aspiration of the adipose tissue. This technique was refined and popularized in the United States by Klein in 1987 [1]. Today, tumescent liposuction is the accepted standard of care for liposuction surgery performed for both aesthetic and non-aesthetic purposes. A key advantage of this approach is the ability to perform the procedure in the outpatient setting, leading to increased patient convenience, decreased risk of nosocomial infection, and lower costs [2].

Adipose tissue is a loose connective tissue that is the site of storage of energy in lipid form, insulation and heat production, and production of several hormones including leptin and estrogen and is divided into two main types based on location: visceral and subcutaneous. Visceral adipose tissue represents approximately 18% of the total body fat and has historically been linked to metabolic disease; however, the role that each type plays in the development of metabolic syndrome is not fully elucidated (5, 5) [3, 4]. Although it has been hypothesized that changing the proportion of visceral to subcutaneous fat through liposuction may unfavorably alter metabolic disease

risk (5) [5], most studies show no post-procedure change in the parameters associated with metabolic syndrome (4, 4, 2b, 2b) [3, 6–9].

The primary aesthetic indication for tumescent liposuction is the correction or removal of disproportionate, localized deposits of adipose tissue (5) [10]. This therapy has successfully treated undesired adiposity in nearly all body sites. Tumescent liposuction is also an effective procedure for non-cosmetic treatment of adipose collections in cases such as breast reduction, lipomas, gynecomastia, lipoedema, and hyperhidrosis. For hyperhidrosis/bromhidrosis specifically, tumescent liposuction is indicated after failure of conventional medical therapies and can be used alone or in combination with curettage. In order to assess treatment efficacy for this indication, pre- and postoperative gravimetry studies should be considered.

Effectiveness of Liposuction

The majority of data indicates that tumescent liposuction results in the effective, durable removal of localized adiposity when used for both cosmetic and non-cosmetic indications. An assessment of changes in body contour after liposuction is largely based on qualitative comparisons using pre-/postoperative photography and circumference measurements. Using more robust 3D digital photoimaging and standardized measuring techniques, Cohen et al. found a 30% decrease in mean abdominal volume after tumescent liposuction (4) [11]. The available literature suggests that most patients are satisfied with the results of liposuction performed for body contouring. Broughton et al. reported that 80% of patients who underwent liposuction at the University of Texas Southwestern Medical Center between 1999 and 2003 were satisfied with the outcome of their procedure (5) [12].

Treatment of lipomas with tumescent liposuction can reduce scarring compared to standard surgical excision. In addition, the use of tumescent anesthesia with epinephrine creates a near-bloodless field and may aid in the disruption fibrous septae leading to easier extraction during surgery or liposuction. A prospective review by Choi et al. described the use of liposuction for the treatment of 31 lipomas located on the head or neck, trunk, abdomen, or extremities in 21 patients (4) [13]. In total, 23 lipomas were removed without complications. The remaining cases were complicated by incomplete fat removal, bruising, hematoma, and dimpling [13]. In the cases of large fibrous lipomas, laser lipolysis followed by liposuction can be necessary (4) [14].

Tumescent liposuction for hyperhidrosis/bromhidrosis can lead to significant improvement in sweating, with patient satisfaction ranging from 80% to 98% (4, 4) [15, 16]. Patients with high sweat rates respond better to liposuction-curettage than those with normal to slightly elevated sweat rates. Posttreatment recurrence rates reported in the literature range from 4.6% to 30% (4, 4, 4) [17–19]. This large variation is due to residual apocrine glands present after treatment opposed to apocrine gland regeneration. Treatment success largely depends on the technique utilized. When compared to open excision, liposuction with curettage results in higher patient satisfaction rates and less severe scarring. However, symptom recurrence is more common among patients treated with liposuction-curettage (3b) [20]. There are a number of papers comparing these two modalities, and although symptom recurrence is more common with liposuction-curettage, most studies show that patients prefer it because it is a procedure with significantly less morbidity. A recently randomized controlled clinical trial comparing liposuction-curettage to neurotoxin for axillary hyperhidrosis showed a statistically significant decrease in heavy sweating with neurotoxin compared to liposuction (2b) [21]. However, neurotoxins have the disadvantages of repeated treatments and are not usually covered by insurance.

Breast liposuction is indicated in male and female patients with enlarged breasts. First introduced in 1991, it is a safe and effective procedure to decrease breast volume and improve breast ptosis (4, 4, 4, 4) [22–25]. In addition, patients report improvement in symptoms associated with large breasts including intertrigo, postural issues,

and neck, back, and shoulder pain. Studies show no significant changes in mammography occur after breast liposuction (4) [24, 26].

Preoperative Evaluation

Proper patient selection is imperative. The ideal patient has localized deposits of adipose tissue recalcitrant to diet and exercise, is otherwise healthy, and has realistic expectations about the procedure. Patients may incorrectly seek tumescent liposuction consultation as a method of weight loss. Tumescent liposuction is not used for weight loss/weight control but rather to improve body contour; any weight loss from the procedure is incidental (5) [27]. Current recommendations suggest that patients should be within 30% of their ideal body weight (5) [28]. Removal of a maximum of 4–5 L of adipose tissue is considered safe during tumescent liposuction (4) [29]. Removal of greater amounts predisposes to higher risk as the risk of complications is proportional to the volume of fat removed.

During the pre-procedure consultation, complete a thorough history of medical conditions and previous surgeries, allergies, and medications, including over-the-counter medications, vitamins, and supplements. Liposuction is contraindicated in patients with severe cardiovascular disease, allergy to lidocaine, and severe coagulation disorders including thrombophilia and during pregnancy. Patients with a history of bleeding diathesis, emboli, thrombophlebitis, infectious diseases, poor wound healing, or diabetes mellitus should receive medical clearance. Ask about history of prior abdominal surgeries or problems during previous surgical procedures. Stop all nonessential medications prior to surgery to minimize the risk of bleeding complications. Discontinue aspirin (ASA) 2 weeks prior to surgery and other nonsteroidal anti-inflammatory medications 5 days prior to surgery. If the patient is on anticoagulation, discuss with the prescribing provider whether perioperative discontinuation is safe. If the patient cannot stop anticoagulants for an appropriate amount of time, they are not a candidate for liposuction. The procedure results in a dead space and a risk of delayed bleeding that creates a greater challenge than conventional surgery. Discontinue any medication that may interfere with lidocaine metabolism 2 weeks prior to the procedure (Table 23.1). If not possible to discontinue a medication that may interfere with lidocaine metabolism, use of a lower total amount of lidocaine or general anesthesia should be considered.

Completion of a psychosocial history is imperative when assessing a patient for liposuction. Ask about dietary habits and exercise, history of weight loss/gain, familial body shape, and patient's emotional ability to endure the procedure. Assess the patient's expectations following the procedure. A history of weight cycling prior to the procedure is often a poor prognostic indicator of the outcome.

After completion of the medical and psychosocial history, perform a complete physical exam with emphasis on the body sites under consideration. Distinguish between subdermal and vis-

ceral fat on the abdomen. Assess skin quality and texture in the affected areas and evaluate for any scars or keloids indicating prior procedures [10]. Check for complete blood count, platelet count, prothrombin times, partial thromboplastin time, and complete metabolic panel and conduct a pregnancy test in women of childbearing age prior to the procedure. A preoperative mammogram is necessary to screen for malignant and benign tumors in women undergoing liposuction for breast reduction. Take high-quality photographs in three dimensions during consultation and preoperatively on the day of surgery.

Best Techniques and Performance

Mark the patient in a standing position paying attention to the areas of interest. Make note of any asymmetries and adjust predicted volume removal accordingly. View each area from the anterior, posterior, and oblique positions to best appreciate the three-dimensional nature of adiposity. After the markings are complete, review with the patient to ensure all areas of concern are addressed. Choose access points that can treat multiple different areas or the same area in multiple different directions. The incisions should be 3–4 mm in length and placed in well-concealed areas (5) [31]. Ultrasound-assisted liposuction requires larger incisions (5–6 mm) because of the placement of skin protectors that minimize heat transfer to the skin [31]. Cannulas with a tapered tip or an increased number of holes near the tip are for more aggressive suctioning. Blunt-tipped cannulas, or those with the holes located further away from the tip, are less aggressive. Most areas can be suctioned with relatively thin cannulas. In large or fibrous areas, it is helpful to start with "aggressive" tips to break up the adipose and fibrous tissue and then switch to a larger gauge blunt-tipped cannula. Small-diameter, blunt-tipped cannulas are used to minimize perforation risk and decrease contour irregularities. Patient positioning depends on the area being treated (see Table 23.2).

Anatomically, fat is separated into layers by Scarpa's fascia, but for the purposes of liposuc-

Table 23.2 Anatomic considerations

Neck
Forward placed hyoid bone may limit ability to fully contour the anterior neck
Enlarged thyroid or submandibular glands may contribute to neck fullness
Micrognathia contributes to chin deformity and skin redundancy
Have patient contract platysma in a grimace to define the preplatysmal fat pad
Two layers of fat: subcutaneous and deep to the muscle. It is important to temper patient expectations in the setting of significant submuscular fat
Abdomen
Lateral hip-flexed (diver's) position helps delineate superficial fat from the muscle and omental fat
Check for abdominal hernia or defects in the rectus
Place the patient in a comfortable supine position
Discuss differences between subcutaneous fat and visceral fat. Temper expectations of the procedure in patients with significant visceral fat
Outer thigh
Determine the extent to which the buttocks' weight contributes to the outer thigh deformity
Flexion of gluteal musculature defines the contribution of adipose in the buttocks to the protuberance of the outer thigh—if the outer thigh decreased on gluteal contraction, the weight of the buttocks is significant
Abduct the thigh using a wedge-shaped pillow to eliminate the "pseudobulge" which is seen over the trochanteric process. This decreases the risk of iatrogenic depression caused by excessive liposuction [32]
Inner thigh
Loose skin and adipose tissue
Place the patient in a modified lateral decubitus position with the uppermost hip flexed in a high-step position and ipsilateral leg resting on surgical positioning pillow. This allows for easy accessibility of the posterior medial fat pad, which is not adequately accessed in a supine position [32]
Back
Dense fibrous fat

Table 23.2 (continued)

Upper arms Distinguish lax muscle and redundant skin from adipose tissue Extensor fat pad overlies the triceps and biceps. Place patient in lateral decubitus position and rest the arm on patient's uppermost side [32] For the volar or axillary portion of arm fat, place the patient in a lateral decubitus position. Raise the arm above the head, with hand resting over or behind the head [32]
Breast Palpate the breast to evaluate for fibrocystic disease and to distinguish between glandular and adipose tissue
Knees Majority of adipose tissue is located on the medial aspect of the knee, but there is suprapatellar and subpatellar extension Place the patient in a modified lateral decubitus position with the uppermost hip flexed in a high-step position and ipsilateral leg resting on surgical positioning pillow [32]
Hips Adipose tissue extends toward the back Place the patient in a lateral decubitus position

tion, it is divided into three layers: superficial, intermediate, and deep. Intermediate and deep layers are suctioned; the superficial layer should remain undisturbed. Liposuction of the superficial layer may lead to dimples and skin irregularities that are cosmetically unacceptable (5) [33]. Anatomic "zones of adherence" are present in both men and women and need to be avoided because of high risk of contour deformities. They are composed of dense fascial extensions extending from the superficial fat to the underlying musculature and help define the natural shape and musculature of the body [4, 28]. Men have more fibrous adipose tissue than women, except in specific situations and locations such as fibrocystic breast disease and on the back. The outer and inner thighs are comprised of soft fat.

Several liposuction treatment modalities exist including suction-assisted ("traditional liposuction"), power-assisted, laser-assisted, ultrasound-assisted, and radiofrequency-assisted liposuction. Deciding on what type of modality to use depends largely on the surgeon's preference. The authors prefer traditional suction-assisted lipectomy with tumescent anesthesia as none of the new modalities have improved patient outcomes or experience. Some of the technology-assisted modalities are preferred by liposuction surgeons, who feel that it decreases the work of the procedure for the physician.

Suction-assisted liposuction is the most common form of liposuction. It involves the use of various sized cannulas attached to the suction to facilitate removal of aspirate. Power-assisted liposuction involves a variable speed motor that provides a reciprocating motion to the cannula facilitating removal of adipose tissue (4) [31, 34]. Some consider the use of power-assisted liposuction in fibrous areas, such as areas of revision, or for large-volume liposuction.

Laser-assisted liposuction involves the use of laser energy to facilitate fat breakdown prior to aspiration. There are several FDA-approved laser lipolysis devices available in the market (5) [35]. The most commonly used wavelengths are 924/975 nm, 1064 nm, and 1319/1320 nm [31, 35]. The procedure is carried out in four stages: infiltration, application of energy to subcutaneous tissues, evacuation, and subdermal skin stimulation. These devices are marketed for the additional benefit of skin tightening. Prado et al. conducted a prospective, randomized, double-blind controlled trial comparing 1064 nm Nd:Yag-assisted lipolysis to suction-assisted liposuction in 25 patients (2b) [36]. Each patient served as their own control with one side treated with laser-assisted lipolysis and the contralateral side with suction-assisted liposuction [36]. No clinical difference was seen between the treatment modalities [36]. Higher concentrations of free fatty acids were seen after laser-assisted lipolysis [36]. One proposed additional benefit of laser-assisted lipolysis is skin tightening from subdermal heating; however, this has never been

substantiated. Traditional liposuction leads to some skin tightening because of retraction. Longer-wavelength lasers have a higher risk of burns because of increased dermal absorption and localized heating [35].

Ultrasound-assisted liposuction uses ultrasound energy to break down fat allowing for easier removal. It may decrease surgeon fatigue and is useful in areas with increased fibrosis. Its primary mechanism is mechanical but cavitation and thermal damage can occur [31]. Vibration amplification of sound energy at resonance (VASER)-assisted lipoplasty is a third-generation ultrasound system that was introduced after mixed results from hollow probe ultrasonic liposuction. A prospective study by Nagy et al. compared the blood loss and skin retraction-associated VASER-assisted lipoplasty versus suction-assisted liposuction in 20 patients. Patients served as their own controls. The VASER-associated lipoplasty resulted in a statistically significant improvement in both skin retraction and blood loss compared to standard suction-associated liposuction (2b) [37]. This small study has not been validated by other studies. The technique is also really slow.

Radiofrequency-assisted liposuction applies electromagnetic energy in a bipolar manner to both the subcutaneous adipose tissue and the subdermal skin surface (4, 4) [38, 39]. A study by Paul et al. demonstrated radiofrequency-associated liposuction leads to rapid preaspiration liquefaction of adipose tissue, coagulation of subcutaneous blood vessels, and uniformed sustained heating of the tissue [38]. Some recent literature has purported radiofrequency-assisted liposuction is faster, reduces tissue trauma, and has potential for skin retraction; however, these studies are small and underpowered (4, 4) [40, 41].

Safety

Tumescent liposuction is a safe procedure with a low complication rate. Several large surveys report of a systemic complication rate of less than 1% (5, 5, 5) [42–44]. Data over a 7-year time period from the Florida Agency for Health Care Administration found eight deaths associated with in-office liposuction, all of which were performed under general anesthesia ($n = 7$) or IV sedation ($n = 1$) (5, 5) [45, 46]. No adverse events were reported with tumescent liposuction [45, 46].

Tumescent anesthesia is a low-risk procedure; proper patient selection coupled with a well-trained physician mitigates these risks even further.

Safety of Tumescent Anesthesia

The use of tumescent anesthesia confers a risk of lidocaine toxicity. The half-life of lidocaine is 120 min, and tumescent anesthesia can lead to levels that cause symptoms of lidocaine toxicity. Most cases of lidocaine toxicity are due to incorrect mixing or dosing of the lidocaine solution. As serum lidocaine levels approach 3 μg/mL, subjective symptoms such as feeling lightheaded, dizzy, and/or drowsy may occur (4) [47]. Muscular fasciculation, tinnitus, and paresthesia occur with serum lidocaine levels >5 μg/ml [47]. Concentrations >9 μg/ml are associated with coma, seizures, respiratory arrest, and cardiac arrest [47].

Klein first showed that 35 mg/kg of tumescent lidocaine was safe, with peak plasma levels reaching at 12 h post infusion (V) [48]. Subsequent studies showed lidocaine doses up to 50–55 mg/kg are safe in tumescent anesthesia (4) [49]. Accordingly, the current guidelines in the dermatology literature recommend a maximum dose of lidocaine in tumescent anesthesia of 50–55 mg/kg (5) [1, 2, 50]. However, the rate of systemic absorption is location dependent with peak serum lidocaine levels reached more quickly when tumescent anesthesia is administered above the clavicles (3b) [51]. The risk of toxicity remains low overall because of the low volume of tumescent anesthesia used in those areas. In contrast, the presence of dilute epinephrine leads to vasoconstriction and slows the systemic absorption of the lidocaine. Finally, the surgical procedure performed following tumescent anesthesia

should influence the total lidocaine dose. A significant amount of lidocaine is removed during liposuction, and this may play a role in peak absorption levels. A recent prospective study by Klein et al. suggested that the maximum tumescent lidocaine dose be limited to 28 mg/kg in patients where tumescent anesthesia was not followed by liposuction. Their data indicate that a significant amount of lidocaine is likely removed by the liposuction procedure and does not reach the systemic circulation (3b) [52]. Data supporting maximum lidocaine dose of 55 mg/kg in tumescent liposuction should not be extrapolated to estimate the maximum dose of tumescent anesthesia for other procedures.

Local and Systemic Complications

Local adverse effects include erythema, ecchymoses, edema, and seromas. Tumescent liposuction can result in significant fluid shift and intravascular volume changes leading to a vasovagal reaction. The most frequent potentially lethal complications associated with liposuction are infection, pulmonary embolism, fat embolism, sepsis, necrotizing fasciitis, and perforation of abdominal viscera [28]. Both Group A strep (GAS) and *Mycobacterium* species have been identified in post-liposuction infections. An investigation into an outbreak of GAS infection following liposuction at a single outpatient cosmetic surgery facility determined that GAS infection was caused by transmission from colonized health workers during the procedure (4) [30]. Although the risk of significant systemic complications from tumescent liposuction is low compared to general anesthesia, when present, they still confer significant morbidity and mortality.

Deaths associated with tumescent liposuction are more common in the plastic surgery literature. A study by Lehnhardt et al. sent out 3500 questionnaires to departments of pathology, intensive care units, insurance companies, and district attorney offices. Two thousand and seventy-five (65%) surveys were returned with 72 cases of reported severe systemic complications. Forty-one of the 72 severe complications were with tumescent anesthesia, four of which resulted in death (4) [53]. The major risk factors for complications were insufficient hygiene standards, increased amounts of tumescent anesthesia, poor patient selection, permissive discharge, and inexperience of the provider [53].

In summary, tumescent liposuction is a safe and efficacious procedure. Increased mortality is seen with aggressive liposuction, large-volume procedures, general anesthesia, or IV sedation. Liposuction under general anesthesia has a higher-than-acceptable complication rate and should be abandoned in practice.

Postoperative Care and Follow-Up

After completion of the procedure, appropriate compression garments should be placed to minimize the risk of bruising, hematomas, seromas, and pain. Application of heavy compression in the first 24 h helps to facilitate drainage followed by mild compression for the next 2–4 days (5) [54]. Prolonged compression may lead to skin creases, pain, swelling, and hyperpigmentation [28]. Educate the patient that swelling and bruising are normal after the procedure. Drainage from the puncture sites may occur in the first 24–48 h after surgery. Encourage the patient to ambulate the night of surgery. The initial postoperative visit is 1 week after surgery. Patients can resume activities immediately but will be sore. Most patients prefer to wait a week. Swelling can persist for 3–4 weeks; final results are expected in 3–4 months [31]. In patients with elastic skin, contour improves after swelling is resolved. In patients with poor elasticity and lax skin, full retraction can take 6–12 months.

Alternative Procedures and Modifications

Although liposuction remains the most popular body-contouring procedure, the need for post-procedure downtime and the desire for noninvasive procedures led to the development of noninvasive procedures for fat reduction such as

high-intensity focused ultrasound (HIFU), radiofrequency, laser-assisted lipolysis, and infrared light (4) [55]. At the forefront of noninvasive fat reduction treatment is cryolipolysis. This treatment is based on the observation that fat cells, relative to those of other tissues, are more sensitive to the cold (4, 4) [56, 57]. A preclinical study by Zelickson et al. showed that a controlled, cold application to the skin leads to selective damage of adipose tissue without adverse effects to the epidermis or dermis [55]. Cold exposure induces crystallization within the adipocytes leading to panniculitis and subsequent necrosis. The procedure is well tolerated. A study by Garibyan et al. showed an average of about 40 cc fat reduction in the treated flank 2 months after a single treatment (3b) [58]. Another study by Dierickx et al. demonstrated a 23% reduction in fat layer thickness at 3 months (3b) [59]. The back, flank, and abdomen were most responsive to treatment [59].

Side effects of treatment are localized pain, erythema, transient changes in sensation, and nodular or diffuse infiltration at the treatment site. All of these side effects are transient and resolve within weeks.

Radiofrequency without associated liposuction is another method of noninvasive body contouring and fat reduction. This procedure utilizes electromagnetic energy to generate heat within targeted tissues (5, 4) [60, 61]. Adipose tissue has high resistance but a low heat transfer coefficient. This enables significant heat generation resulting in adipolysis when radiofrequency passes through the tissue but minimal heat transfer or injury to surrounding structures (4) [62]. Some studies suggest radiofrequency also improves dermal collagen, elastin, and ground substance leading to skin tightening (5,5) [62, 63]. Monopolar, unipolar, bipolar, and multipolar mechanisms of radiofrequency delivery are available. Notably, this procedure works regardless of skin type or chromophore and is not dependent on selective photothermolysis [60]. Adverse effects include erythema, edema, heating sensation, and bruising (4, 4) [64, 65].

High-intensity focused ultrasound (HIFU) uses high-frequency acoustic energy to ablate focal areas of subcutaneous adipose tissue. It rapidly heats the adipose tissue to 55 °C, causing cellular membrane disruption/lysis and coagulative necrosis (5) [66]. It spares damage to the surrounding connective tissue, blood vessels, nerves, and overlying skin. HIFU devices are currently approved by the FDA for noninvasive waist circumference reduction. They target subcutaneous abdominal fat at a focal depth of 1.3 cm [66]. A randomized sham-controlled trial by Jewell et al. showed significantly greater waist reductions in patients in both treatment arms (141 J/cm [2] or 159 J/cm [2]) compared to the sham treatment group (2b) [67]. Mean waist circumference reduction was 2.51 cm ($p < 0.001$) in both treatment arms. Other studies showed similar reductions in mean waist circumference after a single treatment (4, 4, 2b) [68–70]. Unfortunately, circumference is known to be an unreliable measure. Adverse events include ecchymosis, tenderness, focal induration, and edema [66].

The use of infrared lasers and low-light laser therapy (LLLT) for subcutaneous adipose tissue reduction is based on the concept of selective photothermolysis. An in vitro study by Anderson et al. identified the absorption spectra of adipose tissue (1210 and 1720 nm) and suggested selective photothermal targeting of subcutaneous adipose tissue is achievable using infrared lasers that target these spectra (4) [71]. A study by Wanner et al. treated the abdomen of 24 adult patients with 1210 nm laser at 70, 80, and 90 J/cm [2] (10 mm spot size, 5 s pre-cooling, 3 s exposure) [72]. Exposure and control sites were biopsied at 1–3 days and 4–7 weeks (3b) [72]. Histologic evaluation showed laser-induced lipomembranous damage to the fat [72]. The laser treatments were painful and required local anesthesia [72]. Additional prospective studies are needed to elucidate if there is a role for infrared lasers in the treatment of subcutaneous adipose tissue.

LLLT is a noninvasive, nonthermal light source treatment (635 nm) that generates a single wavelength and acts by generating cellular nonthermal or photochemical reactions (2b) [73]. It is hypothesized to work by creating transient pores in adipocytes, allowing lipids to leak out (5) [74]. Used for years in a myriad of conditions across multiple specialties, recently its role in

noninvasive body contouring, in cellulite reduction, and as an adjunct to liposuction has been of some interest [74].

LLLT's role in fat reduction is controversial. A study by Brown et el. did not show any change in the structure or function of cultured human preadipocytes treated with up to 60 min of LLLT (3b) [75]. In this same study by Brown et al., no difference in adipocyte structure was noted in the adipocytes extracted through liposuction (with or without tumescence) following similar transcutaneous exposure times to LLLT in the human or porcine model [75]. A study by Kolari et al. questions the ability of LLLT to penetrate past the dermis into the subcutaneous adipose tissue and can explain the absence of structural/functional change in adipocytes treated with LLLT (4) [76]. However, clinical studies have shown a decrease in abdominal, hip, thigh, and waist circumference (2b, 4) [73, 77, 78]. These studies are limited by lack of clinical controls and short duration of follow-up.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
Effectiveness	
Tumescent liposuction is effective in the removal of localized adipose tissue for cosmetic and non-cosmetic reasons	A
It is a safe and effective alternative for lipoma removal. Advantages include reduced scarring, near-bloodless field created by tumescent anesthesia, and disruption of fibrous septae leading to easier removal	B
Tumescent liposuction with curettage is an effective treatment for patients with brom-/hyperhidrosis	B
Breast liposuction can reduce the volume and improve ptosis in both men and women	B
Preoperative evaluation	
Appropriate patient selection is imperative to maximize treatment outcome and patient satisfaction	A
Complete a comprehensive history to identify any medical or psychosocial issues prior to the procedure	A
The physical exam should focus on the areas of adiposity, amount of visceral vs subdermal fat, and skin quality/texture	A
Best techniques and performance	
Cannulas with tapered tips are more aggressive; blunt-tipped cannulas are less aggressive	A
Pure tumescent anesthesia without sedation is the safest method	A
Some physicians use additional technology including:	
Power assisted: revisions or large volumes	B
Laser assisted and ultrasound assisted: assists in fat breakdown. Skin tightening has not been substantiated	C
All of these technologies are more expensive and have not been shown to be better tolerated by the patient, show superior results, prove better skin retraction consistently, are more comfortable for the patient, and show no decrease in postoperative adverse events	B
Safety	
Tumescent liposuction is a low-risk procedure	A
The maximum dose of tumescent lidocaine is 45–55 mg/kg	A
Increased mortality is seen with aggressive liposuction, large-volume procedures, general anesthesia, or IV sedation	A
Liposuction with general anesthesia is associated with a higher mortality rate	A

Findings	GRADE score: quality of evidence
Postoperative care and follow-up	
Place compression garments after the surgery to minimize bruising, swelling, hematomas/seromas, and pain	D
Improvement in body contour is immediate but full skin retraction can take 6–12 months to occur	D
Alternative procedures and modifications	
Liposuction remains the gold standard	A
Cryolipolysis can improve localized areas of adiposity. Side effects of treatment are transient and resolve in weeks	B
The evidence for the role of radiofrequency, high-intensity focused ultrasound, and low-light laser therapy remains controversial	C

Self-Assessment Questions

1. What key aspects of the medical and surgical history should be documented during preoperative evaluation?
   (a) Previous surgeries with special attention to surgeries performed in the area to be suctioned
   (b) Psychosocial history including history of body dysmorphic disorder
   (c) Recent fluctuations in weight
   (d) Chronic medical conditions (i.e., cardiovascular disease, diabetes)
   (e) All of the above
2. What is the recommended maximum volume that should be aspirated during a single liposuction session?
   (a) 1–2 L
   (b) 2–3 L
   (c) 4–5 L
   (d) 5–6 L
   (e) 7–8 L
3. What is the half-life of lidocaine?
   (a) 30 min
   (b) 60 min
   (c) 90 min
   (d) 120 min
   (e) 180 min
4. What layer(s) of fat are targeted in tumescent liposuction?
   (a) Superficial
   (b) Superficial and intermediate
   (c) Deep
   (d) Intermediate and deep
   (e) Superficial, intermediate, and deep
5. What are the recommended qualifications of a physician performing liposuction?
   (a) Advance Cardiac Life Support certification
   (b) Board certification in a specialty that emphasizes training in cutaneous surgery
   (c) Evidence of liposuction surgery training in residency or documented liposuction-specific training postresidency
   (d) All of the above

Correct Answers

1. e: All of the above. A history of previous surgeries in the area can lead to scarring/fibrosis complicating the procedure. Patients with a history of psychosocial disorders, especially body dysmorphic disorder, can have unrealistic expectations of the outcome making them poor candidates for the procedure. Recent fluctuation in weight is a poor prognostic indicator of surgical outcome. Certain chronic medical conditions may be a contraindication for tumescent liposuction.
2. c: 4–5 L. The maximum amount of adipose tissue that can safely be removed during a single session of tumescent liposuction is 4–5 L. Additional volume can increase the risk of complications. All of the other answers are incorrect.
3. d: 120 min. The half-life of lidocaine is 120 min. All of the other answers are incorrect.
4. d: Intermediate and deep. In tumescent liposuction, intermediate and deep layers are suctioned. The superficial layer should remain undisturbed. Liposuction of the superficial layer may lead to dimples and skin irregularities that are cosmetically unacceptable.
5. d: All of the above. A physician performing tumescent liposuction should be certified in Advanced Cardiac Life Support, board certified in a specialty that emphasizes cutaneous surgery and evidence of postresidency training in liposuction.

Hair Transplant

24

Robert L. Finney and Marc R. Avram

Abstract

Both men and women are candidates for hair transplant surgery. There are a variety of causes that produce hair loss in patients, including genetic male and female pattern hair loss, primary inflammatory and infectious scalp dermatoses, and traumatic hair loss.

Keywords

Hair transplant · Techniques · Preoperative evaluation · Postoperative care · Safety

Indications for Hair Transplant

Both men and women are candidates for hair transplant surgery. There are a variety of causes that produce hair loss in patients, including genetic male and female pattern hair loss, primary inflammatory and infectious scalp dermatoses, and traumatic hair loss.

Hair transplantation is indicated for patients who would like to restore hair in regions of their scalp where they have suffered loss and there is little chance that medical therapy alone will restore their loss.

Ever since the 1990s, transplanting individual follicular units, each consisting of one to three hairs, has emerged as the standard of care (5) [1]. This method consistently produces results where both men and women can expect natural-appearing hair. Currently, two methods are used: follicular unit transplantation (FUT) and follicular unit extraction (FUE) . In FUT, a strip of hair is obtained from the donor area and then individual follicular units are created from the harvested tissue. This method leaves behind a thin linear scar and is not ideal for patients who wish to wear their hair short in the future. Alternatively, in FUE, individual follicular units are harvested directly from the donor area manually or with the help of a robotic system. The resultant pinpoint scars are not visible in patients who wear their hair short. Both methods share equivalent efficacy; however, depending on variable factors, one can be favored over the other (5) [2]. During the consult, the risk-benefit of FUE vs donor elliptical harvesting (FUT) is discussed, and the appropriate technique for each patient is chosen.

With either technique, the amount of donor hair available is critical to candidate selection. A patient with poor or depleted donor density will have little cosmetic impact from hair transplantation. Patients with high donor density are able to transplant a larger number of hair follicles and have greater cosmetic impact from a procedure.

Patients must understand that a hair transplant will not change the natural rate of hair loss from their underlying male or female pattern alopecia and that full correction to their baseline appearance prior to balding is not possible. This procedure is not indicated in patients who do not understand the limited nature of donor hair available and the progressive nature of untreated pattern hair loss.

Effectiveness of Hair Transplants

Hair transplantation surgery is a very effective procedure; grafts that are harvested from the "safe" donor area in the mid-occipital scalp are not susceptible to the effects of androgens and thus survive long term. For a procedure to be considered "effective," it also has to meet the subjective quality assessment of the patient. A significant portion of the discussion in the consultation prior to a hair transplant should be spent assessing the patient's expectations and then conveying the benefits and limitations of hair surgery. It is important that a patient knows prior to receiving a transplant that although a natural cosmetic outcome is likely, full restoration is not possible. The patient will not return to having the hairline and density prior to the onset of their alopecia. Many variables can affect the perceived effectiveness of a surgery, including density and caliber of hair in the donor area, pattern of alopecia and surface area of exposed scalp, width of the scalp, hair color, and whether or not the hair is curly or straight. It is also important to stress that without any concurrent medical therapy, their pattern alopecia will continue as it was genetically programmed to do and that this will affect their hair density moving forward. A patient who is motivated to begin or maintain medical therapy is much more likely to have a better outcome.

From a technical aspect, several variables can affect the success of a surgery, including transection rate, amount of time the grafts are ex vivo, storage solution used, and trauma to the follicular units during the procedure. The reported transection rate for FUT with strip harvesting completed by experienced practitioners is approxiamtely 1.59% (4) [3]. FUE on the other hand can be done manually or robotically with reported transection rates that vary widely from one another. Reports range from a few percent to as much as 30% in some cases. In a study done by Avram et al., 20 patients underwent robotic hair transplantation with an average transection rate of 6.6% (4) [4]. Once successfully harvested, graft survival inversely correlates with how long it sits out prior to transplantation, with rates of survival quoted at 95% at 2 hours and 86% at 6 hours (4) [5]. The holding solution the grafts are placed into can also affect the survival of transplanted hair, with anecdotal studies showing those stored in solutions such as HypoThermosol® or HypoThermosol® + ATP outsurvive those stored in normal saline or lactated ringers (4) [6]. Lastly, graft survival is dependent upon amount of trauma it is subject to, which is why having experienced technicians who minimize trauma to the follicular units are irreplaceable members of the surgical team.

Preoperative Evaluation

The surgical consult is an important aspect of hair surgery. As discussed above, assessing the patient's expectations is an important step. Next, their history with regard to their alopecia onset and rate of progression should be assessed.

The primary reason for hair loss should be confirmed via physical exam. If there is any doubt regarding the etiology of a patient's hair loss, a biopsy should be performed. A complete medical history should be obtained for each patient. If any pertinent positives are present on review of systems, the practitioner should consider ordering bloodwork (i.e., iron studies, thyroid labs, hormone levels) or referring the patient to their primary physician for a medical work-up.

As mentioned in the prior section, once a diagnosis of pattern alopecia is made, the preoperative consult should include a discussion of the current medical therapies available to treat this condition. A hair transplant will have the biggest impact if a patient is able to halt further hair loss, something that is possible for a majority of patients with today's medical treatments. Whether male or

female, minoxidil should be discussed. Multiple clinical trials have proven the efficacy of topical minoxidil (1a). A recent trial showed that 5% minoxidil was effective in not only increasing hair counts but also stabilizing hair density over both the frontotemporal and vertex regions during a 2-year follow-up period [7–12]. Side effects are minimal, with the most common being irritation. Unwanted hair growth is a rare but reversible side effect that can occur, mainly on the face of women [8]. This may only require decreasing the frequency or strength of application in order to reverse the unwanted hair growth. Finasteride which blocks the formation of dihydrotestosterone (DHT), a hormone that promotes the miniaturization and loss of susceptible hair follicles, is also another option that has been proven to halt and potentially thicken hair in roughly 80% of patients (1a) [13–15]. This is only FDA approved for males, however it has been used off-label in postmenopausal females with mixed results (4) [16–18]. Finasteride should not be used by women in child-bearing years. The biggest deterrent in compliance with this medicine tends to be a result of the sexual side effects that can occur in up to 2–4% of patients [13]. There are also rare reports of post-finasteride syndrome, but no true causal link has been reported to date (5) [19]. Low-level laser light therapy is also another treatment offered to patients. Although the data is not as strong, enough studies have shown promising effects in 40–50% of patients and thus warrant discussion (1a) [20–22]. Lastly, platelet-rich plasma (PRP) injections should be discussed with patients. Although true, well-designed placebo-controlled blinded randomized control trials are somewhat lacking, data published to date has been positive enough to warrant this as a first or second line treatment option in both men and women suffering from hair loss. Since a patient's own plasma is being injected, it tends to be tolerated very well (4) [23–24]. It is thought that many of these treatments can be synergistic and a combination approach can be used. It is also likely that medical therapy has a better chance of efficacy, the earlier the stage of alopecia. Patients with advanced stage likely have irreversible follicular dropout that medical therapy may fail to ameliorate.

With respect to age, there are no specific restrictions to surgery. Younger patients have a more unpredictable course of future hair loss and often desire a full restoration, so surgery in this cohort should be planned conservatively and carried out with caution. Given that they may also decide to shave their head in the future, the reduced risk of apparent scarring with FUE makes this the obvious harvesting method of choice in this cohort. A patient should be in good health. If there are any active medical problems, they should get clearance from their physician. If a patient is on a blood-thinning medication that the prescribing physician believes should not be stopped, then the procedure should not be performed.

Best Techniques and Performance

With an experienced surgical team, both FUT and FUE are effective means of harvesting grafts for hair transplantation (Table 24.1). The donor

Table 24.1 Comparison of FUT and FUE

FUT (donor elliptical harvesting)	FUE
Pros	Pros
Average time for a clinician to harvest a strip is only 15 minutes Does not require a patient to trim their whole donor area short, thus ideal for women or men who do not plan to wear their hair short in the future Transection rate reproducibly low	Minimal processing of grafts after harvesting is required, thus minimal support staff needed Resultant scarring is often not apparent Less invasive, sites heal secondarily in 3–5 days
Cons	Cons
Requires a skilled surgical team to harvest follicular units from the strip There will be a linear scar that will be present if a patient decides to trim their hair short in the future Staples or sutures are required to close the donor area, thus an extra office visit required for removal	Time required to harvest is longer than FUT Requires skill of the clinician to harvest if a robotic system is not used Clinician fatigue during long cases Patient is required to trim the entire donor area short Transection rate is more variable

area for both techniques is located on the occipital scalp. Hair in this area is largely exempt from pattern hair loss. The procedure is performed as an outpatient under local anesthesia.

In FUT, an elliptical strip ranging in width from 0.7 to 1.2 cm is excised after trimming the hair in the donor area. This is done after anesthetizing the area with lidocaine and epinephrine, as well as adding normal saline to increase dermal turgor and thus reduce transection of hair follicles. The defect is then closed with either staples or suture. In order to determine the width and length of the strip needed, the density of hair in the donor area and the number of desired grafts must first be known. Individual follicular units are then created carefully from the harvested strip by surgical assistants with or without the use of magnification. This is a time-consuming process and requires expert technique to perform this in an efficient manner with minimal transection or trauma to the follicle. A long-term consequence of harvesting grafts via FUT is the resultant linear scar in the donor area. This scar is usually only noticeable if a patient wears their hair very short in the back, although rarely a hypertrophic scar can occur. The number of grafts obtained is equivalent to FUE. FUT is the ideal method for harvesting grafts in women, because only a small strip of hair needs to be trimmed and, upon leaving, the linear closure can be covered by the surrounding hair. This is also a viable option for males who never plan to wear their hair short enough to reveal the scar created from the ellipse.

Since its creation in 2002, FUE has become an increasingly popular method of donor harvesting [2]. Hair in the donor area is trimmed to 1 mm in length via clippers and then anesthetized with lidocaine and epinephrine. FUE can be performed manually with 0.75–1.2 mm sharp or blunt punches, manually with the help of motorized hand-held systems or by utilizing a completely robotic system (i.e., the ARTAS hair restoration system) (5) [25]. Manual FUE relies on the skilled eye and hand of the practitioner to correctly assess the angle of exit for each follicular unit and harvest the grafts in a random pattern. Depending on the size of the surgery planned and skill of the clinician performing the FUE, this method can be time intensive. The robotic system on the other hand can operate independent of the physician. It autonomously assesses hair density and the angle each follicular unit exits the scalp. It then utilizes a dual sharp/blunt punch system to extract follicular units in a random manner. The clinician can override the software to harvest grafts closer together, further apart, or change the depth at which the graft is cut to. The robotic system allows grafts to be harvested in an efficient manner. The resultant defects left behind from all methods of FUE will heal naturally in 3–5 days without the need for primary closure. The grafts also require very little processing by hair technicians, and thus the procedure could be performed more efficiently in a setting with less support staff. As discussed above, when performing hair surgery via FUE, the transection rates tend to vary more widely and may be higher than FUT performed with experienced hair technicians [4]. The resultant scars left behind tend to be pinpoint, hypopigmented macules and are unnoticeable even when a patient wears their hair clipped short. FUE is thus the preferred method for patients who potentially may wear their hair in the occipital scalp very short in the future. It is also less invasive and ideal for a scenario with younger patients with minimal loss who may only need a smaller surgical restoration.

The hairline and areas for recipient sites to be made should be mapped out and discussed with the patient prior to the procedure with a marking pen. It is important to be cognizant of potential future hair loss when planning the hairline. Planning a receded hairline helps keep cosmetic balance with continued pattern alopecia occurring at the temples and posterior hairline. Once mapped out, the recipient area is then anesthetized with the use of an amide anesthetic combined with epinephrine. The number of sites created should match the total graft count and is commonly made in a random yet even pattern, with the use of a 19–20 gauge needle. Alternatively, several implantation devices have been made that can either just place the hair or also make the site simultaneously. These have been reported to cause less trauma to the follicle and help improve the speed of implantation (5)

[26]. Single-hair follicular units should be utilized for the main part of recreating an irregular natural hair line, whereas follicular units with two to four hairs can be transplanted just posterior to the hairline. The angle of the recipient site should match the hair that is already there, around 30–45 degrees. The angle changes as you approach the vertex and parietal hairlines, and care should be taken as to the direction and angle if the patient has a natural cowlick.

Unfortunately, in all patients, the donor area does not contain enough hair to transplant the entire frontal scalp, mid-scalp and vertex with an acceptable density (5) [27]. From a cosmetic standpoint, the hairline and frontal scalp are key to framing the face, and thus planting the grafts should begin there and be worked back as far as possible based on the number harvested. In patients with an exposed vertex, as the posterior border of transplanted hair is reached, the density should be slowly tapered to create a softer transition between the transplanted area and exposed scalp. Transplanting the vertex should be avoided in most cases. Given that androgenetic alopecia (AGA) is a progressive condition, the surgeon has to operate under the assumption that the patient will continue to progress to a Norwood VII, thus losing all of the hair on the temples/crown/vertex. If this occurs, the hair transplanted to the vertex can appear as an isolated island of hair, almost with the appearance of a donut and thus be a cosmetically regrettable result.

In female pattern hair loss, the frontal hairline usually remains intact and balding begins on the crown, with widening of the part before progressing to involve the crown diffusely. As with males, the frontal hairline and scalp help to frame the face, and a majority of the recipient sites should be made to help fortify this area, prior to reinforcing the crown. In women who bald slowly but diffusely over the entire scalp, transplantation can be difficult, given the lack of density and unpredictable longevity of hair in the donor area. Patients with this pattern are not good candidates for surgery.

Hair transplantation is also successful for patients who have lost density in their eyebrows, which most commonly results from traction alopecia due to years of over-plucking. The same donor area can be used for FUE or FUT via strip or several punch grafts. Unlike scalp surgery, only single-hair follicular units should be utilized for eyebrow surgery, and thus those with two or more hairs should be split under magnification. When planning the donor area, a much more acute angle must be used to create the sites, and they should be placed in a cross-hatched pattern with one another. A patient should be counseled that since scalp hair is being used, they will have to frequently trim the transplanted hairs moving forward.

The average size of any single-hair transplant surgery should be around 1000–2000 grafts. Hair density is a main determinant as to the size of the procedure possible, but scalp laxity and blood supply, as well as support staff and their experience, are other important factors that can play a role depending on the method chosen for harvesting. Many surgeons perform larger surgeries, but graft survival may suffer if the size attempted results in an increased length of time between harvesting and transplanting individual grafts.

Safety

Hair transplant surgery is safe with rare reports of medical or surgical complications. It is performed under local anesthesia and bleeding is minimal. FUT has a small risk of producing a hypertrophic scar. This risk can be reduced but not eliminated by putting minimal tension on the wound. If a hypertrophic scar occurs, it can be improved with intralesional Kenalog and/or a variety of lasers. In FUE, the defects heal secondarily in 3–5 days, and they are usually not noticeable, but there have been reports of a "moth-eaten" alopecia in the donor area of patients who are over-harvested. This can be avoided by spacing grafts out at least 1 mm, but care should be taken to not over-harvest the donor region (4) [28]. No matter the method of harvesting, the risk of infection is minimal in hair transplant surgery. A self-limited folliculitis may be observed. Temporary or permanent numbness in either donor or recipient sites has also rarely been reported. Given the

amount of anesthesia and minor trauma from harvesting and transplanting, a headache and mild discomfort are common. A 3-day course of prednisone 40 mg can help reduce the swelling, and pain can be controlled with extra-strength acetaminophen. Pain after the first day of the procedure is uncommon. If a clinician plans a long, large procedure, it is vital that staff keep track of the total amount of anesthesia utilized to avoid lidocaine toxicity.

Postoperative Care and Follow-Up

If a patient had FUT with a strip performed, there should be a follow-up appointment at 10 days to remove any staples or sutures, unless absorbable sutures were used. If FUE is performed, the sites will heal via secondary intention within 3–5 days, and thus close follow-up is not necessary. All patients are encouraged to contact the office with any questions or concerns.

Appropriate counseling that the transplanted hair will enter telogen directly after the procedure is important so that the patient does not expect there to be any evidence of increased density in the immediate months following the procedure. They should be told that the transplanted hairs will likely begin to grow 6 months after the procedure and that they should hold judgment on the efficacy of the transplantation until 12–15 months postoperatively. One topic of discussion at hair transplant meetings has been focused on using platelet-rich or poor plasma as either a holding solution for the grafts or injected into the recipient area directly in order to have quicker regrowth and higher yield of transplanted hair, but no concrete data is available yet. Regardless, patients should be seen after 1 year to evaluate the growth of the transplanted hair and address any questions or concerns the patients may have regarding the procedure. This is also a good time to reinforce the importance of medical therapy and assess the need or want for further hair transplant surgery.

Alternative Procedures and Modifications

As discussed above, medical therapy should be offered and recommended to all patients who come in for consultation. An in-depth discussion about minoxidil, finasteride, low-level laser light therapy, and platelet-rich plasma injections should precede any discussion of surgical options. For the vast majority of patients, a combination of medical and surgical therapy will create the greatest long-term density and thus cosmesis.

Currently no true alternative exists with respect to hair transplant surgery. Artificial grafts have been tried in the past, but they carried a significant risk of an inflammatory granulomatous reaction and are banned by the FDA (2c) [29]. Research has focused on cloning hair in order to bypass the limited donor area, something that could render full restorations possible in the future. Hair extensions, hair pieces, scalp micropigmentation, and the use of topical artificial hair fibers (i.e., Toppik) are appropriate options for some patients.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations, Assessment, Development, and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
Finasteride has the highest likelihood of all current medical treatments to halt hair loss long term and potentially regrow hair and should be offered to all male patients seeking hair transplant	A
Minoxidil is an effective method for stabilizing and potentially re-growing hair in both males and females and should be offered to all patients (non-pregnant or breastfeeding) with pattern alopecia	A
Platelet Rich Plasma is newer and requires more well-designed trials, but enough evidence exists to support its use as a standalone or adjunct treatment in pattern alopecia. Low level laser light therapy has been well studied but it is more modestly efficacious than other treatment options such as finasteride/minoxidil/PRP and should be used more as an adjunctive therapy.	C
Size of surgery should be limited to what staff can handle and where grafts can be placed safely for natural long-term cosmetic results in an efficient manner to limit the length of time the grafts are ex vivo	B
Given that the donor area does not contain enough follicular units to transplant the entire frontal scalp, mid-scalp, and vertex with an appropriate density, transplanting the vertex should be avoided in the majority of cases due to long-term cosmetic concerns	B
Detailed informed consent, preoperative counseling, and careful patient selection are key predictors of patient satisfaction after surgery	A
Preparation of the recipient bed must include a consideration of continued pattern alopecia when designing the hairline, and care should be taken to create recipient sites at angles naturally occurring in the area of the scalp	C
A well-trained ancillary staff and a well-trained surgeon are associated with minimal transection and optimal outcomes in follicular grafting	B
Hypothermosol, with or without ATP or other holding solutions for grafts may increase graft survival compared to normal saline or lactated ringers	D
Full efficacy of a hair transplant is likely not seen until around 12 months postoperatively	C
FUT should be avoided in patients who desire to wear their hair cropped shortly in the occipital scalp in the future or if they are unsure to	C

Self-Assessment Questions

1. True/false. Transplanting the vertex is appropriate in most patients.
2. True/false. The only instance where all follicular units should be split to contain only one hair is when transplanting hair to the eyebrow.
3. What is the most appropriate harvesting technique for a 50-year-old woman with pattern alopecia and a normal clinical exam/labwork?
   (a) FUE
   (b) FUT
   (c) Either, it does not matter
   (d) The patient is not a good candidate
4. What is the most appropriate harvesting technique for a 35-year-old male who has androgenetic alopecia that is stable on topical minoxidil and who wears his hair relatively short on the sides and back?
   (a) FUE
   (b) FUT
   (c) Either, it does not matter
   (d) The patient is not a good candidate
5. What is the most appropriate harvesting technique for a 60-year-old female who has had stable hair loss on topical minoxidil for 5 years with significant decreased density and miniaturization in the occipital scalp?
   (a) FUE
   (b) FUT
   (c) Either, it does not matter
   (d) The patient is not a good candidate

Correct Answers

1. False. Given the limited donor area, it is more cosmetically appropriate to focus the most on the frontal and mid-scalp.
2. True. Transplanting follicular units with more than one hair would have a very unnatural appearance. Splitting follicular units in scalp surgery is usually not practiced because of the potential unnecessary trauma or transection.
3. b: Most female patients would not want to have the downtime from trimming the whole donor area necessary for FUE, and since they will likely continue to wear their hair long, the scar from FUT is not a cosmetic issue.
4. a: FUE will allow this patient to continue wearing their hair short without a visible scar in the future.
5. d: Patients with diffuse alopecia lack a good donor area and thus are not good candidates for surgery.

Small Caliber Vessel Sclerotherapy

25

Todd V. Cartee and Sean T. McGuire

Abstract

Sclerotherapy is the procedure of introducing a foreign body into a vein with the intent of ablating the vessel through a controlled thrombophlebitic event with resulting scar formation. Circa 460 BC, Hippocrates described a rudimentary precursor of modern sclerotherapy by inducing thrombosis through serially puncturing a vein with a slender iron rod. In the 1600s, Sigismund Eisholtz used distilled plantain water in the earliest recorded use of an injected substance to induce sclerosis. Refinement of the sclerosant material, injection technique, and the addition of foamed formulations over the past century have elevated sclerotherapy to the gold standard in the treatment of reticular and telangiectatic leg veins and an important therapeutic modality for varicose veins and saphenous reflux.

Introduction

Sclerotherapy is the procedure of introducing a foreign body into a vein with the intent of ablating the vessel through a controlled thrombophlebitic event with resulting scar formation. Circa 460 BC, Hippocrates described a rudimentary precursor of modern sclerotherapy by inducing thrombosis through serially puncturing a vein with a slender iron rod. In the 1600s, Sigismund Eisholtz used distilled plantain water in the earliest recorded use of an injected substance to induce sclerosis. Refinement of the sclerosant material, injection technique, and the addition of foamed formulations over the past century have elevated sclerotherapy to the gold standard in the treatment of reticular and telangiectatic leg veins and an important therapeutic modality for varicose veins and saphenous reflux.

Sclerotherapy is utilized to fibrose superficial veins to either address symptomatic venous insufficiency or improve cosmesis. This technique has traditionally been plied for leg veins, but its use on the face, hands, and chest has also been described [1] (Level 4).

Physiology

A working knowledge of the underlying physiology is critical for achieving excellent outcomes. The leg's venous system consists of deep and superficial plexuses that contain 95% and 5% of

the blood volume, respectively. This innate redundancy permits elements of the superficial system to be ablated with minimal impact on overall venous flow. The superficial venous system is centered about the great and small saphenous veins, as well as the lateral venous system. These vessels communicate with the deep venous system both through major anastomoses—the saphenofemoral and saphenopopliteal junctions—and through hundreds of fascial perforating vessels.

Blood flow from the legs to the heart is analogous to a grain elevator. Contraction of the muscles of the deep posterior compartment of the leg generates the necessary pressure gradient to pump against gravity, and a system of intraluminal valves prevents retrograde flow. Incompetence of the valves or failure of the calf muscle pump results in blood pooling in the legs, increasing intraluminal pressures and ultimately distending the vein. This distension may propagate downstream, mechanically separating otherwise competent valves and extending the apparent extent of disease.

Classification and Scope of Chapter

In 2004, the American Venous Forum revised the CEAP scoring system to reflect an updated understanding of venous disease. (Table 25.1) Sclerotherapy can be used in the treatment of C1–C6 disease; this chapter focuses on the treatment of isolated C1 disease and C2 disease in the absence of clinical or ultrasonographic evidence of saphenous insufficiency (truncal disease). One critical caveat: a physician must always be cognizant of signs suggestive of underlying insufficiency. Whenever there is sufficient suspicion for truncal or deep venous reflux, a complete duplex examination of the venous system is indicated before proceeding with visual sclerotherapy.

Table 25.1 CEAP scoring system

Clinical manifestation	C0	No visible or palpable disease
	C1	Telangiectasia (<1 mm diameter) and reticular veins (1–3 mm)
	C2	Varicose veins (>3 mm)
	C3	Edema
	C4a	Pigmentation and eczema
	C4b	Lipodermatosclerosis and atrophie blanche
	C5	Healed venous ulcer
	C6	Active venous ulcer
Etiologic factors	Ec	Congenital
	Ep	Primary
	Es	Secondary (post-thrombotic)
Anatomic distribution	As	Superficial veins
	Ap	Perforator veins
	Ad	Deep veins
Pathophysiologic classification	Pr	Reflux
	Po	Obstruction
	Pr,o	Reflux and obstruction
	Pn	No venous pathology identifiable

Demographics

The Edinburgh Vein Study found that 84% of participants had (at least) C1 disease [2] (Level 3b). A German population-based study, consisting of 3072 men and women aged 18–79, found isolated C1 disease in 59% [3] (Level 3b). A descriptive study assessed the legs of 291 patients presenting to the University of Hong Kong Medical Center vascular clinic and found C1 and/or C2 disease in 50% of assessed limbs [4] (Level 3b). A more ethnically diverse sampling was included in the San Diego Population Study, wherein 55%, 50%, 45%, and 45% of the included non-Hispanic White, Hispanic, African American, and Asian participants demonstrated isolated C1 disease, respectively [5] (Level 3b). The demographic risk factors for telangiectasias and reticular veins appear to parallel those described in more extensive disease of Caucasian race, namely, advancing age, female gender, family history of venous disease, and pregnancy. Of these, age seems to be the biggest risk factor, with 80% of women aged >80 possessing varicose veins [6] (Level 3b). Age is closely followed by family history as a compelling risk factor, with the chance of having varicose veins approaching 90% if both parents are affected [7] (Level 3b).

Effectiveness of Sclerotherapy

Sclerotherapy is considered the gold standard for the treatment of C1 disease, with up to 90% improvement reported in several randomized, blinded trials utilizing polidocanol (POL) [8] (Level 2b). However, generalizing this degree of effectiveness is difficult due to heterogeneity in the reported outcome measures, small sampling size of many studies, differences in sclerosing agent formulation and concentration, postoperative care, and follow-up interval. Furthermore, a disproportionate amount of the literature constitutes small trials performed by a small group of experts. Yet another variable is noted concentration variance of POL in the United States prior to FDA approval in 2010 [9] (Level 5).

Case Series

A retrospective review of a single private practice compared the use of liquid and foamed sodium tetradecyl sulfate (STS) for reticular veins with subsequent glycerin treatment for telangiectasia. Three hundred and twenty-five patients were contacted after an average of 4 years follow-up (range 1–11), and there was no significant difference in degree of improvement between these two agents, and improvement was rated as moderate to good [10] (Level 4).

Goldman performed a double-blinded study in 20 patients comparing the efficacy of liquid POL to STS in telangiectatic and reticular veins, as well as foam formulations of both agents for varicose veins. In aggregate, no significant difference in efficacy, as determined by an independent physician, nor patient satisfaction was noted at 16-week follow-up [11] (Level 2b).

Randomized Trials and Meta-Analysis

The EASI study—a double-blind, randomized, placebo-controlled trial—compared 160 patients with telangiectasias treated with 0.5% POL, 1% STS, and placebo, as well as 156 patients with reticular veins treated with 1% POL, 1% STS, and placebo. No power calculation is provided in the text. Patients received one to three treatments in a 6-week period. Independent evaluation of standardized photos rated improvement as excellent and similar between the POL and STS groups (4.54 and 4.45; $P < 0.00001$ on a scale from 1 to 5, with 4 being "good improvement" and 5 being "complete treatment success"). There was no change in the placebo-treated arm. This provides compelling level I evidence of the overall efficacy of small vessel sclerotherapy. At 26 weeks, 88% of patients treated with POL and 63% of patients treated with STS were satisfied with their treatment. There were significantly higher rates of skin discoloration and ulceration in the STS group. However, STS is a more potent sclerosing agent than POL, and the 1% concentration of STS used in this study is considerably more concentrated than what is typically used in clinical practice for spider and reticular veins. Therefore, it is unclear if the adverse event profile would have been more similar if equipotent concentrations were employed [12] (Level 1b).

An industry-sponsored randomized, blinded, placebo-controlled study in China investigated the efficacy of liquid POL for the treatment of C1 and C2 disease in a Chinese population. As no officially approved sclerosant was available in China at the time of study, industry sponsorship was instrumental in training and procurement of supplies. Veins smaller than 1 mm in diameter were treated with 0.5% POL or placebo, and veins 1–5 mm were treated with 1% POL or placebo. Patients received up to three treatments at intervals of 2–4 weeks or until they achieved >50% response as graded by blinded investigator assessment. The average number of treatments for the two described groups was 1.93 and 1.74. 87% of both groups were assessed to have >50% improvement at 12-week follow-up. Greater than 85% of patients were either satisfied or very satisfied, and >60% of patients were very satisfied. Both were significantly different from placebo [13] (Level 1b).

Preoperative Evaluation

The literature informing the use of diagnostic testing for varicose veins is limited to expert opinion and small retrospective trials. Patients should undergo a directed history and complete physical exam of the entire legs and feet in a standing position to identify any evidence of varicosities (C2 disease) or chronic venous insufficiency (C3–C6 disease). Varicose veins are often not apparent when a patient is recumbent. Individuals with only telangiectasia likely do not require further evaluation beyond visual inspection [14] (Level 5), although others argue that complete management, even of telangiectasias, includes examining the underlying interconnected plexus to identify the origin of reflux through ultrasound exam [15] (Level 5). The American Society of Dermatologic Surgery (ASDS) Consensus Guidelines do not recommend further evaluation for C1 disease beyond a clinical exam if other findings detailed in Table 25.2 are absent [16]. The authors subject all patients with C2 (visible bulging varicose veins) or greater disease to an ultrasound examination of the superficial venous system to assess for proximal sources of reflux that would be best addressed via endothermal saphenous vein ablation or ultrasound-guided foam sclerotherapy prior to embarking on visual sclerotherapy.

Known patent foramen ovale is a contraindication for foamed sclerotherapy [16]. The second European Consensus Meeting on Foam Sclerotherapy does not recommend screening individuals for patent foramen ovale.

Table 25.2 Scenarios in which one should consider diagnostic ultrasound (from ASDS Consensus Guideline, 2014)

Bulging varicosity >4 mm in diameter, especially when located on the medial leg or posterior calf (zones of GSV and SSV influence)
Significant symptoms consistent with venous insufficiency (throbbing, leg heaviness, etc.)
Lower extremity edema
Cutaneous sequelae of venous disease, such as stasis dermatitis
A “star-burst” cluster of telangiectasia of medial calf especially medial malleolus
History of deep vein thrombosis or thrombophlebitis
Prior sclerotherapy or similar intervention with recurrence or poor results

Best Techniques and Performance

Standard Technique

Basic operational technique has been experientially derived from physiologic principles and continues to be refined as new advances are incorporated. Following appropriate patient selection and any indicated preoperative evaluation, the procedure is begun by reclining the patient flat to reduce the intraluminal pressure of the leg veins. The provider selects the appropriate sclerosant, concentration, and formulation. The material is then loaded into a syringe and topped with a 30 gauge needle. Starting with the larger feeding reticular veins and progressing through the vein’s watershed telangiectasias, the provider cannulates the vessel and injects a small amount of sclerosant. The authors prefer the use of foam sclerosant for the treatment of reticular veins. Foam enables the treatment of higher capacitance vessels with much less agent, but increased efficacy has not been established in clinical trials. When treating reticular veins, negative pressure can be utilized to ensure intraluminal position with the flashback of blood. With experience through and the aid of transillumination, most reticular veins can be successfully cannulated and injected with minimal extravasation of agent without confirmation of placement by flashback. Minimal positive pressure is necessary to infuse the selected sclerosant. Upon successful treatment, the vessel should temporally disappear as blood is displaced by the sclerosant. Following session completion, bandages are placed as needed, and compression stockings are applied to the patient while still recumbent.

Foam vs Liquid Formulation

Selecting a liquid or foam formulation depends on operator experience, variance in the size of

vessels to be treated, and the projected amount of sclerosant to be administered. For vessels <4 mm, the ASDS consensus document on sclerotherapy, acknowledging the lack of general consensus, notes that many clinicians utilize liquid sclerotherapy for the treatment of these vessels. The 2013 European Guidelines for sclerotherapy endorses liquid formulations as the standard but notes that foam is an acceptable alternative.

Several well-conducted randomized controlled trials (RCTs) have demonstrated foam to have superior efficacy when treating saphenous or other large diameter veins [17] (Level 3b) [18] (Level 1b). This experience has prompted the widespread use of foam in treating reticular veins and even large telangiectasia (1–2 mm), but the evidence supporting this approach is sparse.

A meta-analysis of studies comparing liquid to foam sclerotherapy found only two studies concerned with reticular veins; no substantial conclusions could be drawn from these studies [19] (Level 2b). The best single study to date was an un-blinded 100-person investigation comparing the efficacy of polidocanol foam and liquid formulations in vessels <4 mm (with concentration based upon subdivided vessel size). This study demonstrated a nonsignificant trend toward foam superiority (84% vs 72% clearance) [20] (Level 3b).

Another question is how to generate foam. Most practitioners utilize room air, but some have advocated for carbon dioxide, which forms smaller bubbles that dissipate more quickly than nitrogen or oxygen. One observational study comparing experience with carbon dioxide to historical experience with room air-generated foam in the treatment of saphenous tributaries and small saphenous veins found a reduced incidence of foam bubble-related side effects including chest tightness, cough, and dizziness but no significant difference in transient neurological events (e.g., visual disturbances) [21] (Level 3b). Only one small trial (20 participants) has been conducted comparing the use of carbon dioxide and room air to develop foam in the treatment of reticular veins and failed to show any difference in efficacy or side effects [22] (Level 4).

Sclerosant Selection

Sclerosant selection is largely driven by expert opinion, provider comfort, and availability of agent. Head-to-head comparisons are scarce and may not influence daily practice due to their required adherence to government-approved concentrations (although these may not mirror typical use) and the variation in treatment approaches and postoperative care.

The previously mentioned EASI study compared vessel-controlled concentrations of polidocanol and sodium tetradecyl sulfate. Its strengths and weaknesses are available above; the principal findings were a higher patient satisfaction with polidocanol at 26 week and a higher rate of side effects with STS at the tested concentrations [8].

In a randomized study, 129 patients presenting with 1–6 mm varicose veins were treated with either liquid STS or POL. Concentrations were adjusted for size of vessel treated and more closely mimic concentrations utilized in active practice than the EASI study, with vessels <1 mm treated with either POL 0.5% or STS 0.25%, 1–3 mm received 1% POL or 0.5% STS, and those 3–6 mm in diameter were treated with 3% POL or 1.5% STS. At week 16 follow-up, the agents were equally effective as assessed by blinded evaluators (both ranked between moderate and complete resolution) [11] (Level 2b).

A single blinded study compared 100% chromated glycerin (CG), 0.25% liquid POL, and 0.25% foamed POL (Monfreux method) in the treatment of C1 disease in 150 patients. Patients received one treatment. A trend toward higher patient satisfaction was noted in those treated with CG than the other two arms ($p < 0.08$), but no difference was noted between POL liquid and foam. Blinded evaluation found a significantly higher efficiency of CG at 2-month follow-up. A trend toward superior efficacy of the foamed vs liquid polidocanol was noted. Treatment with CG was significantly more painful than either POL regimen. No cases of hyperpigmentation or matting occurred in the CG group, while POL liquid and foam encountered three and four such com-

plications, respectively [23] (Level 1b). The equipotency of these treatments has been debated [24] (Level 5).

Kern et al. also compared the efficacy and pain of treating C1 disease with CG and the same mixed with 1% lidocaine-epinephrine in a 2:1 mixture. One hundred two patients were treated as per the protocol and available for 5-week follow-up. Patients who received the lidocaine mixture had significantly less pain and patient satisfaction was equivalent. Objective review by two blinded experts trended toward superiority for chromated glycerin alone (7.84 vs 7.33 on a 10-point scale, $p = 0.07$) [25] (Level 4).

In a separate study, this mixture was used in a two-step fashion in an attempt to further reduce pain by treating all reticular veins first and then returning to the beginning to treat remaining telangiectasias. Fifty-three women were included and asked to rate their pain immediately after standard therapy (treatment of reticular veins followed immediately by treatment of associated telangiectasias) versus a two-step approach with approximately a 5-minute delay between sweeps. Pain was significantly reduced with the two-step approach but reduced physician and patient economy of movement. The author purports that the vasospasm associated with epinephrine dissipated prior to the treatment of telangiectasia in the two-step group [26] (Level 4).

Thirteen patients received 0.25% STS or glycerin 72% solution in the treatment of vessels 0.2–0.4 mm in diameter. Glycerin 72% mixed 2:1 with 1% lidocaine with epinephrine 1:100,000 is the standard glycerin based scleroing solution used in the US as CG is not available. Both of the patients' legs each received different solutions. At 2 to 6 months following one treatment session, glycerin was noted to cause similar and low levels of pain with injection. Glycerin demonstrated a higher rate of vessel clearance than STS (subjectively assessed) while causing less bruising, swelling, and hyperpigmentation. Given the small sample size, no statistical analysis was performed [27] (Level 4).

In a comparison of hypertonic saline (HS) and liquid POL for C1–C2 disease, Peterson et al. performed a split-leg study between 0.5% POL and 11.7% HS for telangiectasia and 1% POL and 23.4% HS for reticular veins of 63 patients. At 16-week evaluation, no significant difference in efficacy was noted, with both groups reporting approximately 70% improvement. Patients noted significantly more pain with injection of HS, and two episodes of ulceration were recorded in the HS group [28] (Level 2b).

Maximum Volume

The European Consensus Meeting on Foam Sclerotherapy recommends no more than 10 mL of foam for injection of the great saphenous vein; this limit has been exceeded in a small trial without consequence in the treatment of reticular veins [1]. For the treatment of reticular veins, in clinical practice, the current authors as well as most expert sclerotherapists safely use more than 10 mL of foam in a single session [16]. Per the package inserts, no more than 10 mL of 1% POL solution, and no more than 10 mL of 1% or 3% STS should be used in one session.

Safety

POL and STS are both FDA approved for the treatment of varicose veins. The other two agents approved by the FDA for sclerotherapy, morrhuate sodium and ethanolamine oleate, are used principally in the treatment of esophageal varices due to a higher rate of anaphylaxis and extravasation necrosis [16].

Case reports detailing major adverse effects of sclerotherapy, such as pulmonary embolism and cerebral vascular events, exist in the literature and must be respected. However, several meta-analyses have demonstrated that these adverse outcomes are rare. In addition, in almost all cases, patients in these studies were undergoing large vessel sclerotherapy.

A meta-analysis detailing the efficacy and safety of foam sclerotherapy was published in 2012 and included 104 original articles, of which 21% included the treatment of reticular veins. The meta-analysis benefitted from the large number of aggregated patients but was limited due to the heterogeneity of included studies and the lack of well-designed clinical trials. Despite these limitations, as well as larger volumes of foam and the treatment of larger vessels, recorded major adverse effects were rare (Table 25.3) [29] (Level 2a). Another meta-analysis released the same year focused principally on neurological adverse effects of foam and liquid sclerotherapy and reported similarly low occurrence rates (Table 25.4) [30] (Level 2a). The 2013 European Guidelines for sclerotherapy designated these side effects as rare or very rare.

Table 25.3 Side effects of foam sclerotherapy (Rathbun)

	Adverse effect	%	*N*
Neurological	Visual disturbance	1.2	15,058
	Seizure	0.15	545
	Cerebral vascular event	0.63	5600
	Migraine	3	4470
Thrombosis	Deep vein thrombosis	0.9	18,203
	Pulmonary embolism	0.11	12,585
	Thrombophlebitis	11	11,900
Skin	Skin pigmentation	18	3811
	Severe allergy	0.2	11,601
	Injection site ulceration	0.98	10,494
	Paresthesia	1.2	9189
	Ecchymosis	28	2027
Other	Myocardial infarction	0.1	620
	Death	0.01	7152
	Coughing	1.6	8056
	Severe pain	7	495
	Required pain medication	13	1290

Table 25.4 Neurologic side effects of foam sclerotherapy (Sarvananthan). Number of patients = 10.819

Transient ischemic attack (TIA) or amaurosis fugax	0.16%
Cerebral vascular attack	0.11%
Visual disturbances (not TIA)	0.77%
Headache	0.70%
Migraine with aura	0.27%

Alternative Procedures and Modifications

For patients with contraindications to sclerotherapy, significant needle phobia, or the presence of vessels too small to cannulate, laser treatment is a viable alternative. Use of this modality is made difficult due to the high variability in vessel size, depth, and degree of oxygen content. As compared to facial veins, where laser therapy is very successful, leg veins are under significantly higher refill pressures, reducing vessel wall apposition and sclerotic potential [31] (Level 5).

Multiple laser modalities have been successfully trialed for veins less than 1 mm in diameter, including potassium titanyl phosphate (KTP) (532 nm), pulsed-dye laser (595 nm), and intense pulsed light. Larger, deeper vessels may respond better to treatment with alexandrite (755 nm) and Nd:YAG (1064 nm) [32] (Level 2c). Only Nd:YAG has been compared directly to sclerotherapy and was shown to have comparable efficacy [33] (Level 2b).

A randomized, double-blinded intra-leg comparison of Nd:YAG and sclerotherapy was performed in 56 patients with C1 disease. The sclerotherapy was performed using foamed 0.5% POL; patients received two treatments in a 6-week period. More improvement was noted at 6-week follow-up in the sclerotherapy group, but no difference was noted at 6 months. Laser treatment was significantly more painful [34] (Level 1b). A prospective intra-leg trial of 30 patients with lower extremity veins 0.5–1.5 mm telangiectasias compared Nd:YAG with sclerotherapy with 75% glucose. Patients received three treatments at 1-month intervals. Laser settings were 100–120 J/cm2 with a pulse duration of either 15 or 30 msec with epidermal cooling; no compression was utilized after treatment. At follow-up 1 week after the final treatment, patients reported significantly more pain and less satisfaction with the laser-treated leg, but independent assessors found no significant difference in vessel clearance [35] (Level 4).

New modalities are constantly being described. A small randomized trial comparing one treatment of telangiectatic leg veins with a

808 nm diode laser augmented by intravenously injected indocyanine dye to one treatment with a 1064 Nd:YAG found superior clearance with the diode cohort at 3 months; it was also more painful [36] (Level 2b). Fifteen of twenty females who were treated with a high-powered KTP device (fluence 13–15 J/cm2) twice in a 12-week period noted >50% improvement [37] (Level 4).

Combination Therapy

The durability of improvement of varicose veins <4 mm in diameter using POL alone and with the addition of 1064 nm Nd:YAG was compared in 320 patients (640 legs). 298 patients completed the study. Regardless of vessel size, microfoamed POL was formulated using 0.3% POL mixed with room air; the laser fluence was adjusted based on vessel diameter. Patients received two treatment sessions in a 3-week interval and were evaluated by three blinded physicians. Combination therapy was significantly superior in both assessed improvement and patient satisfaction at 3-month, 2-year, and 3-year follow-up. At 3-year follow-up, polidocanol alone resulted in a mean improvement of 15% and 18% of vessels of diameter <0.5 mm and 0.5–1.5 mm, respectively; POL followed by Nd:YAG resulted in 89% and 95% improvement. The results are impressive but are limited by the marked discrepancy between observed improvement with POL alone at the 3-month follow-up versus other studies mentioned above and the authors' personal experience [38] (Level 1b).

Postoperative Care and Follow-Up

The ASDS consensus document recommends 15–20 mmHg stockings following the treatment of telangiectasia and 20–30 mmHg stockings after treating reticular veins. The recommended duration is for 2–3 weeks, most critically for the first 3 days after treatment [16].

This recommendation is supported by few heterogeneous comparative trials.

In a study by Weiss, 40 patients were equally allocated to either the use of no compression stockings or of 20–30 mmHg stockings continuously for either 3 days, 1 week, or 3 weeks following the treatment of vessels <3 mm in diameter. A significant difference was noted in overall efficacy and hyperpigmentation between the four groups at 24-week follow-up. Patient satisfaction was not assessed [39] (Level 4).

A 20-patient split-leg study investigated the effect of an additional 3 weeks of ambulatory 20–30 mmHg compression stockings following 1 week of continuously wearing 30–45 mmHg compression stockings post sclerotherapy in both legs. On a 4-point scale, a statistically significant degree of hyperpigmentation was noted (1.3 vs 2.0). There were no differences in efficacy or thrombosis [40] (Level 4).

The strongest data to date comes from a 100-patient study that compared the ambulatory use of 23–32 mmHg compression stockings for 3 weeks, as opposed to no compression, following sclerotherapy of C1 disease. The investigators found a positive but small benefit in vessel disappearance (7.1 vs. 6.3 on a 10-point vessel disappearance score). No significant difference in hyperpigmentation or matting was observed, but rates of both were very low which was attributed to the use of chromated glycerin as the sclerosant. Patient satisfaction scores were similar between the two groups at 7-week follow-up [41] (Level 3b).

A blinded study of 16 patients received either 0.005% betamethasone solution or saline placebo; patients wore compression stockings for 1 week post procedure. No statistically significant difference in efficacy or adverse effects was found [42] (Level 4).

Complications and Management

Post-sclerotherapy hyperpigmentation is mainly a result of dermal hemosiderin staining related to extravasation of blood inherent in sclerotherapy. A wide range of incidence has been noted in various studies, but it is the most commonly reported adverse event in most [43]. The varia-

tion is at least in part due to the absence of a clear definition of hyperpigmentation in these studies. Spontaneous resolution occurs in 70% of cases in 6 months and 99% in 1 year [44] (Level 4). More cases of hyperpigmentation (64% vs 53%) and necrosis (6.6% vs 0%) were noted in a 129-patient split-leg study between STS and polidocanol (concentration and liquid or foam formulation depended on size of vessel treated) [45]. However, a similar study by Rao found no difference in adverse effects [11]. Patients receiving minocycline at the time of treatment may encounter minocycline-induced hyperpigmentation, which is more dark blue-gray in color than hemosiderin pigmentation [46] (Level 4).

Studies concerning the treatment of this persistent hyperpigmentation are mainly small and underpowered and do not permit definitive conclusions. The highest level of evidence comes from a multicenter trial that investigated the effect of post-sclerotherapy microthrombectomy. One hundred patients were divided into those treated for veins <1 mm in diameter and those with veins 1–3 mm. Areas of varicosities were randomized into two halves that received either microthrombectomy or non-intervention 1–3 weeks following sclerotherapy. Photographs obtained 16 weeks later were reviewed by blinded evaluators. Significant improvement in pigmentation and overall improvement were noted in the <1 mm diameter group but not in the 1–3 mm diameter cohort [47] (Level 1b).

In another study, eight patients with post-sclerotherapy hyperpigmentation persistent for over 1 year were treated with a Q-switched ruby laser. Lightening of 75–100% occurred in 58% of treated areas [48] (Level 4). A novel approach of utilizing an IPL + RF device (model S-E 3200, SUS Photon Technology CO., China) to treat post-sclerotherapy hyperpigmentation present for over 18 months was assessed in 21 individuals. Up to ten treatments at 1-month intervals were performed with an average of seven treatments performed. In 19/21 patients, complete resolution was obtained, and average patient satisfaction was 8.7/10. Different fluences were used based upon Fitzpatrick skin type [49] (Level 4).

In the case of minocycline-induced pigmentation, case reports suggest that Q-switched and picosecond alexandrite laser treatment may provide partial to complete improvement [50] (Level 4).

Telangiectatic matting is the new appearance of fine red telangiectasia following sclerotherapy and is thought to represent dilation of collateral veins or an inflammatory effect of treatment. A retrospective analysis of 2120 sclerotherapy patients found a post-treatment incidence of 16%. Identified risk factors were excessive body weight, hormonal therapy, and longer history of venous disease prior to treatment [51] (Level 3b). In a series of 113 patients treated with sclerotherapy for vessels <2 mm, Weiss and Weiss noted that higher concentrations appear to increase the risk of telangiectatic matting and that many cases noted at 1-month follow-up resolved spontaneously at 6-month follow-up [52] (Level 4).

Whereas significant clinical experience and opinions regarding optimal management are plentiful, evidence-based management is unavailable. This is likely due to the relative subtlety of matting compared to the previously apparent varicosities and its self-resolving nature.

Skin necrosis and ulceration is a rare side effect of sclerotherapy. An estimated incidence of approximately 1% derives from several studies with variance in technique as well as sclerosant selection and volume [53] (level 5). If you perform enough sclerotherapy, you will eventually encounter a punctate ulceration, although in the authors' experience, this occurs in far less than 1% of treatments. These typically heal with small scars usually less than 1 cm (similar to a punch biopsy). More extensive ulcerations are exceedingly rare and presumably result from inadvertent injection directly into arteries, although this has been contested [53, 54] (Level 4, 1). Proper visualization of sclerosant placement, potentially with ultrasound, should minimize risk. Ultrasound guidance must be utilized whenever injecting sclerosant into varicose veins that are not bulging and therefore not extremely superficial.

Conclusion

Reticular and telangiectatic veins are widely prevalent in all ethnicities that have been studied. Not surprisingly, therefore, sclerotherapy is a skill in high demand. The treatment of reticular veins and telangiectasias of the leg with sclerotherapy has been shown to be effective with a low incidence of adverse events. While viable alternatives exist, such as laser-based therapy, chemical sclerotherapy remains the gold standard due to its efficacy, tolerability, safety, and relatively low cost. Interestingly, available research, regarding elemental issues, such as sclerosant selection, treatment of complications, and post-treatment care, consists largely of small, underpowered, single provider studies. These limitations affect the conclusiveness and generalizability of their results. Thus, expert opinion and consensus documents currently inform much of clinical practice. With further research efforts, iterative improvements will continue to elevate the general caliber of sclerotherapy.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations, Assessment, Development, and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
Venous disease is remarkably common	A
Sclerotherapy is highly effective for C1 disease	A
POL and STS are equally effective	B
POL may have less hyperpigmentation risk, but this has not been clearly established	C
For C1 disease, liquid is the preferred formulation, but foam may be equally or more effective for reticular veins	B
Post-sclerotherapy compression modestly increases overall improvement; some weak evidence supports a decreased incidence of side effects with its use	B
The optimal duration and amount of compression necessary to produce benefit is unclear	C
Microthrombectomy reduces persistent post-sclerotherapy hyperpigmentation	B
Nearly all hyperpigmentation resolves by 1 year	B
Laser is an appropriate alternative in the correct patient but is more painful	A
Major adverse effects are rare	A

Self-Assessment Questions

1. Which of the following is *not* an FDA-approved sclerosant in the United States?
   (a) Polidocanol
   (b) Sodium tetradecyl sulfate
   (c) Sodium morrhuate
   (d) Glycerin
   (e) Ethanolamine oleate
2. What percentage of patients experience post-sclerotherapy telangiectatic matting?
   (a) 6%
   (b) 16%
   (c) 26%
   (d) 36%
   (e) 46%
3. What percentage of adult females demonstrate isolated C1 disease?
   (a) 0–20%
   (b) 20–40%
   (c) 40–60%
   (d) 60–80%
   (e) 80–100%
4. Which statement regarding post-treatment hyperpigmentation is true?
   (a) 30% of cases resolve within 6 months.
   (b) Incidence is unaffected by compression therapy.
   (c) The underlying mechanism is the extravasation of blood.
   (d) Pretreatment with minocycline is preventative.
   (e) Use of hypertonic saline is a relative risk factor.
5. Which is the correct CEAP classification for a patient with reticular veins 2 mm in diameter due to reflux without evidence of underlying disease?
   (a) C0EsAsPo
   (b) C1EpAsPr
   (c) C2EsApPr
   (d) C2EcAdPr,o
   (e) C2EpApPo

Correct Answers

1. d: a and b are approved for the treatment of leg veins, whereas c and e are approved for the treatment of esophageal varices.
2. b: In a retrospective study by Davis involving 2160 patients, 16% experience telangiectatic matting after sclerotherapy. Risk factors identified in this study were excess body weight, use of hormones at the time of sclerotherapy, family history of spider veins, and a longer duration of spider veins.
3. c: According to results from population-based studies conducted in Germany, China, and the United States, isolated C1 disease was identified in 40–60% of patients. In the Edinburg Vein Study, 84% patients had AT LEAST C1 disease.
4. c: 70% of cases resolve by 6 months. Compression therapy has been demonstrated to reduce incidence. Minocycline use is a risk factor for hyperpigmentation which may be more blue-gray in color. Hypertonic saline has the highest reported rates of the studied sclerosants and glycerin the lowest.
5. b: The C1 designation is for vessels less than 3 mm in diameter, Ep designates no underlying disease, anatomically the veins as superficial, and the underlying etiology is related to reflux.

Endovenous Laser and Radiofrequency Treatments

Rachel Redenius and Margaret Mann

Abstract

Chronic venous disease affects approximately 15% of men and >25% of women in the United States and can cause significant morbidity in those affected (2c) (Beebe-Dimmer et al., Ann Epidemiol 15:175–184, 2005). The preferred treatment options have shifted in the last decade from surgical ligation and stripping in the operating room to minimally invasive procedures such as endothermal ablation in the outpatient setting. Endovenous laser ablation (EVLA) and radiofrequency ablation (RFA) are the two most commonly used thermal techniques. The heat produced by these methods causes denaturation of collagen proteins in the vessel wall resulting in inflammation, thrombosis, and fibrosis of the vein. RFA received Food and Drug Administration (FDA) approval for the treatment of varicose veins in 1999 followed shortly by EVLA with an 810-nm wavelength in 2002. Additional available lasers include the 810-, 940-, 980-, 1319-, 1470-, and 1500-nm diode lasers and the 1064- and 1320-nm neodymium-doped yttrium aluminum garnet (Nd:YAG) lasers. The procedures are safely performed under local anesthesia and are well tolerated with minimal downtime for the patient. Due to their clinical effectiveness and safety profile, endothermal treatments are increasingly supplanting surgery as the treatment of choice for chronic venous disease.

for the treatment of varicose veins in 1999 followed shortly by EVLA with an 810-nm wavelength in 2002. Additional available lasers include the 810-, 940-, 980-, 1319-, 1470-, and 1500-nm diode lasers and the 1064- and 1320-nm neodymium-doped yttrium aluminum garnet (Nd:YAG) lasers. The procedures are safely performed under local anesthesia and are well tolerated with minimal downtime for the patient. Due to their clinical effectiveness and safety profile, endothermal treatments are increasingly supplanting surgery as the treatment of choice for chronic venous disease.

Indications and Contraindications for Endovenous Laser and Radiofrequency Treatments

The primary superficial veins of the lower extremity are the great saphenous vein (GSV), which runs medially from the ankle to the groin, and the small saphenous vein (SSV), which runs laterally from the ankle to the popliteal fossa. These veins drain blood from superficial collecting veins into the deep venous system for return to the heart. Numerous perforating veins pass through the fascia and connect the deep and superficial systems. Venous disease results when any point in this process is interrupted, though incompetent superficial veins are the most common cause. All veins contain one-way valves to prevent retrograde flow. When these valves are dysfunctional, either secondary to trauma or congenital abnormality, reflux occurs, creating high pressures in the superficial veins and subsequent dilation.

The presence of venous insufficiency increases with age and affects <1% of men and <10% of women <30 years and 57% of men and 77% of women ≥70 years (2c) [2]. The severity of the disease has also been shown to worsen with time, with a third of patients in one study showing progression in 6 months (4) [3]. Risk factors include obesity, standing occupation, reduced levels of physical activity, and family history (2c) [2, 4]. Many women report development of varicose veins in pregnancy; however, pregnancy has been inconsistently associated with venous disease in epidemiological studies (2c) [4, 5]. More recently, a large meta-analysis showed pregnancy significantly increased the prevalence of venous disease by 82% ((OR) odds ratio 1.82; 3b) [6]. One theory is that valvular insufficiency may result from the inhibition of smooth muscle contraction and vasodilation caused by progesterone and estrogen, respectively. Additionally, the gravid uterus may obstruct venous return and cause increased hydrostatic pressure. Multiparous women had the highest risk of developing varicose veins in one study, and the risk increased with age and a positive family history (3b) [7]. It is therefore unclear if pregnancy contributes to the development of varicose veins in women who are already predisposed or if it serves as an independent risk factor.

Patients with symptomatic venous insufficiency that is refractory to conservative therapy may be candidates for endothermal ablation. A 2012 international consensus meeting suggested the following veins could be treated with thermal ablation (5) [8]:

GSV (1a)
SSV (1a)
Anterior and posterior accessory saphenous veins (1b)
Giacomini vein and cranial extension of the SSV (1b)
Other superficial veins in the subcutaneous tissue (1c)
Pathologic perforating veins (1c)
Residual intrafascial veins after treatment (1c)
Venous malformations (1c)

All patients are not good candidates for these elective, thermal techniques, and appropriate patient selection following a thorough evaluation is key. Absolute contraindications include acute deep venous thrombosis (DVT), active infection, active superficial phlebitis, and the presence of deep venous obstruction when a collateral vein is the treatment target [8]. Relative contraindications include patients with poor ambulatory status, severe peripheral arterial disease ((ABI) Ankle Brachial Index < 0.5), pregnancy, thrombophilia, and anesthetic allergy precluding the use of tumescent anesthesia.

The anatomical characteristics of the vein may create technical issues and must be considered prior to treatment selection. Tortuous veins may prevent advancement of the laser fiber or radiofrequency catheter and are not ideal for treatment with thermal techniques. Veins that are too small (<3 mm) may be at increased risk of perforation, while large-diameter (>10 mm) veins may be more prone to treatment failure due to decreased contact with the treatment source (2b) [9]. Conflicting reports exist regarding vein size and treatment success; however, one study showed no significant difference in closure rate with the ClosureFAST catheter for veins >12 mm in diameter (2b) [10]. The length of the treated vein (at least 10 cm for the 7-cm catheter and 5 cm for the 3-cm catheter) should also be considered when using the ClosureFAST catheter since segmental ablation is performed.

Effectiveness of Endovenous Laser and Radiofrequency Treatments

A Cochrane review of 13 randomized controlled trials (RCTs) with a combined total of 3081 patients evaluated the effectiveness of EVLT and RFA in comparison to high ligation and stripping (1a) [11]. Eight trials compared EVLT with surgery, five compared RFA with surgery, and an additional three trials compared foam sclerotherapy with surgery (two of the trials compared multiple techniques). There was no significant difference in clinical (as determined by duplex ultrasound [DUS]) or symptomatic recurrence between any endothermal treatment and surgery. Recanalization rate was equal among all groups, but there was significantly less neovascularization and technical failure in the laser group compared to surgery. EVLT has been reported to have an effectiveness >90% in most studies, though this decreases with time. Min et al. reported a closure rate of 99.3% at 3 months falling to 93.4% at 2 years with the 810-nm laser (2b) [12]. Selected studies evaluating the success of EVLT can be seen in Table 26.1.

The first-generation radiofrequency system (Closure, VNUS Medical Technologies, San Jose, CA) showed significantly more treatment failures at 1 year compared to the 810-nm laser, though quality of life and Venous Clinical Severity Score (VCSS), see (Table 26.4) did not differ between groups (1b) [16]. The Closure model was replaced by the second-generation system (ClosureFAST, VNUS Medical Technologies, San Jose, CA) in 2006. This system utilizes higher temperatures (120 °C vs. 85 °C) and segmental ablation rather than a continuous pull-back, making it much quicker than the previous model. There was no difference in effectiveness between the 980-nm laser and the ClosureFAST catheter; however, RFA resulted in less postoperative pain, bruising, and analgesic use in the first 10 days (2b) [17]. This may be due to vein wall perforations caused by hemoglobin-specific lasers, which are not seen with RFA in an animal model (2b) [18]. The perforations lead to extravasated blood in the perivascular space, resulting in increased postoperative bruising and discomfort. In a study comparing the 1470 nm diode laser to RFA in the same 60 patients with bilateral disease, both methods had similar success rates but postoperative pain and time to return to activity were significantly less in the EVLT group (2b) [19].

The Endovenous Radiofrequency Obliteration Versus Ligation and Stripping (EVOLVeS) study evaluated 85 patients treated with RFA or high ligation and stripping (1b) [20]. Treatment success was similar between the two groups with less postoperative pain, analgesic use, earlier return to work and daily activities, higher quality

Table 26.1 Outcomes of selected EVLT studies

References	No. of treated limbs	Wavelength of device (nm)	Closure rate (%)	Follow-up
Min et al. [12]	121	810	93.4	2 years
Agus et al. (2b) [13]	1076	810–980	97	3 years
Schwarz et al. (2b) [14]	312	1470	100	3 months
Moul et al. (4) [15]	1171	1320	99.9	11.4 months

Table 26.2 Outcomes of selected RFA studies

References	No. of treated limbs	RFA device	Closure rate	Follow-up
Merchant and Pichot (2b) [22]	1222	Closure	87.2%	5 years
Proebstle et al. (2b) [23]	256	ClosureFAST	92.6%	3 years
Creton et al. (2b) [24]	220	ClosureFAST	96.9%	1 year
Bisang et al. (2b) [25]	118	ClosureFAST	94.1%	12.2 months

Table 26.3 CEAP classification - Clinical, Etiology, Anatomy, Pathophysiology

C = Clinical	E = Etiology	A = Anatomy	P = Pathophysiology
C0—No visible venous disease	Ec—congenital	As—superficial veins	Pr—reflux
C1—telangiectasias or reticular veins	Ep—primary	Ad—deep veins	Po—obstruction
C2—varicose veins	Es—secondary (post-thrombotic)	Ap—perforator veins	Pr,o—both reflux and obstruction
C3—edema			Pn—no venous pathophysiology identifiable
C4—skin changes C4a—pigmentation /eczema C4b—lipodermatosclerosis or atrophie blanche			
C5—healed ulcer			
C6—active ulcer			

of life scores, and fewer complications in the RFA group at 4 months. The follow-up study 2 years later showed no significant difference in recurrence rates between the two groups (20.9% surgery vs. 14.3% RF) with less neovascularization in the RFA group (1b) [21]. Of note, GSV diameter has continued to decrease over time with a mean size of 6.3 mm 72 h post treatment and 2.9 mm at follow-up 2 years later. Outcomes of selected studies evaluating the effectiveness of RFA can be seen in Table 26.2.

Preoperative Evaluation

Prior to treatment, patients should provide a detailed history and undergo physical exam [8]. Providers should elicit the patient's reason for seeking treatment (medical vs. cosmetic) and document any symptoms suggestive of venous disease such as heaviness, aching, restless legs, pain, tightness, tingling, burning, swelling, skin irritation, and muscle cramps. These symptoms tend to be exacerbated by heat and dependent position, worsen thoughout the day and relieved by leg rest or elevation. Persistent disease can lead to skin changes such as edema, stasis dermatitis, lipodermatosclerosis, and ulcers. Symptoms likely associated with a venous etiology are commonly worse at the end of the day or after prolonged sitting or standing. Elevation and compression may provide symptomatic relief, though long-term treatment with these methods is often impractical.

In addition to the above history, the patient's past medical and surgical history, including any previous venous stripping or thermal ablation, should be obtained. A personal or family history of venous thromboembolism warrants special attention. Though there is no consensus, clinicians often utilize some thrombotic risk assessment such as Caprini's assessment to decide whether thromboprophylaxis should be prescribed (5) [26]. Both EVLT and RFA can be safely performed in the setting of anticoagulation (2b) [27].

A clinical examination is performed to help establish if symptoms are secondary to venous disease or another cause. The presence of bulging varicosities, telangiectasias, corona phlebectasia (cluster of telangiectasias and reticular veins overlying the medial malleolus), edema, and skin changes is documented. The CEAP classification system (Table 26.3) is used to grade the severity

Table 26.4 Venous Clinical Severity Score (VCSS)

	Absent = 0	Mild = 1	Moderate = 2	Severe = 3
Pain	None	Occasional, no activity limitation	Daily, moderate activity limitation	Daily, severe activity limitation
Varicose veins (>3 mm in diameter)	None	Few or corona phlebectasia	Multiple, confined to calf or thigh	Extensive, involving calf and thigh
Venous edema	None	Foot and/or ankle	Above ankle but below knee	Knee and above
Pigmentation	None	Perimalleolar	Diffuse, lower 1/3 calf	Wider distribution, above lower 1/3 calf
Inflammation	None	Perimalleolar	Diffuse, lower 1/3 calf	Wider distribution, above lower 1/3 calf
Induration	None	Perimalleolar	Diffuse, lower 1/3 calf	Wider distribution, above lower 1/3 calf
No. of active ulcers	0	1	2	>2
Active ulcer duration	None	<3 months	>3 months but <12 months	>12 months
Active ulcer size	None	<2 cm diameter	2–6 cm diameter	>6 cm diameter
Compressive therapy	Not used	Intermittent	Most days	Full compliance

of venous insufficiency but cannot assess response to treatment. A standardized outcomes measure such as the Venous Clinical Severity Score is recommended before and after therapy to determine the treatment impact (Table 26.4) [8].

A duplex ultrasound (DUS) is performed to scan the entire deep and superficial venous systems. The diameter of the veins as well as the duration of reflux (if present) is recorded. Reflux ≥0.5 s in the superficial venous system and ≥ 1 s in the deep venous system is considered abnormal. Ruling out obstruction in the deep venous system is also necessary prior to treatment as this may be a cause for insufficiency and a contraindication for thermal ablation.

Best Techniques and Performance

Prior to both techniques, the great saphenous vein is mapped with ultrasound, and the most caudal point of reflux is documented to determine the access point. The physician also checks for tortuous or aneurysmal segments and for areas where the vein may be too small to cannulate. For most patients, access is obtained just above or below the knee. The patient is prepped and draped with sterile technique [8], and 1% lidocaine with epinephrine is injected at the access site. The vein is accessed either percutaneously (Seldinger technique) with a 16–19G needle or directly with a phlebectomy hook. Placing the patient in reverse Trendelenburg position will increase venous filling and make access easier. A warm room, heating pad, or 2% nitroglycerin paste on the access site can also help to minimize vasoconstriction.

RFA

When venous return is observed, a guidewire is passed through the hollow needle into the vein. An introducer sheath is then inserted over the guidewire and the guidewire is removed. The RFA catheter is inserted through the sheath and followed by ultrasound to a location at least 2–3 cm caudal to the saphenofemoral junction, just distal to the epigastric vein. The ends of the catheter contain electrodes, which contact the vein wall and release radiofrequency energy from a generator. Once in place, the provider administers tumescent anesthesia, most commonly 0.1% lidocaine, into the perivenous space under ultrasound guidance to confirm the appropriate placement of the anesthetic circumferentially in the saphenous sheath. The anesthesia serves to numb the area, facilitate compression to improve vein contact with the fiber or catheter, and act as a heat sink to prevent skin burns and damage to surrounding nerves and other structures. The distance from the skin to the treated

vein should be at least 1 cm to prevent skin burns [8]. An infiltration pump can be used to deliver the solution. After anesthetic administration is complete, the location of the catheter is again confirmed with ultrasound. Through retrofeedback, the control unit delivers the minimum power necessary to maintain the temperature at the electrodes. The power starts at 40 W (18 W for a 3-cm catheter) but typically drops to below 20 W (10 W for a 3-cm catheter) within 10 s if the vein is adequately compressed and blood is not flowing to cause cooling. If this does not occur, treatment should be stopped and catheter position should be confirmed (5) [28]. Placing the patient in Trendelenburg position during the procedure helps to empty the vein and increase contact between the device and the vein wall. Two heat cycles may be used near the junction or at wide aneurysmal segments and may even improve outcome without an increase in side effects when used along the entire length of the treated segment (2b) [29, 30]. As mentioned previously, the first-generation system heated the vein to 85 °C and was advanced via continuous pullback at a rate of 2.5 cm/min. The ClosureFast system ablates the vein in 7-cm segments (3-cm segments with the smaller catheter) with 20-s treatment cycles and maintains a temperature of 120 °C. ClosureFast was significantly more effective than the first-generation ClosurePlus in one study with 98% vs. 88% occlusion at 1 week (2b) [31].

EVLT

The GSV is accessed in the same manner as above, and a 200–600-μm laser fiber is advanced through the introducer sheath to a point at least 2–3 cm caudal to the saphenofemoral junction, just distal to the epigastric vein. An aiming beam can be visualized through the skin when the laser is turned on; however, this should not replace the use of ultrasound for localization. Ultrasound should be used in both the transverse and longitudinal views to verify fiber-tip location following tumescent anesthesia [8]. Once the position is confirmed and tumescent anesthetic has been infiltrated, treatment can begin. Protective eyewear specifically designated for the wavelength in use should be worn while the laser is in operation.

The exact mechanism of action of EVLA is still under debate, which has led to a variety of treatment protocols and new devices, each claiming to be superior to its predecessor. There have been five proposed mechanisms for the effectiveness of EVLA (5) [32, 33]. The first is the direct contact between the laser fiber tip and the vein wall. The second is the interaction between the emitted laser light and the vein wall, either through direct absorption of light scattered by blood or conduction of heat from the blood to the wall as the blood absorbs the light. The third mechanism is formation of steam bubbles in front of the laser tip. The fourth mechanism involves the heat transferred from carbonized blood that forms on the fiber tip. The blood surrounding the fiber sticks to the tip and strongly absorbs the emitted light, reaching temperatures up to 1000 °C. The contact between this extremely hot tip and the wall can lead to permanent injury. The fifth proposed mechanism involves formation of a coagulum in the vessel lumen as a result of thermal injury, which may release substances that interact with the vein wall. Doubts exist, however, that enough blood is present in the treated vein for this to be a key contributor. It is currently unclear how these mechanisms interact and which predominate. Increasing our understanding will hopefully prevent overtreatment and lead to more refined techniques that can reduce side effects.

Throughout the published literature, laser settings are often reported as linear endovenous energy density (LEED), the energy delivered per centimeter of the vein. It has been reported that a threshold of 60 J/cm exists for successful obliteration (3b) [34]. Critics feel that this parameter provides very little information and that laser power rather than energy is more important [32]. For example, an LEED of 50 J/cm can be achieved with both 10 W of power and a pullback velocity of 2 mm/sec or 0.1 W of power and a 0.02 mm/sec velocity, though clearly these settings are very different. Providing the exact power and pullback velocity settings rather than LEED allows the procedure to be duplicated by other clinicians. Power settings and pullback rates are dependent on the

laser device used, and the reader should refer to the protocol inherent to each device.

As mentioned previously, there are many different wavelength devices available for EVLA, and it is unclear whether vein wall injury occurs from direct absorption of scattered light or from heated blood. Hemoglobin-specific wavelengths (810, 940, 980, and 1064 nm) were the first developed followed by newer wavelengths (1319, 1320, 1470, and 1500 nm) which target water. Though these newer wavelengths are promoted as targeting the water in the vein wall, significant absorption by the water in blood also occurs, which may explain the minimal, if any, difference in the effectiveness of these devices in studies [32]. Water-specific lasers have been reported to have fewer postoperative side effects, such as bruising and discomfort, which may be related to a lower depth of thermal injury (2b) [35]. Unfortunately, many studies comparing wavelengths also use different fiber tips and energy settings, making it difficult to draw conclusions regarding the exact contribution of wavelength. In an RCT comparing the 940-nm diode laser with the 1470-nm diode laser, there was no difference in treatment success, but the water-specific laser results in significantly less postoperative pain in the first week (1b) [36]. This study used the same fiber tip and settings for both devices. Another study found the same results when a 940-nm diode laser was compared to the 1320-nm Nd:YAG laser; however, this study used lower power settings in the latter group, which may also explain the reduced side effects (2b) [37].

The laser can be fired in a pulsed mode or continuous mode. The pulsed mode exposes the vein to a fixed amount of energy at each distance, and the total energy is dependent on the distance between pulses, the pulse duration, and the power setting. When operating in continuous mode, the laser fiber is pulled back at a constant rate. The total energy in this mode is a result of the pullback speed and power used. Lasers fired in pulsed mode have been associated with fewer vein wall perforations (2c) [38, 39]. As mentioned previously, blood coagulates on the fiber tip, resulting in carbonization and extremely high-tip temperatures that can lead to perforation. Short pulse durations prevent this coagulum from forming on the fiber tip. The short pulse duration also allows a slower heating, which may reduce perforation risk. Many providers prefer the continuous mode with a rate of 1–2 mm/sec due to reduced treatment time. There is also some concern that pulsed mode may lead to undertreatment or skip areas. In one study using an ex vivo model of human veins harvested during phlebectomy, six different lasers were compared, two of which were used in pulsed mode [38]. All devices were operated at the same power. The fewest perforations were seen with use of a protected-tip fiber and with a 1320-nm pulsed Nd:YAG laser. Though different wavelengths were used, this study suggests that delivery mode may also be an important factor in the development of side effects.

The type of laser fiber used may also impact treatment success. In a retrospective study comparing the gold-tip NeverTouch VenaCure laser fiber (AngioDynamics, Queensbury, NY) with the bare-tip fiber, Prince et al. found a statistically significant increase in treatment failures with the gold-tip fiber (11.1% vs. 2.3%) (4) [40]. The authors noted difficulty withdrawing the gold-tip fiber smoothly, which may have resulted in undertreated skip areas along the vein. However, the gold-tip fiber was associated with fewer complications and was also felt to be easier to visualize on ultrasound. There are many types of protected fibers such as jacket-tip fibers [35], radial fibers (2b) [41], and tulip fibers (1b) [42] which have been associated with fewer vein wall perforations and side effects compared to bare-tip fibers, though no difference in treatment effectiveness was observed. There are multiple theories for this reduction in side effects. The construction of the different fibers may disperse energy over a greater surface area compared to the bare-tip fiber, which allows them to be used at lower energy settings [35]. The protected tips prevent direct contact with the vein wall, and in vitro analysis demonstrated a significantly reduced depth of thermal injury with jacket-tip fibers compared to bare-tip fibers at the same energy settings [35]. Additionally, the protected

tips may prevent tip carbonization, which can lead to perforation as discussed above [38, 39].

After completion of the treatment, the laser is placed in standby just prior to withdrawal of the fiber. The vein and junction may be visualized with ultrasound, although it is difficult to determine treatment outcome at this time since the vein has already collapsed from tumescence [8].

Safety

Thermal techniques are minimally invasive and very safe. The safety profile has continued to improve with time as providers become more familiar with the treatments and refine their techniques. Skin burns may occur at the access site as the laser is withdrawn or when a superficial vein is treated. Merchant et al. reported skin burns in 4.2% of patients treated with RFA which decreased to 0% with better use of tumescent anesthesia (2b) [22]. Ensuring that the treated vein is >1 cm below the skin surface prevents this complication. If a burn does occur, it is often self-limited and treated with local wound care.

Thermal injury to a nerve can occur when it lies in close proximity to the treated vein. Though the risk is much less than with surgery (7% with short stripping and 40% with long stripping of the GSV) [43, 44], permanent paresthesias can rarely occur. The saphenous nerve is closest to the GSV below the knee and is at greatest risk when ablation starts at the ankle. The sural nerve lies adjacent to the SSV in the calf, and the rate of injury ranges from 1.3 to 11% (2b) [45]. The overall frequency of paresthesias in a recent Cochrane review was 2.4% with EVLT and 11.7% with RFA, though RFA dropped to 1.7% for studies with follow-up longer than 3 months [11]. Foot drop may also occur with injury to the common peroneal nerve near the fibular head, either due to treatment at the saphenopopliteal junction or with ambulatory phlebectomy. The provider should be aware of these "danger zones" and liberally use tumescent anesthesia to prevent nerve injury.

Deep vein thrombosis (DVT) is the most concerning complication of thermal ablation. Endovenous heat-induced thrombosis (EHIT) is a thrombus that extends from the superficial system into the saphenous junctions and possibly the deep system following recent thermal ablation (Table 26.5).

Table 26.5 Endovenous heat-induced thrombosis (EHIT) classification and treatment

Class	Criteria	Treatment
I	Thrombosis to the saphenofemoral or saphenopopliteal junction, not extending into the deep system	Observe with serial ultrasound
II	Nonocclusive venous thrombosis, extending into the deep system with a cross-sectional area of < 50%	Observe with serial ultrasound Treat with LMWH
III	Nonocclusive venous thrombosis extending into the deep venous system with a cross-sectional area > 50%	Treat as DVT
IV	Occlusive deep venous thrombosis	Treat as DVT

Risk factors for EHIT include GSV diameter > 10 mm, SSV diameter > 8 mm, male gender, and multiple phlebectomies (3b) [46]. Previous history of superficial thrombophlebitis has also been associated (2b) [47]. In a retrospective study of 2470 limbs treated with RFA and 350 limbs treated with EVLA, DVT was found in 0.7% (four were EHIT) and 1% (three were EHIT), respectively (2b) [48]. There was no significant difference between the two thermal techniques [48, 49]. Risk of DVT is accepted to be less than 1% with either technique, and routine use of prophylactic anticoagulation is not recommended [8]. Patients should have a duplex ultrasound done within 10 days of treatment to evaluate for thrombus and be treated accordingly if one is present. Most providers observe EHIT I and treat EHIT III and IV as DVTs. Management of EHIT II is undefined as some providers treat with low-molecular-weight heparin while others observe. Sadek et al. found that increasing the distance from the saphenofemoral junction (SFJ)/ saphenopopliteal junctoin (SPJ) to ≥2.5 cm reduced the incidence of EHIT II, though this difference was not significant (2b) [49].

The most common side effects following thermal ablation are pain and ecchymoses. While

these side effects are expected to some degree in all patients, they are more common with hemoglobin-specific lasers and bare-tip fibers as mentioned previously. Postoperative pain in the first week was significantly less following ETA compared to surgery (1a-) [50]. Patients can be counseled to expect pain for up to 2 weeks following treatment and to take acetaminophen or NSAIDs if needed. Bruising and hyperpigmentation have been reported in 31.3% of EVLT patients and 12.3% of RFA patients [11].

Superficial thrombophlebitis is another common side effect reported in 8.8% of RFA patients and 6.5% of EVLT patients [11]. Treatment is often conservative with NSAIDs and warm compresses, though evacuation of trapped coagulum may be beneficial.

Postoperative Care and Follow-Up

At least two follow-up visits following any endovenous thermal ablation are recommended [8]. The first visit is for a duplex ultrasound within 10 days to ensure a thrombus has not developed. The second appointment is a clinical follow-up with duplex ultrasound 3–6 months later to document successful vein closure.

Compression stockings are typically recommended following ablation to reduce pain and edema and improve treatment outcome. High-quality evidence supporting their use is lacking, however, and the appropriate strength and duration of compression therapy are unknown. A randomized controlled trial of 400 patients examined the benefit of class II compression versus no compression following EVLA (1b) [51]. Patients who wore compression stockings had significantly less pain and edema in the first week, but there was no significant difference at 2 weeks. Additionally, there was no significant difference in quality of life or time to return to work. Another small study found that patients wearing compression stockings for 1 week had reduced pain and improved physical function compared to those wearing stockings for only 2 days post EVLA (2b) [52]. Conversely, Ayo et al. found no significant difference in VCSS scores, pain, or bruising whether compression was used or not (1b) [53]. Patients often find compression stockings uncomfortable and difficult to wear, which results in poor compliance. The available evidence suggests only a mild benefit to compression, and patients may be able to weigh the improvement in postoperative pain and edema with the inconvenience of use.

Alternative Procedures and Modifications

Surgical ligation and stripping has long been the standard of care for treatment of varicose veins and venous insufficiency. The GSV is ligated at the saphenofemoral junction and stripped to the knee or ankle. The SSV is ligated at the saphenopopliteal junction. Recurrence is high at 30–50% in 3–5 years due to neovascularization (2b) [54]. Additionally, surgery requires general anesthesia and is associated with more postoperative pain, wound infections, hematomas, and 3–5 days of additional downtime from work or normal activities [50].

The steam vein sclerosis (SVS) system, which is not currently FDA approved, heats the target vein wall through micropulses of steam at 120 °C. The vein is accessed percutaneously and a 16G infusion catheter is placed. The flexible stainless steel SVS catheter is inserted through the infusion catheter and passed through the vein to a level 2–3 cm caudal to the SFJ. Since the catheter is flexible, it can act as its own guidewire and travels through tortuous vein segments. One pulse of steam has 60 J of energy. In a study by Milleret et al., two pulses were administered every 1 cm for veins up to 7 mm in diameter (4) [55]. Three pulses were used for veins over 7 mm and four pulses for veins over 12 mm. The pulses were delivered every 1 cm of vein as the catheter was withdrawn. Tumescent anesthesia is required with this technique to prevent perivenous damage. In a series of 75 veins, 96% occlusion was observed at 6 months. Side effects were minimal and similar to other endothermal techniques. Further head-to-head studies are needed.

In foam sclerotherapy, a liquid sclerosant is mixed with air and injected into the target vein to cause inflammation, fibrosis, and ultimately occlusion. The foam replaces blood in the vein, which increases the efficacy and reduces the volume of sclerosant needed. Foam is four times more effective than liquid due to increased contact time with the vein wall and significantly more effective in the treatment of truncal veins (2b) [56]. Physician-compounded foam is often mixed with room air in a 1:4 ratio using the Tessari technique (4) [57]. CO_2 may also be used. A low-nitrogen proprietary foam, FDA approved in the United States as Varithena™, was developed following rare reports of serious neurologic events thought to be due to embolism from persistent, large nitrogen bubbles [58]. It is reported to have more consistent bubble size and longer contact time with the vascular endothelium. The GSV is accessed percutaneously under ultrasound guidance, and sclerosant foam is injected once venous return is observed. There is no high-quality evidence regarding injection location (distal or proximal portion of vein) or maximal volume of foam that should be used, though higher volumes are felt to have increased risks of side effects. Experts recommend limiting the volume of foam to 10 mL in a single session (5) [59]. The success rates have been reported to be 88–93% (2b) [60]. Multiple treatments may be required, particularly for larger veins. Local side effects such as phlebitis, hyperpigmentation, and pain are most common (4) [61]. Rare side effects include migraines, neurologic symptoms, and visual changes, which may be more common in a patient with a patent foramen ovale [59].

A disadvantage of all endothermal techniques is the need for tumescent anesthesia, which can cause patient discomfort and add considerable time to the procedure. It is also often the most difficult aspect of the procedure for the physician to learn. Though foam sclerotherapy does not require anesthesia, current studies show it to be inferior to endothermal techniques for treatment of the truncal veins, and it often requires multiple treatments. A newer hybrid technique, referred to as mechanochemical ablation (MOCA), combines endothermal ablation and sclerotherapy. The device, ClariVein, is FDA approved and utilizes a catheter to infuse the sclerosant into the target vein. The end of the catheter has a rotating wire that simultaneously mixes the fluid and injures the intima of the vein wall. The distal tip of the wire is placed 2 cm caudal to the SFJ, and the catheter is withdrawn at a rate of 1–2 mm per s. The wire is reportedly even capable of traversing tortuous GSV segments. In the initial trial, all patients received 12 cc of 1.5% liquid sodium tetradecyl sulfate (4) [62]. A closure rate of 96.7% at 260 days was reported with no cases of DVT, skin injury, or nerve injury, suggesting it is a safe and efficacious procedure that does not require tumescence. A randomized controlled trial comparing MOCA to RFA found no significant difference in occlusion rates, clinical severity scores, or disease-specific quality of life scores at 1 and 6 months (2b) [63]. Patients reported significantly less procedural pain with MOCA compared to RFA. This study also showed that concomitant phlebectomy with MOCA was safe and effective, though it should be noted that pain scores were gathered prior to phlebectomy. Additional head-to-head studies comparing MOCA to endothermal treatments are needed.

Another nonthermal technique that eliminates the need for tumescent anesthesia is VenaSeal closure system (VSCS; Medtronic, Plymouth, Minn), which was FDA approved in 2015. This system uses a modified cyanoacrylate, which is a flexible and viscous substance that rapidly polymerizes on contact with blood or tissue. Its flexibility allows it to withstand the movement of the legs without being perceived by the patient, and its viscosity limits the risk of embolization. An initial case series demonstrated a 92% closure rate at 12 months (4) [64]. No tumescent anesthesia or postoperative compression was used. The vein is accessed percutaneously through ultrasound guidance similarly to other techniques. A 5F introducer sheath is passed through the vein to a level > 5 cm caudal to the SFJ where approximately 0.10 mL of cyanoacrylate is injected at two locations 1 cm apart. This is followed by a 3-min period of compression. Repeat injections are carried out along the length of the vein, each followed by

local compression with a hand or ultrasound probe. The sheath is removed and a bandage is applied. Cyanoacrylate was found to be non-inferior to RFA with a closure rate of 99% at 3 months compared to 94% with RFA in an industry-sponsored RCT (1b) [65]. Adverse events were similar between groups and no serious events occurred.

In addition to incompetent truncal veins, patients may also have symptomatic tributary varicose veins. Some providers advocate observation since they may resolve following treatment of the GSV, while others recommend concomitant phlebectomy to spare the patients a second procedure. Carradice et al. randomized 50 patients to EVLT alone vs. EVLT with phlebectomy (2b) [66]. There was no difference in quality of life scores or postprocedural pain scores, and VCSS scores were significantly lower at 3 months in the group that underwent phlebectomy. In a larger study of 507 limbs with symptomatic tributary varicosities, 30% did not undergo concomitant phlebectomy at the time of RFA, and only 5% of those had resolved with the ablation alone at the time of follow-up (4) [67]. Other patients developed new varicose tributaries post ablation requiring phlebectomy at a later date. The findings in this study support the safety and efficacy of concomitant phlebectomy in patients with symptomatic tributary veins who require saphenous ablation.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development, and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
Endovenous laser ablation is effective and safe for the treatment of venous insufficiency	A
Radiofrequency ablation is effective and safe for the treatment of venous insufficiency	A
Hemoglobin-specific lasers are associated with increased postoperative bruising and pain compared to water-specific lasers	B
Bare-tipped fibers are associated with increased postoperative bruising and pain	B
Tumescent anesthesia during endothermal ablation reduces side effects	A
Thromboprophylaxis should be considered in individuals at increased risk of thrombus	D
Compression stockings should be worn following endothermal ablation	C

Self-Assessment Questions

1. Which of the following is not an absolute contraindication to treating with endothermal ablation?
   (a) Acute DVT
   (b) Active infection
   (c) Allergy to tumescent anesthesia
   (d) Active superficial thrombophlebitis
   (e) Deep venous obstruction when treating a collateral vein
2. Which wavelength of laser is most associated with increased postoperative pain and bruising following EVLA?
   (a) 1320
   (b) 1470
   (c) 810
   (d) 1064
   (e) 1500
3. Which fiber type is associated with more postoperative complications?
   (a) Jacket-tip fiber
   (b) Tulip fiber
   (c) Gold-tip fiber
   (d) Bare-tip fiber
   (e) Radial fiber
4. What is the approximate risk of DVT following ETA?
   (a) 5%
   (b) 1%
   (c) 3%
   (d) 10%
5. MOCA and VenaSeal have which of the following advantages over endothermal techniques?
   (a) No need of tumescent anesthesia
   (b) Fewer side effects
   (c) Increased venous occlusion
   (d) a and b only
   (e) a, b, and c

Correct Answers

1. c: An allergy to tumescent anesthesia is considered a relative contraindication to thermal ablation. The other options listed are absolute contraindications.
2. c: The 810-nm laser is hemoglobin-specific, while the other options are water-specific. The hemoglobin-specific lasers have shown an increase in postoperative bruising and discomfort, possibly secondary to increased vein wall perforations, though additional studies using the same laser settings in both groups are needed.
3. d: Bare-tipped fibers have shown an increase in postoperative pain and bruising compared to the other fiber types, likely due to increased depth of injury and vein wall perforation.
4. b: Risk of DVT with both RFA and EVLA is approximately 1%.
5. a: Neither technique requires tumescent anesthesia, which is an advantage over the endothermal options. While one study showed less procedural pain with MOCA compared to RFA, adverse effects with VenaSeal were similar to RFA. Both options showed similar occlusion rates to the endothermal treatments.

Blepharoplasty

27

Isabella Lai and R. Sonia Batra

Abstract

Blepharoplasty is an operation focused on functional and/or cosmetic restoration of the eyelid by removal of redundant tissue. It is one of the most popular cosmetic procedures due to its relatively low risk profile and rapid visible improvement in facial aesthetics. Current methods of periorbital rejuvenation to restore youthful appearance are more conservative—grounded on concise preoperative evaluation and focused on limited skin resection. In this chapter, the authors present evidence for preoperative evaluation, decision-making and counseling of patients, surgical planning, various operative techniques, and postoperative care in functional and aesthetic blepharoplasty. Evidence on the postoperative complications and alternative complementary procedures is also discussed.

Introduction and Definition

The eyes and periorbital areas are expressive points of human interactions, but they are also points that reflect facial aging. As people age, their skin loses elasticity, leading to excess laxity and skin folds over eyelid margins. These changes in eyelid appearance create an illusion of sadness, fatigue, and loss of energy, all of which decrease the aesthetic appeal of the human face. Furthermore, in severe cases, excess laxity of the skin can obstruct vision.

Blepharoplasty is formally defined as an operation for the restoration of a defect in the eyelid. The goal of the procedure is to repair ptosis, eyelid retraction, entropion, ectropion, trichiasis, or defects resulting from tumor excision. More commonly, this term specifically refers to removal of redundant tissue (e.g., skin, muscle, and fat) from the upper or lower eyelids to provide the eye with a more youthful appearance.

The role of blepharoplasty can be multifold: either cosmetic, to rejuvenate the appearance of the eyes, or functional, to improve visual fields. Blepharoplasty is one of the most popular cosmetic procedures performed in the United States [1]. According to the American Society of Plastic Surgeons, more than 200,000 eyelid procedures were performed in 2016. The popularity of this procedure is derived from its ability to provide a natural, younger appearance with a limited operation time and a low risk profile.

Currently, there are very few high-quality, evidence-based articles on blepharoplasty because aesthetic surgery is still in its infancy. Most articles on this subject are of level IV evidence (case series) and level V evidence (case reports or expert opinion). There are few articles of level III evidence (retrospective comparative case series) and even fewer of level II evidence (prospective comparative studies). Given the nature of the subject, it would be very difficult to create level I evidence studies that are blinded, prospective, randomized, and controlled. Given the current quality of evidence and the variability in published data, meta-analyses have not been performed. Additionally, no consensus statements have been made by the American Academy of Dermatology, American Society for Dermatologic Surgery, American Academy of Cosmetic Surgery, American Society of Plastic Surgeons, American Society of Ophthalmic Plastic and Reconstructive Surgery (ASOPRS), or American Academy of Facial Plastic and Reconstructive Surgery. This is expected as there are few controversies in this field.

This chapter contains different aspects of blepharoplasty and presents evidence from published works and current trends in this surgical technique.

Table 27.1 Indications for blepharoplasty and definitions

Indications for blepharoplasty and definitions
Blepharochalasia Redundant skin of the upper eyelid hangs down, impairing the visual field
Blepharospasm Muscles in the eyelids and around the eyes twitch uncontrollably
Dermatochalasis Excess of eyelid skin; underlying muscle, connective tissue, and fat Most often results from natural aging but can result from specific disorders (e.g., thyroid eye disease, floppy eyelid syndrome, blepharochalasis syndrome, trauma)
Ectropion Turning out or sagging of the upper or lower eyelid; mainly affects the lower eyelid, leaving the eye exposed and dry (excessive tearing is common)
Entropion Abnormal inward rotation of the eyelid; occurs most commonly as a result of aging but may occur after trauma and scar contraction or after surgery
Epiblepharon A congenital horizontal fold of the skin stretches across the border of the eyelid, pressing the eyelashes inward against the eyelid
Rejuvenation
Thyroid disease May cause unilateral or bilateral upper eyelid retraction and proptosis (protruding eye)
Trauma

Indications

Upper and lower eyelid blepharoplasty is performed for various functional or cosmetic indications (Table 27.1 summarizes indications and definitions). Patients undergoing cosmetic blepharoplasty may have different expectations than those undergoing functional blepharoplasty. For this reason, a thorough discussion of anticipated results with the patient is critical prior to the procedure in order to achieve the best outcomes.

Upper Eyelid

The signs of aging on the face are most prominently noticed in the upper eyelids. The current signs of eyelid aging are total orbital volume loss, tissue descent, and increased skin laxity [2]. Apart from causing undesirable aesthetics, these signs of aging can also cause eyelid droopiness and obstruction of the superior visual field. Upper eyelid blepharoplasty can therefore be performed to relieve this obstruction. Repair of blepharoptosis and upper eyelid dermatochalasis provides significant improvement in vision and quality of life.

Functional indications for reconstructive upper blepharoplasty include visual axis obstruction and comprise three essential elements: (1) patients should notice improvement in vision with eyelid skin elevation, (2) visual field testing is needed prior to procedure to document visual field impairment, (3) and there is photographic evidence of upper eyelid skin laying across eyelashes (3b) [3]. Evidence from one retrospective analysis studying downgaze (3b) [3] and from a

case series on superior visual field defects (4) [4] demonstrated that visual impairment from upgaze or downgaze should be a key functional indication. In a prospective survey of patients preoperatively and postoperatively, blepharoplasty was found to be qualitatively beneficial in addressing visual impairment in the head-tilt/chin-lift test, symptoms of discomfort, eye strain, and visual interference (4) [5]. Other functional surgical indications currently considered, albeit with limited evidence, are dermatitis, difficulty wearing a prosthesis in an anophthalmic socket, and temporal visual field impairment; thereby preventing patients from meeting driver licensing standards (4) [5].

Cosmetic upper eyelid surgery is an elective procedure, and its main indication is to improve the appearance of the eyes. Often-cited cosmetic requests of patients are to correct "tired" or "droopy" eyes, improve eyelid symmetry, improve eyelid contour, and rejuvenate the face (5) [6].

Lower Eyelid

Lower eyelid blepharoplasty is performed for both aesthetic and functional concerns. Functional indications include reading difficulty secondary to prolapsed orbital fat and skin covering the bifocal spectacle segment. Other functional indications are trauma, inflammatory disorders of the orbit and eyelids, entropion (inversion of the eyelid margin), and epiblepharon (congenital abnormality where eyelashes are forced against the cornea) (5) [7].

Although there are functional indications, lower eyelid surgery is most commonly performed to correct cosmetic concerns associated with aging. As a person ages, the increasing laxity of the structural supportive tissues and decreasing integrity of the orbital septum cause orbital fat pseudoherniation and appearance of bags in the lower eyelid. Laxity can be hereditary and appear in adolescents as well as the elderly. Orbital fat pseudoherniation leads to deepening of the nasojugal fold and causes the eyes to appear fatigued [8]. Additionally, below the orbital rim, the fatty tissues of the midface, cheek, and suborbicularis oculi fat also lose volume and descend. In a youthful face, cadaveric studies have demonstrated that the suborbicularis oculi fat attaches to the arcus marginalis at the level of the inferior orbital rim [9]. These changes in the midfacial fat, suborbicularis oculi fat, and orbicularis oculi contribute to the increasing potential for eyelid malposition, deepening of the tear trough, and rounding of the eye [9]. Additionally, skin elasticity loss also leads to progressive dermatochalasis with fine and deep rhytids [10]. Rizk and Matarasso conducted a retrospective study of 100 patients to analyze the indications and treatment of lower eyelid blepharoplasty. They concluded that orbicularis oculi muscle hypertrophy is also an absolute indication for lower eyelid transcutaneous blepharoplasty as this requires resection of the preseptal orbicularis muscle (5) [11].

Therefore, aesthetic indications for lower blepharoplasty include patients with lower eyelid fat pseudoherniation with or without orbicularis hypertrophy, excess lower eyelid skin, the appearance of circles under the eyes, or prominent depth in the tear trough deformity (5) [12].

Effectiveness of Blepharoplasty

Blepharoplasty is a procedure associated with a high level of satisfaction for both patients and surgeons. For the patient, blepharoplasty affords the opportunity to achieve a youthful and rejuvenated appearance. For the surgeon, it is a short, in-office procedure that has immense, long-lasting results, and it allows the surgeon to restore facial harmony, preserve anatomical landmarks, and avoid undesirable surgical stigmata.

Although there is a marked increase in medical articles documenting the successes of blepharoplasty, these studies usually focus on patient satisfaction. This is due to the subjective nature of outcomes that hinge on aesthetics. A study by Viana GA et al. surveyed 50 patients after lower blepharoplasty and concluded that blepharoplasty was a safe and effective procedure, had low complication rates, and led to significant improvement of self-esteem assessed 6 months

after the operation (4) [13]. However, although all participants had positive changes in their social lives, seven patients had decreased self-esteem. The researchers believed that the worsening self-esteem of these patients can be explained by external social factors: Three patients were divorced, three had problems with children, and one unexpectedly became a widow during the study period. In a literature review, Figueroa showed that pain and loss could be responsible for the rupture with significant change in body image self-esteem, which could last up to 1 year after the event (5) [14].

To address the issue of biases of patient surveys in determining the efficacy of blepharoplasty, Chauhan et al. sought to create a more objective measure of efficacy (4) [15]. One of the chief motivations of blepharoplasty is to restore a youthful appearance and minimize aging. For this reason, the authors conducted a prospective study to quantify the degree of perceived age change after facial surgical procedures. Patients were separated into three groups based on surgical procedures completed: 22 patients in face- and neck-lift, 17 patients in face- and neck-lift and upper and lower blepharoplasty, and 21 patients in face- and neck-lift and upper and lower blepharoplasty plus forehead-lift. The adjusted means demonstrated that patients were perceived to be 8.9 years younger than their chronological age after surgery. The effects were most dramatic in those who had undergone all three aging face surgical procedures. This study demonstrates that aesthetic facial surgery leads to a significant and consistent reduction in perceived age after aesthetic facial surgery. This effect is more substantial when the number of surgical procedures is increased, an effect unrelated to the preoperative age of a patient and unaffected by other variables (4) [15].

There lacks evidence on the lasting effects of blepharoplasty. It is estimated that these procedures usually last for 10–15 years (5) [15]. This is due to the inevitable fact that treated areas are also subjected to the same aging process as that of the rest of the body.

Preoperative Evaluation

The preoperative evaluation prior to blepharoplasty should include a detailed general medical and ophthalmologic history, focused physical exam, and thorough discussion of expectations with the patient.

Medical History

Multiple review articles have highlighted the importance of a thorough medical history (5) [16, 17]. This history should include chronic medical conditions, e.g., hypertension, diabetes mellitus, cardiac disease, bleeding or hematologic disorders, and thyroid abnormalities. Furthermore, current medications and previous surgeries should also be queried as they can have an impact on wound healing.

Ophthalmologic History

An ophthalmological history is critical during preoperative evaluation. This should include information about vision, prior traumas, and ophthalmologic conditions (e.g., glaucoma, allergic reactions, dry eyes). Dry eye syndrome is a common dysfunctional tear syndrome, described by the patient as dryness, burning, foreign body sensation, blurred vision, photophobia, itching, redness, tearing, and discharge of mucus. Hamawy et al. have published an algorithm for treating dry eyes (3b) [18].

The Schirmer test is no longer indicated for predicting dry eye syndrome. The role of the Schirmer test was evaluated by Rees and LaTrenta in a prospective analysis of 100 patients. Because blepharoplasty can mechanically alter eyelid closure and impair the lubricating mechanism, subclinical dry eye syndrome is an important consideration in any patient contemplating blepharoplasty, especially those with morphologically prone eyes. The authors found that the Schirmer test could not reliably predict the development of postoperative dry eye syndrome

(4) [19]. They state that the morphology of the orbit is a more reliable indicator to signal the predilection to develop this complication (5) [19].

It is especially important to ask regarding prior ocular procedures such as laser-assisted in situ keratomileusis (LASIK) and other refractive surgeries. Patients who have had refractive surgery within the past 6 months are not suitable candidates for blepharoplasty (2b) [20–22].This patient population is at risk for dry eyes and keratopathy because of the alteration in corneal sensation, tear production, and tear film formation [20–22].

Alterations in tear secretion and tear film stability after LASIK and subsequent blepharoplasty were studied by Griffin et al. [23] They performed blepharoplasty on nine patients who had undergone bilateral LASIK in the previous 18 months. This group was compared to a control group of nine patients with no history of LASIK, dry eyes, or contact lens use. The authors found no statistically significant difference in tear characteristics after blepharoplasty between both groups. They concluded that blepharoplasty may be performed after LASIK if an interval of time has passed (3b) [23].

Lifestyle History

A review by Trussler and Rohrich also recommends lifestyle history: e.g., smoking, alcohol consumption, illicit drug use, and over-the-counter herbal supplements as these substances can affect wound healing (5) [21].

Physical Exam

Many surgeons may require a full preoperative ophthalmologic exam to assess visual fields, visual acuity, adequacy of tear film, functionality of periocular muscles, and underlying glaucoma and macular diseases. A detailed periorbital physical exam is recommended; this should include examining the periorbital structures and analyzing the presence of upper and lower eyelid dermatochalasis, lateral hooding, ptosis, angle of the lateral canthal tilt, and lower eyelid laxity [20–22].

The orbicularis and lower lid ligaments are part of the periorbital structures and should be examined with a snap test or attempting to pull the eyelid more than 6 mm from the eye to see if laxity exists. Blepharoplasty in a lax lower lid can worsen lid malposition and cause scleral show or ectropion. If laxity exists, a canthopexy or canthoplasty should be discussed. Additionally, the patient needs to be evaluated for the presence of canthal tilt: when the medial canthal position is 2 mm inferior to the lateral canthal position. If this is not the case, lateral canthal repositioning may be required. Fat excess and appearance should be assessed as well as the tear trough (nasojugal groove) deformity. The orbital rim's position relative to the cornea in the lateral view is important to assess. If the rim is located posteriorly, a negative vector or prominent eye will make lower eyelid surgery more challenging (4) [24].

The upper lid margin normally covers 2–3 mm of the iris. A lower position may indicate ptosis, which needs to be documented and addressed preoperatively. Ptosis in conjunction with a high tarsal fold is indicative of levator dehiscence. The position and shape of the brow needs to be assessed to see if brow lifting or shaping is required in addition to blepharoplasty. The key elements in the problem of the lower eyelid blepharoplasty are the negative vector, sagging lower eyelid, and prominent tear trough. These elements are difficult to correct and their postoperative results may be suboptimal. These elements need to be pointed out to patients preoperatively.

Patient Counseling

With any procedure, managing patients' expectations is crucial to satisfactory outcome (5) [25]. Patients should understand that upper blepharoplasty will make eyes large and more prominent but will not elevate the brows, reduce rhytides, or

lines of expression. Middle-aged patients should not expect to appear as they did in their 20s or 30s. For lower blepharoplasty, patients will have improved infraorbital contour and appear better rested. However, they should not expect this procedure to address sagging malar eminence because this is done through a different procedure.

A discussion of complications postoperatively should also be explained during the session. Patients should also be informed regarding postoperative care and length of recuperation. This is best done in the form of a handout which details expectations following surgery.

Although upper eyelid blepharoplasty requires minimal bandaging, upper eyelid visibility and swelling will be noticeable and may take months to resolve. Ointments may help with wound healing, but depending on the components within the ointment (e.g., antibiotics), contact dermatitis may result.

For lower lid blepharoplasty, the patient should be aware of the risk of conjunctival irritation and dry eyes. Artificial tears can be provided for these conditions.

If laser resurfacing is to be performed, then the patient needs to be educated about prolonged erythema and wound care. Most importantly, patients should be informed that due to postoperative swelling, the final results of the surgery may not be fully apparent for 3 months.

Surgical Treatment

In blepharoplasty, the current trend is toward minimalism—preserving and even augmenting volume loss (5) [26]. While aggressive procedures can have outstanding results, more complications can also arise; as such, "less is more." In this section, we will discuss the evidence behind the surgical techniques of blepharoplasty, as it relates to preoperative markings, instruments used, and the various types of incisions (Table 27.2).

Table 27.2 Level of evidence

Evidence-based summary	
Findings	Evidence level
Blepharoplasty is a safe and effective procedure, with low complication rates, and leads to improvement of patient self-esteem assessed 6 months after the operation	A
Functional indications for reconstructive upper blepharoplasty is indicated when visual axis is obstructed. Functional indications for lower eyelid blepharoplasty include reading difficulty secondary to prolapsed orbital fat and skin covering the bifocal spectacle segment	B
Patients undergoing blepharoplasty should have a thorough periorbital and ophthalmologic examination. They should be asked about specific medical conditions which could affect the procedure and postoperative healing	C
Patients who have had refractive surgery (LASIK) within the past 6 months are not suitable candidates for blepharoplasty	B
Managing patients' expectations is crucial to satisfactory outcome	D
In blepharoplasty, the current trend is toward minimalism—preserving and even augmenting volume loss	D
Compared to cold steel surgery, the CO_2 laser leads to improved hemostasis, reduced operative time, less bleeding, greater intraoperative visibility, and decreased ecchymosis and edema	D
The laser diamond scalpel and Colorado needle offer the surgeon tactile feedback	B
No statistical difference was noted when comparing radiofrequency device with CO_2 laser for blepharoplasty incision	B
No statistical difference was noted when comparing the Colorado needle with traditional scalpel in terms of ecchymosis, cosmesis results, or scar formation	B
Electrocautery was not inferior to cold steel scalpel in terms of healing/scar formation of the skin incision	C
Upper eyelid skin removal is often more liberally done than lower eyelid skin removal because showing of the tarsal skin (2–3 mm above the eyelid margin) is desirable in the upper eyelid for makeup application and visibility	D

Table 27.2 (continued)

Evidence-based summary	
Findings	Evidence level
Lower eyelid blepharoplasty is based on the more conservative removal of a pinch of skin, as excessive skin removal leads to scleral show	D
Malposition of the eyelid is the most frequently reported complication associated with transcutaneous lower eyelid blepharoplasty	D
Inadequate removal of fat is the most common complication after transconjunctival lower eyelid blepharoplasty	C
Due to ethnic anatomical differences and perception of aesthetics, Asian eyelid surgery requires modified techniques	C
While rare, blepharoplasty does incur complications, including bleeding, structural, infection, and vision loss. Patients should be informed of these complications	B
The most feared complication of blepharoplasty is permanent vision loss, most commonly secondary to retrobulbar hemorrhage; however, vision loss can also be caused by globe perforation, ischemic optic neuropathy, and angle closure glaucoma	B
Even though rare because of the extensive vascularization of the region, infections postblepharoplasty do occur and require early appropriate treatments (i.e., antibiotics, debridement, drainage, and possible hyperbaric oxygen)	B
Lower eyelid malposition is the most commonly reported complication of lower eyelid blepharoplasty. Addressing this complication requires identification of the affected lamella.	B
If initial ocular lubrication fails to address dry eye symptoms, anti-inflammatory eye drops (such as topical cyclosporine) should be used, followed by punctal occlusion	A
Consistent use of lubricating eye drops can prevent corneal abrasions during the early postoperative period	A
While they do not offer outcomes comparable to those of blepharoplasty, botulinum toxin A and hyaluronic acid injections are alternative procedures that address eyelid concerns	C

Preoperative Markings

Zoumalan and Roostaeian summarized preoperative markings in their review on blepharoplasty [27]. These incisional markings are individualized for patients and their desires. Markings should be performed when patients are sitting upright with eyebrows and eyelids in neutral position.

Instruments

There are various options for cutting devices in blepharoplasty: cold steel scalpel, cautery, radiofrequency (RF), Colorado needle, and laser. Each instrument offers its own advantages and disadvantages (Table 27.3).

Cold steel scalpel and laser have been compared in some studies. In an observational study on patients who underwent blepharoplasty, Coleman et al. note that while laser can create less bleeding, it increases inflammatory response when compared to scalpel (5) [28]. In contrast, a review by Gladstone reported laser improved hemostasis and less collateral damage with laser incision (5) [25]. Biesman discussed in a review article the perceived efficiency of utilizing the carbon dioxide (CO_2) laser, as it serves as both a blunt dissection device and a cautery unit (5); additionally, he also noted improved hemostasis with CO_2 laser [29]. Further studies by David and Sanders on 13 patients showed reduced operative time, less bleeding, and decreased ecchymosis and edema. Scars were indistinguishable at 30 days in both groups (2a) [30]. In a randomized study, Morrow and Morrow did not observe differences in healing; however, the authors noticed increasing patient comfort and shorter recuperation time with laser (2a) [31]. In a study by Baker et al., blinded observers were not able to distinguish clinically significant outcomes between diamond scalpel and CO_2 laser; however, the scalpel provided improved tactile feedback to surgeons and allowed for the ability to incise at varying levels of hemostasis (2a) [32].

Table 27.3 Instruments used for incision in blepharoplasty: evidence-based advantages and disadvantages

Cold steel scalpel	Electrocautery	Colorado needle	Radiofrequency	CO_2 laser
Advantages				
Decreased inflammation Decreased collateral damage Allows tactile feedback	Simultaneous incision and hemostasis	Decreased thermal damage Allows tactile feedback	Simultaneous incision and hemostasis Decreased collateral damage Allows tactile feedback	Simultaneous incision and hemostasis Improved intraoperative visibility Decreased operative time Decreased collateral damage Increased patient comfort Decreased ecchymosis/edema Decreased recuperation time
Disadvantages				
Requires separate device to achieve hemostasis	Possible increased inflammation	Possible necrosis	Possible greater depth of tissue damage	Possible increased inflammation No tactile feedback

The short-pulse CO_2 laser was compared to the Colorado needle tip with electrocautery in a randomized trial by Rokhsar et al. [33] Twelve patients were studied. Mean intraoperative time with the Colorado needle was shorter than that with the laser. Histologic examination revealed less thermal damage of the tissue harvested with the Colorado needle. However, no difference in healing parameters was noted by the patient or physician 1 month postoperatively. The Colorado needle offers the advantages of the short-pulse CO_2 laser along with greater tactile feedback (3a) [33].

A radiofrequency device was compared with CO_2 laser in a randomized controlled trial by Niamtu on 30 patients. Each eye was randomly treated with one modality. Five blinded board-certified surgeons did not observe any statistically significant difference in scar quality at 12 months. The author concluded that both devices incise and provide coagulation simultaneously, minimize collateral damage, and produce indistinguishable scars (2a) [34].

Radiosurgery has also been compared with conventional scalpel surgery. In a prospective study on opposite eyelids by Ritland et al., 13 patients found better wound healing and a higher Hollander score at 1 week ($p = 0.014$) with radiosurgery, but no statistically significant difference at 3 months (3b) [35]. In a prospective, randomized, blinded, comparative, interventional study by Kashkouliet al. in 2008, eyelid scar formation and histology on 46 eyelids were assessed by two masked observers. They found that while scar formation was insignificantly less in the radiosurgery group ($p = 0.055$), the histologic zone and depth of tissue damage was greater in the radiofrequency group (2b) [36].

The Colorado microdissection needle and scalpel were studied in a prospective, comparative case series by Arat et al [37]. A total of 254 eyelids of 101 patients underwent bilateral upper or transcutaneous lower blepharoplasty, and ecchymosis, cosmesis, and histologic tissue damage of incisions made by a scalpel versus a Colorado needle were compared. Histologically, necrosis was only noted with the Colorado needle sides ($p = 0.001$). No clinical difference was noted between the two groups in terms of ecchymosis, cosmesis results, or scar formation (2b).

Albeit the numerous studies that have shown the benefits of electrocautery when compared to traditional scalpel, electrocautery is not commonly thought of as a cutting device due to deep fears for

burns, poor wound healing, and excessive scarring. It is usually thought of as a device for underlying dissection and hemostasis. In a prospective, randomized, double-blind study by Afuwapeet al., electrocautery and scalpel were compared in 197 native African patients as it relates to postoperative pain, duration of wound healing, and occurrence of infection. It was concluded that electrocautery in making a skin incision is associated with reduced incision time ($P < 0.001$), incisional blood loss ($P < 0.001$), and postoperative pain ($P < 0.001$). However, there was no statistically significant difference in wound infection and wound epithelialization time ($P = 0.206$) (2b) [38]. In a comparative, observational study by Lee et al., patient and blinded observer perspectives on wound healing and scar formation were assessed. The observers rated incision vascularization, pigmentation, thickness, and relief. Patients rated incision pain, itching, discoloration, stiffness, thickness, and irregularity. Results showed that electrocautery was not inferior to cold steel scalpel in terms of healing/scar formation of the skin incision (3b) [39]. To summarize, many studies have shown that electrocautery does offer advantages such as rapid hemostasis, faster dissection, and reduced blood loss, without affecting wound healing time, rates of infection, and postoperative complications [40–45].

Laser blepharoplasty offers many advantages. A review of laser blepharoplasty by Lessner and Fagien found the same advantages to the laser technique as mentioned previously. The authors caution surgeons to remove less skin during blepharoplasty if resurfacing is planned for the same site as thermal collagen contracture will occur after laser resurfacing (5) [46]. In a review article by Leciere et al., long-term outcomes of CO_2-laser assisted blepharoplasty were studied in a prospective controlled trial of 52 patients. It was found that ptosis surgery is a safe and reproducible technique particularly appreciated by patients. The procedures led to improved hemostasis, decreased operating time, and improved postoperative appearance (2c) [47].

No studies in humans have been performed to directly compare carbon dioxide laser, radiosurgery, and scalpel incision. However, these three modalities were compared in Hodson et al. study on snakes. The design of the study was to examine the histologic skin response in snakes after a 2 cm skin incision was made by either CO_2 laser, radiosurgery, or scalpel incision. Necrotic and fibroplastic tissue were measured in histologic sections; samples were assessed and scored for total inflammation, histologic response (based on the measurement of total inflammation score, necrotic tissues, and fibroplastic tissues), and other variables. Frequency distributions of gross and histologic variables associated with wound healing were calculated. It was found that skin incision using a scalpel was less necrotic, followed by radiosurgery, and then laser (5) [48].

Upper Eyelid

Upper eyelid blepharoplasty is performed by an external incision in the upper eyelid crease and excision of redundant skin by various modalities as discussed previously. In general, upper eyelid skin removal is often more liberally done than lower eyelid skin removal. This is because showing of the tarsal skin (2–3 mm above the eyelid margin) is desirable in the upper eyelid for makeup application and visibility (5) [49].

Along with the skin, the underlying orbicularis oculi muscle and fat can also be removed if redundancy is observed. Surgeons often consider preservation of the orbicularis oculi muscle to prevent development of lagophthalmos [27]. Nasal herniated fat pads are removed, while central fat pads are often kept to maintain upper eyelid fullness. The wound is then carefully closed with either interrupted, simple running, or running subcuticular closure. Glue and Steri-Strips can also be placed depending on the surgeon's preference.

For upper eyelid surgery, ptosis correction is most commonly encountered. For the correction of involutional ptosis, Ben Simon et al. retrospectively compared an external approach for levator advancement (81 eyelids, 37 with blepharoplasty and 51 alone) with a Muller's muscle–conjunctival resection (184 eyelids, 104 with blepharoplasty and 80 alone) [50]. Patients who underwent

Muller's muscle–conjunctival resection attained a better cosmetic outcome and had a lower reoperation than the other patients (3b). Brown and Putterman showed that a decreased eyelid raising effect of a Muller resection ptosis procedure can be accomplished with concomitant blepharoplasty that includes orbicularis resection [51]. Erb et al. showed that after levator advancement for unilateral ptosis repair, 17% of patients had a decrease in contralateral eyelid height of more than 1 mm due to the Hering dependence phenomenon with 5% of patients requiring surgical repair during the first postoperative year (3b) [52].McCulley et al. found that 8.7% of patients with primary acquired good-function blepharoptosis underwent additional surgery after external levator aponeurosis advancement (3b) [53]. The authors observed an increased risk of persistent postoperative blepharoptosis in patients with severe ptosis [53].

Lower Eyelid

Lower eyelid blepharoplasty is based on the more conservative removal of a pinch of skin, as excessive skin removal leads to scleral show (4) [54]. The ideal approach for treating lower eyelid blepharoplasty is under debate. There exist two distinct methodologies: (1) external transcutaneous incision and (2) internal transconjunctival incision.

The transcutaneous method involves an external skin incision to remove excess skin while accessing the underlying fat compartments and the orbicularis muscle. This is performed by a subciliary incision under the lower eyelash line to remove redundant skin. After the removal of redundant skin, an incision is made in the orbital septum to remove the orbicularis oculi muscle flap and the pseudoherniated fat pads. There are variations in the transcutaneous approach—e.g., skin-only flap, skin–muscle composite flap, and separate skin and muscle flap. Currently, there are no prospective comparative studies on these techniques; the current studies are based on surgeons' experiences on a particular technique.

The transconjunctival technique involves a retroseptal approach. This allows the surgeon access to the fat compartment while avoiding the anterior and middle lamellae. An incision is made in the tarsoconjunctival aspect of the lower tarsal plate. The lower eyelid fat pads herniate through this incision. In a study by de Castro in 2004, a transconjunctival approach was performed on 100 blepharoplasties, and preoperative, intraoperative, and postoperative periods were analyzed. The patients, surgeon, and a third person evaluated the results, and photographs of postsurgical eyelid positions were displayed in the article [26].

The transcutaneous approach has not only variations of the techniques but also multidisciplinary principles that affect the results. In a prospective study on lower eyelid physiology, the Atlanta group showed that there is very little muscle denervation (by preoperative and postoperative electromyography determination) with a transcutaneous incision, skin–muscle flap, and orbicularis suspension (5) [55]. In a study by Liao et al., a total of 408 female patients underwent modified subciliary lower blepharoplasty between 2002 and 2010 [56]. The severity of eyebags (dynamic wrinkle numbers and prolapse) was compared through preoperative and postoperative photos. While this modified transcutaneous approach led to improved dynamical wrinkles and prolapse in the eyebags, the results were dependent on periorbital aging and dynamic wrinkle numbers ($P < 0.001$) prior to the procedure (2b).

The transcutaneous incision results in high patient satisfaction. In a prospective, randomized, controlled trial conducted between April 2005 and May 2007, Viana et al. studied the satisfaction of aesthetic results of 50 surgical patients following two variations of the transcutaneous lower eyelid blepharoplasty. It was concluded that the transcutaneous approach was safe and effective and led to improvement in self-esteem assessed 6 months after the operation (2b) [13].

Gladstone examined the two parallel approaches to treat lower blepharoplasty and discussed an unpublished retrospective review of

4460 transcutaneous blepharoplasty cases and 3438 transconjunctival blepharoplasties. Malposition of the eyelid was the most frequently reported complication associated with the transcutaneous approach, which occurred in 1.4% of patients vs. 0.7% with the transconjunctival technique (3b) [25].

Interestingly, with incorporation of concomitant canthal suspension and eyelid-shortening techniques, eyelid malposition complications have become less frequent. In a retrospective chart review of primary lower transcutaneous blepharoplasty series over a 10-year period by Codner et al., 264 patients were followed up for a median of 264 days. Eyelid malposition requiring operative correction occurred in nine patients (3.5%). It was concluded by the authors that lateral canthal support should be considered a routine component of lower transcutaneous blepharoplasty to obtain a natural eyelid shape (3b) [57]. The percentage of malposition reported by Codner et al. is substantially less than that reported by Kim and Bucky, where its incidence after conventional transcutaneous blepharoplasty was reported to be as high as 15–20% [58]. Castro conducted a similar prospective study of 100 lower eyelid blepharoplasty cases. The transcutaneous approach (with and without canthopexy) was compared to the transconjunctival approach (with and without fat removal and canthopexy). The author found that each patient's treatment must be individually tailored (5) [59].

In a recent retrospective study, Sultan et al. found in 100 patients undergoing transcutaneous bilateral skin–muscle flap lower eyelid blepharoplasty that the mean distance of malposition was 0.33 mm from the pupil to the lower eyelid margin and 0.32 mm from the lateral limbus to the lower eyelid margin. For patients undergoing concurrent canthopexy, there was a significantly greater change in the eyelid position ($p < 0.001$). Therefore, the authors concluded that transcutaneous skin–muscle lower eyelid blepharoplasty with selective performance of canthoplasty or canthopexy causes a small, predictable eyelid position change in this population with a low rate of revision procedures (3b) [60].

Over the past few decades, attempts to reduce rates of lower lid malposition led to popularization of the transconjunctival approach. With lower eyelid transconjunctival blepharoplasty techniques, herniated fat compartments were debulked. Excess skin resulting from this approach was corrected by skin pinching, ablative laser, or chemical peels.

In their article, Zarem and Resnick described their experience with 104 patients over 2 years and reported no observation in lower eyelid retraction problems, presumed to be due to avoiding the middle lamella (5) [61]. Baylis et al. reviewed 122 patients who underwent transconjunctival blepharoplasty over a 24-month period. The main complication was underexcision of fat (7.4%). The authors had no cases of lower eyelid retraction, which is the most common complication of the transcutaneous technique that has been previously noted (4) [62]. A more recent review of the literature by Baylis et al. also reports inadequate removal of fat as the most common complication after transconjunctival blepharoplasty, occurring in as many as 20% of cases (4). The author advises patients that the goal of lower blepharoplasty is to remove 90% of the excess fat (5) [63]. Taban et al. found no difference in the lower eyelid position after the transconjunctival approach for fat removal with and without skin removal by the pinch technique in their retrospective analysis on patients undergoing bilateral lower blepharoplasty (3b). The authors postulated that the position of the eyelid is not affected either way because the middle lamella was not violated [64].

Rizk and Matarasso reported that the transconjunctival approach for lower eyelid blepharoplasty avoids damage to the orbital septum as compared to the transcutaneous approach [11]. In addition to trauma to the septum, the transcutaneous technique may lead to denervation with consequent retraction, scarring, and rounding of the eye and scleral show, even with conservative technique. However, the transconjunctival approach limits the surgeon's ability to correct redundant skin (5).

Griffin et al. performed a randomized controlled trial of 36 patients to compare transcutaneous

blepharoplasty without resurfacing to transconjunctival blepharoplasty with resurfacing. The study found no statistically significant difference in lower eyelid bulging and wrinkles between the two groups. Lateral eyelid rounding with scleral show and ectropion developed in 3.2% of the transcutaneous blepharoplasty patients. The authors point out that the main advantages of the transconjunctival technique, namely, lack of eyelid malposition and visible scar formation, can become a concern when transconjunctival surgery is combined with adjuvant CO_2 laser resurfacing or chemical peels (2b) [65].

Managing Excess Skin

There are multiple ways to manage excess skin after lower eyelid blepharoplasty, including skin pinching, ablative laser, or chemical peels. The difficulty lies in deciding if the excess skin needs to be removed and how much should be removed to optimize the patient's results.

If severe skin excess is present after volume preservation lower eyelid blepharoplasty, skin flap elevation and excision should be performed to correct excess skin excess that extends along the entire length of the lower eyelid.

For moderate excess, a skin pinch can be performed. Kim and Bucky published a retrospective review of 71 patients who underwent pinch blepharoplasty of the lower eyelid, a technique that does not involve skin undermining [58]. The authors believe that avoiding skin undermining allows for a decreased risk of contraction and hence less postoperative lower eyelid malposition. Their study also found that the pinch method allows resection of more skin and allows the addition of simultaneous laser resurfacing (5). Rosenfield published a case series of 77 patients who underwent pinch blepharoplasty [54]. Of these patients, none had postoperative lower eyelid malposition. Additionally, these patients did not require taping, had no scleral show, and did not develop ectropion. This series suggest that pinch blepharoplasty can reliably remove crepe-like skin with less chance of scleral show and eyelid malposition (4) [54].

For mild skin excess (<2 mm) and rhytides following lower eyelid blepharoplasty, ablative skin resurfacing techniques—such as ablative laser or chemical peels—can be employed. These procedures should generally be reserved for patients with Fitzpatrick skin type III or lower. Because of the risks of pigmentary alterations in patients with type IV skin or higher, caution should be taken when considering these procedures. Pretreatment with a 4- to 6-week nightly regimen of topical retinoic acid (0.05% or 0.10%), hydroquinone (4–8%), and alpha hydroxy acid (4%–10%) up until 1 week before treatment is recommended [27]. In a retrospective chart evaluation by Herbig et al., a combination of Jessner's and 35% trichloroacetic acid chemical peel was applied on 115 female patients. The author concluded that this method was an effective, safe resurfacing tool that treats superficial to moderate rhytides (3b) [66]. Laser facial ablative resurfacing is also an option to correct excess skin as summarized by Roy et al. in a review article; commonly used lasers are CO_2 and erbium:yttrium–aluminum–garnet lasers. While these platforms are effective, they can also lead to risk for prolonged healing time, erythema, edema, and hypopigmentation (5) [67]. For this reason, fractional laser resurfacing has nearly supplanted the traditional full-field laser resurfacing. In Yates' review article, he discussed that fractionated ablative platforms can help lead to faster re-epithelialization and therefore quicker healing times (5) [68].

Closure

Subtleties in surgical technique—such as sutures used for incision closure—can drastically affect cosmetic outcomes. Suture materials commonly used include polypropylene, monofilament nylon, fast-absorbing gut, and ethylcyanoacrylate.

A randomized controlled trial by Greene et al. assessed the efficacy of octyl-2-cyanoacrylate tissue glue in blepharoplasty against traditional

running suture closure [69].Twenty upper blepharoplasty patients were studied. One surgical site was closed with tissue glue; the opposite incision was closed with a running suture. Five blinded observers did not find any statistically significant difference in wound quality using a visual analog scale and a modified Hollander scale. No significant difference was found in the duration of healing, inflammation, and wound complications. The authors concluded that octyl-2-cyanoacrylate glue is an excellent alternative to suture closure. Tissue glue did not result in any inflammatory complications and withstood the forces of closure (2a) [69]. Scaccia et al. conducted a prospective study of 30 patients to compare subcuticular closure using 5–0 polypropylene suture with running 6–0 fast-absorbing catgut suture for approximation after blepharoplasty. Both materials resulted in comparable morbidity and postoperative discomfort levels (5) [70].

In a randomized, split-eyelid, single-blind, prospective study by Kouba DJ (2011) et al. on upper eyelid blepharoplasty, three subgroups were tested (ECA versus fast-absorbing gut, ECA versus polypropylene, and fast-absorbing gut versus polypropylene). Although sutured epidermal closure and tissue adhesive are highly efficacious for upper eyelid blepharoplasty, physicians and participants felt that cosmesis with ECA was superior to that with fast-absorbing gut (2b) [71].

Asian Eyelid

Upper eyelid blepharoplasty is the most popular cosmetic procedure in Asia. To perform surgery on the Asian eyelid requires understanding of the ethnic differences in anatomy. A review by Lee CK et al. analyzed the ethnic anatomical differences, e.g., the increased amount of preseptal fat, high variability in the superior palpebral fold, and presence of a medial epicanthal fold (5) [72]. In a separate review article, Chen et al. discussed many differences between the Asian and Caucasian eyelids and the supraorbital bones surrounding the eyelid. The different standards and public preferences for aesthetic double eyelids are due to these anatomical differences (5) [73]. An overview article by Chee and Choo discussed that the aim of Asian upper blepharoplasty is to create a pleasing and permanent upper eyelid crease (5) [74].

In a level V evidence study by Gao et al., 65 articles describing objective criteria in Caucasian and East Asian populations found that there lack objective and scientific studies regarding Asian aesthetic criteria. These objective criteria are needed to ensure successful aesthetic surgeries (5) [75].

Recent Trends

The current trend in lower eyelid blepharoplasty is toward greater preservation and even augmentation of volume during lower eyelid blepharoplasty. While debulking fat compartments still plays an important role in this procedure, recent studies theorize the importance of fat preservation for facial rejuvenation. In an article by Mendelson et al., the surgical anatomy of the midcheek is defined. This is further supported by Rohrich et al. who published a cadaveric study in which eight hemifacial fresh cadaver dissections were performed to study the anatomy of the midface adipose tissue. It was concluded that loss of deep fat compartments leads to a change in shape and contour, leading to the perception of aging. These anatomical observations defined targets for future augmentation and rejuvenation (5) [76].

The importance of midface fat preservation is discussed in recent literature. In a separate study in 2011, Rohrich et al. reviewed 50 lower eyelid blepharoplasties (a total of 100 operated lids) and used software to define aesthetics (e.g., positioning of the tear trough, lower eyelid relative to the pupil, and intercanthal angle). Through this review, the investigators defined five steps to improve blepharoplasty: (1) augmentation of malar fat compartment, (2)preservation of lower eyelid orbicularis muscle and minimal fat removal, (3) release of the orbicularis retaining

ligament, (4) strengthening of the lateral canthal support, and (5) minimal skin removal (5) [77]. Einan-Lifshitz et al. published a study on volumetric rejuvenation. In their study, they reviewed 57 patients who underwent lower eyelid blepharoplasty (a total of 114 eyes) with fat reposition and/or fat transfer. They found that volumizing the tear through fat reposition and/or transfer can improve outcomes (3b) [78].

In situations where fat repositioning is inadequate to correct infraorbital hollowing, autologous fat grafting to the deep malar cheek pads and the remaining periorbital areas should be considered. Periorbital and midface volume loss arise as a patient ages. Fat grafting allows for comprehensive augmentation of facial fat compartments.

Complications

While blepharoplasty has a tolerable risk profile, complications with blepharoplasty should be thoroughly understood by the surgeon. Lelli and Lisman reviewed complications and categorized them into early, intermediate, and late phases [79]. Figure 27.1 summarizes these complications.

Early Postoperative Period (Within the First Week)

Vision Loss

In the early postoperative period (first week), the most feared complication is permanent vision loss. The most common cause of this complication is retrobulbar hemorrhage, although other causes such as globe perforation, ischemic optic neuropathy, and angle closure glaucoma have been reported.

DeMere et al. reported the incidence of retrobulbar hemorrhage as 0.04% [80]. Hass et al. conducted an analysis of 237 questionnaires completed by the members of the ASOPRS. They found that the incidence of orbital hemorrhage after cosmetic eyelid surgery is 0.055% (1:2000). The incidence of hemorrhage with permanent visual loss is 0.0045% (1:22000). The authors recommend that physicians remain available for at least 24 h after surgery as the majority of cases occur in the immediate postoperative period (5) [81].

A suspicion of orbital hemorrhage and/or vision loss should not be taken lightly. Total vascular insufficiency of 60–120 min can produce permanent visual loss. Presenting signs include eye pain, pressure, loss of vision, diplopia, nausea, vomiting, proptosis, dilated or unresponsive

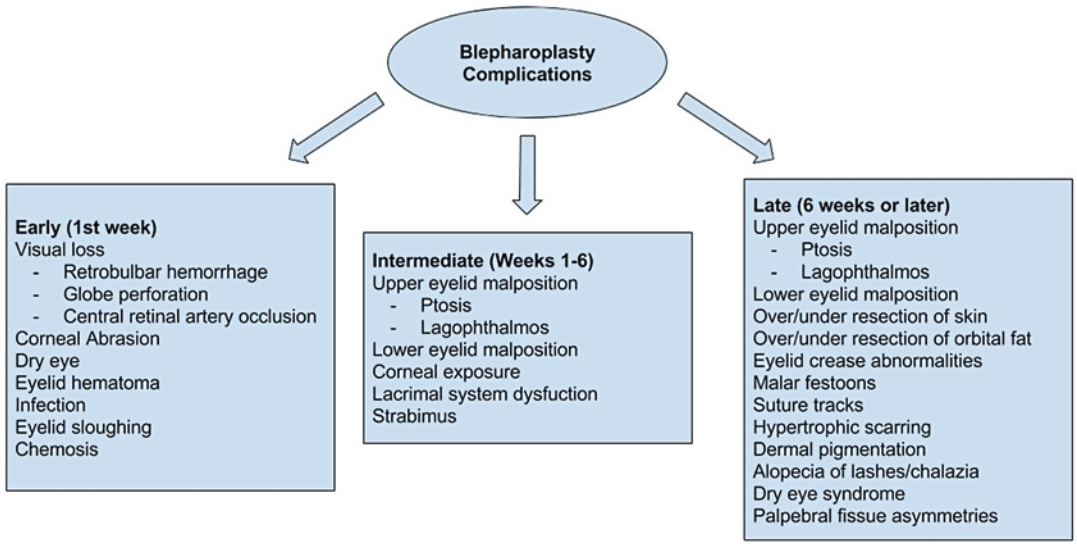

Fig. 27.1 Blepharoplasty complications. (Adapted from Lelli and Lisman)

pupils, limited extraocular movement, and lid ecchymosis. If vision is threatened, immediate ophthalmologic consultation and medical and/or surgical treatment should be obtained. Medical treatment may include intraocular pressure-reducing medications such as mannitol, acetazolamide, steroids, and beta-blocker eye drops.

Surgical treatment includes wound exploration, hemostasis, and hematoma evacuation (5). In an experimental study by Zoumalan et al., ten human cadaver orbits were injected to simulate retrobulbar hemorrhage [82]. The effectiveness of various surgical techniques such as canthotomy, cantholysis, and septolysis was studied. Orbital pressure and intraocular pressure decreased with these techniques; however, the effect was short-lived in the setting of continued simulated hemorrhage (5).

Infection

Another complication that may occur within the first operative week is infection. While rare due to extensive vascularization of the region, infections do occur and need early appropriate antibiotic treatment. The infection rate after blepharoplasty has been estimated to be 0.2% [83]. Case reports of postoperative infection with Group A Beta-hemolytic Streptococcus have been described. Suner et al. presented a case of necrotizing fasciitis after bilateral upper blepharoplasty in a patient with diabetes mellitus (5) [84]. Jordan et al. reported a similar case of necrotizing fasciitis after blepharoplasty. In this case, the patient's son was found to have had impetigo before the procedure (5) [85]. Goldberg and Li described a comparable case in a healthy patient who presented for 30 hours postoperatively, demonstrating that necrotizing fasciitis is initially indistinguishable from cellulitis (5) [86].

While orbital abscess is rare, diagnosis by physical signs is not sufficient; a case of orbital abscess diagnosed with ultrasonography has been described by Rees et al. and the authors recommend utilizing ultrasonography to aid diagnosis [87]. In a case report by Juthani et al., a patient with postoperative orbital cellulitis caused by methicillin-resistant *Staphylococcus aureus* was promptly identified and treated with IV antibiotics. While the Centers for Disease Control and Prevention recommends early antimicrobial prophylaxis and routine surveillance of MRSA, the authors suggest that antimicrobial prophylaxis should be considered in immunocompromised hosts or patients colonized with methicillin-resistant *S. aureus* (5) [88].

To summarize, early postoperative pain and edema should not be taken lightly as these may be early signs of infection. Immediate treatment with intravenous antibiotics, debridement, drainage, and possible hyperbaric oxygen is recommended (5) [79].

Corneal Abrasion

Corneal abrasion is a generally reversible cause of vision changes and is caused by inadvertent damage to the surface corneal epithelial layer. The diagnosis is made by patient symptoms (pain, foreign body sensation, light sensitivity) and is usually apparent immediately after surgery. The diagnosis is confirmed by evaluating the cornea under a cobalt blue light after instillation of fluorescein. Abrasions are treated with ophthalmic antibiotic ointment four times daily and should resolve within 24 hours. Persistent signs and symptoms should prompt ophthalmologic evaluation.

Intermediate Postoperative Period (Weeks 1–6)

Multiple complications can arise during the intermediary time after operation: these include upper eyelid malposition, lower eyelid malposition, corneal exposure, and lacrimal system dysfunction.

Upper Eyelid Malposition

Upper eyelid malposition complications include ptosis and lagophthalmos. For ptosis, no data exists on frequency. Mechanical ptosis is believed to be caused by postoperative edema or ecchymosis, which can resolve with conservative treatment with cool compresses (5). In the observational case series of six patients with postoperative ptosis by Rainin et al., it was hypothesized that myotoxic effects of local anesthetics may lead to

degeneration and subsequent regeneration of muscle fibers of the levator or extraocular muscles, resulting in temporary or permanent muscle weakness (4) [89].

Lagophthalmos is the inability to completely close the eyelids and is usually a transient postoperative complication. Reasons for lagophthalmos include excessive skin removal, trauma to the orbicularis muscle or peripheral seventh cranial nerve, tethering of the eyelids by sutures or Steri-Strips (3 M, St. Paul, MN), and postoperative pain, leading to guarding and incomplete closure. In a study by Kornet al., a retrospective chart review of six patients who had both LASIK and blepharoplasty demonstrates that these patients had increased frequency of dry eye syndrome [90]. The authors warn that patients who have a history of LASIK are at a higher risk of exposure keratopathy, and hence, a thorough preoperative assessment should be performed to minimize complications (4). Lagophthalmos is usually temporary, and lubrication and eyelid massage are advisable in the intermediate postoperative period (5).

Lower Eyelid Malposition

The most commonly reported complication after lower eyelid blepharoplasty is lower eyelid malposition, which may range from mild inferior scleral show as reported by Baylis et al. [91] to severe cicatricial ectropion in 1% of patients as reported by McGraw et al. [92] Predisposing factors include globe proptosis, high myopia, hypoplasia of the malar eminence, and thyroid ophthalmopathy. Treatment options include wound gapping, which allows for granulation of a portion of the eyelid. Topical steroid ointment and massage are employed during granulation to stretch and counter the forces of contraction. Further surgical management is delayed until late postoperative period (5).

Lacrimal System Dysfunction

Epiphora (excessive watering of the eye) can result secondary to dry eye, exposure keratopathy, or an impaired lacrimal pump. Data does not exist on the frequency of this postoperative complication. However, dysfunction often returns to normal. If tearing persists, punctal malposition or canalicular damage should be evaluated further (5) [79].

Strabismus and Extraocular Muscle Disorder

Diplopia is a rare but potentially disabling complication of blepharoplasty. Signs that make diplopia less worrisome are preoperative history of strabismus, monocular diplopia that clears with blinking (suggestive of precorneal tear film abnormality), and intermittent occurrence.

Persistent binocular diplopia requires additional consideration. In a case series, Syniuta LA et al. reported 12 patients who developed acquired strabismus after cosmetic blepharoplasty. This was believed to be from superior oblique muscle palsy or inferior rectus paresis (4) [93]. In a review of 920 blepharoplasties performed in Manhattan, the risk of persistent strabismus was approximately 0.2% (4). The explanation offered for this phenomenon is a Volkmann-type contracture of the extraocular muscles following edema and hemorrhage into the muscle sheath [94].

Late Postoperative Period (After 6 Weeks)

Late postoperative complications include similar complications to the intermediate postoperative period, e.g., ptosis, lagophthalmos, and lower eyelid malposition. Additionally, patients are also at risk for malar Festoons and dry eye syndrome.

Lower Eyelid Malposition

The late lower eyelid malposition has some additional complications when compared to the intermediate postoperative period. Identifying the affected lamella (anterior, middle, or posterior)—usually caused by a deficient tissue or cicatrization—is important in rectifying the issues.

An anterior lamellar deficiency is often the result of transcutaneous blepharoplasty. It is diagnosed by noting lower eyelid movement with opening of the mouth. Surgical repair involves skin grafting. Tarsal suspension may be performed

alone as an indirect secondary procedure in those patients who are unhappy with the thought of skin grafting VI.

Middle lamellar deficiency is a result of adhesions at the level of capsulopalpebral fascia and orbital septum. This may lead to eyelid retraction ("scleral show") of the lateral one-third of the lower eyelid, with associated rounding and inferior displacement of the lateral canthus. Repair involves lysis of adhesions if conservative stretching fails. Shorret et al. describes the "Madame Butterfly" procedure, which addresses the triad of lysis of the middle lamellar cicatrix, lateral canthus reconstruction, and cheek elevation as a successful way of addressing cicatricial lower eyelid retraction [95]. The authors showed in their study that this new procedure can be used to elevate the lower eyelid rather than lower the upper eyelid in cases of postblepharoplasty lagophthalmos with exposure keratopathy, thus allowing for cosmetic and functional repair (5).

Posterior lamellar deficiency usually presents as entropion (an inward folding of the lower eyelid). The repair often involves the addition of posterior lamella. A retrospective study by Li et al. compared 35 patients undergoing grafting of the alloplastic material AlloDerm (LifeCell Corporation, Branchburg, NJ) to 25 patients undergoing hard palate grafting. They did not notice any statistically significant differences between the two materials. They recommended that surgeons weight advantages and disadvantages when choosing the material for lower eyelid spacer graft to prevent contraction of the posterior lamellae (4) [96].

Malar Festoons

Malar festoons occur in patients predisposed to fluid accumulation, e.g., those with a history of thyroid disease, renal failure, sinusitis, and allergies. According to the review article by Lisman, the best method to prevent this complication is early preoperative diagnosis and intraoperative intravenous steroids or postoperative oral steroids for those at the highest risk [97]. Other treatments include diuretics such as furosemide (20–40 mg daily) or hydrochlorothiazide (25–50 mg daily). Although persistent malar festoons can be excised, the success rate is low. If the underlying condition is systemic, eyelid surgery cannot locally correct the problem.

Dry Eye Syndrome

If dry eyes persist even after resolution of early and intermediate sicca symptoms, then this is considered a late postblepharoplasty complication. Dry eyes postblepharoplasty can result from widened palpebral fissures or dermatochalasis.

Initial treatment of dry eye consists of ocular lubrication. Treatment failure should prompt ophthalmologic examination. In a randomized, multicenter, controlled trial, Stevenson et al. described the importance of using antiinflammatory eye drops (such as topical cyclosporine) to improve moderate-to-severe dry eye syndrome (2b) [98]. Punctal occlusion can also be considered.

Vold SD et al. suggested that upper eyelid blepharoplasty should be considered if dry eyes is a result of dermatochalasis. In his retrospective chart review on 141 patients with dermatochalasia, 33 out of 38 patients who underwent upper eyelid blepharoplasty (86.8%) reported subjective improvement in dry eye symptoms (4) [99].

In summary, although blepharoplasty surgery appears straightforward, all surgeons encounter complications. These complications can be minimized by a thorough preoperative evaluation, adequate expectations, meticulous and individualized surgical judgment, and early recognition of adverse events with immediate appropriate interventions.

Alternative and Complementary Procedures

Although there are no options with outcomes comparable to those of blepharoplasty, there are alternative and complementary procedures to correct eyelid cosmesis.

Upper Eyelid

For the upper eyelids, alternatives include surgical brow lift, nonsurgical brow lift (e.g., Botox

injection or hyaluronic acid gel (HAG) injection), or noninvasive brow lift (e.g., Ultherapy). In a retrospective chart review by McElhinny et al. on 16 patients with pseudoptosis, administration of botulinum toxin A injection at low doses (an average of two injection sites with 2 units per site) into the pretarsal orbicularis muscle demonstrated that the drug can raise a relatively ptotic eyelid by weakening the orbicularis oculi muscle, thus shifting the balance toward the eyelid elevators (4) [100]. The average lift is approximately 1 mm. The injection is subcutaneous, as deeper injection raises the risk of inadvertently worsening the ptosis due to levator weakening.

In a pilot study conducted by Mancini et al., eight patients with upper eyelid margin asymmetry relating to relative upper eyelid retraction were injected with hyaluronic acid gel in the upper eyelid. At follow-up, 8 of 8 demonstrated persistent improvement in asymmetry when compared with pretreatment ($p = 0.018$). The authors concluded that hyaluronic acid gel filler may be an effective nonsurgical alternative to improve upper eyelid margin asymmetry in cases of relative upper eyelid retraction (4) [101]. HAG injections administered into the central and lateral subbrow regions can also address postsurgical and/or age-related superior sulcus volume loss [102].

Lower Eyelid

For the lower eyelid, options include injectable fills and resurfacing (laser or chemical peel). Lower eyelid retraction, scleral show, and volume loss of the orbital rim can all be improved nonsurgically using HAG fillers [101, 103].

Complications

Botulinum toxin A and HAG injections also have complications. Complications occurring after administering botulinum toxin injection include injection-related ecchymosis, inadvertent eyelid or eyebrow ptosis, lower eyelid retraction, diplopia, dry eye, and lagophthalmos (5) [104–106].

The literature of complications with HAG injections continues to grow. HAG injection complications include periocular injections are minor and include temporary erythema, edema, and ecchymosis at the injection site; contour irregularities; fluid accumulation; and bluish discoloration secondary to light scattering. If the complications are severe, enzymatic dissolution with hyaluronidase may be necessitated. Some rare, albeit severe complications can also occur, including cutaneous hypersensitivity reactions, vascular occlusions including branch retinal artery occlusion and vision loss, and infections including biofilm-type processes (5) [107].

Postoperative Care

Postoperative management varies greatly according to the surgeon's preference. A recent review by Zoumalan et al. recommended multiple steps, which have been echoed by other review articles [27, 100]. From the immediate postoperative period to 72 hours, patients should use ice-water-soaked gauze or cool packs. Head position should be above the heart level to reduce edema. Patients who develop severe pain should be immediately evaluated to rule out retrobulbar hematomas and infection. Suture removal can be done on postoperative days 5–7.

During the first 1–2 weeks, antibiotic eye drops (i.e., erythromycin) should be prophylactically applied two times per day. If a conjunctival incision is made, antibiotic with or without a steroid component should be applied four times per day. Consistent use of eye drops and lubricating eye ointments are necessary to prevent corneal abrasions during this time (5) [108]. In the first 2 weeks, the patient should also be advised to avoid strenuous activity. Edema may persist 2 weeks postoperatively, and asymmetric residual swelling can continue for 3–6 months.

In conclusion, blepharoplasty is a functional and cosmetic surgical procedure with high patient satisfaction. Preoperative evaluation and setting expectations are crucial. There are various instruments and operative techniques that can be employed during blepharoplasty.

Complications can arise at any time postoperatively. Successful blepharoplasty depends on the surgeon's understanding of facial anatomy and the aesthetic interplay of the eyes and periorbital structures.

Self-Assessment Questions

1. Patients who underwent refractive surgery within the past 6 months are not suitable candidates for blepharoplasty because of the increased risk of dry eyes and keratopathy. Which of the following is NOT a reason for this increased risk?
   (a) Alteration in corneal sensation
   (b) Alteration in tear production
   (c) Alteration in vision
   (d) Alteration in film formation
   (e) None of the above
2. Which is not a predisposing condition for malar festoons?
   (a) Thyroid disease
   (b) Renal Failure
   (c) Sinusitis
   (d) Allergies
   (e) Angina
3. What are the two methods for lower eyelid blepharoplasty?
   (a) Transconjunctival
   (b) Transcutaneous
   (c) Transcilliary
   (d) a & b
   (e) None of the above
4. Within the first few days postoperatively, what recommendations should a surgeon give to a patient who just underwent blepharoplasty?
   (a) Do not use antibiotic eye drops as these drops can cause inflammation and impede healing
   (b) Light and strenuous activities are tolerated and encouraged
   (c) Use cool packs on eyes and position the head above the heart level to reduce edema
   (d) If severe pain develops, please return immediately to get sutures removed
   (e) All of the above
5. Which choice provides a list of ways to manage excess skin after lower eyelid blepharoplasty?
   (a) Skin pinching, ablative laser, chemical peels, and excision
   (b) Botox, hyaluronic acid fillers, ablative laser, and excision
   (c) Skin pinching, ablative laser, Botox, and hyaluronic acid injection
   (d) Chemical peel, skin pinching, ablative laser, and Botox
   (e) None of the above

Correct Answers

1. c: Patients who underwent refractive surgery within the past 6 months are not suitable candidates for blepharoplasty (2B) [20–22]. This patient population is at risk for development of dry eyes and keratopathy because of the alteration in corneal sensation, tear production, and tear film formation. The goal of LASIK is to improve vision; improved vision does not lead to increased risk of dry eyes or keratopathy.
2. e: Patients who are predisposed to fluid accumulation may develop malar festoons. Conditions that can predispose patients include thyroid disease, renal failure, sinusitis, and allergies. Angina (chest pain) in isolation is not a usual condition that can lead to fluid accumulation in eyelids. Of note, congestive heart failure may cause fluid retention. The best method to prevent fluid buildup is early preoperative diagnosis and intraoperative intravenous steroids or postoperative oral steroids for those at the highest risk. Other treatments include diuretics such as furosemide (20–40 mg daily) or hydrochlorothiazide (25–50 mg daily); however, these medications should be used with caution as they require vigilant monitoring of renal function. The success of malar festoon excision is low.
3. d: Lower eyelid blepharoplasty is based on the more conservative removal of a pinch of skin, as excessive skin removal leads to scleral show (4) [54]. The ideal approach for lower eyelid blepharoplasty is under debate. There exist two distinct methodologies: (1) external transcutaneous incision and (2) internal transconjunctival incision. Transcilliary is not one of the methods for lower eyelid blepharoplasty.
4. c: From the immediate postoperative period to 72 hours, patients should use ice-water-soaked gauze or cool packs. The head position should be above the heart level to reduce edema. Antibiotic eye drops are recommended twice a day for prophylaxis. Consistent use of lubricating eye drops and ointment is necessary to prevent corneal abrasions during this period. Strenuous activities are discouraged. If the patient develops severe pain, then they should be evaluated for possible retrobulbar hematomas or infection, not to get their sutures removed.
5. a: There are multiple ways to manage excess skin after lower eyelid blepharoplasty; this includes skin pinching, ablative laser, chemical peels, and skin excision in severe cases. The difficulty lies in deciding if the excess skin needs to be removed and how much should be excised to optimize the patient's results. Botox and hyaluronic acid fillers are not ways to manage excess skin.

Rhytidectomy

Introduction

The goal of the facelift, or rhytidectomy, is to restore the anatomical changes which occur through the natural process of aging. There are a variety of surgical techniques the cosmetic surgeon can utilize to accomplish this restoration. These rejuvenating procedures can be performed in the ambulatory, office-based setting with local anesthesia and optional sedation.

There are numerous rhytidectomy techniques that produce excellent results. Each surgeon must adopt a technique which is best suited for his or her patient. Ideally, the technique should be safe, consistent, reproducible, and applicable to a range of anatomic defects. The surgeon must also have the versatility to modify his or her technique to the needs and desires of each patient.

It is important for both practicing physicians and patients to understand the benefits of the various procedures and techniques as well as how they compare in both safety and efficacy.

Indications and Technique

The changes that occur in the aging face are multifactorial. This process is characterized by loss of skin elasticity, fat and bone resorption, and loss of muscle tone and volume. Although the facial skeleton is responsible for the morphologic basis of aging, boney augmentation is limited, which leaves the soft tissue as a target for facial rejuvenation. Soft tissue ptosis leads to deep creases of the aging face and represents the target of surgical correction. As facial soft tissue ptosis develops with aging, the vector of descent is primarily downward.

Current surgical management seeks to reverse this descent often through elevation of the superficial musculoaponeurotic system (SMAS), which underlies the skin and subcutis and overlies the muscle and deep neurovascular structures. There have been a large number of surgical facelift techniques described ranging from the skin-only facelift to a variety of procedures that address the SMAS and various other deep-plane techniques. Absorbable and nonabsorbable suspension sutures have also been used to achieve tissue lifting via a minimally invasive approach.

A number of techniques are employed to specifically address the particular patient's needs; these are summarized in Table 28.1. The classic subcutaneous lift involves subcutaneous undermining of the face with advancement and excision of excess skin to achieve the effective lift [1]. This procedure requires minimal operative time with few complications and a hastened recovery; however, the lift may not be as durable as it does not address the underlying issues of the aging face.

The basic approach to lifting the SMAS is achieved via SMAS plication or imbrication [2]. Using this technique, the SMAS is folded upon itself and secured without additional undermining. A primary advantage to this approach is that there are minimal complications as the sub-SMAS structures including the facial nerve are left undisturbed and intact. The lateral SMASectomy approach popularized by Baker [3] is similar to plication in that no undermining of the SMAS is performed. For the lateral SMASectomy, a strip of the SMAS overlying the parotid gland is first resected. Using absorbable sutures, the resected edges of the SMAS are joined which elevates the lower portions of the SMAS. With Baker's technique, the facial nerve is protected by the parotid gland at the site of SMAS resection. More extensive rhytidectomies are performed by creating a limited SMAS flap (conventional SMAS facelift) or an extended SMAS flap. The creation of the SMAS flap is in addition to the skin flap and is separately repositioned, potentially in multiple vectors. This procedure may be referred to as a "deep-plane" rhytidectomy and requires careful localization and avoidance of deep neurovascular structures, including the facial nerve and its branches. Barton also described the "high SMAS" technique [4], which is characterized by suspending the SMAS more superiorly above the zygomatic arch. Dissection of a composite flap transitions from sub-SMAS to a subcutaneous plane above the zygomatic major, helping to efface the nasolabial fold. This procedure ensures release of the zygomatic ligaments allowing a true superior pull of the malar and zygomatic soft tissues.

The continued desire for a less invasive facelift prompted the development of an even more minimally invasive approach than the standard SMAS plication facelift. These so-called short-scars or mini-lifts include procedures such

Table 28.1 Facelift techniques

Facelift technique	Essential features	Comments
SMAS plication	Skin flap created. SMAS is folded on itself with no undermining	Straightforward. Limited anesthetic requirement. Minimal risk of nerve injury
Lateral SMASectomy	Skin flap created. SMAS overlying parotid is resected and tightened. No SMAS undermining	Possibly more effective contour change. Minimal risk of nerve injury
SMAS lift (extended/conventional)	Skin flap created. Separate SMAS flap created. Flaps independently advanced	Benefit is uncertain. Extended SMAS lift enables greater flap mobility
S-lift and variants	Skin flap created. No SMAS undermining. SMAS is plicated with purse-string-type suture	Similar to SMAS plication. Limited anesthetic requirement
High SMAS	Skin flap created. Composite flap from sub-SMAS to subcutaneous plane with superior vector advancement	Release of zygomatic ligaments allowing superior pull
Subcutaneous lift	Skin flap created only. Advancement and excision of excess	Straightforward. Minimal complication. Less durability

as Saylan's "S-lift" [5] and Tonnard's "minimal-access cranial suspension" [6]. The common features of these approaches are a limited facelift incision, conservative skin flap creation, and the use of sutures in a loop configuration to plicate the deeper tissues. When compared to the traditional rhytidectomy procedure, two clear advantages of the short-scar rhytidectomy procedure are the quicker recovery time and the potentially decreased expense to the patient.

Preoperative Evaluation

Preoperative assessment of patients undergoing facelift involves a thorough review of particular aspects of the history and physical exam. Specific preoperative medical evaluation and associated data are summarized in Table 28.2.

Age

Many facelift patients are elderly but may not have apparent or concerning comorbidities. In a multicenter, prospective cohort study of 11,300 patients, Gupta et al. [7] (1b) did not find a significant difference in complication rates for older patients who were 70 years of age and older. In a retrospective review of 216 patients, those older than 65 years were compared with a group younger than 65 years [8] (3b) which also demonstrated no difference in major complications (2.9% vs. 2.0%, $p = 0.65$) or minor complication rates (5.9% vs. 6.1%, $p = 0.99$). The study may have been underpowered, but the age differential was significant (average age of 70.0 years vs. 57.6 years). Becker et al. also demonstrated the safety of facelifts in patients older than 75 with similar complication rates to matched controlled younger patients [9] (3b).

Table 28.2 Preoperative evaluation

Evaluation	Evidence	Quality of evidence
Age	Equal safety in older (>65 and >70) vs. younger age groups	B
Body mass index	Body mass index >25 had increased risk of hematoma and infection	C
Smoking	Smoking associated with complications, more likely minor	B
Hypertension	Hypertension may increase risk of hematoma	C
Diabetes	Diabetes is a risk factor for complications in other surgical procedures, but may not affect facelifts	C
Aspirin	Aspirin use is associated with hematoma risk	C
Infection risk	Infections in facelifts are very rare	D

Body Mass Index

Increased body mass index not only places a patient at greater risk of developing comorbidities but also increases surgical morbidity. A 2012 retrospective review of 620 patients revealed that a body mass index greater than 25 resulted in an increased complication rate (9.5% vs. 4.7%) [10] (3b). A larger 2016 prospective cohort study reported a body mass index greater than 25 as a significant risk factor for infection with a relative risk of 2.78 [7]. However, this study only had a minority of patients having a body mass index greater than 25 (38.5% vs. 71.1% in the previous mentioned study [10]).

Smoking

While preoperative smoking cessation is recommended for all cosmetic procedures, there are no established guidelines. Smoking creates an environment of relative tissue hypoxia and delayed wound healing. The incidence of facelift skin flap necrosis was found to be 12.5 times greater in smokers than in nonsmokers [11] (4). Another prospective study confirmed a strong association between active smoking and skin slough in facelift patients [12] (2b). Nonsmokers had a 5% incidence of superficial skin slough compared with active smokers who experienced a 19.4% incidence of skin slough. Another large retrospective study in 2001 found an increased hematoma rate

in smokers undergoing facelift [13] (2b). Conversely, a larger prospective cohort study did not demonstrate smoking to be a significant risk factor for major complications (2.0% vs. 1.8%, $p = 0.4$) [7]. The authors attribute this to caution exerted by surgeons when deciding to operate on patients who smoke. Additionally, many of the complications attributed to smoking such as wound healing and infections were not as easily evaluable in their database.

Hypertension

Multiple studies have reported a higher incidence of hematoma in facelift patients with perioperative hypertension. In a retrospective study of 985 patients undergoing facelift by a single surgeon, the incidence of hematoma decreased from 8.7% to 4.6% after a strict perioperative antihypertensive regimen was initiated [14] (4). Another retrospective review of 1078 patients demonstrated that preoperative systolic blood pressure above 150 mm Hg increased the risk of hematoma 3.6 times ($p = 0.02$) [13]. Hypertension again showed a strong tendency to develop hematoma (8.2% vs. 3.5%, $p = 0.017$) [15] (4). However, hypertension was not found to be an independent predictor of hematoma on multivariate analysis ($p = 0.19$).

Diabetes

Previous studies suggest that diabetes mellitus in patients undergoing other surgical procedures may increase the risk of infection and decrease the healing capacity. In their prospective cohort study, Gupta et al. [7] did not show diabetes to be a significant risk factor for complications for patients undergoing a facelift. Of the 303 diabetic patients, 3.3% had a complication compared to 1.8% among nondiabetics ($p = 0.07$).

Aspirin

Grover et al. found that aspirin use held a 2.3-fold increase in risk ($p = 0.04$) for hematoma in their retrospective review of 1078 patients [13]. Aspirin use was also associated with postoperative hematoma formation in a single-center study of 620 patients [15].

Infection Risk

Infections in facelift surgery are rare, and thus the studies evaluating their prevention and treatment are poorly powered. A 2015 systematic review performed by Dauwe et al. [16] (3a) evaluated topics of bacterial decolonization, prophylactic antibiotics, and body temperature regulation. However, recommendations were based on expanded criteria to studies evaluating surgical site infection in clean cosmetic procedures as well as expert opinion rather than facelift-specific data-driven studies.

Safety

Studies evaluating the safety of facelifts are summarized in Table 28.3.

A large prospective cohort study of 11,300 patients undergoing facelift between 2008 and 2013 assessed the safety and preoperative risk factors for complication [7]. Gupta et al. found that facelifts had a 1.8% complication rate, similar to the 2% rate associated with other cosmetic surgeries. The most common complications encountered were hematoma (1.1%) and infection (0.3%). As a result, the authors concluded that rhytidectomy is a very safe procedure.

A meta-analysis of 41 studies published between 2001 and 2013 found a 1.8% incidence of hematoma following facelift [17] (2a). The authors performed meta-analyses for subsets of the three most popular facelift techniques (SMAS flap, SMAS plication, and deep-plane) and found no significant difference in hematoma rates. However, the study demonstrated significantly less hematoma formation following limited incision facelift compared with non-limited techniques. The authors note that this reduction is not surprising given the reduced dissection, but note that there are many other considerations when choosing a specific facelift technique.

Table 28.3 Summary of studies evaluating rhytidectomy safety

Study	Type	Evidence	Quality of evidence
Mustoe et al. [17]	Meta-analysis, 41 studies	1.8% incidence of hematoma	B
Gupta et al. [7]	Prospective cohort, 11,300 patients	1.8% complication rate; hematoma (1.1%), infection (0.3%)	B
Tanna et al. [18]	Retrospective review, 1000 short-scar facelifts	<1% risk of poor scarring	C
Grover et al. [13]	Retrospective cohort, 1078 consecutive facelifts	4.2% incidence of hematoma	C
LeRoy et al. [19]	Retrospective cohort, 6166 consecutive facelift	Infection requiring admit was 0.18%, no identifiable risk factors	C
Rees et al. [20]	Retrospective cohort, 1236 consecutive facelifts	1.86% incidence of hematoma	C

Several other retrospective cohort studies and case series assessing safety and efficacy have also been published. Tanna and Lindsey [18] (2b) have published one of the largest series of short-scar rhytidectomies in which they assessed their experience of 1000 short-scar rhytidectomies. In this study, all patients safely underwent the procedure with local anesthesia. An additional one third of patients also required oral sedation but none required general or intravenous anesthesia. Postoperative suture extrusion was the most frequently observed complication occurring in 148 patients, followed by hematomas in 10 patients. Hyperpigmentation and hypertrophic scarring occurred with an incidence of less than 1%, and there were no episodes of nerve injury, skin flap necrosis, alopecia, or parotid injury. Although the cosmetic results from this series were not systematically analyzed, the authors assert that their patients were pleased with their results. They concluded that the short-scar rhytidectomy is an excellent option for patients with mild to moderate aging of the face.

Grover et al. published a retrospective study of 1078 consecutive facelifts by two surgeons to determine associations with hematoma formation [13]. The multivariate analysis found a 4.2% hematoma rate. They found many significantly associated factors (hypertension, sex, aspirin use, smoking) that are discussed previously in the preoperative section of this chapter. A factor that was not significant was the type of facelift technique performed.

Another retrospective study evaluated infection rate in 6166 consecutive facelifts performed by 35 surgeons at one institution [19] (2b). The authors found no associations regarding medical history, use of perioperative antibiotics, drains, technique, or surgical equipment. The incidence of infections requiring hospital readmission was 0.18%. Although the study is limited by bias, the study included a relatively large sample size.

Rees et al. published a retrospective review of 1236 consecutive facelifts performed by 50 surgeons at one institution [20] (2b). This study found an overall hematoma incidence of 1.86%. SMAS plication had a higher hematoma rate than moderate or extensive SMAS dissection ($p = 0.002$) but became nonsignificant when controlled for the performing surgeon. Age, preoperative tests, medical history, gender, perioperative medications, blood pressure, type of anesthesia, or number and combination of procedures did not independently affect the incidence of hematomas.

In addition to larger retrospective series assessing facelifts for overall safety and efficacy recently, there have been multiple case series and cohort studies that have examined more specific features of facelifts. These include studies that describe and test novel techniques, improvements upon existing methods, and methods to avoid potential complications.

Technique and Effectiveness

Due to the large variety of procedures and surgeon variations, it is not surprising that the literature is inconclusive regarding outcomes as

determined by the technique. Due to the elective nature of the facelift procedure, patients are reluctant to be randomized to a given treatment modality. The private practice settings in which many of these procedures are performed and differences in operative technique across surgeons have impeded the completion of multiple large studies and meta-analyses.

A systematic review performed by Chang et al. [21] (2a) conducted a literature search from 1950 to 2009 and found ten articles in which comparisons of techniques were performed. No conclusions demonstrating superiority of one technique over another were made. Overall, the authors concluded that there exist no quality data that have shown better efficacy of one facelift technique over another and noted a need for higher-quality studies in the future.

One study published nearly 20 years ago randomized 21 patients to undergo limited/conventional SMAS facelift on one side of their face and extended SMAS/composite rhytidectomy on the other [22] (3b). Patients were then followed for 1 year postoperatively. The results were photographed and assessed by three independent facelift surgeons, the operating surgeons, and the patients. At 24 h, 6 months, and 1-year follow-up, neither the independent surgeon evaluator nor the operating surgeon nor the patient could detect a difference in the facelift result between the two sides. The results of this study support the use of less invasive techniques. However, differences could become evident with longer postoperative follow-up.

In a similar although nonrandomized study, Prado et al. [23] (4) compared the outcomes of minimal access cranial suspension to lateral SMASectomy. There was no difference in cosmetic results between the two techniques at 1-month and 2-year follow-up. However, it was noted that SMASectomy required a longer surgery time, but the patients experienced less pain. More than half of the cases needed a revisionary tuck procedure in both groups, and the long-term persistence of efficacy was not compared.

The largest study was a retrospective analysis by Kamer and Frankel of 634 patients comparing a deep-plane technique to a conventional SMAS technique performed by a single surgeon [24] (3b). They evaluated the need for a secondary tuck procedure as a marker for a less efficacious and less optimal facelift. The revision rate was significantly lower with the deep-plane technique (11.4% vs. 3.3%; $p = 0.0001$) than the conventional SMAS technique.

Perioperative Treatment, Additional Complications, and Avoidance Strategies

A variety of complications are seen in association with rhytidectomy. These include hematoma formation, infection, neuropraxia, paralysis, skin necrosis, disfiguring scar, and alopecia. There are few studies evaluating peri- and postoperative treatments of complications which are summarized in Table 28.4.

Alopecia

Temporal alopecia resulting from traumatized hair follicles is an unpleasant complication that detracts from the final appearance post-rhytidectomy. In an attempt to prevent temporal hair loss, Eremia et al. [25] (3b) studied the use

Table 28.4 Complications and treatment

Complication	Therapy	Quality of evidence
Alopecia	Post-rhytidectomy temporal alopecia can be avoided with the use of minoxidil	C
Facial edema	Perioperative steroid administration does not reduce facial edema following rhytidectomy	C
Hematoma	Fibrin glue may decrease hematoma formation; however, its clinical relevance is not proven Surgical drains do not decrease hematoma incidence	C
Nerve injury	Nerve injury is uncommon and the majority of injuries resolve spontaneously within 6 months	C

of minoxidil. In their series, 60 women underwent either standard SMAS/flap technique or plication and were treated with either 2% or 5% topical minoxidil for 2 weeks prior to surgery and 4 weeks postoperatively. Subjects were followed for 3–6 months. The use of minoxidil resulted in a 0% incidence of permanent alopecia and a 1.7% incidence of temporary alopecia (one patient developed alopecia that resolved upon resuming 5% minoxidil). In comparison, historical controls [26] reported the incidence of temporary alopecia at 8.4%. Therefore, minoxidil appeared to provide a protective benefit when used before and after facelift. However, since the historical controls were from 1977, it is uncertain to what extent the two groups of patients were comparable.

Tissue Sealants

Postoperative hematomas can cause facial edema, tissue ischemia, and hyperpigmentation which may necessitate placement of drains. Drain placement is not without risk as drains can serve as a portal of entry for bacteria into the wound leading to infection and the potential for scarring. It is therefore desirable to prevent hematomas intraoperatively. Fibrin glue has been widely studied in the plastic surgery community for this purpose. Zoumalan and Rizk [27] (3b) studied whether spraying fibrin glue underneath the flap prior to closure reduced hematoma formation. In this nonrandomized study of 600 patients, a significant difference ($p = 0.01$) in hematoma formation was detected among patients who did and did not receive fibrin glue. Patients who did not receive fibrin glue developed hematomas at a rate of 3.4% compared to 0.4% in those who did receive the fibrin glue. In this study, all the hematomas from both groups were minor, managed with needle aspiration, and did not require repeat operation.

A recent meta-analysis evaluating the use of tissue sealants in facelifts analyzed ten randomized trials of which three were found to be suitable for analysis as randomized, prospective, blinded trials [28] (2a). Although not statistically significant, the use of tissue sealants demonstrated a strong trend toward reduction of drainage at 24 h postoperatively and ecchymosis at 1 week. Conversely, tissue sealants did not decrease postoperative edema. These data combined with the series published by Zoumalan and Rizk [27] strengthen the argument for routinely using tissue sealants intraoperatively during facelift procedures.

Surgical Drains

In a prospective, randomized, controlled study involving 50 patients in which drains were used on one side but not on the other, there was no significant difference in hematoma formation, but there was a reduction in ecchymosis ($p = 0.005$) [29] (3b).

Edema

A prospective, randomized study by Owsley et al. [30] (3b) sought to ascertain whether the use of a steroid medication could reduce facial edema following facelift surgery. Fifteen patients were treated with methylprednisolone 500 mg preoperatively followed by a 6-day tapering course. When compared to 15 patients who did not receive steroids, there was no difference in facial edema. There is potential risk for decreased wound healing encountered in patients on steroids. Based upon equivocal results, steroids may not be routinely recommended as prophylaxis for facial edema reduction.

Nerve Injury

Historically, one of the more concerning complications of rhytidectomy has been nerve injury. The great auricular nerve is the most commonly injured nerve, occurring in 1–7% of procedures [31] (3b). Other nerves at risk include the lesser occipital nerve, branches of the facial nerve (marginal mandibular and temporal branch with incidence of 0.3–2.6%), and spinal accessory nerve.

The distinction between marginal mandibular nerve pseudoparalysis and true nerve injury should be made with the appropriate physical exam, as cervical nerve injury may masquerade as pseudoparalysis of the marginal mandibular nerve in 1.7% of surgeries [32] (4). Fortunately, more than 80% of facial nerve injuries (and the majority of sensory nerve injuries) from rhytidectomy are expected to spontaneously resolve within 6 months [31].

Alternative Procedures and Modifications

Suspension Suture Techniques

One variant of the limited facelift uses suspension sutures to achieve tissue lifting via a minimally invasive approach. Placement of these sutures without the need to make an incision is thought to be less time intensive and also potentially safer than more conventional facelift procedures. However, there are sparse data confirming the safety, efficacy, and longevity of suspension suture lifts. Table 28.5 summarizes publications that evaluated suspension sutures.

Villa et al. [33] (3a) recently reviewed the literature to evaluate the clinical efficacy and longevity of various types of barbed sutures, overall safety, and the risk of serious adverse events including injury to the facial nerve. Only six studies met their inclusion criteria for analysis. The authors concluded that the clinical efficacy, peak correction, and longevity of effect were inconclusive. Adverse events did occur although they were noted to be mostly minor and self-limited. They concluded that objective outcome measures and long-term follow-up data are not available in a systematic manner in the currently published literature.

A retrospective study by Kaminer et al. [34] (4) assessed the long-term patient satisfaction

Table 28.5 Recent studies on suspension suturing techniques

Type of suture	Reference	Quality of evidence	Results/conclusion
Contour lift—barbed, anchored, unidirectional, nonabsorbable	Kaminer et al. [34]	C	The barbed suture lift provides moderate long-term improvement for facial laxity up to 16 months post-procedure
	Garvey et al. [38]	C	42% underwent secondary procedure at 8 months, 31% required revision at 9 months, and 11% required removal of threads. Suspension suture technique is limited
Silhouette suture—a 3-0 polypropylene suture with ten absorbable hollow cones equally interspersed with knots	Bisaccia et al. [36]	C	In appropriately selected patients, excellent correction of ptotic facial and neck tissues was achieved
Monogram suture—2-0 absorbable monofilament with five to nine equally spaced knots through which 7–9-mm bits of similar suture material with 0 thickness are secured	Eremia and Willoughby [37]	C	In conjunction with open facelifts, excellent results are achieved at 1 year. Results from pure suspension lift were lost in 80–100% of patients after 1 year
2-0 Polypropylene— using a Khawaja-Hernandez or Keith needle	Khawaja and Hernandez-Perez [39]	C	Nearly 80% of patients were satisfied with their results at 1 year
Various barbed sutures	Villa et al. [33]	C	Clinical efficacy, peak correction, and longevity of effect were inconclusive. Adverse events are minor and self-limiting
Aptos Thread and 2G	Sulamanidze et al. [35]	C	All complication incidence was < 3%. Results were inconsistent and had early relapse of deformity

and longevity of improvement following a lifting procedure utilizing barbed, anchored, unidirectional, and nonabsorbable sutures. In this series, both patients and independent dermatologists assessed the results after 6 months. Interestingly, patients rated their average satisfaction as 6.9 on a scale of 1–10, while independent scorers rated the average improvement as 4.6 out of 10. This discrepancy prompted the authors to question what defines a successful operation. However, based upon patient satisfaction scores, they advocated the continued use of suspension sutures.

Sulamanidze et al. [35] (3a) performed a large retrospective review of 12,788 face and neck thread lift procedures from 1998 to 2010. The study of 6098 patients showed inconsistent results and early relapse of deformity with the Aptos Thread and Aptos Thread 2G methods. All complications were less than 3% and included thread visibility or migration, skin dimpling, hypo- and hypercorrection, transient paresthesias, and a small number of cases of injury to underlying structures. The incidence of complications correspondingly decreased in the latter part of the series as new devices were developed, and the technique was refined. Of note, the authors of this study are also the co-owners of all patents held on Aptos products.

In a case series by Bisaccia et al. [36] (4), the Silhouette suture (a 3-0 polypropylene suture with ten absorbable hollow cones equally interspersed with knots) is described for the elevation of sagging tissues of the face and neck. Patients who underwent rhytidectomy with this procedure experienced improvement leading the authors to conclude that the Silhouette suture will become a useful addition to the field of facial rejuvenation. However, this data was obtained using nonrandom selection techniques and further validation is warranted. A similar product now available in the United States is the Silhouette InstaLift suture (Sinclair Pharmaceuticals, Irvine, CA) which is entirely absorbable, made of polyglycolide/L-lactide.

Eremia and Willoughby [37] (3b) published a controlled study evaluating the use of the Monogram suture technique. The Monogram suture is a 2-0 absorbable monofilament; in the procedure, five to nine equally spaced knots are placed to secure 7–9-mm portions of similar suture material of 0 thickness. In this comparative study, one group of patients had suspension suture elevation with no skin excision, and the other group had suspension suture elevation in combination with conservative open surgical facelifts. Patients for whom the Monogram suture was used in conjunction with open facelifts experienced excellent results that persisted for up to 1 year. Conversely, the benefits from the pure suspension lift were lost in 80–100% of patients after the 1-year mark.

In another case series by Garvey et al. [38] (4), a single surgeon's experience with 72 patients undergoing thread lifts was retrospectively reviewed. Minor complications were common and usually self-limited. Ultimately, 42% of patients underwent a secondary procedure following primary threadlift after an average of 8.4 months, while 31% required revision surgery for cosmetic reasons after an average of 8.7 months. Finally, 11% of patients required removal of palpable threads. This study highlights the limitations of this technique and its high rates of revision surgery.

Khawaja and Hernandez-Perez [39] (4) published a series of 19 patients who underwent a transcutaneous facelift. In their procedure, a 2-0 polypropylene suture was anchored to the periosteum of the temporal bone which was then utilized to pull up the SMAS. The follow-up ranged from 6 months to 1 year postoperatively. Based upon a patient satisfaction survey, nearly 80% of patients were pleased with their results.

Minimally Invasive Techniques for Particular Facial Subunits

Traditional facelift procedures address aging associated with the entire face. However, such invasive procedures may not be appropriate for younger patients with specific concerns. Furthermore, avoiding the possible morbidity of an invasive operation is extremely desirable. Limited facelift procedures aimed at addressing

specific facial subunits have been developed to provide patients with tailored results while decreasing overall complications.

In 2004, authors from Columbia University published their 2-year experience [40] (4) with 30 patients who underwent a minimally invasive facelift procedure to correct mid-facial aging. Although the results were not systematically analyzed, the authors asserted that most patients were pleased with the results, and maintenance of correction achieved with this technique persisted for up to 2 years. Similarly, Fulton et al. [5] (4) published a series of 23 patients who underwent an S-lift facelift utilizing purse-string sutures placed in the SMAS from the zygoma to the jawline. They concluded that after a follow-up period of 6 months, there were no episodes of skin necrosis or patients requiring repeat correction.

For patients with specific desires pertaining to upper facial rejuvenation, a subcutaneous brow and forehead lift may be preferable. Niamtu [41] (4) recently published a series of 50 female patients who underwent such a procedure. After 30 months, there were no reported cases of relapse, and only two patients experienced flap necrosis. However, it is worth noting that the results were not well categorized or systematized.

Combined Procedures

In a multicenter, prospective cohort study of 11,300 patients, Gupta et al. [7] found that the majority of facelifts (57.4%) were performed in combination with other aesthetic surgery procedures. The most often combined procedures included blepharoplasty, brow lift, and liposuction. Combined procedures were found to be a significant risk factor for overall complications with a relative risk of 1.44. The overall major complication rate increased from 1.5% with facelift alone to 2.0% with one additional procedure and 2.5% with additional procedures on more than two body regions. An additional procedure was also an independent risk factor for postoperative infection with a relative risk of 3.52. The increase in complication rate in combined procedures remained less than the sum of the complication rate of each procedure separately. However, careful consideration should be taken given the increase in major complications following elective surgery.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development, and Evaluation (GRADE). See Tables 28.1, 28.2, 28.3, 28.4 and 28.5.

Self-Assessment Questions

1. Which of the following is true of the SMAS plication?
   (a) It must be performed under general anesthesia.
   (b) It involves extensive dissection and mobilization of the sub-superficial musculoaponeurotic system structures, such as the facial nerve.
   (c) It is a complicated and difficult to learn procedure.
   (d) The procedure relies upon folding the SMAS upon itself and securing it without additional undermining.
2. What distinguishes the SMAS plication from the lateral SMASectomy?
   (a) In the lateral SMASectomy, there is undermining of the SMAS.
   (b) In the lateral SMASectomy, a strip of the SMAS overlying the parotid gland is resected.
   (c) In the lateral SMASectomy, the facial nerve is divided.
   (d) In the lateral SMASectomy, no effort is made to elevate the lower portions of the SMAS.
3. Which of the following is the most likely to occur after rhytidectomy?
   (a) Infection
   (b) Hematomas
   (c) Hyperpigmentation and hypertrophic scarring
   (d) Alopecia
4. Which of the following is the most significant for increasing a patient's risk for post-rhytidectomy hematoma?
   (a) Increasing age
   (b) Diabetes
   (c) Hypertension
   (d) Type of facelift technique
5. What methods have been described to prevent temporal alopecia resulting from traumatized hair follicles following rhytidectomy?
   (a) Either 2% or 5% of topical minoxidil for 2 weeks prior to surgery and 4 weeks postoperatively
   (b) Phototherapy
   (c) Ethanol injection
   (d) Topical steroids

Correct Answers

1. d: The procedure relies upon folding the SMAS upon itself and securing it without additional undermining. When performing the SMAS plication, the SMAS is folded upon itself and secured, without additional undermining. A primary advantage to this approach is that there are minimal complications as the sub-SMAS structures, including the facial nerve, are left undisturbed and intact. This is a straightforward procedure with limited anesthetic requirements.
2. b: In the lateral SMASectomy, a strip of the SMAS overlying the parotid gland is resected. The lateral SMASectomy approach is similar to plication in that there is no undermining of the SMAS. With the lateral SMASectomy, a strip of the SMAS overlying the parotid gland is resected. Effort is made to elevate the lower portions of the SMAS. The facial nerve is protected by the parotid gland in the area of SMAS resection.
3. b: Hematoma. Postoperatively after rhytidectomies, hyperpigmentation, hypertrophic scarring, infection, and alopecia are all relatively rare complications.
4. c: Hypertension. Multiple studies have reported a higher incidence of hematoma in facelift patients with perioperative hypertension. Studies include those by Grover et al., Baker et al., and Abboushi et al.
5. a: Either 2% or 5% of topical minoxidil for 2 weeks prior to surgery and 4 weeks postoperatively. Eremia and colleagues studied the use of minoxidil. Subjects were followed for 3–6 months. The use of minoxidil resulted in a 0% incidence of permanent alopecia and a 1.7% incidence of temporary alopecia. In comparison, historical controls reported the incidence of temporary alopecia at 8.4%. Therefore, minoxidil appeared to provide a protective benefit when used before and after facelift.

Genital Rejuvenation

29

Min-Wei Christine Lee

Abstract

Female rejuvenation includes a range of functional and aesthetic procedures in the female genital region. More than half of the female population over age 50 suffers from stress urinary incontinence or some degree of uterine or pelvic organ prolapse. Almost all postmenopausal women have vaginal atrophy, dryness, dyspareunia, and other symptoms associated with menopause. Many of the symptoms associated with these common gynecologic disorders can be effectively and safely treated with lasers and other noninvasive devices. This is a comprehensive review and assessment of the scientific evidence regarding procedure selection, effectiveness, and safety of the available procedures in the area of female genital rejuvenation.

The aging of tissue generates laxity, and the vaginal mucosa is no exception. Age, vaginal deliveries, weight fluctuations, hormonal changes, instrumentation, and surgeries in the vaginal canal can cause disorders in the vaginal mucosa, producing a sensation of permanent dilation. This can also lead to damage to the pelvic floor which can result in uterine or pelvic organ prolapse and stress urinary incontinence (SUI).

Vaginal relaxation syndrome (VRS) is a quite common medical condition described as a loss of the optimal vaginal structure and is usually associated with vaginal child delivery and natural aging. Multiple pregnancies and deliveries contribute to a worsening of VRS, as well as the onset of menopause, which causes a decline in hormone levels and vaginal atrophy. VRS results in a decrease or loss of sexual gratification [1].

The genitourinary syndrome of menopause (GSM) is the new definition for the variety of menopausal symptoms associated with physical

changes of the vulva, vagina, and lower urinary tract and is caused by estrogen deficiency. The genitourinary syndrome of menopause (GSM), caused by estrogen deficiency, is responsible for the appearance of symptoms affecting qualify of life, such as vaginal dryness and/or dyspareunia or urinary symptoms, and affects at least 50% of postmenopausal women [2].

Female stress urinary incontinence (SUI) is a highly prevalent lower urinary tract dysfunction, most commonly affecting middle-aged and elderly women [3]. Although the etiology of SUI is not fully understood, the risk factors for the condition include congenital factors, pregnancy, childbirth, hypoestrogenism, cognitive impairment, obesity, and advanced age. Its prevalence has been estimated to be as high as 40% in European countries [4–6] and 50% in the USA [7].

There are many possible nonsurgical and surgical therapies for SUI; however, TVT (tension-free vaginal tape) has been considered the gold standard in SUI [8, 9]. Initial therapy involves nonsurgical options such as behavioral changes in terms of diet reduction for overweight patients, smoking cessation, bladder training, and pelvic floor muscle training (PFMT). Although good results can be achieved with PFMT, long-term improvement is hard to maintain due to lack of training and poor patient persistence. Mechanical devices such as pessaries, vaginal cones, and urethral obturators and electrical stimulation play an integral part in the management of these patients. Drug therapy also may reduce SUI.

Surgical procedures are more effective for SUI than nonsurgical therapies, but are sometimes associated with adverse effects and complications, such as bleeding, bladder perforation, urethral injury, infection, groin pain, and a sexual abstinence period of 6 weeks after surgery. It also has risk of complications of failure of sexual function, discomfort during intercourse, creating excessive obstruction of the lower urinary tract, neuritis of the obturator nerve, and postoperative restrictions. In addition, the recurrence rate for urinary incontinence after surgery ranges from 5.7% to 30–40% [10].

Noninvasive therapies such as electrical stimulation, radiofrequency, and laser photothermal therapy have been replacing surgical treatment as safer treatment options. Studies have demonstrated collagen remodeling effects of laser irradiation to help strengthen the pelvic floor supportive structures by heating pelvic floor tissue. Many studies have shown erbium:YAG laser therapy to be an effective and safe option for different gynecological applications, such as SUI, vaginal relaxation syndrome, and vaginal atrophy (A) [11–14].

In terms of evaluating effectiveness of laser procedures, the areas of genital rejuvenation can be broken down into three distinct areas: [15] vaginal atrophy and laxity, [16] stress urinary incontinence, and [1] uterine/pelvic organ prolapse. The laser procedures can further be categorized as follows: noninvasive vs. invasive. The only noninvasive laser procedure on the market is a nonablative fractional erbium:YAG laser (Intimalase and Incontilase, Fotona). All the other laser wavelengths are invasive and include fractional carbon dioxide (CO_2), fractional ablative erbium:YAG, and fractional ablative erbium:YAG combined with nonablative 1470 diode laser. Devices using radiofrequency are also noninvasive (Table 29.1).

Table 29.1 Summary of vaginal lasers on the market grouped by mechanism of action

Nonablative fractional erbium:YAG (250-msec long pulse duration)
Intimalase and Incontilase (Fotona, Dallas, TX) (the only laser with this unique wavelength)

One of the first reports on the use of erbium:YAG (Er:YAG) laser technology for gynecological treatments dates back to 2000 when Dr. Claudia Pidal and colleagues reported on the use of a Fotona Fidelis erbium:YAG laser (now known as the Intimalase and Incontilase, Fotona) for treating vaginal tissue [15, 16]. The results were impressive. The treatment was effective and painless and led to the rapid development of various erbium ablative procedures, including the treatment of human papilloma virus infections, cervical ectropion, vulvar intraepithelial neoplasia, dystrophic lesions, melanosis, and many other conditions. These treatments have also obtained US FDA clearance, and since then thousands of such procedures have been performed in many countries. A high rate of success, with only minor complications, was reported when performing ablation of the lower genital tract, treatment of multifocal and multicentric lesions, excisions, and tissue coagulation [16].

As an interesting and unexpected side effect, many patients reported that they felt a vaginal tightening effect following these erbium:YAG treatments, which resulted also in their enhanced sexual experience. This discovery initiated further research in the direction of developing a minimally invasive, nonsurgical, and nonablative erbium treatment for vaginal relaxation syndrome (VRS) [16].

There is a large spectrum of various VRS treatment options on the market ranging from behavioral (Kegel exercises) through pharmacological therapies (hormonal, tightening creams and sprays) to various more or less invasive surgical procedures. While behavioral and pharmacological therapies are noninvasive and safe, they have limited efficacy. On the other hand, various surgical procedures promise a much better final result at the price of higher associated risks [1].

Surgical procedures require the cutting and rearrangement of vaginal and peripheral tissue in order to reduce the size of the vaginal canal. Operating on or near sensitive vaginal tissue is inherently risky and causes scarring, nerve damage, and decreased sensation. Furthermore, patients require an extended recovery period, and the procedure involves considerable pain, discomfort, and risk of infection and serious complications associated with surgery and general anesthesia, including mortality [1].

Vaginal relaxation syndrome (VRS) is a quite common medical condition described as a loss of the optimal vaginal structure and is usually associated with vaginal child delivery and natural aging. Multiple pregnancies and deliveries contribute to a worsening of VRS, as well as the onset of menopause, which causes a decline in hormone levels and vaginal atrophy. VRS results in a decrease or loss of sexual gratification [1].

The first studies of the thermal effects of a nonablative erbium:YAG on human soft tissue using Fotona Intimalase with SMOOTH mode were performed by Majaron and colleagues in 2000 [17] and Drnovsek and colleagues in 2004 [18]. Based on these findings, the nonablative SMOOTH-mode erbium also began to be used on mucosal tissue. The first experiences in targeting mucosal tissue were intraorally. Application of the SMOOTH mode on the soft palate produces tissue contraction, which is an ideal noninvasive method for treating snoring and sleep apnea complications [16]. The first trials with SMOOTH-mode erbium tightening of the vaginal canal had already begun in 2008/2009 [13]. Tightening of the vaginal canal and consequently the improvement of sexual gratification were observed [13].

These trials also revealed that the SMOOTH-mode erbium results in improvement of stress urinary incontinence (SUI) in women. This resulted in the development of two protocols for two new minimally invasive, nonsurgical, and nonablative procedures: Intimalase (for VRS) and Incontilase (for SUI) [13, 19, 20]. These protocols are based on heating the vaginal wall mucosa up to approximately 65° C and include two treatment sessions with a 4–6-week interval. The time needed to execute the Intimalase protocol is approximately 8 min and for Incontilase around 15 min [16].

The wide use of erbium SMOOTH-mode technology brought further discoveries—in 2013 Bizjack-Ogrinc and Sencar reported excellent results achieved in the reduction of pelvic organ prolapse, [21] and in the same year Gaspar presented his pioneering work on vaginal atrophy [22]. The protocol for treatment of pelvic organ prolapse is based on the sample principle of

collagen hyperthermia as are the protocols for vaginal tightening and SUI, although with a difference in the treatment intensity (increased) and the location of the major area treated (the prolapsed part of the vaginal wall). This protocol requires three to five sessions at 4–6-week intervals. The number of sessions is dependent on the severity (grade) of the prolapse [16].

The vaginal atrophy protocol is based on a slightly different concept of milder hyperthermia, whereby the mucosa is warmed up to 45° C, thus causing the stimulation of cell proliferation via heat shock protein activation, an increase of collagen production as well as anti-inflammatory action. This protocol consists of three sessions at intervals of 3 weeks. After immediate tissue shrinkage, the process of neocollagenesis could take up to 6 months to complete [16].

Table 29.2 from the Palacios article shows the level of evidence of treatments for GSM. The vaginal laser received grade I-A level of evidence for improvement of symptoms and tropism for treatment of genitourinary syndrome of menopause (GSM) [23].

GSM, caused by estrogen deficiency, is responsible for the appearance of symptoms affecting qualify of life, such as vaginal dryness and/or dyspareunia or urinary symptoms, and affects at least 50% of postmenopausal women [2].

Treatment for GSM is aimed to restore the urogenital epithelium and relieve symptoms. For symptoms such as vaginal dryness, dyspareunia, or other symptoms associated with this syndrome, the first line of treatment is moisturizers (Evidence I-A) and vaginal lubricants (Evidence II-B) (Table 29.2). If they do not provide adequate improvement of symptoms or if moderate to severe symptoms continue, estrogens are used. Estrogens are the most effective treatments. In cases of vaginal atrophy, the choice is local estrogen therapy (Evidence I-A). Local estrogenic or systemic treatments can be combined with moisturizers and lubricants (Table 29.2) [23].

New therapeutic alternatives such as ospemifene (Evidence I-A) have recently appeared. Ospemifene is a selective estrogen receptor modulator (SERM) that selectively exerts agonist effects on the vaginal tissue. It is the first nonhormonal oral alternative for vulvovaginal atrophy or the genitourinary syndrome of menopause. Vaginal laser has also emerged as a possible option for noninvasive treatment of GSM (Evidence I-A) (Table 29.2) [23].

Table 29.2 Level of evidence of treatments for genitourinary syndrome of menopause [23]

Treatments	Level of evidence
Lifestyle	
Sexual activity	II-2B
Obesity	III-C
Exercise	III-C
Smoking	II-3B
Vaginal moisturizers 2–3 times/week for improvement of symptom	I-A
Vaginal lubricants for sexual activity	II-2B
Other treatments	
Homeopathy	III-D
Phytotherapy	III-D
Phytoestrogens	II-3D
Systemic and local hormonal therapy	
Improvement of symptoms	I-A
Tropism	I-A
Vaginal laser for improvement of symptoms and tropism	I-A

Effectiveness of Procedures

Nonablative Erbium for GSM and VSR

Gambacciani et al. conducted a pilot prospective longitudinal study performed in 45 postmenopausal women suffering from GSM. Nineteen of these women also suffered from SUI. They were treated with nonablative erbium laser (Fotona), receiving three laser applications every 30 days with follow-up visits up to 24 weeks after the last laser treatment. A control group of 25 postmenopausal women were treated with an established treatment for GSM of topical estriol vaginal gel twice weekly for 3 months. Results showed significant improvement of both vaginal dryness and dyspareunia. In postmenopausal women suffering from mild to moderate SUI, there was also significant improvement of SUI scores (A)(1b) [12].

In another prospective study by Gambacciani, 65 postmenopausal women suffering from GSM

were treated with 3 laser applications of nonablative erbium laser (Fotona) every 30 days and followed up to 1 month. In addition, 21 of the patients suffering from mild to moderate SUI were also evaluated for changes in these measurements. Results showed statistically significant improvement in vaginal dryness and dyspareunia in all patients at 4 weeks posttreatment. In the 21 patients with SUI, the laser treatment induced a significant decrease in the SUI scores. The nonablative nature of the erbium laser allows several passes on the vaginal canal that are necessary for the treatment of the anterior vaginal wall in women suffering from SUI. This is not possible with ablative lasers such as fractional CO or ablative erbium due to tissue necrosis and pain limiting the number of passes that can be performed or tolerated (A)(1b) [11].

In a prospective study, 43 postmenopausal breast cancer survivors were treated by Gambacciani et al. with 3 laser applications of Fotona erbium laser every 30 days. It was found to be effective and safe for the treatment of genitourinary syndrome of menopause (GSM). Effect of the laser treatment on dryness and dyspareunia was measured up to 18 months from the last laser treatment. At each visit, the Vaginal Health Index Score (VHIS) was calculated. The VHIS evaluates the appearance of the vaginal mucosa and consists of five parameters: elasticity, pH, vaginal discharge, mucosal integrity, and moisture. Results showed improvement in both dryness and dyspareunia and subsequent VHIS calculations, inducing a rapid and long-lasting positive effect on vaginal tissues, up to 12 months after the last laser treatment. There was still improvement at 18 months compared to baseline, but there was a diminishing effect by this timepoint. This study had the limitation of the lack of randomization with a sham treatment and/or standard treatment (A)(1b) [24]. In a previous study performed by the same authors, they compared the vaginal erbium laser with low-dose vaginal estriol administration, a standard GSM treatment, and showed that the estrogen effects fade away 12 weeks after the end of treatment, whereas the laser treatment group maintained the results for 6 months (up to the end of the follow-up period) [12]. This study had a shorter follow-up period (6 months) than the previous study (18 months). Thus, as expected, laser therapy cannot be considered a definitive cure for GSM, but the vaginal erbium laser inducing no tissue ablation or injury could be repeated on an annual basis when the beneficial effects seem to decrease [24].

A prospective study with control group was conducted by Gaspar et al. Fifty patients with GSM were divided into 2 groups: 1 group received topical estriol treatment for 8 weeks and the other group received laser treatment with the Fotona erbium laser in nonablative mode. The laser group received three sessions over an 8-week period. Patients were followed up to 18 months posttreatment. Results showed that the erbium laser treatment successfully relieved symptoms of GSM and that the results were more pronounced and longer lasting compared to topical estriol treatment. The major benefit of the laser treatment in comparison to the 8-week local estriol treatment is that the laser treatment produces a long-lasting effect characterized by an improved vascularization and increased extracellular matrix component, while estriol-only treatment increases the glycogen level in the vaginal epithelium and its turnover, with less effect and only transient effect on vascularization and changes in the lamina propria, requiring maintenance treatment for the effects to be sustained. Due to these enhanced effects, the laser treatment provides great improvement in GSM which remains evident for a longer sustained period up to 12 months. There was diminishing effect at the 18-month follow-up, although the improvement was still highly significant compared to baseline. The authors emphasized that since the treatment is safe and noninvasive, it could be repeated once the patients feel the return of symptoms and in that way sustain the beneficial mucosal state (A)(1b) [25].

Gaspar et al. performed previous studies using a fractional CO_2 laser for vaginal rejuvenation [26]. Salvatore et al. also performed a 3-month follow-up study showing that treatment with a fractional CO_2 laser improves symptoms of GSM [27]. Gaspar pointed out in the latter erbium laser study article that the major difference between

CO_2 and the erbium laser method used in the latter study was in the ablative characteristics of the CO_2 laser, which works by vaporizing columns of tissue. Tissue vaporization of epithelial layer surface is necessary to expose deeper, underlying connective tissue, which is more abundant in water, to the thermal effects of the CO_2 laser pulse for achieving the desired photobiomodulatory effect [28]. In contrast, erbium laser with nonablative SMOOTH mode (unique only to the Fotona laser) creates heat pulses without damaging the mucosa. The temporal distribution of energy delivered with the special nonablative SMOOTH mode allows the heat to slowly dissipate to depths of approximately 200–500 μm, thus achieving the same biological effects and the thermal effects of a CO_2 laser pulse, with the additional benefit of avoiding mucosal damage. Consequently, the risk of infection, necrosis, scarring, and other side effects is minimized compared to CO_2 laser [25]. Gaspar used the first generation of Deka's CO_2 laser (SmartXide2) (which was much more robust and aggressive than today's MonaLisa Touch) when he did his comparison of CO_2 and erbium:YAG in 2012. After seeing the high incidence of adverse side effects, they reduced the depth of drilling in the current fractional CO_2 MonaLisa Touch (Deka, Cynosure) to about 200 μm (earlier it was much more) and produced new much gentler accessories (almost exact copies of Fotona's G-set adapters).

In this prospective study examining the effects of laser treatment on vaginal atrophy, Bojanini et al. had 40 patients who were split into 2 groups: 20 patients in postmenopausal group with no history of gynecologic cancer (group A) and 20 menopausal patients with a history of gynecologic cancer (group B). The 20 patients in group B also were breast cancer survivors. Patients received two laser treatments with a nonablative erbium laser (Fotona) with 3-week intervals between treatments. They were followed up to 3 months posttreatment. All patients reported improvement in all measured endpoints including dryness, dyspareunia, improvement in sexual life, and overall satisfaction (B)(2b) [29].

Gaviria et al. conducted a pilot study on 21 patients receiving treatment with nonablative erbium laser (Intimalase, Fotona) for vaginal tightening between June 2011 and January 2012. All patients received two treatments with 15–30-day intervals between treatments and were followed up to 3 months. Vaginal relaxation syndrome (VRS) is quite common and associated with vaginal child delivery and natural aging. Multiple pregnancies and deliveries contribute to a worsening of the VRS condition, as well as the onset of menopause, which causes a decline in hormone levels and vaginal atrophy. Ninety-five percent of patients reported significant (moderate and strong) improvement of their vaginal tightness, and also all of their partners confirmed an improvement of vaginal tightness during sexual intercourse. Ninety-five percent of patients reported better sex after the treatment. Five patients had prolapse (stage 1–3 in severity) before receiving the treatment; all experienced improvement in prolapse after the laser treatment. Three patients with SUI reported significant improvement in two and complete resolution in one. Limitations of this study were small size, lack of a control group, and short follow-up time (B)(1b) [1].

Gaviria et al. conducted a prospective study examining VRS treated with laser with 3-year follow-up. A total of 103 patients suffering from vaginal relaxation syndrome (VRS) were treated with a nonablative erbium laser (Intimalase, Fotona) between June 2011 and May 2014. Sixty patients received follow-up at 3 years after the last laser procedure. The patients reported that the average duration of effect was 16 months, with significant improvement of SUI and prolapse. The majority of the results lasted 18–24 months, and the effect of the therapy started to fade 2 years after the treatment. Results showed that 83.33% of participants would be willing to repeat the therapy. The majority (67%) of the patients with persisting results received two treatments (B)(1b) [30].

Ablative Fractional Erbium for VRS

In a prospective study, Lee et al. treated 30 postpartum women with VRS or vaginal atrophy.

They received four laser treatments at 1–2 weekly intervals using an ablative erbium laser (Petit Lady, Lutronic). They were followed up to 2 months. Patients' partners were asked for input and 76.6% reported increased perception of vaginal tightening. Seventy percent of patients reported improved sexual satisfaction. This study was limited by small sample size and very short follow-up (C) [31].

Ablative Fractional CO_2 for Vaginal Atrophy

In this pilot study, Salvatore et al. treated 50 postmenopausal women with three applications of fractional CO_2 laser (Monalisa, Deka) over 12 weeks. Results showed improvement in vaginal dryness and dyspareunia at 12-week follow-up. Satisfaction with the laser procedure was reported by 84% of the women treated. One patient could not be treated because her vagina was too narrow and the laser probe could not be inserted. Pain reported during the study was related to insertion and movements of the laser probe during treatment. The limitations of this study are small sample size, short duration of the study, lack of long-term follow-up, and absence of a comparator (placebo or other active treatment) (C)(2b) [32].

Zerbinati worked with Salvatore in this pilot study [32] and recruited 5 out of the 50 postmenopausal women, nonestrogenized, for the histological study. The microscopic and ultrastructural findings obtained from the vaginal mucosa biopsies of these five women showed restoration of the normal structure and functionality in the epithelial and connective tissue, restoring the vaginal mucosa structure to a premenopausal condition without any hormonal therapy. These histologic findings corresponded to the clinical relief from symptoms reported by the patients after fractional CO_2 laser treatment (B)(2b) [28].

Salvatore treated 15 women with 3 applications of fractional CO_2 laser (Monalisa, Deka) over 12 weeks. Results showed improvement in vaginal dryness and dyspareunia. There was also significant improvement in sexual function and quality of life. The major limitation of this study was its small sample size, short duration of the study, and lack of long-term follow-up (C)(2b) [33].

Perino et al. treated 48 postmenopausal women with symptoms related to vulvo-vaginal atrophy with a fractional CO_2 laser (Monalisa, Deka). They received three sessions with 1 month between treatments. They were followed up to 30 days posttreatment. Results showed improvement in vaginal dryness and dyspareunia. As many as 91.7% of patients reported satisfaction with the treatment. The limitations of this study were absence of a control group (i.e., traditional local estrogen therapy), small sample size, extremely short follow-up, and lack of long-term follow-up (at least 1 year) (C)(2b) [34].

Nonablative Erbium for SUI

Fistonic et al. conducted the first study using nonsurgical laser treatment for SUI. This first-time open-labeled prospective single-center pilot study had a total of 39 women suffering from mild to moderate SUI who underwent one treatment with nonablative erbium laser (Fotona) and were followed up to 6 months. The patients all showed improvement in measurements used to assess reduction in SUI symptoms and also reported improved sexual gratification. These preliminary results showed that the nonablative erbium laser offers efficacious treatment for SUI and is associated with a high level of safety, and patients find it comfortable and noninvasive with no recovery period (B)(2b) [19].

Khalafalla et al. conducted a prospective study on 50 women with SUI who were treated with a nonablative erbium laser (Incontilase, Fotona) following the Incontilase protocol. They were followed up to 6 months posttreatment. SUI was diagnosed by patients' symptoms, urine analysis, and urodynamic studies. All measurements of SUI were improved after treatment (B)(2b) [35].

In another prospective study, Tien et al. treated 35 women with SUI with a nonablative erbium laser (Incontilase, Fotona) and found that the

effect of the laser for mild SUI was moderate at 6-month follow-up but was not effective for pad weight >10 g. The overall success rate of the 1-h pad test at 6 months posttreatment was 78.6% [36]. It improved lower urinary tract symptoms, qualify of life, and sexual function of both partners. They concluded that further studies should be performed to assess long-term sustained efficacy. They also noted that subjective and objective improvements in SUI symptoms were not as extensive as those that follow midurethral sling surgeries (MUS) especially in moderate and severe cases [37]. MUS surgery which has a long-term subjective cure rate of 77–85% remains one of the first-line surgeries for SUI [38, 39]. They stated that the laser procedure should not replace MUS surgery as standard therapy for SUI patients who fail to improve following first-line therapy. In addition, the injection of bulking agents has been reported to have a cure rate of 53–73.2% [40, 41] which is better than the cure rate of the laser procedure. The authors further state that the laser procedure should not replace the injection of bulking agents as the sole minimally invasive procedure for SUI [36]. The authors concluded that based on its minimally invasive nature and the lack of significant side effects, the nonablative erbium laser (Incontilase, Fotona) may be used as an alternative therapy for mild SUI cases and that further studies should be performed to assess long-term sustained efficacy (B)(2b) [36].

Pardo et al. conducted a prospective study on 42 women with mild to severe SUI who were treated with a nonablative erbium laser (Incontilase, Fotona). Improvement was evident almost immediately after treatment and lasted at least 6 months. As many as 78.6% reported improvement (including patients with severe SUI), 38.1% a complete healing of SUI at follow-up, 66.7% reported high satisfaction, and 81.8% of sexually active women reported improvement of sexual gratification. Only mild pain during the treatment was reported as an adverse effect in some patients. No other adverse effects were reported in any patient. The authors concluded that nonablative erbium laser seems to provide a quick and highly successful ambulatory procedure for treatment of SUI, producing significant reduction of SUI symptoms, lasting at least 6 months. The procedure is minimally invasive, with no cutting, no ablation, and no bleeding, virtually painless, and requires no anesthesia or special pre- or postoperative preparation. The authors also discussed that the use of fractional CO_2 and ablative erbium laser for vaginal rejuvenation treatment, addressing also SUI symptoms, has been described but is based on ablation of mucosal tissue, and although described as minimally invasive, a long recovery time was still needed, accompanied by bleeding, pain, and burning sensation after the treatment [26]. In contrast, the nonablative erbium laser provides a safer option, creating a controlled temperature increase within the mucosal tissue without any ablation, having no recovery time and no significant adverse effects (B)(2b) [14].

Fistonic et al. treated 73 women in a prospective cohort, single-center study with a nonablative erbium laser (Incontilase, Fotona) followed up to 6 months. Results showed there was a clinically relevant, short-term improvement of SUI with minimal adverse events. The reduction was significantly higher in women with normal body mass index and in younger women (B)(2b) [42].

In a pilot study, Fistonic et al. treated 31 women with SUI with a nonablative erbium laser (Inctonilase, Fotona). This is a pilot study with lack of a control group, high loss to follow-up, and relatively short follow-up time. All patients with SUI showed improvement in the measured efficacy endpoints. The authors concluded that the nonablative erbium laser induces deep thermal effect on the vaginal wall, which seems to result in a clinically meaningful improvement of female SUI, but that randomized control trials are needed for further evaluation (C)(3a) [43].

In another prospective study, Ogrinc et al. treated 175 women with stress urinary incontinence (SUI) (66%) and mixed urinary incontinence (MUI) (34%) with symptoms ranging from mild to very severe with a nonablative erbium laser (Incontilase, Fotona). SUI is the most prevalent type of UI and is defined as involuntary loss of urine due to sphincter failure during physical activity, coughing, or sneezing, which all cause

an increase in abdominal pressure. MUI is a combination of SUI and urge urinary incontinence (UUI). UUI, sometimes also termed overactive bladder syndrome, encompasses the symptoms of urgency, frequency, and nocturia and is associated with urgency contraction due to detrusor overactivity. MUI has a prevalence of 7.5–25% [44, 45]. Patients received two laser treatments a month apart and were followed up to 12 months posttreatment. At 1-year follow-up, 62.3% of the patients were dry. Seventy-seven percent of SUI patients improved. Thirty-four percent of MUI patients improved. The outcome was significantly dependent on the type of incontinence diagnoses before the induction of therapy. While the procedure cured the majority of women with SUI, it was of benefit only in one third of women with MUI. The percent of women cured after 1 year in the study was similar to the results obtained after surgical procedures; yet, compared to surgical outcome, the reported side effects were negligible [44, 46]. The authors concluded that the nonablative erbium laser efficiently improved SUI in the majority of patients, but on the other hand, it seems that the therapy is not suited for the treatment of MUI (B)(1b) [46].

Multicenter Studies of Nonablative Erbium on VRS and SUI

The results of multicenter clinical studies of the nonablative erbium laser (Intimalase and Incontilase, Fotona) are presented in this chapter [13]. All five centers involved in the studies of the Intimalase treatment reported positive results in a large majority of patients (i.e., improvement in vaginal tightness). Similarly, all four studies of the Incontilase treatment showed improvement in SUI in a large majority of patients (A)(1a) [13]. Rivera reported on two studies of laser vaginal tightening using the nonablative erbium laser (Intimalase, Fotona). The first group of 135 patients was treated in the period from June 2009 to September 2010. On 1-month follow-up after the first session of Intimalase treatment, 90.4% of patients expressed their satisfaction with the tightening improvement, while 9.6% declared improvement but asked for a second session. On the next follow-up interviews at 3 months and 6 months, all patients expressed their satisfaction with tightening improvement. The second group of 27 patients was treated during March 2011 with a single session of Intimalase therapy. Patients reported improvement in sexual gratification. Vaginal tightening was achieved in all patients, ranging from 3% to 28%, resulting in an average shrinkage of 17% (or 12 mm) [47].

Fistonic et al. evaluated the efficacy and safety of the nonablative erbium laser (Intimalase, Fotona) procedure in this pilot study conducted on 17 women for vaginal tightening in a period between September 2010 and January 2011. Patients were followed up to 3 months. Six patients also had SUI on which Fistonic performed also the Incontilase (Fotona) treatment. All patients with SUI showed improvement at the 1- and 3-month follow-ups (B)(2b) [48].

Guimaraes et al. reported on a laser vaginal tightening study using the nonablative erbium laser Intimalase (Fotona) treatment protocol. Twenty-three patients were treated during a period from August to December 2011. All patients received one treatment and were followed up to 4 months. In this study, the patients' male partners were also interviewed regarding any improvement of tightness sensation. At 1-month follow-up, 87% of patients reported mild-to-excellent improvement, while 13% responded that there was no improvement. At 4 months after the treatment, 69% of partners assessed their improvement as excellent, 27% as good, 4% as mild. None of the patients' partners claimed "no improvement" either at the 2- or 4-month follow-ups (B)(2b) [49].

Gaviria et al. reported on a study which was performed during June 2011 and January 2012 on 21 patients, with two sessions of the nonablative erbium laser Intimalase (Fotona) treatment with 15–30 days between sessions and followed up to 3 months. Ninety-five percent assessed the change of their vaginal tightness as strongly or moderately improved, 5% as mildly improved. Twenty out of 21 patients reported better sex after treatment. Five patients had prolapse of stages

1–3, but all of them improved after the first session of Intimalase (B)(2b) [50].

Garcia et al. presented their results of laser vaginal tightening using the nonablative erbium laser Intimalase (Fotona) treatment performed on 29 patients in a period between October 2011 and January 2012. Improvement in vaginal tightness was reported in 96.6% of the cases. Results of the feminine sexual function index also improved after treatment (B)(2b) [51].

Rivera et al. treated 115 patients suffering from SUI using the nonablative erbium Incontilase (Fotona) protocol during the period from March to August 2009. At follow-up at 1 month after the second treatment, the success rate was 97.4% for mild SUI and 89.5% for moderate SUI (B)(2b) [47].

Guimaraes et al. treated 28 patients with SUI using the nonablative erbium laser Intimalase (Fotona) protocol during the period from August to December 2011. At the first follow-up at 1 month, there were 87% of patients with improvement and 17% of patients without changes. Over time, the SUI further improved so that at 4 months, only 6% of patients were still reporting no change, while 94% of patients reported improvement and 68% of all patients claimed to be free of SUI symptoms (B)(2b) [49].

Saracoglu et al. reported on his experiences with treating SUI and laser vaginal tightening using a single session of the Incontilase or Intimalase protocols (Fotona), depending on the patients' indication. Thirteen patients were recruited in this pilot study, nine of them having reported SUI, while the remaining four had vaginal relaxation syndrome. All 13 patients had various stages of prolapse, 9 had prolapse of stage 1, while 3 had stage 2, and one patient had stage 3. At follow-up at 6 weeks, 50% improved their prolapse stages, five patients by one stage, while one patient (having stage 3) improved by two stages. Measurements of SUI were all improved [52].

The initial clinical results from these nine clinical studies from six centers using the Intimalase and Incontilase (Fotona) treatment protocols showed safety and efficacy in patients suffering from VRS and SUI [13]. These studies were limited by short follow-up but later studies used larger number of patients and with longer follow-up times, some of which have already exceeded 12 months (B)(2b) [1, 19].

Multicenter Study of Nonablative Erbium on GSM and SUI

The protocol and rationale and design for a large multicenter study on the evaluation of the efficacy and safety of vaginal erbium laser for the treatment of GSM and SUI were presented in a paper published by the Vaginal Erbium Laser Academy Study (VELAS). This study will evaluate the effects of three laser applications using the nonablative erbium laser (Fotona) in 1500 postmenopausal women. They will be followed up to 1 year [53]. They carefully considered all the available evidence on nonablative erbium and fractional CO_2 laser before concluding that the nonablative erbium would be the ideal candidate for the thermal treatment of vaginal walls. Studies using nonablative erbium laser [11, 12, 22, 31, 54–56] showed advantages compared to fractional CO_2 laser because it provides a nonablative option for correction of GSM. In addition, nonablative erbium but not CO_2 laser treatment has been reported to induce a significant decrease of clinical symptoms in postmenopausal women suffering from SUI [11, 12, 22, 31, 54–56].

Studies using fractional CO_2 laser [27, 28, 34, 57, 58] showed that it may improve vaginal health in postmenopausal women. The effects measured were vaginal dryness and dyspareunia. However, it is important to note that fractional CO_2 was rarely used in studies to examine SUI and not been used in studies to examine pelvic organ prolapse. Only the nonablative erbium laser (Fotona) has been used in studies examining SUI or prolapse and shown to be effective and safe for treatment of SUI and pelvic organ prolapse [21, 53]. The VELAS selected the nonablative erbium laser because it has been safely used to treat GSM in women suffering from SUI, but not CO_2 laser [53].

The VELAS study obtained all the available data with the fractional CO_2 laser and nonabla-

tive erbium laser. Although both lasers were reported to be effective in reducing clinical symptoms of postmenopausal vaginal atrophy, only the nonablative erbium laser treatment was associated with a reduction in SUI symptoms. The nonablative erbium laser is performed using a particular vaginal speculum introduced as a guide for the handpiece laser beam delivery system. Thus, the patients do not feel the several longitudinal passes performed using a step-by-step retraction of the handpiece, and the nonablative erbium laser effects on vaginal mucosa induce ideal treatment compliance [12, 53]. In comparing data available on fractional CO_2 with nonablative erbium laser, the VELAS groups discussed that the innovative techniques used in the nonablative erbium laser procedures can guarantee not only efficacy but also an intrinsic safety, since the nonablative erbium beam cannot damage the tissues in depth. This eliminates the risk of tissue necrosis, in a nonablative form, without cut, abrasion, or bleeding. These characteristics make the nonablative erbium laser an ideal candidate for the thermal treatment of the vaginal walls. The characteristics of the CO_2 laser are different and may induce different compliance and patient satisfaction [53]. Table 29.3 shows Adrian Gaspar's study comparing the effects of these two systems [53].

Table 29.3 Difference between CO_2 and Er:YAG lasers in the treatment of genitourinary syndrome of menopause (GSM) [53]

	CO_2	Er:YAG
Absorption in water	15 × less than Er:YAG	15 × more than CO_2
Optical penetration	50 μm	3–5 μm
Mechanism of action	Ablation	Thermal diffusion
Aggressiveness of treatment	Always partial necrosis and associated adverse effects	Surface of mucosa is not ablated (damaged)
Depth of penetration	3 mm or more	200–500 um
Operative time (min)	20	15
Pain level during treatment on scale of 0–10	5	0
Pain level posttreatment on scale of 0–10	3–5	0
Treatment zone	Vaginal canal	Vaginal canal and introitus
Tissue-healing phase	20 days	2 days
Return to normal sexual activity	10 days	3 days
Laser release	Operator-dependent	Uniform and controlled

The VELAS is the largest multicenter prospective study underway to evaluate effects of laser on GSM. The protocol does not include a placebo-treated arm since a double-blind treatment with a sham procedure is not feasible, the effect of laser on vaginal tissue being physically evident during the treatment [53]. The VELAS groups concluded that the nonablative erbium laser has unique properties that make it ideally suited for treatment of the vaginal mucosa and gynecologic conditions due to its ability to deliver uniform controlled tissue heating, in a safe and harmless ambulatory procedure without ablation and carbonization of the tissue, and ability to avoid the risk of perforation with accidental lesions of the urethra, bladder, or rectum (a feature unique and specific only to the Fotona laser modality) [53]. Findings from the VELAS have the potential to affect clinical care practice and health decisions for millions of women worldwide for a nonhormonal treatment for GSM and a noninvasive treatment for SUI.

Gaspar et al. conducted a prospective study comparing treatment group with control group. Forty-three patients were in the laser treatment group and received 3 treatment sessions of a nonablative erbium laser (Incontilase, Fotona) with intervals of 1 month in between the sessions. Twenty-nine patients were placed in the control group and received 2 weekly sessions of pelvic floor muscles exercises with perineometry, which lasted 3 months (24 sessions in total). Only patients with SUI were recruited into the study. Follow-ups were performed at 3, 6, and 12 months. Standardized 1-h pad test was used to evaluate the efficacy of the treatment. The decrease in pad weight was more pronounced in

the laser group. More importantly, the effect in the laser group remained constant up to the 12-month follow-up, while the results in the control group showed a diminishing trend. The author concluded that the results can last for at least a year after treatment. He also concluded that since the treatment is noninvasive, it could also be repeated once the results start diminishing (B)(1b) [59].

Gaspar et al. treated eight patients with SUI with three sessions of a nonablative erbium laser (Incontilase, Fotona) with 1-month interval between the sessions. They were followed up to 12 months. The largest average reduction of leaking frequency and quantity was measured at 2-month follow-up. There continued to be significant reduction of frequency and quantity up to 12 months. The author concluded that 3-day voiding diary was a useful objective tool to measure effects on SUI and that the results of this small pilot study show that the laser therapy could produce significant reduction of SUI symptoms which is lasting at least 12 months (B)(3b) [60].

Gaspar et al. treated 43 patients with SUI in the laser group with 3 sessions of a nonablative erbium laser (Incontilase, Fotona) with 1-month interval between the sessions. The control group of 29 patients received perineometry sessions (Kegel exercises plus perineometry) (2 per week during 3 months). In the first phase of the study, both groups were followed up to 18 months after the initial session. The control group then exited the study, while the laser group received three additional maintenance sessions of laser treatment—at 18, 24, and 30 months—and was followed up to 36 months after the study start. Results of the pad test and SUI questionnaire showed that the laser group insignificantly improved after 6, 12, and 18 months. After three maintenance sessions at 18, 24, and 30 months, the scores again dramatically improved at 24-, 30-, and 36-month follow-ups. There was no significant improvement in the control group. The authors concluded that the nonablative erbium laser is a highly efficient, minimally invasive nonsurgical therapy for SUI with long-term results (B)(1b) [61].

Lukanovic et al. separated 120 patients with SUI and sexual dysfunction into a laser treatment group [62] and a control "sham" laser group [62]. Each group was treated with one session of a nonablative erbium laser (Incontilase, Fotona) and followed up to 3 months after the treatment. One patient dropped out of each group. In all measured values, the laser group achieved better results than control group. In the two most important assessment tools for SUI and sexual dysfunction, the improvements of the laser group were significantly better than the control group (B)(2b) [63].

Ablative Erbium for SUI

Leshunov et al. treated 37 women with mild and moderate SUI with an ablative erbium laser (Juliet, Asclepion). They were followed up to 6 months posttreatment. The measurements of SUI showed improvement. There were significant side effects. Fifty-five percent of the patients had presence of bloody discharge, 16% had low-grade fever, and 6% had cystalgia (C) [64].

Fractional CO_2 Laser for SUI

Bader treated one patient with SUI using a fractional CO_2 laser (FemiLift, Alma). The patient received three laser sessions performed at 4-week intervals. The author states that the patient had complete remission of symptoms but did not have a follow-up visit for this patient. The author did state at the end of the paper that results "… reach their peak six months after the end of the third session" but did not provide any evidence to back this up (D) [23, 62].

A retrospective multicenter evaluation of 133 patients with SUI symptoms who underwent fractional CO_2 laser treatments (FemiLift, Alma) appeared in an Alma white paper. Patients were interviewed 3–12 months following completion of treatment to evaluate their symptoms and satisfaction. As many as 66.7% of patients reported satisfactory global improvement. They stated that no adverse events were

reported by any patients or recorded in patient charts (D) [65].

Perino et al. treated 30 postmenopausal women with a fractional CO_2 laser (Monalisa, Deka), receiving three treatments over a period of 30 days. Nine of the 30 patients who suffered from incontinence episodes had improvement after the laser treatment. Results also showed improvement in vaginal dryness and dyspareunia. The major limitations of this study are the small sample size, lack of long-term follow-up, and absence of randomization or a control group of patients. The authors recommend that based on these preliminary results, it would be advisable to perform a new study that includes a control arm (i.e., intravaginal estriol administration) to compare CO_2 laser with other proposed therapeutic options evaluating the long-term outcomes (C)(2b) [66].

Nonablative Erbium for Treatment of Prolapse

In this pilot study, Ogrinc et al. treated 28 patients with grades 2–4 cystocele using a nonablative erbium laser (Intimalase and Incontilase, Fotona). They received between one and three treatment sessions with intervals of 2 months in between the sessions. They were followed up to 6 months. All but 1 patient reduced their prolapse grades by at least one grade (96.4%), 12 of them by two grades (42.9%), and 2 by three grades (7.1%). In conclusion, the author stated they are planning longer follow-ups at 12 and 24 months (C)(1b) [27, 67].

Ogrinc et al. treated 65 patients with grades 2–4 cystocele using a nonablative erbium laser (Fotona). Patients received between one and five treatment sessions with intervals of 2 months in between the sessions. Patients were followed up to 12 months. Improvement was achieved in all stages of pelvic organ prolapse. A reduction of 1.6 stages on average was achieved. Ninety-eight percent of patients achieve an improvement of at least one stage. All of the stage 4 patients achieved an improvement of two grades or more. Patients reported high satisfaction with the procedure and better quality of life. There were no adverse events. The author concluded that the treatment should be included as a first line of defense in early pelvic organ prolapse in order to avoid or postpone surgery (B)(1b) [68].

Summary of Laser-Based Devices for Vaginal Rejuvenation

The vast majority of articles published on vaginal laser treatment has been for the Fotona nonablative erbium laser. It is the only laser on the market which utilizes a nonablative laser that causes no injury to the vaginal mucosa. All other laser devices utilize either fractional CO_2 or ablative erbium laser which cause ablation and injury to the vaginal mucosa. Radiofrequency devices are also noninvasive, but the published studies are few compared to the large number of articles published on the nonablative erbium laser and has been for GSM and VRS and not for SUI and pelvic organ prolapse. There is rightful concern in the medical communities that so many laser companies are trying to claim efficacy and safety using the fractional CO_2 or ablative erbium which have higher risk of adverse effects without providing long-term studies especially when the convincing evidence to treat these conditions has been produced with the nonablative laser which is a better and safer option—both from the standpoint that it has the scientific studies to back it up and there is minimal risk with the procedure. When faced with a more invasive option with higher adverse effects with less scientific data compared to a safer noninvasive option with no adverse effects with high volume of scientific data, it would appear prudent for a physician considering performing procedures in this area to consider the noninvasive option especially if they were already skeptical about whether these procedures have any effect.

Lasers also have important applications in treatment of conditions involving the external genitalia. Ablative erbium laser has many useful applications for treatment of gynecologic disorders such as ablating various lesions on the cer-

vix and vaginal wall, for the removal of genital warts, resurfacing, whitening and tightening of the vulvar region, as well as labioplasty, lichen sclerosus et atrophicus, and many other procedures [16].

Radiofrequency Devices for Vaginal Rejuvenation

Although multiple radiofrequency (RF) devices are being used for vaginal rejuvenation, few studies have been published showing efficacy and safety for this application. The RF devices are not FDA approved for use in the vaginal or genital region—all their use in these areas has been off-label.

Steven conducted a single-center study with 14 healthy female patients investigating the safety and efficacy of a bipolar RF device (ReVive, Viora) for labial skin laxity and texture. This bipolar RF device utilizes three distinct RF frequency channels (0.8 MHz, 1.7 MHz, and 2.45 MHz) and an additional fourth multichannel mode, combining all three RF frequencies using the unit's V-ST handpiece. Patients received an average of 5.6 treatments with no anesthesia, and duration of session was 30 min and intervals of 2–3 weeks between sessions. Results showed moderate improvement in labial skin laxity and texture with 67% of the patients reporting satisfaction with the treatment results (C) [69].

BTL (Boston, MA) has a new intravaginal monopolar RF device called the Ultra Femme which is the first of its kind on the market. They incorporate a "ring solution" which is a circumferential 360° band of RF delivery at the end of a phallus-shaped intravaginal probe that is inserted into the vaginal canal. This ring solution provides homogeneous heating throughout the entire vaginal canal and introitus. There is also a separate external tip that is used to treat the external genitalia. The intravaginal procedure takes 10 min and the external genitalia requires 20 min.

Fistonic et al. treated 17 female patients with labial laxity with a focused monopolar RF device. They received four treatments at 7-day intervals and were followed up to 1 month after the last treatment. Improvement was measured on a 1–4 scale determined by three blinded evaluators. An average of 2.9 (maximum of 4) points improvement rate in vulvar appearance was observed. They also reported improvement in sexual gratification with statistical significance. The author concluded that this study demonstrates the positive effect of a focused monopolar RF device for noninvasive labial tissue tightening. This study was limited by a small sample size, lack of a control group, and short follow-up (C)(2b) [70].

ThermiVa from ThermiAesthetics (Southlake, TX), another RF device, uses an S-shaped, long, thin treatment probe with a thermistor tip that can treat the internal and external vaginal tissue by direct contact requiring the operator to use a rubbing back and forth or thrusting motion. Compared to the BTL Ultra Femme, the ThermiVa has complicated movements, does not heat homogeneously (there are cold spots), and is reliant on the operator's manual thrusting motions to deliver heat in an inconsistent manner, requiring a longer treatment time (30 min to treat only the intravaginal canal) without the assurance that the tissue is heated uniformly. The BTL Ultra Femme heats homogeneously in all directions and eliminates operator error, and tissue is heated to the target temperature in a shorter time.

In a prospective study, Alinsod treated 23 female patients with mild to moderate vulvovaginal laxity, sexual dysfunction, and mild to moderate SUI using a transcutaneous temperature-controlled radiofrequency (TTCRF) device (ThermiVa, ThermiAesthetics) for approximately 5 min per zone (left and right labia majora; ventral, dorsal, left, and right surfaces of the vaginal wall). Clinical endpoint was achievement of the target temperature in the range of 40–45 ° C for approximately 3–5 min per zone. Total treatment time was <30 min. A complete treatment course consisted of three treatments with intervals of 4–6 weeks between treatments and followed up to 30 days after the last laser treatment. Six patients were lost to follow-up. Results showed statistically significant improvement in laxity with visible aesthetic improvement and significant reduction of orgasmic dysfunction. The patients with SUI and atrophic

vaginitis also reported resolution of these symptoms. The limitations of this study are small sample size, lack of a control group, and extremely short follow-up time (C)(2b) [71].

A proprietary procedure called the Geneveve treatment is performed using the only cryogen-cooled monopolar RF (CMRF) (Viveve, Sunnyvale, CA). The reverse thermal gradient cools and protects the surface mucosa, while delivering significant volumetric deep heating. Capacitive coupling ensures energy is distributed evenly across the treatment tip for uniform heating, while parameters and algorithms are preset for reproducible delivery of controlled heating and cooling. It is a 30-min treatment that works by targeting the vaginal introitus to rejuvenate collagen production, resulting in tightening and increase in sensation.

A pilot study by Millheiser in 2010 investigated transurethral monopolar radiofrequency (RF) for vaginal laxity after vaginal childbirth. Twenty-four premenopausal women who had at least one full-term vaginal delivery were included in this study. A seven-point vaginal laxity scale was used to assess subjective patient perception of laxity. Cryogen cooling was used concurrently with the RF probe inside the vagina to manage potential unwanted thermal damage due to overtreatment. At 1 month posttreatment, 67% of patients reported improvements of 2–4 points on the scale and all patients reported at least 1 point of improvement. By follow-up at 6 months, 87% of subjects reported improvement of 2–4 points. Of the 12 patients who had reported diminished sexual function following delivery, all reported notable improvement in sexual function as well. The procedure was well tolerated and no adverse events were reported. The author concluded that these findings warrant further study (C)(2b) [72].

Sekiguchi et al. more recently reported on a prospective study of low-energy radiofrequency (Viveve) for vaginal introital laxity of 30 premenopausal women, each receiving a 30-min treatment with follow-up at 6 and 12 months. Results showed statistically significant improvements in sexual function, vaginal laxity, and reductions in distress during sexual activity were noted at 6 months and maintained through the 12-month endpoint (C)(1b) [75].

The Viveve I trial is a prospective, randomized, single-blinded, and sham-controlled study. Nine study centers in Canada, Italy, Spain, and Japan participated. Premenopausal women presenting with vaginal laxity and having at least one full-term vaginal delivery were included in this study. Patients were randomized (2:1) to receive RF therapy Active (90 J/cm2) vs. Sham (1 J/cm2). Patients were followed up to 6 months posttreatment. A single treatment of RF therapy was found to be safe and associated with both improved vaginal laxity and improved sexual function. Treatment adverse events were reported by 11.1% in the Active group and 12.3% in the Sham group. This was the first randomized, controlled, blinded, clinical study of RF for the treatment of vaginal laxity (A)(1a) [76].

Observations and Recommendations

Nonablative erbium laser is an effective and safe treatment for a wide variety of gynecological disorders including but not limited to vaginal laxity and VRS, vaginal atrophy, GSM, and other symptoms associated with menopause, SUI, and uterine and pelvic organ prolapse (A). There is only one device (Intimalase and Incontilase, Fotona) that utilizes a nonablative erbium laser in an intravaginal device that delivers thermal energy to the entire vaginal wall without causing injury or ablation to the vaginal mucosa. The vast majority of studies in the medical literature on this subject are using the nonablative erbium laser (Intimalase and Incontilase, Fotona) which is the only device (with rare exception) that has been used on a large number of patients with long-term follow-up for SUI and pelvic organ prolapse (B).

Many different types of lasers including nonablative erbium, ablative and fractional erbium, fractional CO_2 lasers, and radiofrequency (RF) devices have been shown to be effective and safe for treatment of vaginal laxity, vaginal atrophy, and enhancement of sexual gratification (A).

Some preliminary observations and small studies have been made looking at the possibility of using ablative and fractional erbium, fractional CO_2, and RF devices for the treatment of SUI (none for pelvic organ prolapse), but there are limitations in performing adequate studies due to the invasive nature of the various lasers that may prevent the operator from being able to deliver enough heat to significantly tighten the pelvic floor and surrounding wall structures and delicate tissue around the urethral meatus without causing injury to the tissue, and also limitations in the delivery device to reach all areas within the vaginal canal and treat surrounding structures safely (C).

Randomized controlled trials with long-term follow-up, including comparative effectiveness trials to established procedures/treatments, are necessary to further evaluate the efficacy of these technologies. In the USA, the current view by the medical establishment thus far is that vaginal rejuvenation and vaginal tightening for any indication regardless of the procedure/device utilized are considered *investigational*.

In 2007 (reaffirmed 2014), the American College of Obstetrics and Gynecology (ACOG) issued a Committee Opinion number 378: Vaginal "Rejuvenation" and Cosmetic Vaginal Procedures that states: So-called 'vaginal rejuvenation,' 'revirgination,' and 'G-spot amplification' are vaginal surgical procedures being offered by some practitioners. These procedures are not medically indicated, and the safety and effectiveness of these procedures have not been documented. Clinicians who receive requests from patients for such procedures should discuss with the patient the reason for her request and perform an evaluation for any physical signs or symptoms that may indicate the need for surgical intervention. Women should be informed about the lack of data supporting the efficacy of these procedures and the potential complications, including infection, altered sensation, dyspareunia, adhesions, and scarring.

The ACOG position statement was issued in 2014 and there have been many studies published since then. The new research has been very promising, so the medical establishment may need to reexamine their opinion based on the newer evidence and especially as more studies are published. Despite the promising research, the skepticism and caution expressed by the medical establishment are warranted due to confusion and lack of understanding of the many different lasers being marketed for vaginal rejuvenation without adequate studies being performed by the vast majority of the companies. Most of the companies are copying the design of the nonablative erbium laser but using a different ablative laser wavelength and then marketing the device to physicians saying the laser can be used for the same applications and indications but without any studies to prove that the ablative laser would have the same efficacy and safety profile.

Self-Assessment Questions

1. What types of lasers are used for vaginal rejuvenation?
   (a) Nonablative erbium
   (b) Ablative erbium
   (c) Fractional CO_2
   (d) Combination fractional ablative erbium and nonablative diode
   (e) All of the above
2. What types of radiofrequency devices are used for vaginal rejuvenation?
   (a) Cryogen-cooled monopolar RF
   (b) Transcutaneous temperature-controlled RF
   (c) Bipolar RF
   (d) Monopolar RF with ring applicator
   (e) All of the above
3. What are the factors contributing to vaginal relaxation syndrome (VRS)?
   (a) Aging
   (b) Multiple pregnancies
   (c) Obesity
   (d) Cesarean deliveries
   (e) a and b
   (f) All of the above

4. What is the gold standard for treatment of stress urinary incontinence?
   (a) Diet reduction
   (b) Kegel exercise
   (c) Tension-free vaginal tape
   (d) Pessary
   (e) Electrical stimulation
5. What are risk factors for stress urinary incontinence?
   (a) Childbirth
   (b) Hyperestrogenism
   (c) Pregnancy
   (d) a, b, and c
   (e) a and c

Correct Answers

1. e
2. e
3. e: Obesity contributes to stress urinary incontinence and pelvic organ prolapse. VRS is associated with vaginal child delivery, natural aging, multiple pregnancies [vaginal deliveries, not C-section], and menopause.
4. c: Initial therapy consists of diet reduction, smoking cessation, bladder training, and pelvic floor muscle training such as Kegel's, but if these do not work, then the gold standard therapy has been tension-free vaginal tape.
5. e: Risks factors for SUI include congenital factors, pregnancy, childbirth, hypoestrogenism (not hyperestrogenism), cognitive impairment, obesity, and advanced age.)

Cosmeceuticals

30

Zoe Diana Draelos

Abstract

The terms cosmeceutical and evidence-based may not belong in the same phrase. Cosmeceuticals are considered by many scientists to represent fluff without stuff, and indeed the reader may come to a similar conclusion at the end of this chapter. Nevertheless, it is worthwhile to examine the state of the science for cosmeceuticals as they represent an ever-expanding field in dermatology with perhaps much yet unrealized promise. Cosmeceuticals extend beyond cosmetics to enhance skin functioning, usually aiming to return the skin to a more youthful state. For example, wrinkle-reducing moisturizers, antioxidant serums, and skin-lightening salves all fall into this category. Cosmeceuticals are somewhat confusing, however, as both prescription and over-the-counter (OTC) products have been labeled by this term. Drug cosmeceuticals include topical retinoids for improving dermal collagen production, topical minoxidil for enhanced scalp hair growth, and eflornithine for facial hair growth reduction. These products will not be discussed, as they are not available to the consumer except by prescription. The second category of cosmeceuticals includes OTC drugs, such as sunscreens and antiperspirants. These also are outside the realm of this chapter. The discussion will focus on cosmeceuticals that are topically applied for the purpose of improving skin appearance.

labeled by this term. Drug cosmeceuticals include topical retinoids for improving dermal collagen production, topical minoxidil for enhanced scalp hair growth, and eflornithine for facial hair growth reduction. These products will not be discussed, as they are not available to the consumer except by prescription. The second category of cosmeceuticals includes OTC drugs, such as sunscreens and antiperspirants. These also are outside the realm of this chapter. The discussion will focus on cosmeceuticals that are topically applied for the purpose of improving skin appearance.

Cosmeceutical Development

The marketing of new ingredients and formulations with captivating advertising claims drives the cosmeceutical realm. The unending introduction of new products on a monthly basis makes generalization difficult, yet there are some basic concepts that apply to cosmeceutical development. These will be reviewed to help the reader better interpret the evidence to support cosmeceutical efficacy. First, cosmeceuticals are basically cosmetics and as such must be safe. This means that the best source of new materials for formulation would be substances derived from either plants or food components. Second, cosmeceutical additives must be available as a powder or liquid, since the majority of cosmeceuticals must be elegantly applied to the external body. Third, cosmeceuticals must have some easily identifiable benefit upon which to base a functional claim. For all of these reasons, the majority of cosmeceutical ingredients have their origin in the botanical realm or in foods.

New cosmeceutical ingredients in the botanical realm are identified based on the algorithm presented in Table 30.1. Once the botanical active is identified and synthesized, it is typically applied to a fibroblast gene chip to determine if it affects any key cellular event. After demonstration of a presumed physiologic effect, the active is tested in vitro to determine an effect on cultured fibroblasts. If positive data are obtained, the active is studied in a mouse model for confirmation. The active is then placed in a vehicle suitable for human application and clinical studies are undertaken. Successful human clinical studies pave the way for successful introduction into the marketplace via ingredient licensing arrangements.

The search for botanicals suitable for formulation into cosmeceuticals has led to the gathering of flowers, seeds, roots, leaves, twigs, and berries from plants all over the world. It is important to remember, however, that the constituents of a plant component are influenced by the season in which the plant material was picked, the growing conditions, and the processing of the agent. These variables are summarized in Table 30.2.

Table 30.1 Steps in cosmeceutical ingredient development

1. New botanical material received in the laboratory
2. Various fractions of the botanical extracted
3. Fractions analyzed for relationship to known chemical compounds
4. Purified fraction exposed to gene array chip
5. Analysis completed for upregulation or downregulation of key events in cellular oxidation, inflammation, or irritation
6. New isolate studied in an in vitro model of cell culture for confirmation of gene array results
7. Positive in vitro findings lead to isolate analysis in mouse model, focusing on markers of possible cutaneous benefit
8. Positive mouse findings lead to formulation in a vehicle suitable for human use
9. Human model testing conducted to determine if active has any cutaneous value
10. Formulation fine-tuned and patented
11. New ingredient licensed to cosmetic manufacturer
12. New technology enters the marketplace

Table 30.2 Sources of cosmeceutical actives

Plant source Leaves, roots, fruits, berries, stems, twigs, barks, flowers
Growing conditions Soil composition, amount of available water, climate variations, plant stress
Harvesting conditions Time from harvest to transport, care of plant materials during shipping, storage conditions prior to manufacture
Preparation method Crushing, grinding, boiling, distilling, pressing, drying
Final extract status Liquid, powder, paste, syrup, crystal
Concentration Sufficient amount of active to produce biologic effect

Cosmeceutical Efficacy

Cosmeceuticals have been introduced for many different purposes including improving skin texture, radiance, smoothness, tone, and pigmentation. The main benefit of most cosmeceutical formulations is a reduction in transepidermal water loss from the application of occlusive and humectant ingredients to the skin surface. Occlusive substances include petrolatum, mineral oil, vegetable oils, lanolin, and silicone oils. Humectant substances include glycerin, sodium pyrrolidone carboxylic acid (PCA), hyaluronic acid, propylene glycol, and proteins. There is no doubt that skin hydration is an important cosmeceutical benefit known as moisturization. Most cosmeceutical ingredients are placed in a moisturizing vehicle, making placebo-controlled studies inadequate. Cosmeceutical efficacy must be determined based on a double-blind comparison between the vehicle and the cosmeceutical active as compared to the vehicle alone. This study design would provide the most compelling evidence that the cosmeceutical ingredient produced a documented benefit. As the reader will discover, few cosmeceutical ingredients are studied with this methodology.

The claims pertaining to skin texture, radiance, and smoothness are moisturizer claims. These are primarily derived from vehicle effects. The more novel antiaging claims that this chapter will investigate are improvements in skin tone and pigmentation. Skin tone is a somewhat ambiguous term by design to allude to improvement in the characteristics of the skin associated with aging. Most of the ingredients that deliver on this benefit are antioxidants. The claim of pigmentation improvement is related to the ability of the cosmeceutical to lighten melasma and lentigines while overall improving skin color. The rest of this chapter will be devoted to the evidence surrounding the efficacy of antioxidants and pigment-lightening ingredients in cosmeceutical formulations.

Antioxidants

Antioxidants form one of the most popular categories of cosmeceutical ingredients. This is due to the fact that the major cause of cutaneous aging is oxidation of skin structures from highly reactive oxygen molecules present in our oxygen-rich environment. It is amazing to think that the life-giving oxygen required to survive is also the same oxygen responsible for aging the human body. The primary source of cosmeceutical antioxidant ingredients is botanical extracts, since all plants must protect themselves from oxidation following UV exposure.

Antioxidant botanicals function by quenching singlet oxygen and reactive oxygen species, such as superoxide anions, hydroxyl radicals, fatty peroxy radicals, and hydroperoxides. There are many botanical antioxidants available from raw material suppliers to the cosmeceutical industry, which can be classified into one of three categories as carotenoids, flavonoids, and polyphenols. Carotenoids are chemically related to retinoids, while flavonoids possess a polyphenolic structure that accounts for their antioxidant, UV-protectant, and metal chelation abilities. Lastly, polyphenols represent a chemical subset of flavonoids. These classes of antioxidants are discussed utilizing popular ingredients to take an evidence-based approach.

Carotenoids

Carotenoids are derivatives of vitamin A and have found widespread use in cosmeceuticals due to the established topical antiaging benefits associated with the prescription retinoid tretinoin. The carotenoids are a large family of orange-, red-, and yellow-appearing substances that perform vital antioxidant roles when ingested and are less well established as topical antioxidants.

Astaxanthin

Astaxanthin is a pink carotenoid found in high concentration in salmon, accounting for the characteristic pink color of the fish. This is the rationale for antiaging diets recommending the ingestion of a serving of salmon five times weekly [1] (IV,B). For topical application purposes, astaxanthin is obtained from the marine microalgae *Haematococcus pluvialis.*

The efficacy of astaxanthin is attributed to its cell membrane, composed of two external lipid layers, which has been touted to possess stronger antioxidant abilities than vitamin E [2] (IV,B). It is both water and oil soluble, only being produced by algae when exposed to intense UV radiation.

Few topical studies exist to confirm the topical effect of astaxanthin [3] (VI,C), but it has been studied extensively as an oral supplement [4] (IV,B). It is used as a homeopathic treatment for macular degeneration because unlike canthaxanthin, another carotenoid, it does not crystallize in the eye. It crosses the blood–brain barrier and has been studied in brain dysfunction to include spinal cord injuries and Parkinson's disease [5] (VI,C). Even though other carotenoids, such as beta-carotene, have been proven ineffective in reducing the oxidative stress associated with cardiovascular disease, astaxanthin is currently undergoing further investigation [6] (IV,B).

Astaxanthin in concentrations of 0.03–0.07% produces a pink-colored cream. This limits the concentration that can be used, but no topical adverse reactions have been associated with this carotenoid. The topical antioxidant benefits of astaxanthin have not been established.

Lutein

Another carotenoid found in topical cosmeceuticals is lutein. It is naturally found in green leafy vegetables, such as spinach and kale. Lutein is an antioxidant in the plant kingdom, also being used for blue light absorption. In the animal kingdom, lutein is found in egg yolks, animal fats, and the corpus luteum. It is a lipophilic molecule, not soluble in water, characterized by a long polyene side chain composed of conjugated double bonds. These double bonds are degraded by light and heat, a universal characteristic of carotenoids to a greater or lesser degree [7] (IV,B).

Lutein is used as a natural colorant due to its orange-red color resulting from the absorption of blue light. Its largest use is as a food supplement for chickens, which results in more vivid yellow yolks. In humans, lutein is concentrated in the macula and has been linked to the prevention of macular degeneration [8] (IV,B). It has been available as a nutritional supplement since 1996 and can be administered as a sublingual spray for elderly patients with macular degeneration. Most well-conducted studies evaluating the benefit of lutein for macular degeneration have been inconclusive [9] (IV,B). No recommended daily allowance has been established for lutein, but 6 mg/day has been published [10] (VI,C). Most of the lutein used for food additives is derived from marigolds.

The question remains as to whether lutein topically is of value. Again, data are lacking, but excess lutein intake can result in carotenodermia, and excess topical application results in bronzing of the skin. It may be of interest that lutein fed to chickens results in the characteristic yellow appearance of chicken skin, which is felt to be more attractive than the natural white skin. I am not sure that this would be the case in humans.

Lycopene

Another potent carotenoid is lycopene, found in most fruits and vegetables with a red color including tomatoes, watermelon, pink grapefruit, papaya, gac, red bell pepper, and pink guava. The highest lycopene-containing food is ketchup, but lycopene is not an essential human nutrient. The Mayo Clinic website rates the evidence for the use of lycopene as an antioxidant as a C, since it is not clear if lycopene has these effects on the human body [11] (IV,B). Lycopene oral supplements have been purported to reduce the risk of prostate cancer, but the FDA concludes there is little scientific evidence to support this claim [12] (VI,C).

Lycopene is a highly unsaturated hydrocarbon containing 11 conjugated and 2 unconjugated double bonds, which makes it a longer molecule than any other carotenoid. This makes its absorption into the skin doubtful. It undergoes *cis*-isomerization possibly when exposed to sunlight. Even though lycopene was the new oral supplement added to many commercial multivitamins this year, its topical value has never been documented. It is safe for skin application, but may stain the skin in high concentration.

Table 30.3 Cutaneous effects of topical retinoids

Gross dermatologic effects
Improvement in fine and coarse facial wrinkling
Decreased tactile roughness
Reduction of actinic keratoses
Lightening of solar lentigines
Histologic dermatologic effects
Reduction in stratum corneum cohesion
Decreased epidermal hyperplasia
Increased production of collagen, elastin, and fibronectin
Reduction in tonofilaments, desmosomes, melanosomes
More numerous Langerhans cells
Angiogenesis
Decreased glycosaminoglycans
Reduced activity of collagenase and gelatinase
Normalization of keratinization of the pilosebaceous unit

Retinol

Of all the topical carotenoids, retinol is the best understood, since it is necessary for vision and possesses a well-characterized skin receptor [13] (II,A). Prescription retinoids, such as tazarotene and tretinoin, are well studied for their ability to induce the skin changes noted in Table 30.3; however, OTC retinoids may demonstrate some of the same effects, to a lesser degree [14, 15] (II,A).

It is theoretically possible to interconvert the retinoids from one form to another. For example, retinyl palmitate and retinyl propionate, chemically known as retinyl esters, can become biologically active following cutaneous enzymatic cleavage of the ester bond and subsequent conversion to retinol. Retinol is the naturally occurring vitamin A form found in red, yellow, and orange fruits and vegetables. It is the pigment responsible for vision, but is highly unstable. Retinol can be oxidized to retinaldehyde and then oxidized to retinoic acid, also known as prescription tretinoin. It is this cutaneous conversion of retinol to retinoic acid that is responsible for the biologic activity of some of the new stabilized over-the-counter vitamin A preparations designed to improve the appearance of benign photodamaged skin [16] (II,A). Unfortunately, only small amounts of retinyl palmitate and retinol can be converted by the skin, accounting for the increased efficacy seen with prescription preparations containing retinoic acid.

The main problem with prescription retinoids is their irritancy. Unfortunately, as the biological efficacy of the retinoid increases, so does the irritancy. This is also the case with the OTC retinoids. Retinol is more irritating than the retinyl esters and also more unstable. It is for this reason that cosmeceutical formulations not manufactured under strict oxygen-free conditions prefer to add retinyl palmitate to moisturizing creams. However, the retinyl palmitate may present to act as an antioxidant for the lipids present in the moisturizer.

The topical benefit of retinol has been documented by well-controlled studies [17] (II,A). It is commonly felt among dermatologists that retinol is of benefit [18] (IV,B), but it is difficult in moisturizer studies that do not include vehicle control to separate the retinol benefit from the moisturizer benefit. Nevertheless, of all the carotenoids available for formulation, retinol has the most evidence to support topical application efficacy.

Flavonoids

Flavonoids are aromatic compounds, frequently with a yellow color, that occur in higher plants. Five-thousand flavonoids have been identified with a similar chemical structure possessing 15 carbon atoms and possessing a variety of biologic activities (Table 30.4) [19] (VI,C). Flavonoids can be divided into flavones, flavonols, isoflavones, and flavanones, each with a slightly different chemical structure. Currently, the most

Table 30.4 Biologic activity of flavonoids

Photoprotection against UVB
Quenching of reactive oxygen species
Metal chelation
Inhibition of targeted enzymes
Hormonal modulation
Anti-inflammatory activity
Microorganism growth inhibition
Antioxidant effect of multiple organ systems

common isoflavones incorporated into cosmeceuticals are daidzein and genistein derived from soybeans. Other sources of flavonoids include curcumin, silymarin, pycnogenol, and gingko. These will be discussed next.

Soy

The soybean-derived isoflavones genistein and daidzein function as phytoestrogens when orally consumed and have been credited with the decrease in cardiovascular disease and breast cancer seen in Asian women [20] (III,B). These isoflavones are present when the soy is fermented [21] (II,B). Other purported systemic benefits include improvement in immunity [22] (IV,C), reduction of prostate cancer [23] (IV,C), and improvement in cognition [24] (IV,C). Some of the cutaneous effects of soy have been linked to its estrogenic effect in postmenopausal women. Topical estrogens have been shown to increase skin thickness and promote collagen synthesis [25] (II,A). It is interesting to note that genistein increases collagen gene expression in cell culture; however, there are no published reports of this collagen-stimulating effect in topical human trials. Genistein has also been reported to function as a potent antioxidant scavenging peroxyl radicals and protecting against lipid peroxidation in vivo [26] (III,B). The only studies that document the ability of soy to protect against UVB-induced skin damage are in mice where a topical application of nondenatured soy extracts reduced UVB-induced cyclooxygenase-2 expression and prostaglandin-E2 secretion and inhibited p38 mitogen-activated protein (MAP) kinase activation [27] (II,B).

Curcumin

Curcumin is a popular natural yellow food coloring used in everything from prepackaged snack foods to meats. It is sometimes used in skin care products as a natural yellow coloring in products that claim to be free of artificial ingredients. Curcumin comes from the rhizome of the turmeric plant and is consumed orally as an Asian spice, frequently found in rice dishes to color the otherwise white rice yellow. However, this yellow color is undesirable in cosmetic preparations, since yellowing of products is typically associated with oxidative spoilage. Tetrahydrocurcumin, a hydrogenated form of curcumin, is off-white in color and can be added to skin care products not only to function as a skin antioxidant but also to prevent the lipids in the moisturizer from becoming rancid. The antioxidant effect of tetrahydrocurcumin is said to be greater than vitamin E by cosmetic chemists. It is said to provide antioxidant skin benefits by quenching oxygen radicals and inhibiting nuclear factor-κB [28, 29] (V,C).

The effects of curcumin as a topical antioxidant in the skin have not been as well studied as its oral ingestion in rodents for the correction of cystic fibrosis defects and inhibition of tumor proliferation [30, 31] (V,C).

Silymarin

Silymarin is an extract of the milk thistle plant (*Silybum marianum*), which belongs to the aster family of plants including daisies, thistles, and artichokes. The plant is named milk thistle because the oldest recorded use of the extract was to enhance human lactation and the plant produces a white milky sap. The extract consists of three flavonoids derived from the fruit, seeds, and leaves of the plant. These flavonoids are silybin, silydianin, and silychristine. Homeopathically, silymarin is used to treat liver disease, but it is a strong antioxidant preventing lipid peroxidation by scavenging free radical species. Its antioxidant effects have been demonstrated topically in hairline mice by the 92% reduction of skin tumors following UVB exposure [32, 33] (VI,C). The mechanism for this decrease in tumor production is unknown, but topical silymarin has been shown to decrease the formation of pyrimidine dimers in a mouse model [34] (VI,C). It has also been found to improve the healing of burns in albino rats [35] (VI,C).

Silymarin is found in a number of high-end moisturizers for benign photoaging to prevent cutaneous oxidative damage and to reduce facial redness. A double-blind placebo-controlled study

in 46 subjects with stage I–III rosacea found improvement in skin redness, papules, itching, hydration, and skin color [36] (III,B). This was felt to be due to its direct activity on modulating cytokines and angiokines. Other well-controlled human trials are lacking.

Pycnogenol

Pycnogenol is an extract of French marine pine bark (*Pinus pinaster*), which grows only on the southwest coast of France in Les Landes de Gascogne. The extract is a water-soluble liquid containing several phenolic constituents, including taxifolin, catechin, and procyanidins. It also contains several phenolic acids, including p-hydroxybenzoic, protocatechuic, gallic, vanillic, p-couric, caffeic, and ferulic [37] (VI,C). It is a trademarked ingredient that is sold for oral consumption as a preventative for cardiovascular disease [38], a treatment for diabetic microangiopathy [39], and a pain reliever for muscle cramps [40] (IV,B). It is a potent-free radical scavenger that can reduce the vitamin C radical, returning the vitamin C to its active form [41] (VI,C). The active vitamin C in turn regenerates vitamin E to its active form, maintaining the natural oxygen-scavenging mechanisms of the skin intact.

Pycnogenol is the ideal antiaging additive since it demonstrates no chronic toxicity, no mutagenicity, no teratogenicity, and no allergenicity [42] (VI,C). It is consumed orally to enhance the production of nitric oxide, which inhibits platelet aggregation in coronary artery disease, thus it is also deemed safe for topical use. Its use for skin indications is less well documented, however. In B16 melanoma cells, it was shown to inhibit tyrosinase activity and melanin biosynthesis [43] (IV,B). Many discussions of antioxidant flavonoids include a mention of pycnogenol, but little quality data are presented [44] (VI,C).

Ginkgo

Ginkgo biloba, also named the maidenhair tree, is the last member of the Ginkgoaceae family, which grew on earth some 200–250 million years ago. For this reason, ginkgo contains flavonoids not found in other botanicals. It possesses bilobalide (a sesquiterpene), ginkgolides (diterpenes with 20 carbon atoms), and other aromatic substances such as ginkgol, bilobdol, and ginkgolic acid. It is a plant with numerous purported benefits which has been a common part of homeopathic medicine in the Orient for 4000 years. The plant leaves are said to contain unique polyphenols such as terpenoids (ginkgolides, bilobalides), flavonoids, and flavonol glycosides that have anti-inflammatory effects. These anti-inflammatory effects have been linked to antiradical and antilipoperoxidant effects in experimental fibroblast models [45] (IV,C). Ginkgo flavonoid fractions containing quercetin, kaempferol, sciadopitysin, ginkgetin, and isoginkgetin have been demonstrated to induce human skin fibroblast proliferation in vitro. Increased collagen and extracellular fibronectin were also demonstrated by radioisotope assay [46] (IV,C). Thus, ginkgo extracts are added to many cosmeceuticals to function as antioxidants and promoters of collagen synthesis based on nonhuman models of oxidative damage.

Polyphenols

Polyphenols are a subset of flavonoids used in many cosmeceuticals. Two main sources of polyphenols are teas and fruits. This section presents green tea and pomegranate as examples of the evidence available to support polyphenol biologic activity.

Green Tea

Tea, also known as *Camellia sinensis*, has been botanically popular in the Orient for 5000 years, used both topically and orally. Teas are a rich part of the Oriental culture used to stay alert during extended meditation. An Indian legend tells of a Prince Siddhartha Gautama, the founder of Buddhism, who tore off his eyelids in frustration over his inability to stay awake

during meditation. A tea plant is said to have sprouted from where his eyelids fell, providing the ability to stay awake, meditate, and reach enlightenment. Tea reached Western cultures during the sixth century from Turkish traders.

There are several different types of teas: green, black, oolong, and white. The different teas come from the same plant, but different processing imparts different properties. Green tea is made from unfermented tea leaves and contains the highest concentration of polyphenol antioxidants [47] (VI,B). Black tea leaves are fermented days before heating. Oolong tea originates in the Fukien province of China, and the leaves are treated much like black tea, except that the withering and fermentation times are minimized. White tea comes from young tea leaves that are harvested for a few days each spring when the plant emerges from the ground. These leaves are said to be very high in antioxidants. The highest-quality white tea is obtained from buds that are just ready to open, known as needles or tips.

The evidence to support the anticancer benefits of topical and oral green tea use was felt to be inadequate by the FDA. On June 30, 2005, the FDA concluded, "that there is no credible evidence to support qualified health claims for green tea consumption and a reduced risk of gastric, lung, colon/rectal, esophageal, pancreatic, ovarian, and combined cancers. Thus, the FDA is denying these claims. However, FDA concludes that there is very limited credible evidence for qualified health claims specifically for green tea and breast cancer and for green tea and prostate cancer, provided the claims are appropriately worded so as not to mislead consumers" [48] (VI,C). In addition, the evidence to support cardiovascular benefits was inadequate. On May 9, 2006, in response to "Green Tea and Reduced Risk of Cardiovascular Disease," the FDA concluded "there is no evidence to support qualified health claims for green tea or green tea extract and a reduction in a number of risk factors associated with cardiovascular disease" [49] (VI,C). Some FDA advisers have voiced concern that teas may contain high levels of pesticides and heavy metals.

Green tea is manufactured from both the leaf and bud of the plant. Orally, green tea is said to contain beneficial polyphenols, such as epicatechin, epicatechin-3-gallate, epigallocatechin, and eigallocatechin-3-gallate (EGCG), which function as potent antioxidants [50] (IV,B). EGCG is the most potent of the polyphenols, sold as a white caffeine-free powder [51] (VI,C). Oral studies with EGCG have demonstrated increased fat oxidation and improvements in heart rate and serum glucose levels with 300 mg [52, 53] (V,B). Other alkaloids present in green tea include caffeine, theobromine, and theophylline.

Green tea can be easily added to topical creams and lotions designed to combat the signs of photoaging, but it must be stabilized itself with an antioxidant, such as butylated hydroxytoluene. The Mayo Clinic Drugs and Supplements rates the evidence to support green tea as a photoprotectant as a C [54] (VI,C).

A study by Katiyar et al. demonstrated the anti-inflammatory effects of topical green tea application on C3H mice. A topically applied green tea extract containing GTP ((−)-epigallocatechin-3-gallate) was found to reduce UVB-induced inflammation, as measured by double skin-fold swelling [55] (IV,B). They also found protection against UV-induced edema, erythema, and antioxidant depletion in the epidermis. This work was further investigated by applying GTP to the back of humans 30 min prior to UV irradiation, which resulted in decreased myeloperoxidase activity and decreased infiltration of leukocytes as compared to untreated skin [56] (III,B).

The application of topical green tea polyphenols prior to UV exposure has also been shown to decrease the formation of cyclobutane pyrimidine dimers [57] (IV,B). These dimers are critical in initiating UV-induced mutagenesis and carcinogenesis, which represent the end stage of the aging process. Thus, green tea polyphenols can function topically as antioxidants, anti-inflammatories, and anti-carcinogens, making them a popular cosmeceutical additive [58, 59] (III,B).

Pomegranate

Similar to lycopene, another oral supplement appearing in health drinks and vitamin is pomegranate extract. Pomegranate, botanically known as *Punica granatum*, is a deciduous tree bearing a red fruit native to Afghanistan, Pakistan, Iran, and Northern India [60]. It was brought to California by the Spanish settlers in 1769 and is commercially cultivated for its juice. The pomegranate became famous in Greek mythology when Persephone was kidnapped by Hades and taken to the Underworld to be his wife. Persephone had consumed four pomegranate seeds while in the Underworld and thus had to spend 4 months every year in Hades, during which time nothing would grow. This gave rise to the season of winter.

Pomegranate juice, commonly consumed in the Middle East, provides about 16% of the adult requirement of vitamin C per 100 mg serving. It also contains pantothenic acid, also known as vitamin B5, potassium, and antioxidant polyphenols. These substances have been demonstrated to protect against UVA- and UVB-induced cell damage in SKU-1064 human skin fibroblasts [61] (IV,B). Pomegranate juice has also been purported to reduce oxidative stress, affect low-density lipoprotein (LDL), and platelet aggregation in humans and apolipoprotein e-deficient mice [62, 63] (IV,B). It has also been studied for improving hyperlipidemia in diabetic patients [64] (IV,B).

Other Antioxidants

Aloe Vera

Probably the most widely used cutaneous botanical anti-inflammatory is aloe vera. The mucilage is released from the plant leaves as a colorless gel and contains 99.5% water and a complex mixture of mucopolysaccharides, amino acids, hydroxy quinone glycosides, and minerals. Compounds isolated from aloe vera juice include aloin, aloe emodin, aletinic acid, choline, and choline salicylate [65] (VI,C). Reported cutaneous effects of aloe vera include increased blood flow, reduced inflammation, decreased skin bacterial colonization, and enhanced wound healing [66] (VI,C). The anti-inflammatory effects of aloe vera may result from its ability to inhibit cyclooxygenase as part of the arachidonic acid pathway.

The MedlinePLus Herbs and Supplements rates the evidence to support the use of aloe vera in the treatment of dry skin and burns as a C. Other studies have evaluated the effect of aloe vera on burn wounds and acne [67, 68] (V,C). Aloe vera cream was found to show no tanning or sunburn protection and no efficacy in sunburn treatment as compared to placebo [69] (III,B). Reuter et al. studied a 97.5% concentration of aloe vera for its anti-inflammatory effects and demonstrated positive results in a sunburn cell assay as compared to 1% hydrocortisone [70] (III,B). These data provide evidence for the anti-inflammatory effect of pure aloe vera gel; however, most products sold over-the-counter for under $10 do not contain a high enough percentage of aloe vera to induce clinically relevant inflammation reduction.

Coenzyme Q10

An endogenous antioxidant that has been incorporated into antiaging moisturizers is Coenzyme Q10, also known as ubiquinone or CoQ10. For a topical antioxidant to be clinically effective, it must penetrate into the skin. Hoppe and colleagues from Beiersdorf demonstrated the topical penetration of Coenzyme Q10 into the viable epidermis and a reduction in oxidation as measured by weak photon emission. They were also able to show a significant decrease in the expression of collagenase in human dermal fibroblasts following UVA radiation and improvement in orbital wrinkling [71, 72] (III,B). However, oral supplementation had no effect on the main antioxidant defenses or prooxidant generation in tissues in mice. It also did not affect the life span in mice according to Sohal et al. [73] (III,B). A human study by Passi et al. administered 50 mg

vitamin E, 50 mg Coenzyme Q10, and 50 mg selenium. An increase in stratum corneum Coenzyme Q10 was noted after 15 and 30 days of ingestion, but the significance of this finding was not evaluated [74] (II,B).

Other evidence suggests that topical Coenzyme Q10 may provide additive antioxidant benefits when combined with colorless carotenoids phytoene and phytofluene. This effect was demonstrated in fibroblast cultures [75] (IV,C).

Pigment-Lightening Agents

Facial hyperpigmentation is one of the most common signs of photoaging. Many different patterns can be seen. Focal hyperpigmentation in the form of small lentigines across the lateral cheeks usually begins at about age 25–30, depending on cumulative sun exposure, with continued accumulation of lesions throughout life. Pigmentation can also present in the form of melasma with reticulated pigment over the sides of the forehead, lateral jawline, and upper lip. Lastly, hyperpigmentation can present as overall darkening of the skin from a combination of melanin pigment, fragmented elastin fibers, and residual hemosiderin. Cosmeceutical treatments for hyperpigmentation are problematic. A successful treatment must remove existing pigment from the skin, shut down the manufacture of melanin, and prevent the transfer of existing melanin to the melanosomes.

Many cosmetic products are available to lighten skin and improve even skin tone. These products typically do not contain hydroquinone, but rather other botanically derived products that interrupt melanin synthesis. These botanicals include ascorbic acid, licorice extract, alpha-lipoic acid, kojic acid, aleosin, and arbutin. Hydroquinone has been eliminated from most cosmetics, since the European Union and Asia have removed hydroquinone from the over-the-counter market. Most cosmetic companies are international in their distribution and formulate for the global market and not the US market specifically, where over-the-counter hydroquinone is still allowed. This section evaluates the data to support the efficacy of the most popular botanicals in skin lightening.

Ascorbic Acid

Ascorbic acid, also known as vitamin C, is used in cosmeceuticals for hyperpigmentation because it interrupts melanogenesis by interacting with copper ions to reduce dopaquinone and blocks dihydrochinindol-2-carboxyl acid oxidation [76] (II,A). Ascorbic acid, an antioxidant, is rapidly oxidized when exposed to air with limited stability. For this reason, many cosmeceuticals are using the more stable magnesium ascorbyl phosphate, which is metabolized to ascorbic acid in the skin. High concentrations of ascorbic acid must be used with caution, however, as the low pH can be irritating to the skin. Pigment-lightening cosmeceuticals may contain ascorbic acid as a pH adjustor or to function as an antioxidant preservative. It is important to recognize that ascorbic acid is a multifunctional ingredient with very minimal pigment-lightening capabilities.

Licorice Extract

Licorice extracts are found in cosmeceuticals to decrease facial redness and reduce pigmentation. The extract contains liquiritin and isoliquiritin, which are glycosides containing flavonoids [77] (III,B), which induce skin lightening by dispersing melanin. To see clinical results, the liquiritin must be applied in the dose of 1 g/day for 4 weeks. Irritation is not a side effect as is so frequently observed with hydroquinone and ascorbic acid, but efficacy is minimal.

Alpha-Lipoic Acid

Alpha-lipoic acid is found in a variety of antiaging cosmeceuticals to function as an antioxidant [78] (II,B), but it may also have very limited pigment-lightening properties. It is a disulfide derivative of octanoic acid that is able to inhibit tyrosinase. However, it is a large molecule, and

cutaneous penetration to the level of the melanocyte is challenging, significantly reducing its efficacy.

Kojic Acid

Kojic acid, chemically known as 5-hydroxymeth yl-4H-pyrane-4-one, is one of the most popular cosmeceutical skin-lightening agents found in cosmetic over-the-counter skin-lightening creams distributed worldwide. It is a hydrophilic fungal derivative obtained from *Aspergillus* and *Penicillium* species. It is the most popular agent employed in the Orient for the treatment of melasma; however, it is highly unstable [79] (IV,B). Newer formulations have incorporated kojic dipalmitate, but the efficacy of this derivative has not been well studied. Some research indicates that kojic acid is equivalent to hydroquinone in pigment-lightening ability [80] (IV,B). The activity of kojic acid is attributed to its ability to prevent tyrosinase activity by binding to copper.

Aleosin

Aleosin is a low-molecular-weight glycoprotein obtained from the aloe vera plant. It is a natural hydroxymethylchromone functioning to inhibit tyrosinase by competitive inhibition at the DOPA oxidation site [81, 82] (IV,B). In contrast to hydroquinone, it shows no cell cytotoxicity; however, it has a limited ability to penetrate the skin due to its hydrophilic nature. The effects of aleosin have been largely demonstrated in pigmented skin equivalents, not human use studies [83] (IV,B). It is sometimes mixed with arbutin, our next topic of discussion, to enhance its skin-lightening abilities.

Arbutin

Arbutin, chemically known as 4-hydroxyphenyl-beta-glucopyranoside, is obtained from the leaves of the *Vaccinium vitis-idaea* and other related plants. It is a naturally occurring glucopyranoside that causes decreased tyrosinase activity without affecting messenger RNA expression [84] (IV,C). It also inhibits melanosome maturation. Arbutin is not toxic to melanocytes and is used in a variety of pigment-lightening preparations in Japan at concentrations of 3%. Higher concentrations are more efficacious than lower concentrations, but a paradoxical pigment darkening may occur. Arbutin-beta-glycosides have been produced that are less cytotoxic than arbutin [85] (VI,C).

Growth Factors

Growth factors are the newest cosmeceutical ingredients to enter the marketplace. Since growth factors are instrumental in modulating cellular behavior, their ability to improve the functioning of aging skin cells represents intriguing technology. Of the many human growth factors, epidermal growth factor (EGF) is most important due to its direct influence on keratinocyte growth and differentiation [86] (5,A). The concept of growth factor incorporation into moisturizers began with the utilization of spent fibroblast media derived from the culture of fetal foreskins [87] (5,A). This spent media was previously discarded as the fibroblasts were cultured for a variety of medical uses. The spent media contained some remaining unused nutrients and numerous substances secreted by the fibroblasts during their growth [88] (5,B). The spent media product utilized a unique two-chamber design whereby the fibroblast media was dispensed from one orifice while the moisturizer was expressed from a second separate orifice. The two chambers were encased in a single tube dispenser.

This early growth factor introduction and the increased ability to engineer problems led to synthesis of recombinant growth factors and their incorporation into cosmeceutical moisturizers. The recombinant manufacturing technique removed the materials obtained from the host, insuring increased purity and quality, without possible contamination. Further, the technique allowed a standardized dose to be obtained, which provided for better clarification of how a

specific amount of growth factor affected skin appearance. However, growth factors are large protein molecules with limited penetration through the stratum corneum, thus the recombinant growth factor can be formulated as a lyophilized powder subsequently placed into a nano-liposome solution for enhanced delivery [89] (5,C). This novel approach to delivery overcomes some of the prior challenges in formulating growth factor-containing cosmeceuticals.

Another technology involves deriving growth factors from neonatal fibroblasts cultured in a bioreactor on dextran microcarrier beads under low oxygen conditions (1–5%) mimicking embryonic conditions. The cells are cultured for 8 weeks without the need for fetal bovine serum constituents in the final product. This method creates two products. The first is a naturally secreted extracellular matrix (ECM) used in wound healing, and the second is the hypoxic conditioned culture media (HCCM) for antiaging appearance improvement purposes. The HCCM is then concentrated using a 10 kDa filter and tested for sterility, as well as the following constituents: endotoxin, vascular endothelial growth factor (VEGF), and keratinocyte growth factor (KGF) [90] (5,A). An analysis of the HCCM material as compared to standard cell conditioned media cultured under normoxic conditions revealed that the hypoxic culture environment resulted in a 11.51-fold increase in KGF and a 4.33-fold increase in VEGF-B [91] (5,B). This multipotent growth factor has been investigated in healing diabetic foot ulcers [92] (5,C), improving appearance in facial aging [93] (5,C), and treating adverse events associated with photodynamic therapy [94] (5,C).

Cosmeceutical Barrier Cream Devices

A new use of cosmeceuticals is approval through the 510 K route of devices designed to improve the skin barrier. These creams utilize ingredients found in OTC products, but obtain approval to become medical devices and are designed to be used in conjunction with prescription products in the treatment of dermatoses demonstrating barrier defects, such as eczema and atopic dermatitis. While these products are regulated as devices, they are utilized as cosmeceuticals because they contain moisturizing ingredients combined with other OTC technologies to improve skin appearance and functioning.

Typically, these cosmeceuticals contain a moisturizing vehicle to which ingredients to build the intercellular lipids, minimize itch, and reduce inflammation are added. Most vehicles contain dimethicone and petrolatum as occlusive moisturizers to create a temporary skin barrier, combined with glycerin as a humectant to attract and hold water in the stratum corneum and epidermis. In order to speed barrier repair, some products contain pseudoceramides, which are synthetic ceramides designed to augment the natural ceramides present in the intercellular lipids deficient in many eczematous dermatoses. One example of such a ceramide is ceramide PC-104, with the corresponding chemical name *N*-(3-hexadecyloxy-2-hydroxypropyl)-*N*-2-hydroxyethylhexadecanamide. It is a synthetic pseudoceramide free of contaminants, as many natural ceramides are derived from bovine sources [95] (5,A) [96] (5,A). Topical pseudoceramides have been shown to improve stratum corneum water holding properties and facilitate barrier repair important in sensitive skin conditions [97] (5,B), [98] (5,B), [99] (5,B).

The second need of a sensitive skin moisturizer is itch reduction. Palmitoylethanolamine (PEA), also known as palmitamide MEA, belongs to the family of *N*-acylethanolamines (NAE). Cells naturally produce these substances in order to downregulate the inflammatory response via cannabinomimetic action on cannabinoid (CB) receptors [100] (5,A). This observation has led to the postulation that this family of molecules might possess analgesic, antioxidant, and anti-inflammatory skin benefits. CB 1 receptors are found in the brain and peripheral tissues, while CB 2 receptors are distributed throughout the immune system and in cutaneous nerve fibers [101] (5,A). Cannabinoid receptor agonists, such as PEA, reduce histamine-induced itch and

vasodilation when applied topically prior to histamine [102] (5,A), [103] (5,A).

The third need of sensitive skin is inflammation reduction. Many of the antioxidants previously discussed in this chapter also function as anti-inflammatory ingredients and are used in barrier repair cosmeceuticals for this purpose. Commonly used anti-inflammatory botanicals include grape seed extract, which contains the antioxidants proanthocyanidin and polyphenol, and a licorice extract, containing glycyrrhetinic acid. Proanthocyanidin possesses antioxidant free radical neutralizing effects 20 times more potent than vitamin C and 50 times more potent than vitamin E [104] (5,C).

Summary

Cosmeceuticals form an important part of the over-the-counter skin treatment market, but evidence for efficacy is clearly lacking. This chapter has scanned the reputable literature looking for research to substantiate the use of topical antioxidants and pigment-lightening agents to improve skin functioning and appearance. It may be surprising that so little good research has been conducted on products that are ubiquitous in the current marketplace. While there is never a good rationale for product sales without documentation, many cosmetic manufacturers are slow to engage in this type of research. Data that demonstrate convincing efficacy in large double-blind, vehicle-controlled trials would possibly raise the specter that a previously classified over-the-counter formulation could be reclassified as a drug.

An excellent example of reclassification is a lash growing cosmetic that was removed from the market by the FDA. A liquid for stimulating lash growth was recently marketed by a physician and spa dispensed cosmeceutical company. The product performed amazingly well, resulting in documentable lash lengthening after 3 months of use. The product enjoyed high sales until it was discovered that the product contained a chemical similar to a prescription glaucoma drug. The product was removed from the market because the FDA felt that the drug had been misbranded as a cosmetic. Products that perform too well are subject to inspection.

Development of a cosmeceutical category, similar to the quasi-drug category in Japan, would pave the way for better evidence in the cosmeceutical realm. This would provide an open opportunity for manufacturers to fully understand the efficacy or lack thereof for specific ingredients and final formulations. Until this legislation in enacted, cosmeceuticals will lack the evidence-based knowledge required for legitimacy.

Evidence-Based Summary

1. Cosmeceuticals are unregulated cosmetics that do not always adhere to evidence-based scientific methods of study.
2. The most active ingredients in cosmeceuticals are the moisturizing ingredients that compose the vehicle, which is challenging when conducting vehicle-controlled studies as part of an evidence-based approach.
3. Antioxidants are a major category of cosmeceuticals, which include carotenoids, flavonoids, and polyphenols.
4. Developing evidence-based therapeutic antioxidants is challenging because antioxidants provide protection against future oxidative skin insults and cannot repair past damage, requiring large sample size multiyear longitudinal studies.

Self-Assessment Questions

1. How do antioxidants function to prevent oxidative damage?
   (a) Antioxidants quench singlet oxygen through electron translocation.
   (b) Antioxidants donate an electron to reactive oxygen species.
   (c) Antioxidants consume oxygen to stabilize reactive oxygen species.
   (d) a and b
   (e) b and c
   (f) a and b and c
2. The carotenoids include
   (a) Astaxanthin
   (b) Soy
   (c) Lutein
   (d) Lycopene
   (e) a and b and c
   (f) a and c and d
3. Cosmeceutical pigment-lightening agents function by
   (a) Inhibiting tyrosinase
   (b) Stabilizing melanin
   (c) Providing photoprotection
   (d) a and b
   (e) a and c
   (f) a and b and c
4. Cosmeceuticals are classified in the United States as
   (a) Over-the-counter drugs
   (b) Quasi-drugs
   (c) Prescription drugs
   (d) No classification currently exists
   (e) a and b
   (f) a and d
5. Cosmeceutical ingredients are derived from
   (a) Leaves
   (b) Twigs
   (c) Animals
   (d) Algae
   (e) a and b
   (f) All of the above

Correct Answers

1. b: Antioxidants donate an electron to reactive oxygen species. Reactive oxygen species are highly energetic and damaging to the skin due to loss of an electron. Antioxidants possess an extra electron that can be donated. Once the antioxidant donates an electron, it becomes oxidized itself.
2. f: a and c and d. Astaxanthin, lutein, and lycopene are all carotenoids. Lycopene is rich in tomatoes, while lutein is found in egg yolks and is necessary for oxidative protection of the retina. Astaxanthin is present in salmon.
3. e: a and c. Unfortunately, there are no substances yet discovered that stabilize melanin. Substances that induce skin lightening do so by decreasing melanin production. This can be accomplished by decreasing tyrosinase, the rate-limiting step in melanin synthesis, or preventing pigment darkening through photoprotection.
4. d: No classification currently exists. Cosmeceuticals are considered cosmetics by the US FDA, and thus no classification currently exists.
5. f: All of the above. All parts of the plant are used as botanical ingredients in cosmeceuticals. Each part possesses different ingredients, which are largely antioxidants, conferring different purported skin benefits.

Repairs of the Ear

31

Sean R. Christensen and Christopher R. Stamey

Abstract

The external ear, or auricle, is a complex three-dimensional structure with an intricate topography that presents unique reconstructive challenges. Consideration of the anatomic, functional, and cosmetic requirements of the auricle facilitates effective surgical reconstruction. Repairs of the ear can be divided into four major categories that address these requirements in different ways: linear and wedge repairs, skin grafts, single-staged flaps, and multi-staged flaps. There is strong evidence to support the efficacy and safety of auricular reconstruction, and specific categories of repair are optimally suited to particular types of defects. However, with few exceptions, there is a paucity of high-level evidence that directly compares the outcomes of one repair type to another. This chapter provides an evidence-based review of each of the major categories of auricular reconstruction. As an alternative to reconstruction, healing by second intention can be a viable option for surgical defects of the ear, and long-term functional and cosmetic outcomes may be comparable to primary repair for appropriately selected defects.

Keywords

Surgical reconstruction · Linear repair · Wedge repair · Local cutaneous flap · Chondrocutaneous flap · Interpolation flap · Skin graft · Second intention healing

Introduction

The external ear, or auricle, is a complex three-dimensional structure with an intricate topography. An understanding of this structure and its individual anatomic subunits is essential for optimal surgical reconstruction. Different reconstructive techniques may be best suited for specific auricular defects based on size, depth, and anatomic subunits affected. In the most simplistic categorization, the ear can be considered to have two surfaces: the anterior (lateral) and posterior (medial) surfaces. The posterior surface of the auricle is composed of epidermis, dermis, and a thin layer of subcutaneous adipose that is loosely affixed to the relatively smooth contour of the underlying cartilaginous structure. The skin of the posterior surface has moderate laxity, is adjacent to a large reservoir of redundant skin in the

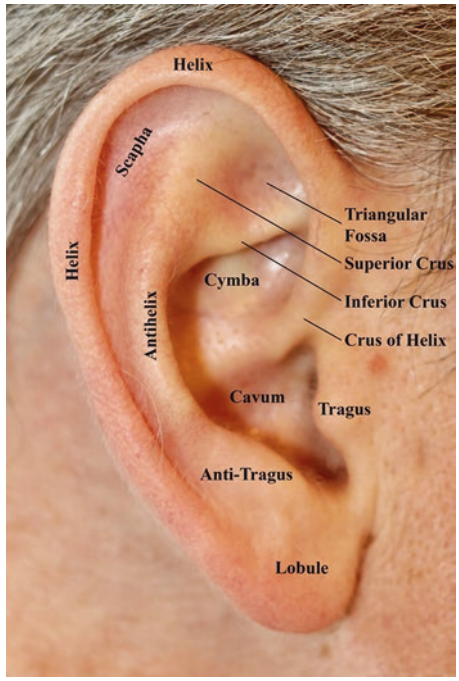

Fig. 31.1 Surface anatomy of the anterior (lateral) auricle. As discussed in the text, the main cartilaginous ridges are the helix with its crus and the antihelix with its superior and inferior crura. The cymba and the cavum together comprise the conchal bowl, which is contiguous with the external auditory canal. The lobule is largely devoid of cartilaginous support

postauricular crease, and is generally amenable to various methods of surgical manipulation. The skin of the anterior surface, in contrast, is composed of epidermis and a thinner dermis that is adherent to the undulating ridges and furrows of the more complicated cartilaginous structure. These ridges define the key anatomic subunits of the auricle as depicted in Fig. 31.1. Recognizable cartilaginous ridges are the helix and its crus, the antihelix and its crura, and the tragus and antitragus. The concavities between these ridges include the scapha, triangular fossa, and the cymba and cavum, which together comprise the conchal bowl that is contiguous with the external auditory canal. The lobule is the inferior portion of the ear that is largely devoid of cartilaginous support.

Consideration of the anatomic, functional, and cosmetic requirements of the auricle facilitates effective surgical reconstruction while minimizing the risk of significant complications. This chapter aims to provide an evidence-based framework with which to guide auricular reconstruction. While there is substantial evidence to support the efficacy and safety of auricular reconstruction in general, there is limited high-quality evidence comparing different operative techniques. Experience and judgment are required to select the optimal method of reconstruction for individual defects in unique patients and clinical scenarios.

Indications for Auricular Reconstruction

For dermatologic surgeons, the majority of reconstructive needs arise after surgical excision of malignant neoplasms including basal cell carcinoma, squamous cell carcinoma, and melanoma. While the resulting surgical defects may be extensive, the remaining adjacent skin and cartilage of the ear usually provide an adequate framework for immediate reconstruction. It is critical, however, to ensure that all surgical margins are free of carcinoma prior to surgical reconstruction, particularly in cases that require significant tissue rearrangement. In cases when immediate pathologic margin verification is not possible, delayed reconstruction should be considered. The surgeon can be confident that a delay of 1–3 weeks will not affect the final outcome, particularly in light of the fact that most excisional wounds of the auricle are able to heal completely by second intention (see Alternative Procedures below).

Aside from excision of malignant tumors, other conditions of the ear may benefit from surgical reconstruction. Benign tumors such as epidermal cysts can often be simply excised, and the resulting defects repaired with simple or more advanced reconstructive techniques as indicated (4) [1]. Keloids and hypertrophic scars can be repaired with a variety of reconstructive techniques but with the important addition of adjuvant therapy such as intralesional corticosteroids to prevent recurrence (4) [2–5]. Traumatic injury of the ear, most commonly affecting the helical rim or lobule, is also amenable to reconstruction

with many of the surgical approaches described in this chapter. Complete ear reconstruction for congenital malformations or massive thermal or physical injury is outside the scope of practice of most dermatologic surgeons and will not be discussed here. The reader is referred to the otolaryngology and plastic surgery literature for detailed discussion of these techniques [6, 7].

Effectiveness of Auricular Reconstruction

The goal of auricular reconstruction is to achieve complete wound closure while preserving the cosmetic appearance and functional requirements (patent external auditory meatus for sound conduction and physical support structure for eyeglasses or hearing aids) of the external ear. This should be accomplished with a minimum of discomfort or risk to the patient. Based upon published studies in the literature, auricular reconstruction in general is remarkably effective in appropriately selected patients. As outlined in Tables 31.1, 31.2, 31.3, and 31.4, over 2500 cases have been reported with successful outcomes and a low rate of complications (<5% overall). In most reported studies, cosmesis and adequate closure of the surgical defect were primary outcomes. Cosmesis was primarily measured in terms of ear contour, symmetry, and normal projection angle from the head (lack of protrusion or pinning of the affected ear). Many studies also described patient perceptions of cosmetic outcome in the form of visual analog scales, which may provide a more reliable measure of patient satisfaction. Most published studies on auricular reconstruction, as discussed in detail below, are retrospective series without defined inclusion and exclusion criteria and without systematic outcomes assessment. This somewhat limits the applicability of these results to all patients, and the surgeon must therefore exercise care in appropriate patient selection when considering reconstructive techniques. Additional research is likely to improve our understanding of which techniques are best suited to specific defects or clinical scenarios and which techniques may optimize efficiency in terms of healing time and financial burden.

Preoperative Evaluation

During the preoperative evaluation, past medical and surgical history, social history (including substance use), medication use, and overall functional status are essential factors to consider. It is important to note that older patients or patients in poor general health may be unable to tolerate lengthy or complex procedures. In these patients, simpler methods of reconstruction, even those that result in less than optimal cosmetic results, may be more appropriate, although there is a lack of specific evidence to support this. Tobacco use is often noted as a critical factor affecting reconstructive outcomes. In a prospective trial of antibiotic use for skin grafts on the nose, Kuijpers et al. found that smoking was associated with an increased rate of graft failure: at 1 week, mean graft survival was 81% in non-smokers and only 38% in smokers (2b) [8]. This finding is supported by larger studies in patients undergoing plastic surgery revealing higher rates of wound healing complications and dehiscence in smokers. Goltsman et al. found that smokers had a higher likelihood of surgical complications (OR, 1.37; $p < 0.0001$), medical complications (OR, 1.24; $p = 0.0323$), wound complications (OR, 1.49; $p < 0.0001$), and wound dehiscence (OR, 1.84; $p < 0.0001$) (2b) [9]. Additional studies also provide evidence to support grade A/B recommendations in favor of discontinuing smoking prior to reconstructive surgery procedures [10].

Indications for prophylactic antibiotic use to prevent infection at the site of ear reconstruction, as in dermatologic surgery in general, remain poorly defined. The majority of studies on ear reconstruction do not specifically comment on the use of prophylactic antibiotics. In three studies utilizing second intention healing and full-thickness skin grafting, prophylactic antibiotics were prescribed although the criteria for use were not specified [11–13]. However, the overall rate of soft tissue skin infections in all reconstructive methods, with or without antibiotics, was

Table 31.1 Wedge and linear

Author, year	Reference	Study type	Intervention	Size of study	Complications/adverse events	Outcome	Level of evidence
Reddy (2004)	[31]	Retrospective case series	Linear repair (among others for various defects)	9 linear repairs	No complications reported	Satisfactory form and function (not specifically defined)	4
Ibrahim (2014)	[30]	Retrospective case series	Linear repair (among others for various defects)	4 linear repairs	No complications reported	Satisfactory form and function (not specifically defined)	4
Kitchens (1989)	[33]	Retrospective case series	Wedge repair of auricular defects	30 patients	No complications reported	Subjectively reported as good cosmesis in all patients	4
Taylor (2014)	[34]	Retrospective case series	Wedge repair of helix defects	12 patients	Mild ear projection in all patients	Satisfactory cosmesis, mean score 9.08 (of 10) on visual analog scale	4

Table 31.2 Grafts

Author, year	Reference	Study type	Intervention	Size of study	Complications/adverse events	Outcome	Level of evidence
Full-thickness skin grafts (FTSG)							
Dessy (2010)	[19]	Randomized prospective trial	Pedicled flap vs FTSG for conchal defects	40 patients (20 flaps and 20 FTSG)	30% of FTSG had partial necrosis and delayed healing	Significantly higher visual analog scores with flap reconstruction	2b
Hochwalt (2015)	[11]	Retrospective cohort study	FTSG vs second intention healing of helix defects	18 FTSG vs 29 defects with second intention healing (SIH)	No difference in minor complications (12% SIH vs 14.3% FTSG)	No statistical difference in VAS scores	2b
Trufant (2016)	[35]	Retrospective case series	FTSG	1519 grafts	1.2% graft failure, 0.3% hematoma, 0.1% infection rate	Subjectively reported as good to excellent cosmesis	4
Leibovitch (2006)	[12]	Prospective case series	FTSG	216 grafts	<3% partial failure, <1% contracture, trapdoor, complete failure, infection, acute bleeding	Satisfactory form and function (not specifically defined)	4
Petersen (2015)	[36]	Retrospective case series	FTSG	43 grafts	Partial necrosis/crusting in 2 patients, 1 infection	Subjectively reported as good cosmesis	4
Split-thickness skin grafts (STSG)							
Wines (2001)	[40]	Retrospective case series	Skin graft (and other) repairs of conchal bowl	152 STSG, 32 FTSG	Graft failure: 9.4% in FTSG and 3.9% in STSG; other complications <5%	Satisfactory form and function (not specifically defined)	4
McCary (1995)	[39]	Retrospective case series	STSG to external auditory canal	16 patients	12 patients (75%) with partial or complete canal stenosis, majority had conductive hearing loss	Satisfactory form and function (not specifically defined)	4
Lear (2010)	[38]	Retrospective case series	Combined FTSG and STSG to helix	4 patients	1 patient had partial necrosis of FTSG	Subjectively excellent cosmesis in 3 of 4 cases	4
Composite grafts							
Sage (2012)	[41]	Retrospective case series	Composite grafts to auricle (and other sites)	16 of 307 grafts used for auricle	Of all sites: 12.5% had nodularity; other complications <5%	Satisfactory form and function (not specifically defined)	4
Kontis (2003)	[42]	Retrospective case series	Composite graft to scapha and helical rim	2 patients	None reported	Subjectively assessed acceptable to excellent cosmesis	4

Postauricular scalp interpolation flap							
Johnson (1997)	[62]	Retrospective case series	Staged postauricular interpolation flap to helix	26 patients	No complications reported	Subjectively assessed good to excellent cosmesis	4
Farber (2012)	[61]	Retrospective case series	Staged interpolation flaps to facial and auricular sites	20 patients	No complications reported	Satisfactory form and function (not specifically defined)	4
Ottat (2010)	[63]	Retrospective case series	Staged postauricular interpolation flap to auricle	19 patients	No complications reported	Subjectively assessed good to excellent cosmesis	4
Deng (2014)	[60]	Retrospective case series	Staged postauricular interpolation flap with cartilage graft	14 patients	3 hematomas, 7 hypertrophic scars (4 treated with corticosteroids)	Subjectively assessed good cosmesis	4
Tubed flap							
Iljin (2016)	[68]	Retrospective case series	Multi-stage tubed flap from postauricular skin to helical rim	12 patients	Transient venous congestion in 2 cases, delayed healing in 2 cases	Subjective patient assessment: 10 completely satisfied, 2 moderately satisfied	4
Di Mascio (2004)	[66]	Retrospective case series	Multi-stage tubed flap from postauricular skin to helical rim	7 patients	No complications reported	Subjectively assessed satisfactory cosmesis	4
Ellabban (2003)	[67]	Retrospective case series	Two-stage tubed flap from postauricular skin to helical rim	3 patients	No complications reported	Satisfactory form and function (not specifically defined)	4
Temporoparietal fascial flap							
Demirdover (2011)	[73]	Retrospective case series	Temporoparietal fascial flap reconstruction to the auricle, orbit, and face	57 patients, 7 with auricle reconstruction	No complications reported in auricle reconstruction	Satisfactory form and function; donor site scalp alopecia was noted in 2 of 7 cases	4
Cheney (1993)	[72]	Retrospective case series	Temporoparietal fascial flap to auricle and orbit	21 cases, 14 with auricle reconstruction	1 partial flap necrosis, 1 delayed complete flap necrosis requiring second reconstruction	Satisfactory form and function (not specifically defined)	4
Olson (2002)	[74]	Retrospective case series	Temporoparietal fascial flap for various sites including auricle	15 patients, 5 with auricle reconstruction	1 case mild conductive hearing loss after reconstruction of external auditory canal	Satisfactory form and function (not specifically defined)	4
Rose (1990)	[75]	Retrospective case series	Temporoparietal fascial flap for various sites including the auricle	12 patients, 4 with auricle reconstruction	No complications reported in auricle reconstruction	Satisfactory form and function (not specifically defined)	4

Table 31.5 Second intention healing (SIH)

Author, year	Reference	Study type	Intervention	Size of study	Complications/adverse events	Outcome	Level of evidence
Hochwalt (2015)	[11]	Retrospective cohort study	FTSG vs second intention healing of helix defects	29 defects SIH vs 18 FTSG	No difference in minor complications (12% SIH vs 14.3% FTSG)	No statistical difference in VAS scores	2b
Levin (1996)	[13]	Retrospective case series	Second intention healing of various auricular defects	133 defects SIH	3 local wound infections (2.3%)	Satisfactory function in all; 71% with acceptable cosmesis; unacceptable in 58% of helical rim or lobule	4
Reddy (2004)	[31]	Retrospective case series	Review of various auricular defects	12 defects SIH	No complications reported	Satisfactory form and function (not specifically defined)	4

exceedingly low at less than 1% of all patients (Tables 31.1, 31.2, 31.3, and 31.4).

Antibiotic prophylaxis may also be used to decrease the risk of hematogenous infection in selected high-risk patients. The American Heart Association and American College of Cardiology have provided guidelines, recently updated in 2014, for prophylactic antibiotic use in cardiac patients. From a dermatologic surgery perspective, prophylaxis is recommended for prevention of infective endocarditis only in cases with breach of mucosa or infected skin in select high-risk patients [14, 15]. This includes patients with prosthetic valves, a history of infective endocarditis, transplant patients with structural valve abnormalities, patients with unrepaired congenital cyanotic heart disease, or repaired cyanotic heart disease with a prosthetic valve or residual structural defects. The use of prophylactic antibiotics to prevent septic arthritis in patients with artificial joint replacements, however, remains poorly defined [16]. Without clear evidence, preoperative antibiotics may be considered for minor surgical procedures in the first 6–12 months following artificial joint replacement.

Modification of anticoagulant therapy may be considered prior to reconstruction of the ear, but is often not required, and was not performed in the majority of studies described here. The only identified study to discontinue anticoagulants was that of single-stage pedicled flaps by Larcher et al. [17]. All patients on anticoagulants had their medications held 7 days prior to the procedure. It is not clear whether this decreased bleeding complications as other studies utilizing a similar reconstructive technique did not hold anticoagulation therapy and complications related to postoperative bleeding were rare [17–28]. Kirkorian et al. found that, in their respondents to a national survey, the majority of surgeons discontinue prophylactic aspirin, nonsteroidal anti-inflammatory medications, and Vitamin E, while only a minority of surgeons discontinue perioperative therapeutic aspirin and warfarin [29]. Antiplatelet medications and newer anticoagulants were not included in the data.

Best Techniques and Performance

There is a wide array of approaches to auricular reconstruction that offer the surgeon a large armamentarium from which to choose for a given defect. Given the complex anatomy and contour of the ear, certain techniques are more suitable for certain sites. The body of knowledge regarding appropriate strategies to reconstruct surgical deficits of the ear is primarily based on case series and experiential findings as few large retrospective or prospective studies exist. Despite the general lack of high-level evidence, the literature nevertheless provides a foundation of how to apply these techniques in an evidence-based fashion. Herein we present an overview of these reconstructive approaches. They are best divided into increasing order of complexity. In general, linear repairs are the most simplistic while staged interpolation flaps based on an established vascular supply are the most complex. For simplicity, we have organized them into four major groups: (1) linear and wedge repairs, (2) skin grafts, (3) single-stage flaps, and (4) multi-stage flaps. A summary of published studies, including the level of evidence provided by each, is provided in Tables 31.1, 31.2, 31.3, 31.4, and 31.5.

Linear and Wedge Repairs

Many defects of the ear are amenable to direct closure in a linear fashion. There are limited reports of direct linear closure in ear reconstruction, perhaps because of publication bias favoring more novel reconstructive techniques. Nevertheless, two series have examined closure methods among Mohs surgeons and have determined that linear closure is one of the most commonly performed reconstructive procedure for defects of the auricle (4) [30, 31]. Reddy et al. found that for defects up to 0.7 centimeters in diameter with little to no cartilaginous defect, linear closure was the most utilized reconstructive technique. In their study of nine patients repaired with linear closure, this was applicable to posterior (medial) auricular defects, lobule defects, and defects over the helical rim, and all were

described as successful (4) [31]. Ibrahim et al. found that linear closure was performed for defects with sizes ranging from 9 mm to 30 mm, also with universal success (4) [30].

Wedge excision, although inherently more complex than linear closure, can provide a relatively simple single-staged method for reconstruction of defects involving the helical rim. The technique surrounding wedge repairs rests on the proper design of its shape. It consists of an isosceles triangle with a base located along the helical rim and the apex tapering medially toward the conchal bowl [32]. This wedge of tissue is excised in a full-thickness manner, including cartilage and both anterior and posterior cutaneous surfaces. The remaining free edges of the cartilage and skin are directly approximated in a linear fashion. Wedge excision has been employed for helical rim defects ranging in size from 0.4 to 3.0 cm with subjectively reported good cosmetic and functional results (4) [31, 33, 34]. However, an important limitation to wedge repair is that larger defects are more prone to anterior/lateral protrusion and cupping of the ear. To counteract this, Taylor et al. have reported a modified wedge with a shorter triangular shape that does not extend into the conchal bowl [34]. In a small series of 12 patients with average helical rim defects of 2.19 centimeters, this modification provided good cosmetic results with no reports of significant complications (4) [34].

Skin Grafts

Skin grafting proves a viable technique for repairing defects of varying sizes at many different sites of the auricle. Full-thickness skin grafts (FTSG), comprised of epidermis and dermis, are usually preferred by dermatologic surgeons because of their superior cosmetic match to the surrounding skin compared to split-thickness skin grafts (STSG). In addition, donor sites for auricular reconstruction are often less than a few centimeters in diameter and are amenable to direct linear repair. In general, skin grafts for auricular reconstruction are harvested from the ipsilateral postauricular mastoid or preauricular region. Some authors suggest utilizing supraclavicular skin for larger donor site excisions to prevent pinning of the ear caused by repair of a large donor site from the postauricular skin [35]. After templating the defect and excising the graft from the donor site, FTSG are thinned by removing fat from the undersurface of the dermis. The graft is then trimmed to size and secured in the defect with peripheral and, if needed, central basting sutures. Fenestrations may be placed in the graft itself to facilitate wound bed drainage [36]. Tie-over bolster dressings may be used to enhance graft approximation to the wound bed, but are not universally required (4) [37].

The available literature suggests that full-thickness grafting can be utilized at many auricular sites (Table 31.2). Historically it has been used for upper-third helical defects with variable cartilaginous deficits [11, 35]. Trufant et al. complied a large, retrospective review of 1519 grafts to the auricle and showed that the upper helix was the most common site to utilize this reconstructive method [35] However, they also showed that FTSG can be utilized at all sites on the auricle with good functional results and minimal complications (4). The mean postoperative defect reconstructed in this series was 2.09 centimeters with a range of 0.7–5.5 centimeters. Complications were exceptionally rare, with local infection, hematoma, or graft failure identified in only 0.1%, 0.3%, and 1.2% of patients, respectively. In two smaller series, 259 total FTSG were reported with functional success and a consistently low rate of complications, including rare instances of necrosis, infection, and bleeding [12, 36].

In addition to the above case series, Hochwalt et al. performed a retrospective cohort study comparing FTSG to second intention healing (SIH) of the helix. Defects in the study ranged in size from 1.3 to 3.0 centimeters. The investigators used a standardized visual analog scale to compare cosmetic outcomes between the two repair methods. There was not a statistically significant difference in cosmetic outcomes between SIH and FTSG (2b) [11]. Additionally, Dessy et al. performed a randomized prospective trial comparing FTSG to a single-stage pedicled flap

(see below) for Mohs defects of the conchal bowl, using a visual analog scale to compare the two groups [19]. The pedicled flap had statistically significantly better outcomes with regard to the visual analog score compared to FTSG (2b). The authors attribute this to the higher rates of graft failure, color mismatch and external auditory canal stenosis seen with FTSG. Thus, it is likely that FTSG is less efficacious than single-stage pedicled flaps for selected defects of the conchal bowl. However, the evidence described above also suggests that FTSG can have exceptional cosmetic and functional outcomes in the appropriate clinical circumstances.

Split-thickness skin grafts (STSG) are utilized less frequently than FTSG but may be appropriate for defects in the conchal bowl, where tissue bulk is not required. After the defect has been templated onto the donor site and adequate local anesthesia is obtained, the STSG is harvested (either manually or with a dermatome) within the dermal plane. This creates a thinner graft than a FTSG and leaves a variable portion of the dermis in the donor site intact to facilitate healing by second intention. The graft is then trimmed to fit and secured in the defect in an analogous fashion to FTSG. Split-thickness grafting has been included in several studies of repairs of the conchal bowl, antihelix, and external auditory canal (4) [38–40]. Wines et al. reported reduced rates of graft failure with STSG compared to FTSG, as expected from the relatively decreased nutritional requirements of STSG [40]. STSG may be particularly well suited for repair of the external auditory canal, where thin grafts are advantageous. Even with STSG, however, canal stenosis has been reported [39]. Overall, the studies presented in Table 31.2 provide limited evidence that STSG can provide functional healing and adequate cosmesis for selected defects of the auricle.

Composite grafts, composed of cartilage plus epidermis, dermis, and a variable amount of subcutis, may also be used in auricular reconstruction. Composite grafts may be harvested as a contiguous graft of cartilage and skin or may be harvested separately as an isolated cartilage graft resurfaced with a FTSG. There is very limited data describing outcomes of composite grafts for ear reconstruction. Sage et al. described the use of cartilage grafts from the antihelix and conchal donor sites for repair of Mohs surgical defects in general (4) [41]. Of 307 cartilage grafts in the study, 16 were used to reconstruct the auricle (typically the helical rim). While auricular composite grafts were not described in detail, most cartilage grafts were effectively resurfaced with a separate FTSG, and the reported complication rate was low (less than 5%). There is one additional study that includes only two patients and is listed in the table for completeness [42]. The authors used composite grafts to effectively repair scapha and helical defects from acquired and congenital causes (4).

Single-Stage Flaps

Single-stage flaps may be technically more complex than primary closures or grafts but may have great utility in reconstruction of the ear. They are best conceptualized by dividing into three categories that include local cutaneous flaps, chondrocutaneous flaps, and single-stage pedicled flaps. Within each of these categories, there are still numerous variations on each type of flap that can be utilized. Here we present an overview of the three categories and an evidence-based approach to their use in ear reconstruction.

Local Cutaneous Flaps

Local cutaneous flaps are tissue rearrangements of adjacent skin and soft tissue without manipulation of the cartilaginous framework of the auricle. The vascular supply of these flaps derives from adjacent dermis and subcutis. While there are comparatively few studies reported with local cutaneous flaps specifically for auricular reconstruction, several groups have described the use of typical advancement, rotation, rhombic, and bilobe flaps on the ear (Table 31.3) [43–48]. Goldberg et al. and Kimyai-Asadi et al. described small case series of effective helical rim reconstruction via local advancement flaps (4) [44, 48]. In addition, Alam and Goldberg reported their anecdotal experience of helical rim reconstruction with a modified bilobe flap with excellent results (4) [49].

Local cutaneous flaps are also widely utilized for repair of lobule defects, in which the lack of an underlying cartilaginous framework facilitates local tissue rearrangement. Several studies have utilized modifications of rhombic flaps, Z-plasty, and W-plasty for lobule repair, particularly after traumatic injury resulting in a cleft lobule [43, 45–47]. These reconstructions have been shown to produce satisfactory functional and cosmetic outcomes as assessed subjectively by the authors (4). The only complications mentioned were by Singh and Singh and included tip necrosis that did not affect the final cosmetic result [46].

Chondrocutaneous Flaps

The prototypical chondrocutaneous flap is the Antia-Buch advancement flap for reconstruction of helical rim defects, first described in 1967 [50]. Flap execution involves incision and advancement of the skin of the anterior ear along with the underlying cartilage of the helical rim (or antihelix, depending on the specific defect). This skin and cartilage incision often extends the entire length of the helical rim to the tissue reservoir of the lobule. Skin of the posterior surface of the ear may or may not be incised to facilitate advancement. Because these flaps require incision and mobilization of the cartilaginous framework of the ear, they are best suited for defects with either missing or compromised cartilage (e.g., from ischemia or desiccation).

The majority of the evidence supporting the use of chondrocutaneous flaps is in the form of case series (4) [50–56]. In over 50 reported cases, these flaps have been used for reconstruction of the helical rim and also modified to repair defects of the antihelix, scapha, and triangular fossa. The smallest defect reported in these series was approximately 1.2 centimeters while the largest was 4.2 centimeters [50, 54]. All repairs achieved restoration of form and function without reported complications. Given the robust vascular supply of the helical rim, ischemic complications of these flaps, when properly executed, are rare. Chondrocutaneous advancement flaps are generally perceived as superior to wedge excision for helical rim defects greater than 1 centimeter, since these advancement flaps are less prone to cupping, protrusion, or distortion of the auricle. It should be noted, however, that no direct comparative studies have been performed. In addition, chondrocutaneous flaps do not replace lost cartilage, they merely advance the remaining helical rim into the defect. Thus, there is an inherent loss of tissue volume in the reconstructed ear, which may be noticeably smaller than the contralateral ear.

Single-Stage Pedicled Flaps

Single-stage pedicled flaps are an extremely versatile technique that can be tailored to reconstruct many different anatomic locations of the anterior auricle. Here, we use the term pedicled flap to describe several variations of single-stage skin flaps based on a subcutaneous or muscular pedicle from the postauricular or mastoid surface that is transposed or advanced to the anterior surface of the auricle. In the literature, these flaps have been variably described as retroauricular island flaps, pull-through flaps, tunneled flaps, revolving door flaps, and flip-flop flaps. Execution of the repair is generally performed by first using a template of the anterior surface defect to mark the flap and a sufficient subcutaneous pedicle on the posterior auricular surface, postauricular crease, or mastoid area. Descriptive anatomic studies have indicated that the vascular supply of this area, loosely based on the posterior auricular artery and the superior auricular artery (both branches of the superficial temporal artery), is sufficiently robust to support a random pattern subcutaneous or muscular pedicle [18, 57]. The flap is incised and completely separated from its dermal attachments, preserving a subcutaneous vascular pedicle that is dissected in a supra-perichondrial or periosteal plane. The flap is then pulled through the ear to the anterior surface defect and sutured in place, with excision of intervening cartilage as needed. Depending upon the location of the defect and the flap donor site, a subcutaneous tunnel may be created in the postauricular area to allow passage of the flap's vascular pedicle. The flap donor site is typically repaired in a linear fashion.

Compared to other methods of auricular reconstruction, there is strong evidence to support the use of single-stage pedicled flaps for defects of the conchal bowl and antihelix (Table 31.3). As

noted above, Dessy et al. performed a randomized prospective trial comparing single-stage pedicled flap reconstruction to full-thickness skin grafting for defects of the conchal bowl with a maximum diameter between 2 and 4 centimeters [19]. The investigators noted that there were no complications in 20 patients with single-stage pedicled flap repair, while partial necrosis and delayed healing were observed in 6 of 20 patients (30%) repaired with FTSG. In addition, visual analog scores (VAS) by blinded physician observers were significantly greater (indicating superior cosmetic outcomes) for pedicled flap repair versus FTSG. While this is only a single study and outcomes will certainly depend on surgical technique, this study provides level 2b evidence to support the use of single-stage pedicled flaps for reconstruction of the conchal bowl, an area where skin grafts may be sub-optimal.

Several retrospective case series have also described effective reconstruction of the ear with single-stage pedicled flaps (Table 31.3). Similar to the randomized trial described above, these flaps are most often used on conchal bowl defects of varying sizes but have also been applied to other defects on the scapha and antihelix as well (4) [17, 18, 21, 23, 24, 26–28, 58, 59]. The cosmesis achieved with these flaps is generally satisfactory to excellent; however 16 of 62 patients in one study had adequate to poor outcomes in subjective patient assessments [24]. Notable cosmetic sequelae that may result include pinning of the ear from repair of the flap donor site and excess bulk of the skin flap leading to the trapdoor phenomenon. The overall rate of flap necrosis, failure or infection, however, remains very low. Overall, there is a substantial body of evidence to support the use of single-stage pedicled flaps for various defects on the anterior surface of the auricle (level 2b–level 4, depending on anatomic site).

Multi-stage Flaps

Multi-stage flaps comprise some of the most complex methods for reconstruction of the auricle and may be effective when other methods are not appropriate for more extensive surgical defects. Multi-stage flaps often rely on a named vascular supply and afford the ability to move a large volume and surface area of tissue into place. They require a greater investment of time from both the patient and the surgeon since at least two operative sessions, usually separated by an interval of several weeks, are required. While all of the flaps can be performed under local anesthesia, more complex or extensive cases have historically been performed under general anesthesia. Three major categories of multi-staged flaps used in dermatologic surgery are postauricular scalp interpolation flaps, tubed flaps, and temporoparietal fascial flaps.

Postauricular Scalp Interpolation Flaps

Postauricular scalp interpolation flaps are most often utilized to reconstruct large defects of the helical rim. Execution of the flap begins with an assessment of the overall defect size and creation of a template from the defect on the postauricular scalp, sometimes extending to the postauricular sulcus and posterior ear. The flap is incised and elevated, and the anterior aspect is sutured to the defect on the anterior ear, leaving the vascular pedicle intact in the mastoid area of the scalp. After 3–4 weeks of vascularization and collateral blood supply development, the flap is incised posteriorly, thinned as needed, draped over the posterior aspect of the defect, and sutured into place [60–62].

As mentioned above, these flaps have been utilized predominately for defects comprising a substantial portion of the helix that cannot be restored by local flaps without unacceptable loss of helical volume. While the evidence base for these flaps comprises only small case series, all of the cosmetic outcomes reported have been satisfactory to excellent at restoring normal form of the helix, and complications are uncommon (Table 31.4). Perhaps as expected from the more complex nature of the flap, postoperative complications may be more likely than with simpler repairs. Hematoma is a known possible complication and was reported in 3 of 14 patients (21%) by Deng et al. [60]. Hypertrophic scars may also be more common and were reported in 7 of 14 patients (50%) in the same study, yet all

patients reported good cosmesis at 12 months (4). The remaining case series in the literature have not reported similar complications, and additional research is needed to define the optimal use and execution of these flaps (Table 31.4) [60–63].

Tubed Flaps

Tubed flaps have been in use for decades and were described by Harold Gillies as early as 1917 [64, 65]. Since that time they have been adapted to various surgical defects of the helix. The tissue reservoir for the flap is derived from either pre- or postauricular skin and is typically created and transferred to the helix in three separate surgical stages. First, the flap is created by incising a vertical band (1–2 centimeters wide) in the donor site and suturing it to itself to create a cutaneous tube that remains attached by a pedicle at both the superior and inferior edges. In the second stage, the tube is freed at one of these edges and partially sutured to the helical defect. After appropriate vascular maturation, the remaining pedicle is freed and the flap is thinned and completely inset into the defect.

There are only a small number of case series regarding the use of tubed flaps in helical reconstruction and they were performed in patients with traumatic injuries (Table 31.4) [66–68]. While there are no case series utilizing this technique for reconstruction of Mohs surgical defects, it has been applied in single case reports [69, 70]. As stated previously, the flap is best utilized for large helical defects, and Di Mascio and Castagenetti used 2.5 centimeters as a minimum-size threshold to perform this procedure (4) [66]. There were no complications reported in any of the series and cosmesis was subjectively reported by the authors as satisfactory. Data is significantly lacking on the use of this flap in dermatologic surgery and additional research would be helpful to define its optimal use.

Temporoparietal Fascial Flaps

The temporoparietal fascial flap (TPFF) is an axial pattern flap utilizing the richly vascularized temporalis muscle and fascia, which is supplied by the superficial temporal artery. The flap is typically used in multi-stage reconstruction to provide volume and vascular support that is then resurfaced with a skin graft. It has been adapted to various sites on the face and auricle. The flap can be executed with local anesthesia but has historically more commonly been performed under general anesthesia.

There are several small- to medium-size studies (Table 31.4) utilizing this technique to repair auricular defects of varying etiologies, notably including those from skin cancer excision (4) [71–76]. All of the included series were performed under general anesthesia, but there are case reports of repair after Mohs surgery that were performed under local anesthesia (4) [77]. The majority of defects in which the flap was best suited were subtotal or complete loss of the auricle requiring a combination of a cartilage framework, vascular supply from the TPFF, and skin graft resurfacing. There were few complications listed across all of the studies; however Cheney et al. reported distal flap necrosis and partial distal flap loss in 2 of 14 cases (14%) [72]. Based on the available evidence, the TPFF may be a useful reconstructive technique for particularly large or challenging defects of the ear. In these cases, reconstruction using the TPFF with cartilage and skin grafts as needed can restore a functional structure with a cosmetic resemblance to a natural auricle. Additional research to define the use of this technique in dermatologic surgery will be informative.

Safety

The safety profile is excellent for nearly all reported methods of ear reconstruction. In all of the studies examined there were no reports of any serious adverse events or death. Minor complications in these studies were rare. Rates of infection or bleeding were exceedingly low when reported. In the wedge and linear repair studies, there were no reported complications of postoperative bleeding, infection, or wound dehiscence (Table 31.1). It was noted that the

most common complication in wedge excision was ear projection, tissue redundancy at the site, and slight reduction in the size of the auricle. In full-thickness skin grafting there were reports of contracture, graft failure, local infection, and acute bleeding that all were generally less than 3% (Table 31.2). The complication rate in split-thickness skin grafts was relatively low as well, but McCarey et al. did note that 12 out of 16 patients (75%) who underwent STSG of the external auditory canal had stenosis in the weeks to months after the procedure [39]. Wines et al. noted partial graft necrosis in 9.4% of FTSG and 3.9% of STSG in the conchal bowl; this increased rate of necrosis compared to other studies may be due to the specific location with relatively immobile tissue and diminished vascular supply [40]. The safety profile was excellent in all single-stage flaps with few complications other than rare tip necrosis of the flaps or hematoma (Table 31.3). Multi-stage flaps also had low complication rates, although hematoma formation may be more common in these more complex procedures (Table 31.4). Given the general lack of direct comparative studies, however, there is insufficient data to compare rates of adverse events of any of the reconstructive approaches to one another.

Postoperative Care and Follow-Up

Following reconstruction of the auricle, routine postoperative wound care and follow-up is recommended and does not differ from that of other reconstructive procedures. Most patients will require at least one postoperative visit in the first few weeks for a wound check or suture removal. Additional visits may be required for staged procedures or if the patient develops symptoms or signs of complications. None of the studies examined compared wound care regimens or dressing types. In the majority of studies, follow-up for long-term cosmesis was generally conducted between 1 and 6 months or longer. As with all reconstruction, it is important to note that beneficial scar maturation can continue for 12–18 months.

Alternatives Procedures and Modifications

Second intention healing (SIH) has been long recognized as a viable alternative to primary repair of surgical defects on many body sites. However, studies on SIH are relatively sparse with regard to auricular repairs (Table 31.5). Levin et al. performed a retrospective study of 133 patients examining SIH of auricular wounds ranging in size from 63 mm^2 to 3500 mm^2 on all aspects of the ear (4) [13]. The majority of the cases on the helix achieved acceptable results with SIH when perichondrium was intact. If there was a loss of perichondrium, wound healing was delayed but still successful. If a true cartilaginous deficit was present, many of the cases resulted in notching of the helix. Favorable healing was reported as well with the concha, but webbed scar formation was noted if the defect traversed a large area. The study also achieved acceptable to excellent results with wounds on the tragus, pretragus, and posterior aspect of the auricle, while SIH of the lobule generally produced unfavorable results. This poor healing on the lobule was attributed to the lack of a cartilaginous framework for proper healing and led most often to distortion. The authors noted that the deeper the cartilaginous defect at any site, the less favorable the site was for SIH.

While almost any site on the auricle is amenable to SIH, there are few studies comparing it to other reconstructive techniques. There is, however, a single retrospective cohort study of FTSG vs SIH of the helix that showed no statistically significant differences in adverse events or in visual analog scores for cosmetic outcome (2b) [11]. This suggests that FTSG and SIH can produce comparable cosmetic outcomes with minimal complication risk for appropriately selected defects. This study was limited to defects ranging in size from 1 to 3 centimeters without significant cartilage defects. It is likely that SIH can provide a viable alternative to primary reconstruction of auricular defects in specific clinical scenarios, although additional studies are needed to confirm this.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
Surgical reconstruction of the ear is a safe and effective mechanism to restore function and cosmesis of the auricle	B
For defects of the conchal bowl, reconstruction with a single-stage pedicled flap may provide faster healing and superior cosmesis compared to reconstruction with full-thickness skin grafts	C
Various skin flaps and full-thickness grafts can be effective for auricular defects of different anatomic subunits, and selection of the type of repair should depend upon the size, depth, and location of the defect	C
Second intention healing can provide long-term function and cosmesis that is comparable to full-thickness skin grafts for auricular wounds of 1–3 centimeters without significant cartilage loss	C

Level of Evidence

Evaluating level of evidence for individual studies: Oxford Centre for Evidence-Based Medicine 2009 Levels of Evidence

Level	Therapy/prevention, etiology/harm	Prognosis	Diagnosis	Differential diagnosis/symptom prevalence study	Economic and decision analyses
1a	SR (with homogeneity) of RCTs	SR (with homogeneity) of inception cohort studies; CDR validated in different populations	SR (with homogeneity) of level 1 diagnostic studies; CDR with 1b studies from different clinical centers	SR (with homogeneity) of prospective cohort studies	SR (with homogeneity) of level 1 economic studies
1b	Individual RCT (with narrow confidence interval)	Individual inception cohort study with >80% follow-up; CDR validated in a single population	Validating cohort study with good reference standards; or CDR tested within one clinical center	Prospective cohort study with good follow-up	Analysis based on clinically sensible costs or alternatives; systematic review(s) of the evidence; and including multi-way sensitivity analyses
1c	All or none	All or none case series	Absolute SpPins and SnNouts	All or none case series	Absolute better-value or worse-value analyses
2a	SR (with homogeneity) of cohort studies	SR (with homogeneity) of either retrospective cohort studies or untreated control groups in RCTs	SR (with homogeneity) of level > 2 diagnostic studies	SR (with homogeneity) of 2b and better studies	SR (with homogeneity) of level > 2 economic studies
2b	Individual cohort study (including low-quality RCT; e.g., <80% follow-up)	Retrospective cohort study or follow-up of untreated control patients in an RCT; derivation of CDR or validated on split-sample only	Exploratory cohort study with good reference standards; CDR after derivation or validated only on split-sample or databases	Retrospective cohort study or poor follow-up	Analysis based on clinically sensible costs or alternatives; limited review(s) of the evidence or single studies; and including multi-way sensitivity analyses

Produced by Bob Phillips, Chris Ball, Dave Sackett, Doug Badenoch, Sharon Straus, Brian Haynes, Martin Dawes since November 1998. Updated by Jeremy Howick March 2009
SR systematic review; *RCT* randomized clinical trial; *CDR* clinical decision rule, i.e. an algorithm or scoring system that leads to a prognostic estimation or a diagnostic category; *SpPin* a diagnostic finding whose Specificity is so high that a Positive result rules-in the diagnosis; *SnNout* a diagnostic finding whose Sensitivity is so high that a Negative result rules-out the diagnosis

Assigning quality of evidence for each recommendation: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Code	Quality of evidence	Definition
A	High	Further research is very unlikely to change our confidence in the estimate of effect Several high-quality studies with consistent results In special cases: one large, high-quality multicenter trial
B	Moderate	Further research is likely to have an important impact on our confidence in the estimate of effect and may change the estimate One high-quality study Several studies with some limitations
C	Low	Further research is very likely to have an important impact on our confidence in the estimate of effect and is likely to change the estimate One or more studies with severe limitations
D	Very low	Any estimate of effect is very uncertain Expert opinion No direct research evidence One or more studies with very severe limitations

Self-Assessment Questions

1. Based on the available evidence, allowing a Mohs defect to heal by second intention would be least favorable for which of the following sites:
   (a) Helical rim defect of 7 mm with intact perichondrium
   (b) Conchal bowl defect of 5 mm
   (c) Helical rim defect of 7 mm with loss of perichondrium
   (d) Defect of 7 mm of the lobule
   (e) A defect on the antihelix of 5 mm without loss of perichondrium
2. Which of the following statements is true:
   (a) Second intention healing has shown significantly higher scores in visual analog scales compared to full-thickness skin grafts for helical defects.
   (b) Single-stage pedicled flaps have shown significantly higher visual analog scale scores when compared to full-thickness skin grafts for repair of conchal defects.
   (c) Full-thickness skin grafts have shown significantly higher visual analog scores when compared to split-thickness skin grafts for defects of the helix.
   (d) Single-stage pedicled flaps have shown significantly lower visual analog scale scores when compared to full-thickness skin grafts for repair of conchal defects.
   (e) Second intention healing has shown significantly lower scores in visual analog scales as compared to full-thickness skin grafts for helical defects.
3. Based on the available literature, chondrocutaneous advancement flaps are best utilized in which of the following situations:
   (a) A defect of 2 centimeters on the helical rim with cartilage loss
   (b) A defect of 1 centimeter on the helical rim with cartilage loss
   (c) A defect of 1 centimeter on the helical rim without cartilage loss
   (d) A defect of 1 centimeter in the conchal bowl with cartilage loss
   (e) None of the above
4. Which of the following is true regarding expected complications in appropriately selected wounds of the auricle repaired with full-thickness skin grafts:
   (a) Local infection occurs in approximately 5% of cases.
   (b) Acute bleeding occurs in approximately 3% of cases.
   (c) Hematoma formation occurs in approximately 1–3% of cases.
   (d) Graft failure/necrosis occurs in approximately 5% of cases.
   (e) Graft failure/necrosis occurs in 1–3% of cases.
5. For small (<1 centimeter) surgical defects of the auricle following Mohs micrographic surgery, which of the following is the most commonly employed reconstructive technique:
   (a) Linear repair
   (b) Wedge repair
   (c) Full-thickness skin graft
   (d) Chondrocutaneous advancement flap
   (e) Single-stage pedicled flap

Correct Answers

1. d: According to Levin et al. in their review of 133 cases, lobular defects with second intention healing produced contracture and deformity of the lobule in the majority of cases. While loss of perichondrium on the helix was shown to delay healing and produce some degree of notching, this was generally not significant.
2. b: Dessy et al. found in their prospective, randomized trial that single-stage pedicled flaps provided significantly higher VAS scores compared to full-thickness skin grafts for defects of the concha.
3. a: The literature available on helical reconstruction suggests the use of chondrocutaneous advancement flaps can be appropriately applied to larger defects of the helix that involve cartilaginous loss. Defects of 1 centimeter or less, or without loss of supporting cartilage can be repaired by simpler methods or allowed to heal by second intention.
4. e: In two of the largest studies of full-thickness skin grafts for auricular reconstruction (Trufant et al. and Leibovitch et al.), the most common complication was partial or complete graft failure in 1–3% of cases. All other complications occurred in less than 1% of patients.
5. a: While many different reconstructive methods can be utilized effectively and it is difficult to account for patient and surgeon variables, two studies (Reddy et al. and Ibrahim et al.) have documented that small defects of the auricle are most commonly repaired with linear closure.

Repairs of the Nose

32

Mark E. Burnett and John A. Zitelli

Abstract

Few anatomic sites challenge the skill of a reconstructive surgeon as the nose. With preservation of airway function as a sine qua non, the surgeon must also adhere to complex aesthetic demands. Topographic complexity, limited laxity, high adnexal density, and regional variation in skin thickness combine to present a formidable challenge to restoring form and function. The conspicuity of the nose also provides little latitude for error in execution, making the slightest degree of asymmetry perceptible. Reliable operative results require a systematic reconstructive approach based on wound size, depth, anatomic location, and characteristics of adjacent skin.

Introduction

Few anatomic sites challenge the skill of a reconstructive surgeon as the nose. With preservation of airway function as a sine qua non, the surgeon must also adhere to complex aesthetic demands. Topographic complexity, limited laxity, high adnexal density, and regional variation in skin thickness combine to present a formidable challenge to restoring form and function. The conspicuity of the nose also provides little latitude for error in execution, making the slightest degree of asymmetry perceptible. Reliable operative results require a systematic reconstructive approach based on wound size, depth, anatomic location, and characteristics of adjacent skin.

Objective scientific evidence supporting procedure selection, however, is limited. With few exceptions, the reconstruction literature is composed primarily of observational studies, evidence which is largely subjective in nature and thus considered to be relatively low in the hierarchy of study designs. Nonetheless, there are a select number of well-designed observational studies which provide high clinical value to the reconstructive surgeon. Unfortunately, the crucial components of more desirable study designs, such as blinded participants or placebos, are incompatible with the ethical practice of reconstructive surgery.

It should be noted that a thorough appraisal of each of the many flaps described in the nasal

reconstruction literature would be both onerous to the reader and subject to bias. Furthermore, most of the data supporting various repair options is similar in quality, limiting the ability to discern a meaningful difference. Lastly, it is important to recognize that even slight variations in the surgical techniques used to carry out a particular repair may result in strikingly different outcomes. To that end, we provide a conceptual framework of nasal construction in which surgical defects are bifurcated into those that fall on the upper two-thirds of the nose and those that occur within the lower third of the nose (Fig. 32.1). A limited number of reliable repair options for each of the nasal cosmetic subunits are discussed within these two larger categories. Secondary intention healing, primary closure, graft, and flap options are discussed sequentially within each subsection.

Secondary Intention Healing: *Primum non nocere*

Few surgeons in recent history ever had as much experience with secondary intention healing for facial defects as Frederic E. Mohs, whose use of zinc chloride for in situ tissue fixation often necessitated subsequent granulation. In 1946, he first reported on the excellent outcomes achieved through healing by second intent on the nose (4) [1]. More than three decades ago, Zitelli described the first set of guidelines on the use of secondary intention healing of facial defects (3b) [2, 3]. These guidelines demonstrated that anatomic location was the most important predictor of cosmetic outcome and have since been substantiated by numerous separate studies (3b, 4) [4–14]. Broadly speaking, concave surfaces predictably heal with excellent cosmesis, while flat surfaces heal with satisfactory results and convex surfaces heal with relatively unpredictable results (Fig. 32.1). In practice, however, the decision to allow secondary intention healing is a much more nuanced process and will be described below. When applied appropriately, the cosmetic outcomes attainable from secondary intention healing are often superior to those obtained through the application of a flap or graft (Fig. 32.2).

The decision to pursue second intention healing should be informed by an understanding of wound healing biology and wound contraction. Wounds that are very superficial in nature undergo a negligible degree of contraction and are primarily healed through the process of re-epithelization. In contrast, wound contraction plays a more prominent role in the healing process of partial- and full-thickness defects. Wound

contraction in these defects is mediated by myofibroblasts through a complex process resulting in collagen production and remodeling. Once a wound has fully contracted, the remaining granulation tissue is replaced by comparatively acellular scar tissue [15, 16]. This implies an inverse relationship between the extent of wound contraction and the amount of scar tissue formed. Clinically, this relationship is influenced by variables which are unique to each anatomic location, including local tissue architecture, free-margin proximity, surrounding laxity, and motion or adherence from underlying musculature and/or tissue. The sum of these factors must be considered when attempting to predict outcomes of healing by second intention.

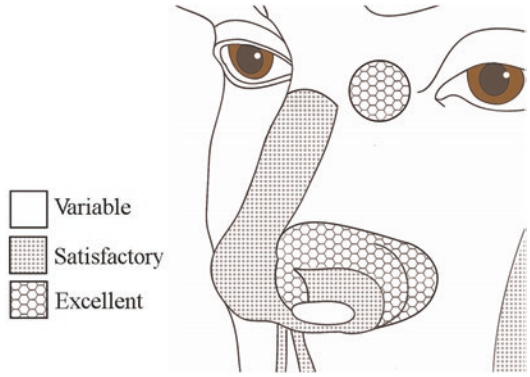

Fig. 32.2 Anticipated cosmetic results of second intention healing for wounds on the nose by anatomic location

Upper Two-Thirds of Nose

The upper two-thirds of the nose includes the sidewalls and dorsum above the nasal tip. In contrast to the lower third of the nose, the skin of the upper two-thirds is typically more mobile and less sebaceous and lacks the complex juxtaposition of concave and convex surfaces.

Nasal Dorsum

Partial- and/or full-thickness defects on the nasal dorsum can be expected to heal secondarily with satisfactory cosmetic results (Fig. 32.3) (4) [2, 3]. In an observational study of 24 patients who underwent secondary intention healing for full-thickness defects on the nasal dorsum, "acceptable" cosmesis was achieved in 67% (16/24) of patients (4) [8]. The authors noted a correlation between the area of the full-thickness defect and cosmetic outcomes, suggesting that only small full-thickness defects (average defect area = 288 mm^2) may be suitable for granulation. As such, primary fusiform closure should be considered the first repair option for midline defects of the appropriate size and shape on the nasal dorsum (4) [14, 17].

If primary closure is utilized, careful attention to closure design should be taken to avoid

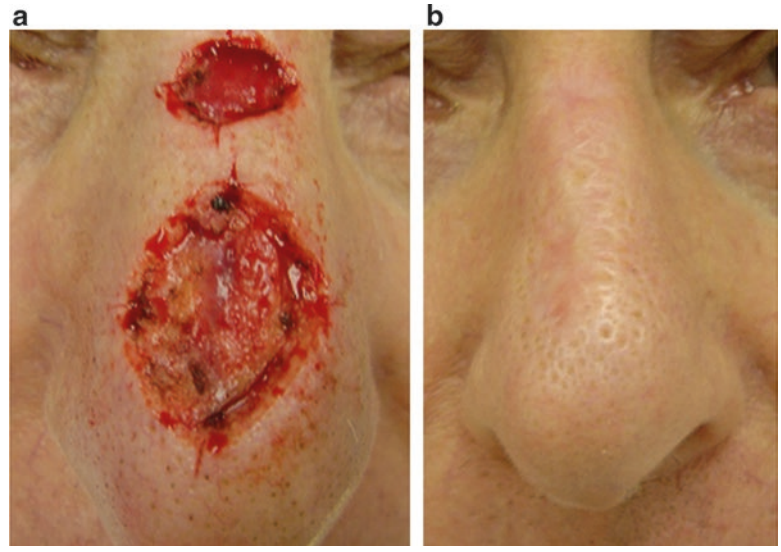

Fig. 32.3 (**a**) Two superficial defects of the nasal dorsum in a 76-year-old man. (**b**) Result at 1-year follow-up after healing by secondary intention

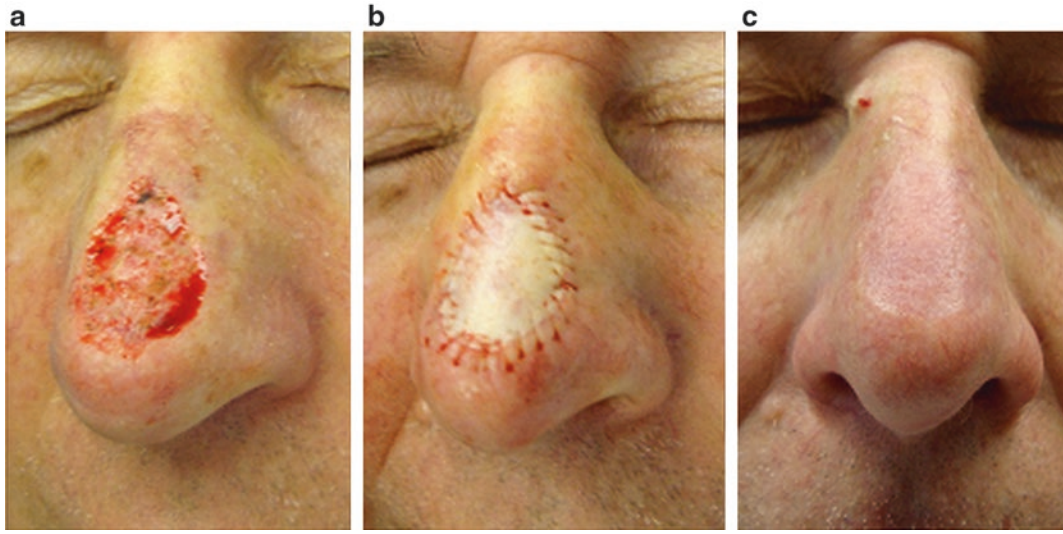

Fig. 32.4 (**a**) Defect of the nasal dorsum in a 67-year-old man. (**b**) Reconstruction of nasal dorsum defect with a full-thickness skin graft. (**c**) Result at 5-month follow-up

distortion of the nasal profile by standing cone deformities. Extension of the length:width ratio of the fusiform repair to 5:1 (or greater) has been shown to overcome this problem. This is frequently accomplished by extending the distal pole of the ellipse onto the inferior nasal tip and the proximal pole superior to the junction of the nasal bone and cartilaginous septum (4) [17].

Large defects or insufficient tissue laxity may seem initially to preclude linear closure on the nasal dorsum. However, extensive undermining may facilitate recruitment of adjacent tissue reservoirs, such as the skin of the remaining dorsum or sidewall in order to allow the appropriate closure. This approach offers the advantages of excellent color and texture match. For very large defects on the nasal dorsum, which cannot be adequately closed using adjacent skin, a full-thickness skin graft (Fig. 32.4) or forehead flap (Fig. 32.5) may be the only suitable repair option.

Nasal Sidewall

The cosmetic outcome of secondary intention healing for nasal sidewall defects is variable. In the observational study referenced above, 34 patients had defects confined to the nasal sidewall for which secondary intention healing was utilized. The authors described these defects as "mostly superficial" (to subcutaneous tissue) and reported that 85% (29/34) achieved an "acceptable" cosmetic result with second intention healing. While the average defect area was 308 mm^2, the authors noted that there was no obvious relationship between wound size and cosmetic or functional outcome (4) [8]. Conversely, a much smaller retrospective chart review of secondary intention healing outcomes for sidewall defects of any thickness reported poor outcomes in 58% (10/17) of patients (4) [11]. Contrasting outcomes such as these underline the unpredictability of healing by second intention for defects on the nasal sidewall.

For small defects on the nasal sidewall amenable to linear closure, the design of ellipse should be oriented obliquely, running parallel to a line extending from the inner canthus to the nasal tip [14]. When large defects on the nasal sidewall are closed in a fusiform fashion, however, upward alar retraction may result on the ipsilateral side. Instead, large surgical defects on the nasal sidewall are ideally repaired with a local transposition flap, with the donor site closed in a vertical line. Regional differences between the inferior and superior nasal sidewall direct the optimal repair approach.

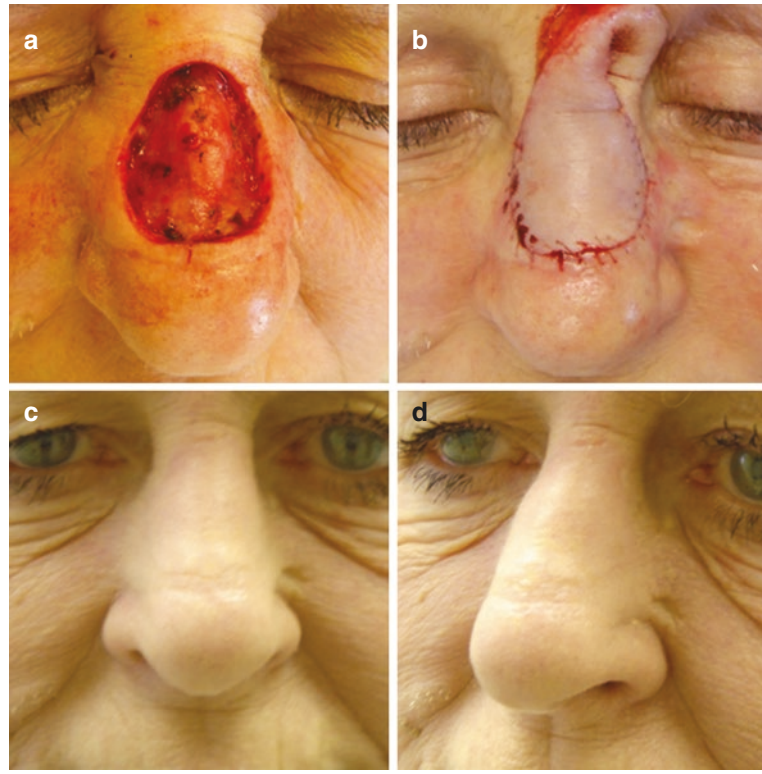

Fig. 32.5 (**a**) Defect of the nasal dorsum in a 65-year-old woman. (**b**) Reconstruction of nasal dorsum cosmetic subunit with forehead flap. (**c, d**) Results at 6-month follow-up

The rhombic transposition flap is one of the most reliable, efficient, and cosmetically elegant local flaps for defects on the superior or lateral nasal sidewall. In most cases, the laxity of the superior sidewall favors an inferiorly based flap as a donor site. Defects located on the inferior or medial aspect of the nasal sidewall may be more optimally repaired using a bilobed flap, as the skin of the upper sidewall and nasal root can be easily mobilized (4) [18]. The defect size suitable for these repair types is a function of the amount of laxity available but is typically ≤1.5 cm in diameter.

Surgical defects measuring greater than 1.5 cm on the lateral or inferior portion of the lateral sidewall are readily repaired with a nasolabial transposition flap (Fig. 32.6). In 1990, Zitelli reported a case series of 32 patients describing the use of this repair technique. Of the 32 patients, 7 patients had defects confined strictly to the nasal sidewall. All defects were repaired in a single stage and none required a revision over an average follow-up period of 3.5 years (4) [19].

Lower Third of the Nose

The lower third of the nose includes the subunits of the tip, soft triangles, alae, and columella (Fig. 32.7). The limited mobility of the skin in this area makes it difficult to manipulate freely, magnifying even the slightest amount of tissue movement.

Nasal Tip

For small, superficial defects on the nasal tip, the process of healing by secondary intention often yields cosmetic results superior to surgical incisions. This is especially useful for patients with thick, sebaceous skin where suturing may be difficult and result in a less predictable outcome. However, partial- or full-thickness defects of the nasal tip do not typically heal favorably by second intention. In a study reporting the results of secondary intention healing by cosmetic subunit on the nose, only 32% (24/74) of defects of the nasal tip healed with an acceptable cosmetic result, suggesting that this approach should be used sparingly [8]. Special

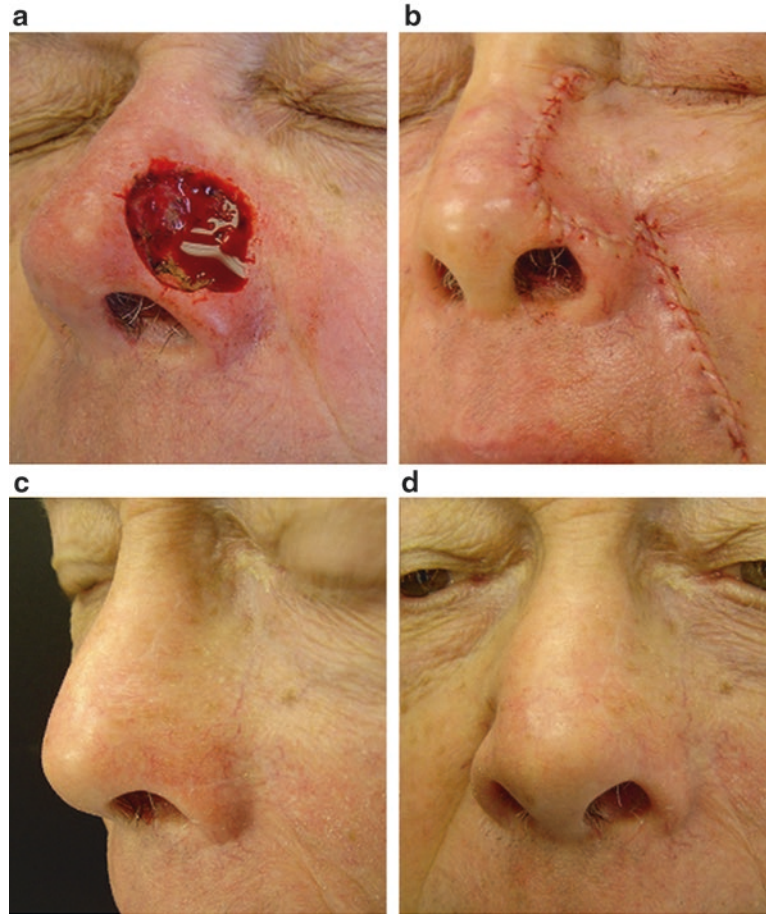

Fig. 32.6 (**a**) Defect of the nasal sidewall and ala in an 80-year-old man. (**b**) Reconstruction with a single-stage nasolabial transposition flap. (**c**, **d**) Results at 9-month follow-up

attention should be paid to avoiding secondary intention healing on the cosmetic subunits of the soft tissue triangles. Defects isolated to these concave subunits rarely heal favorably by secondary intent.

One approach reported to optimize the final outcome of nasal tip defects allowed to heal secondarily may be the use of immediate dermabrasion, which aims to soften the transition between the defect and surrounding skin. The particular method by which this "shave and sand" technique is accomplished has been outlined elsewhere [20]. In a series of 1334 nasal reconstruction cases, primary dermabrasion was reported to optimize cosmetic outcomes when used at the wound margins, irrespective of the defect location or type of repair (4) [21].

A caveat to second intention healing on the nasal tip is the unpredictability of the cosmetic outcome in patients with thin, non-sebaceous skin. In these patients, excellent functional and cosmetic results can be obtained with surgical repair of full-thickness defects of the nasal tip [17]. This is because surgical incisions are often less perceptible in patients whose skin lacks a significant sebaceous component.

Grafts

Skin from the pre- or post-auricular area is often utilized as a donor site for full-thickness skin grafts. However, the skin of the conchal bowl may provide the best cosmetic outcome on the nasal tip. This is because color and texture similarity between the nose and conchal bowl is underpinned by histologically comparable sebaceous gland density (4) [22]. Furthermore, the donor site may be allowed to heal secondarily for even large grafts given the rigid support of the underlying cartilage.

Primary Closure

Results from primary closure on the midline of the nasal tip are largely dependent on the skin type in which the defect occurs. Thin, non-sebaceous skin is easier to manipulate and repair primarily than thick, sebaceous skin. When complete closure with a fusiform repair is unattainable, excellent cosmesis can be obtained by shaping a Burow's graft to fit the remaining defect (4) [23–26].

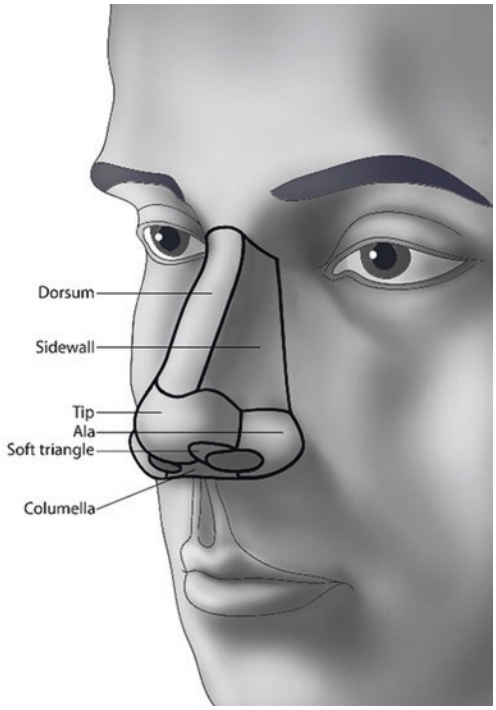

Fig. 32.7 The nine cosmetic subunits of the nose include the dorsum, paired sidewalls, alae, and soft triangles as well as the nasal tip and columella

Local Flaps

Off-midline defects on the nasal tip warrant consideration of an advancement, rotation, or transposition flap. Small off-midline nasal tip defects can often be readily repaired with a Burow's advancement flap. This repair utilizes offset tissue triangles above and below the defect to provide reliably excellent results (Fig. 32.8).

In many cases, the skin of the nasal tip may be especially limited in its laxity. Such a situation frequently requires recruitment from donor skin from the upper two-thirds of the nose where greater tissue mobility can be found. Among the several options available for nasal tip defects measuring ≤1.5 cm, the bilobed flap provides optimal tissue dynamics. The double transposition movement of the bilobed flap is analogous to the motion of a double Z-plasty. When designed and executed correctly, the resulting redistribution of tension vectors prevents distortion to either the primary defect or surrounding free margin. The modification described by Zitelli [18] in a case series of 20 patients with nasal tip defects has been successfully implemented and reported by numerous reconstructive surgeons (4) [27–34]. Critical to avoiding alar rim distortion is vertical

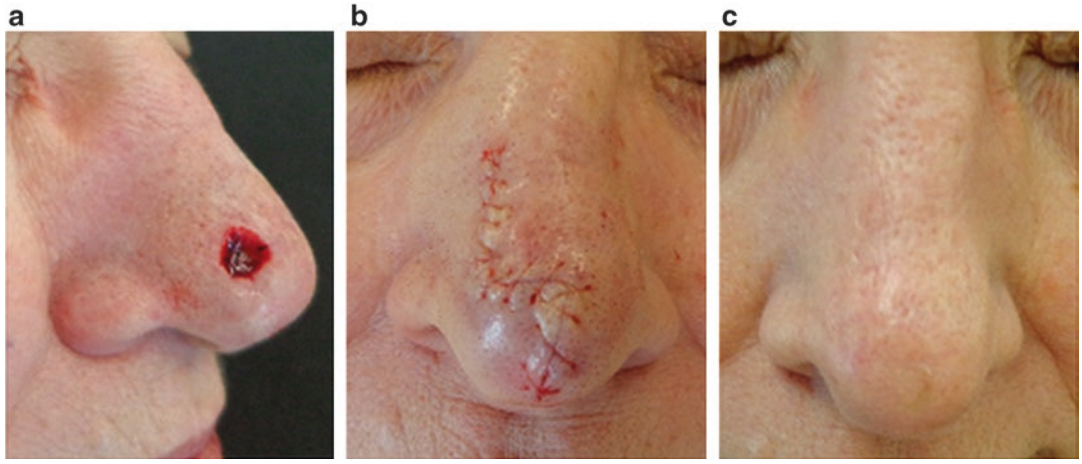

Fig. 32.8 (**a**) Defect on the lateral nasal tip in a 71-year-old woman. (**b**) Burow's advancement flap on the nasal tip. (**c**) Results at 3-month follow-up

orientation of the secondary defect and wide undermining over both sidewalls (4) [35, 36].

For very large defects of the nasal tip, maintenance of the cosmetic subunit approach to reconstruction is best achieved through the use of a forehead flap. However, patients for whom a forehead flap is being considered, but who may also have difficulty with the necessary follow-up, a single-stage local rotation flap may be a more suitable option. The dorsal nasal (aka dorsonasal or Rieger flap) flap was popularized by Rieger in 1967 for the repair of nasal tip defects ≤2 cm in diameter [37]. Numerous authors have reported excellent results for the repair of defects on the lower third of the nose using this approach (3b, 4) [38–44]. A retrospective analysis of 48 cases in which the dorsal nasal flap was used to repair nasal tip defects outlined optimization of its use when three criteria are met: a defect diameter of ≤2 cm, no defect extension onto the soft triangles or columella (so-called tip-defining points), and a defect location ≥1 cm from the alar rim (4) [45]. Other authors have reported its use for defects located ≥5 mm from the alar rim (5) [46]. Numerous modifications have been made to overcome some of the drawbacks to this particular flap, which include the development of bulkiness secondary to the presence of glabellar skin on the nasal dorsum and the conspicuous angled scars required to elevate the flap.

Forehead Flaps

Originally described by Burget and Menick, the subunit principle as it applies to nasal reconstruction dictates the replacement of an entire subunit if the defect involves over 50% of the subunit [47]. This approach is most relevant for defects of the nasal tip for which a forehead flap would provide the best aesthetic outcome. Improved aesthetic outcomes are achieved when the remainder of the cosmetic subunit of the nasal tip is resected prior to reconstruction. This is because removal of the remainder of the nasal tip along the borders of neighboring cosmetic subunits effaces the contour asymmetry that might otherwise result from a repair through the center of this conspicuous subunit (Fig. 32.9).

Cadaveric and human studies have reported on the central function of the supratrochlear artery

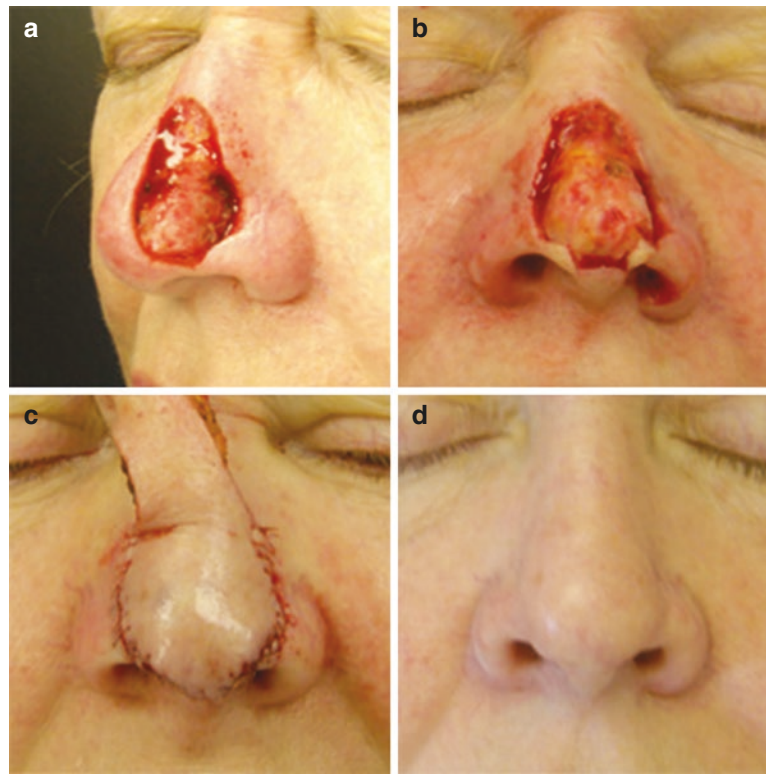

Fig. 32.9 (**a**) Defect of the lateral nasal tip and lower dorsum in a 60-year-old woman. (**b**) Remainder of nasal tip cosmetic subunit excised. (**c**) Reconstruction of entire nasal tip subunit with forehead flap. (**d**) Results at 6-month follow-up

as the primary blood supply for the traditional design of the paramedian forehead flap [48, 49]. However, a recent microanatomic study of flap vascularity in 50 forehead flaps demonstrated equivalent clinical outcomes and complication rates between flaps whose pedicles were based by simply measuring 1.2 cm from the glabellar midline ("paramidline") and those which intentionally included the supratrochlear artery ("paramedian") design [50]. Notably, the paramidline designs had more arteries within their pedicles than Doppler-based paramedian designs, suggesting that the blood supply for this flap may be based on a plexus of arterioles rather than a single artery. Thus, the flap may be safely and consistently designed as a random pattern flap using surface landmarks.

Ala

Repair of alar defects is complicated by the presence of highly sebaceous skin, limited tissue mobility, and the proximity of a free margin. As such, both superficial and deep wounds which are small and limited to the area of the concave alar crease may be allowed to heal by second intent (4) [3]. Recently, a small case series suggests an expanded range of nasal alar defects for which secondary intention healing may be appropriately applied. The authors reported excellent functionality and cosmesis, even for large or deep defects. This included patients whose defects extended from the alar sulcus onto the convex surface of the ala. They emphasized the importance of adequate structural support of the alar rim as an important consideration in patient selection (4) [51]. Proximity of the defect to the alar rim was also emphasized in the study by Becker et al. [8] as a sensitive predictor of alar retraction deformity. Wound healing in this area is via a contraction process that may result in subtle elevation of the entirety of alar rim. In contrast, wounds on the ala which are close to the rim may heal with a more noticeable notched appearance. The use of cartilage grafts to support the rim may prevent elevation and notching.

Grafts

Repair of alar defects with full-thickness skin grafts are typically limited by a resultant skin color discrepancy. However, for alar defects for which full-thickness skin grafts are appropriate, the conchal bowl should be the preferred donor site. The skin thickness and sebaceous quality from this area provide the best possible match, compared to pre- or post-auricular skin.

Flaps

Small partial- or full-thickness alar defects measuring ≤1.5 cm may be reliably repaired using a medially based bilobed flap (Fig. 32.10).

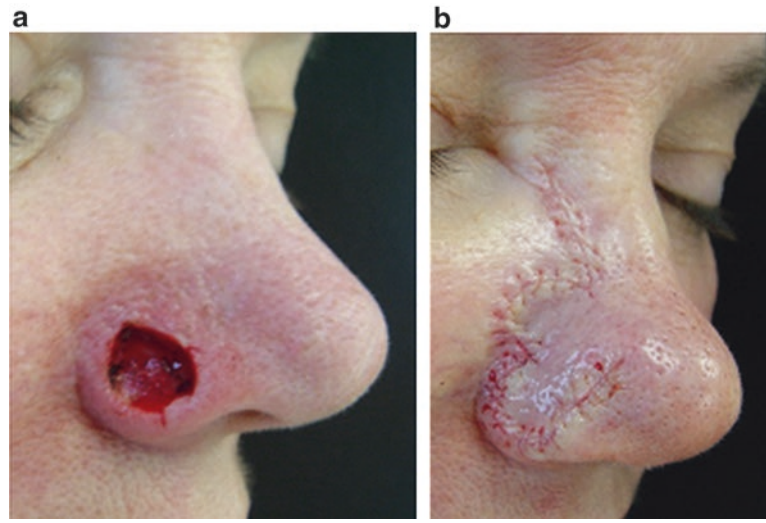

Fig. 32.10 (**a**) Full-thickness defect of the ala in a 54-year-old woman. (**b**) Reconstruction with a medially based bilobed flap

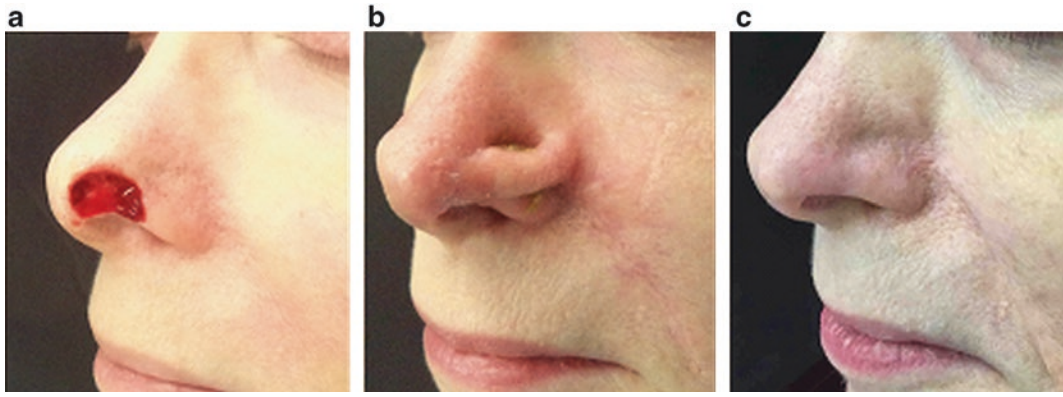

Fig. 32.11 (**a**) Partial-thickness defect on the nasal ala and lateral tip of a 66-year-old woman. (**b**) Reconstruction with an interpolated melolabial flap. (**c**) Result at 6-month follow-up

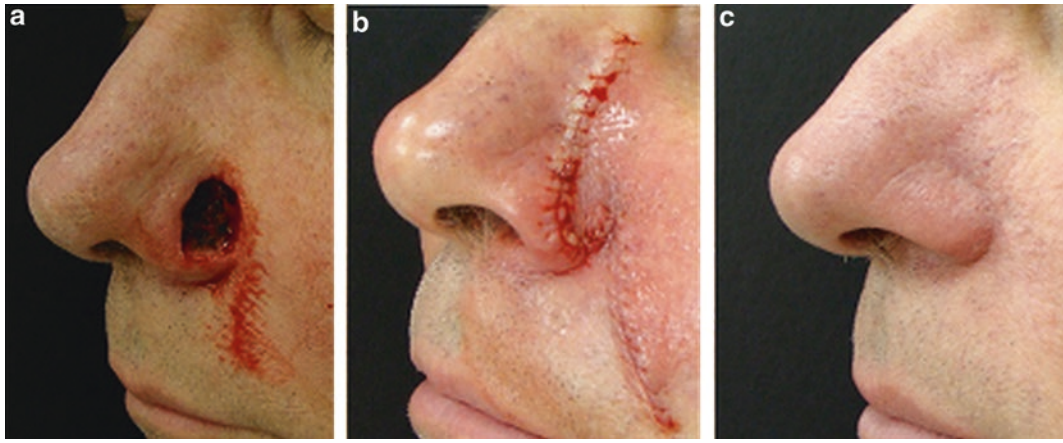

Fig. 32.12 A single-stage nasolabial flap is useful for wounds of the sidewall, including those that may extend onto the ala. (**a**) Defect of the left sidewall and ala in a 59-year-old man. (**b**) Repair with single-stage nasolabial flap. (**c**) Result at 6-month follow-up

Full-thickness alar defects measuring ≥1.5 cm often present the reconstructive surgeon with the option to use an interpolated flap. A two-stage interpolation flap is often used in tandem with cartilage grafts for full-thickness defects limited to the ala (Fig. 32.11) [52]. A recent study of 107 patients with nasal defects did not show a statistically significant difference in flap failure rates between the two-stage interpolated nasolabial flap and the paramedian forehead flap (4% vs. 6%, respectively) [53]. Interestingly, the use of cartilage was not seen to affect failure rates in either flap.

The Spear flap, a modification of the nasolabial flap described by Scott L. Spear, MD in 1987, is an excellent repair option for full-thickness loss of the ala and vestibular lining extending to the alar crease (4) [54]. When executed correctly, this single-stage approach preserves the hemicylindrical convexity of the alar rim. For partial- or full-thickness defects ≤2.5 cm in width, which include the sidewall but extend on the ala, the single-stage nasolabial transposition flap discussed earlier provides favorable outcomes and can be easily executed to minimize trapdoor formation [19] (Fig. 32.12). A case series of 105 patients undergoing alar reconstruction with this single-stage transposition flap reported excellent cosmesis and no flap failures after a minimum of 6 months follow-up

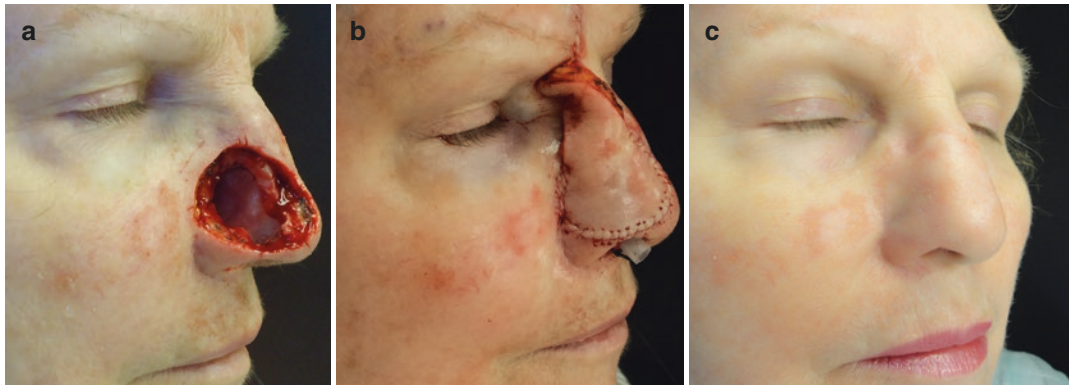

Fig. 32.13 (**a**) Full-thickness loss of the ala, ipsilateral vestibular lining, and lateral half of nasal tip. (**b**) Repair with a fold-under paramidline forehead flap and cartilage strut. (**c**) Result after second-stage inset of flap

(4) [55]. For large alar defects that are not amenable to a single-stage transposition flap, a two-stage interpolation flap or a Spear flap, a forehead flap may provide the best functional and aesthetic outcome (Fig. 32.13). When executed correctly, each of the above options may adequately re-establish the complex architecture of the alar subunit.

Additional Considerations

Structural Reinforcement

The application of suspension sutures and/or cartilage grafting may be necessary in cases where the rigidity of the ala or distal sidewall is compromised after tumor extirpation. Such defects result in functional impairment of the nasal valve(s). Re-establishing nasal contour as a matter of cosmesis may also necessitate structural support. Determining when structural support is necessary is a process informed by a combination of clinical examination and experience.

To date, the available literature does not provide a definitive answer regarding the application of structural support in nasal reconstruction. A large, heterogenous body of literature has demonstrated the feasibility of nasal reconstruction without the use of structural support. In contrast, however, comparative studies were lacking until recently. Ezzat and Liu published a small retrospective review of 38 patients with defects involving the nasal ala and/or sidewall (mean diameter of 2.04 cm) in which they compared reconstruction with and without structural reinforcement (3b) [56]. The authors reported that postoperative nasal obstruction occurred in 16% (3/19) of repairs which utilized only soft tissue (i.e., no cartilage or suspension sutures) versus 0% (0/19) of those that utilized structural support. Importantly, repairs utilizing structural support were substantially larger than those that were not reinforced (2.56 cm vs. 1.53 cm, respectively). This makes it difficult to draw a conclusion regarding reinforcement alone, since the likelihood of functional impairment – and thus the choice to use structural support – is proportional to defect size.

Conclusions

Among reconstructive surgeons, the standards for nasal reconstruction no longer tolerate a compromise between form and function. Patients are equally exacting in their expectations. In fact, prospective study of patients undergoing skin cancer surgery has demonstrated that the perceived quality of care is correlated most strongly with cosmetic outcome (4) [57].

Fundamental to the application of nasal reconstructive techniques is a careful analysis of the defect, including the soft tissue, cartilaginous or bony support and intranasal lining. Architecture,

surrounding skin quality, and defect characteristics (i.e., size, depth, location) combine to facilitate selection of the appropriate reconstructive option. In many cases, simplicity provides the most elegant results.

The reconstructive ladder presented herein is limited in scope to the defects encountered by most dermatologic surgeons and further limited to repair options which provide consistently high-quality results. In our experience, a limited number of reliable repair options for each of the cosmetic subunits may be utilized to achieve consistently superb results. At times, the advantages of one repair option or another are not clear and become a choice informed solely by personal experience. The appropriate use of secondary intention healing was emphasized, especially when underpinned by critical consideration of wound size, depth, and anatomic location (see Table 32.1). Irrespective of study, it is important to remember that the cosmetic results reported from second intention healing are based on subjective evaluation. Finally, evidence-based reconstruction is confounded by the fact that results are very operator dependent.

The use of bone grafts, intranasal flaps, and other complex techniques is beyond the scope of this chapter. The management of more complex defects, such as hemi or subtotal rhinectomy has

Table 32.1 Summary of studies assessing healing by second intention for each nasal cosmetic subunit

Summary of studies of secondary intention healing for defects of the nose by subunit				
Authors	Nasal dorsum	Nasal tip	Nasal sidewall	Nasal ala
Zitelli [2, 3]	Nasal dorsum and tip defects grouped within a single anatomic zone, defined as the "convex surface of the nose." Variable and unpredictable for all but very superficial defects. Full-thickness wounds may result in flat, depressed, or hypertrophic scars		Defects may heal with satisfactory cosmetic results	Excellent cosmetic results for wounds alar crease, irrespective of depth. Defects close to alar rim may cause upward rim retraction
Goldwyn et al. [4]	Series of 20 cases, 7 of which included the nose. Of seven, four were limited to nose alone. Smallest defect measured 2 × 1.5 cm, no indication of depth. Of seven cases involving the nose, three (43%) rated as having "excellent scar"			
Becker et al. [8]	Acceptable cosmesis achieved in only 67% (16/24) defects of all depths (average defect area = 421 mm^2)	Acceptable cosmesis achieved in 32% (24/74) of defects of all depths (average defect area = 298 mm^2)	Acceptable cosmesis achieved in 85% (29/34) of "mostly" partial-thickness defects (average defect area = 308 mm^2)	Satisfactory cosmesis achieved in 41% (28/69) of (average defect area = 237 mm^2). Most defects also involved adjacent cosmetic subunits
Van der Eeden et al. [11]	"Poor-average-good" outcome in the only two nasal dorsum defects evaluated. Depth and size of wound by cosmetic subunit not provided	"Poor-average-good" outcome in the single nasal tip defect evaluated. Depth and size of wound by cosmetic subunit not provided	"Poor-average-good" outcome in 56% (10/18). Excellent" outcome in remaining 8/18 (44%). Depth and size of wound by cosmetic subunit not provided	"Poor-average-good" outcome in 2/4 (50%) alar defects evaluated. Excellent" outcome in remaining 2/4 (50%). Depth and size of wound by cosmetic subunit not provided
Mott et al. [13]	Nasal dorsum and tip defects grouped within a single anatomic zone, defined as the "convex surface of the nose." Acceptable cosmesis achieved in 11/19 (58%) of defects (average defect area = 248 mm^2)		Acceptable cosmesis achieved in 5/5 (100%) of defects (average defect area = 146 mm^2)	Acceptable cosmesis achieved in 29/30 (97%) of "perinasal ala" defects defined as the "concave surface of the nose" (average defect area = 166 mm^2)
Neuhaus et al. [51]	–	–	–	Various defect sizes and depths amenable if adequate alar structural support is present

been presented elsewhere and are typically case reports or small case series outlining particular techniques.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
A paucity of strong evidence precludes definitive guidance for the multitude of scenarios encountered in nasal reconstructive practice	NA
The distinct regional variation existing between the skin of the upper two-thirds and lower third of the nose should guide the application of any repair option	A
Secondary intention healing should be the first option considered as it may provide excellent functional and cosmetic outcomes when applied to the appropriate area of the nose, defect type, and patient	A
Reconstruction algorithms should prioritize simplicity (e.g., primary fusiform repair) and employ changes to the design and surgical technique utilized as means to accomplish this (i.e., lengthening fusiform repair and/or wide undermining)	A

Self-Assessment Questions

1. Which of the following types of wounds are amenable to secondary intention healing on the nasal dorsum?
   (a) Full-thickness wounds
   (b) Partial-thickness wounds
   (c) Very superficial wounds
   (d) Both full and partial-thickness wounds
   (e) None, all wounds on the nasal dorsum should be repaired
2. Which of the following types of wounds are amenable to second intention healing of the ala?
   (a) Full-thickness wounds
   (b) Partial-thickness wounds
   (c) Very superficial wounds
   (d) All of the above given adequate surrounding structural support of the alar rim
   (e) None of the above; all alar defects should be repaired with a flap or graft.
3. Why may the pedicle of a forehead flap be designed by simply measuring 1.2 cm from the glabellar midline (so-called paramidline)?
   (a) Because the supratrochlear artery is typically found within 1.2 cm from the glabellar midline.
   (b) Because branches of the supraorbital artery are typically found within 1.2 cm from the glabellar midline.
   (c) Because the paramidline designs have been shown to have more arteries within their pedicles than Doppler-based paramedian designs.
   (d) They may not be designed in this manner; the supratrochlear artery must be localized within the pedicle template using Doppler ultrasound.
4. Which of the following factors should be considered in order to optimize the cosmetic outcome of nasal tip defects allowed to heal secondarily?
   (a) Allowing only small, very superficial defects of the nasal tip to heal secondarily
   (b) Immediate or delayed dermabrasion
   (c) Avoiding the use of secondary intention healing in patients with thin, non-sebaceous skin of the nasal tip
   (d) All of the above
   (e) None of the above
5. Skin from which of the following donor sites is most histologically similar to the skin of the lower third of the nose?
   (a) Supraclavicular skin
   (b) Conchal bowl skin
   (c) Pre-auricular skin
   (d) Post-auricular skin
   (e) Upper eyelid skin

Correct Answers

1. c: Superficial wounds on the nasal dorsum may be allowed to heal by second intention. Large and/or full-thickness wounds may result in a depressed scar and distortion of the nasal tip.
2. d: Even full-thickness defects of the ala may be allowed to heal secondarily if the structural support of the alar rim is sufficient to resist the forces of scar contraction and avoid distortion of the free margin.
3. c: Microanatomic study of "paramidline" forehead flap designs had more arteries within their pedicles than Doppler-based paramedian design, suggesting that the blood supply for the paramidline flap is supported by a plexus of arterioles rather than a single artery.
4. d: Superficial defects on the nasal tip can readily be allowed to heal by second intention. Dermabrasion may maximize the cosmetic outcome by softening the transition between the defect and the surrounding skin. Lastly, choosing the right skin type to pursue this approach is critical to achieving the very best possible cosmetic outcome.
5. b: The skin of the conchal bowl provides a reservoir that is similar in color, texture, and quality to the skin of the lower third of the nose. This is underpinned by histologic study demonstrating similar adnexal density.

Topical Anesthesia

33

C. Blake Phillips, Melissa McEnery-Stonelake, and Conway C. Huang

Abstract

Topical anesthetics offer effective, uniform skin anesthesia while avoiding the discomfort and needle anxiety associated with injected local anesthetics. In the context of dermatology, they may be used to provide primary anesthesia or as an adjuvant pretreatment for alternative locoregional anesthesia. Unlike traditional injection anesthetics, two or more agents are typically combined in a vehicle for topical use. Because efficacy, indications, contraindications, and application techniques vary for these combination agents, this chapter aims to review the most common FDA-approved agents with a focus on best available evidence.

Indications for Topical Anesthetics

Topical anesthetics offer effective, uniform skin anesthesia while avoiding the discomfort and needle anxiety associated with injected local anesthetics. To that end, dermatologists have used a variety of agents to minimize the pain of injections, cutaneous laser surgery, cryotherapy, debridement, and various other minor procedures in patients of all ages.

Local anesthetics may be grouped by intermediate chain structure into amide and ester classes. The amide class of anesthetics includes lidocaine, prilocaine, bupivacaine, mepivacaine, and etidocaine among others. Metabolism of amides is via hepatic conversion. Notable ester anesthetics include procaine, cocaine, tetracaine, and benzocaine which are metabolized by plasma cholinesterases.

While single-agent analgesic preparations of lidocaine, benzocaine, and tetracaine are available over the counter, their utility in dermatologic procedures is limited. Compounded and FDA-approved prescription agents are of variable potency and efficacy dependent on drug concentration and delivery vehicle. Selected preparations may be found listed in Table 33.1.

In the context of dermatology procedures, two or more anesthetics are typically combined in a vehicle with or without an added vasoconstricting agent. All FDA-approved agents are

Table 33.1 Topical anesthetics [1–3]

Topical anesthetic	Active ingredients	Vehicle	Recommended application time	Duration after removal	Maximum dose/ surface area recommended
EMLA	2.5% lidocaine, 2.5% prilocaine	Oil-in-water emulsion	60 min with occlusion for superficial dermal; 120 min with occlusion for deeper dermal; 15 min for mucosa	60–120 min	20 g/200 cm2 for adults
LMX4/ LMX5 (ELA-max/ ELA-max 5)	4%/5% lidocaine	Liposomal cream	15–45 min	60 min	600 cm2 (adults) 100 cm2 (children) Maximum application time 2 h
Pliaglis	7% lidocaine, 7% tetracaine	Cream that hardens into pliable film	30–60 min	11 h	59 g/400 cm2 up to 120 min
Synera	70 g lidocaine, 70 g tetracaine	Patch with heating element	30 min	At least 100 min	Maximum application time 30 min
Topicaine	4 or 5% lidocaine	Gel	30–60 min	60 min	600 cm2 (adults) 100 cm2 (children)
Vapocoolant	Ethyl chloride	Spray	Instant	60 s	
LET	Lidocaine 4%, epinephrine 0.1%, tetracaine 0.5%	Aqueous solution or methylcellulose gel	20–30 min, non-intact skin only	45–60 min	6 cm
TAC	Tetracaine 0.5%, adrenaline or epinephrine 0.05%, cocaine 11.8%	Aqueous solution	20–30 min, non-intact skin only	45–60 min	

indicated for pre-procedural anesthesia on intact skin. Studies support the use of a subset of agents for open wounds as in laceration repair.

Effectiveness of Topical Anesthetics

Anesthetic efficacy is determined by a preparation's active ingredient concentration, delivery vehicle, and time of contact. Head-to-head studies are few with most trials comparing an active drug against placebo.

Eutectic mixture of local anesthetics (EMLA) has been referenced as a gold standard by which other agents may be compared. Its efficacy has been demonstrated in cutaneous laser treatments (4) [4], genital cryotherapy (1b) [5], wound debridement (1b for 3, 4 for 4) [6, 7], and IV insertion [7]. A systematic review, however, identified tetracaine, liposome-encapsulated tetracaine, and liposome-encapsulated lidocaine as equally efficacious or superior to EMLA (1a) [8].

A small prospective trial compared efficacies of EMLA, ELA-Max, 4% tetracaine gel, and Betacaine-LA ointment applied under occlusion for 60 min to adult forearms. EMLA and ELA-Max showed superior anesthesia at removal of occlusion as well as 30 min thereafter (4) [9].

Based on a pediatric study, occluded application of liposomal lidocaine for 30 min is as effective as a 60 min application of EMLA for producing topical anesthesia (2b) [10].

More recently, an FDA-approved preparation of 7% lidocaine/7% tetracaine in a self-occluding cream (Pliaglis) has proven efficacious after 30–60 min of contact time with studies largely focusing on cutaneous laser procedures. Some studies support anesthetic superiority of EMLA (2c for 8, 5 for 9, 1a for 10, 1b for 11, 1b for 12, 1b for 13, 1b for 14, 2c for 15) [11–18].

A systematic review of 22 randomized controlled trials involving >3,000 patients reviewed topical anesthetics for repair of dermal lacerations with the majority of reviewed topical agents demonstrating equal or superior efficacy of anesthesia as compared to intradermal infiltration. There was no significant difference noted in the level of anesthesia achieved between cocaine-containing anesthetic and six cocaine-free topical anesthetic formulations (1a) [19].

Several studies have found that topical and infiltrative anesthesia are equally effective in providing cutaneous anesthesia for harvesting of split-thickness skin grafts, arterial cannulation, and repair of minor dermal lacerations (particularly those located on the head and neck) (1b for 17, 1b for 18, 4 for 19, 1a for 20, 1a for 21) [19–24].

Several studies in the emergency medicine field have reported the efficacy of various topical anesthetics, including EMLA, TAC (tetracaine, adrenaline, and cocaine), amethocaine, prilocaine, and bupivacaine-containing compounds, for repair of lacerations in children and have encouraged these as a less painful and less frightening option to lidocaine infiltration for pediatric patients (4 for 22, 1b for 23, 1b for 24, 2b for 25) [25–28]. A prospective, randomized, double-blind, controlled trial showed that application of topical anesthesia to simple lacerations on pediatric patients during emergency department (ED) triage significantly reduced the total time of ED treatment by 30 min [26]. For the repair of simple lacerations on extremities of pediatric patients, EMLA appears to provide superior anesthesia compared to TAC and less often required supplemental anesthesia during laceration repair [28].

Due to variability of preparations, efficacy of compounded products will not be discussed.

Preoperative Evaluation

FDA package insert guidelines should be followed for any topical anesthetic agent. Given restrictions on applied anesthetic per skin cm^2, determination of targeted skin surface area is necessary to avoid overapplication and potential toxicity. While side-effect profiles are generally minimal, inquiry into the following risk factors may be warranted:

- Contact allergy to PABA (ester anesthetics)
- Cholinesterase deficiency (ester anesthetics)
- Hepatic failure (amide anesthetics)
- Methemoglobinemia (benzocaine)

Best Techniques and Performance

Topical anesthesia may be applied by the patient prior to arriving for their procedure, if they have been provided with proper instructions, or may be applied in office. Prior to application, the skin should be cleansed with mild soap and water, chlorhexidine, acetone, or other effective degreasing agent to remove dirt, oil, make-up, and other contaminants that could impede the absorption and effectiveness of the anesthesia. Washing with benzoyl peroxide should be avoided (4) [29]. A flat-surfaced tool such as a tongue depressor or a gloved finger should be used to apply the topical anesthetic in a thin uniform layer approximately one-eighth-inch thick (2c for 27, 2c for 28) [30, 31]. Depending on the specific topical anesthetic, the agent should remain in place for 30 min–2 h prior to the procedure in order to obtain optimal levels of anesthesia. Occlusion with plastic wrap or a transparent medical dressing such as Tegaderm can promote more rapid onset of cutaneous anesthesia. Prior to the procedure, the anesthetic should be completely wiped off the skin with a dry gauze followed by a water-dampened gauze. This is of heightened importance when the ensuing procedure can produce a spark or flame [31].

The amount of topical anesthetic absorbed depends on drug concentration, vehicle, duration of medication application, and the surface area exposed (2c) [32] (see Table 33.3). A recent review of the literature has shown that damaged or diseased skin, such as in patients with psoriasis or atopic dermatitis, is associated with increased skin permeability and greater chemical absorption (2c) [33].

Selected Agents

Eutectic mixture of local anesthetics (EMLA) is an oil-in-water emulsion cream, comprised of 2.5% lidocaine and 2.5% prilocaine. It is a eutectic mixture, formed from combining the crystalline forms of both lidocaine and prilocaine, causing the mixture to have a lower melting point and greater penetration than either substance alone [19]. EMLA cream may be used for procedures on intact skin or on genital mucosal membranes. For minor dermatological procedures, anesthesia will be achieved in 60 min under an occlusive dressing. For major dermatological procedures, such as split-thickness skin graft harvesting, allow 2 full hours under occlusion to reach peak anesthesia (5) [34]. Anesthesia can be reached in only 5–10 min on genital mucosa. The duration of application correlates to the depth of anesthesia achieved with an average depth of 2.9 mm after 60 min and 4.5 mm after 120 min (4) [35]. Maximum anesthesia in the dermis is reached at 2–3 h of application and persists for 1–2 h after removal of the cream. It is not recommended to apply more than 20 gm over 200 cm^2. EMLA cream may also be used on pediatric patients with the maximum application times and areas shown in Table 33.2 [34].

LMX4 and LMX5 (previously ELA-Max and ELA-Max 5) are 4 or 5% liposomal lidocaine creams. Liposomes are microscopic lipid vesicles that encapsulate lipid- and water-soluble drugs and appear to enhance the absorption and increase protection against rapid metabolism of the compound. Liposomes are readily absorbed into the stratum corneum without penetration to deeper levels of the epidermis or dermis (2c for 33, 2c for 34) [1, 36]. It has been shown that 5% liposomal tetracaine cream has significantly improved anesthetic effect as compared to EMLA cream after 60 min of application (1b) [37]. Cutaneous anesthesia for LMX4 and LMX5 occurs within 15–45 min of application, and occlusion is not needed. The maximum application area for pediatric patients under 20 kg is 100 cm^2 and up to 600 cm^2 for adult patients (2c) [1, 38].

Table 33.2 Pediatric patients: Maximum recommended dosages, application times and areas for EMLA cream [34]

Age and body weight requirement	Maximum total dose of EMLA	Maximum application area	Maximum application time
0–3 months or <5 kg	1 g	10 cm^2	1 h
3–12 months and >5 kg	2 g	20 cm^2	4 h
1–6 years and >10 kg	10 g	100 cm^2	4 h
7–12 years and >20 kg	20 g	200 cm^2	4 h

Pliaglis cream is an emulsion containing 7% lidocaine, an amide local anesthetic, and 7% tetracaine, an ester local anesthetic. It forms a flexible membrane when exposed to air and applied to skin. Pliaglis cream should only be applied to intact skin. Anesthesia can be achieved within 30–60 min of application. No more than 59 g over 400 cm^2 for 120 min should be applied [1, 11, 12].

Four percent tetracaine (amethocaine or Ametop) is an ester and is more lipophilic than amides and better able to penetrate the stratum corneum. It is typically applied under occlusion, achieves anesthesia within 30 min, and lasts approximately 4 h. Maximum recommended application area is 600 cm^2 for adult patients and 100 cm^2 for pediatric patients (5 for 37) [1, 38, 39]. Amethocaine promotes vasodilation and is hypothesized to promote improved venous access for cannulation (2c) [2].

TAC is a combination of 0.5% tetracaine, 0.05% adrenaline, and 11.8% cocaine and was the first topical anesthetic used for repair of head and face lacerations (2c) [40]. Dosing of 1 ml/cm of lacerated tissue is recommended to be applied with firm pressure for 20–40 min. It is ineffective on intact skin. However, due to concerns regarding cost and rare toxicity, largely from systemic absorption of cocaine, this product is rarely used. Complications are notable for seizures and sudden cardiac arrest, and rarely, death has been reported (2c for 40, 5 for 41) [1, 38, 40–42].

LET comprises 4% lidocaine, 0.1% epinephrine, and 0.5% tetracaine and is considered a safer and more affordable alternative to TAC. It is often used for repair of cutaneous lacerations and is ineffective on intact skin. One to 3 mL of gel or

solution may be applied directly into non-mucosal wounds with firm pressure for 15–30 min. Due to the vasoconstriction resulting from epinephrine, avoid applying to end-arteriolar areas on the body such as the digits [1, 38, 40].

Topicaine is a 4% lidocaine gel microemulsion. An application time of 30–60 min is recommended with a surface area maximum of 600 cm^2 for adults and 100 cm^2 for children. Local adverse effects include mild erythema, edema, and blanching (2c for 42) [1, 38, 43]. A randomized, double-blind, controlled trial has shown that Topicaine and LMX5 applied for 30 min produced effective anesthesia for treatment with Q-switched Nd:YAG laser; however, EMLA cream and Topicaine produced the highest level of anesthesia 30 min after removal of the topical anesthetic (4) [3].

Benzocaine is often prepared as a topical anesthetic spray with 10% or 20% benzocaine. A safe spraying time has not yet been determined due to the variability of the compound as it is applied (4 for 44) [41, 44].

Lidoderm (USA) and Versatis (Europe, South America) are slow-release patches containing an adhesive material with 5% lidocaine. The Lidoderm patch size is 10 cm × 14 cm. Each adhesive patch contains 700 mg (50 mg/gm adhesive) of lidocaine in an aqueous base. Up to three patches may be applied for a maximum of 12 h each per 24 h period. Lidoderm is FDA approved for treatment of post-herpetic neuralgia and is intended for use on intact skin only (5 for 45) [1, 2, 45].

Betacaine-LA is a petrolatum-based ointment that contains a combination of lidocaine, prilocaine, dibucaine, and phenylephrine. It is a proprietary anesthetic, and the exact concentrations of each ingredient are not revealed. Topical anesthesia can be achieved within 30–45 min without occlusion, and it should not be applied to a surface area >300 cm^2. It is not recommended for use in children [1, 38, 43].

Adjuvant Strategies

Topical anesthetics may cross the stratum corneum either through the cornified cell itself, through the spaces between cornified cells, or through openings in hair follicles, sweat glands, and sebaceous glands. Conjunctivae and oral and genital mucosa lack a stratum corneum and, therefore, are more easily penetrated by topical anesthetics [1]. There are several methods that can help enhance permeation and promote absorption of topical anesthetics through the stratum corneum and into the dermis. Removal of the stratum corneum by cutaneous tape stripping has been shown to increase transepidermal water loss through mechanical damage and has been shown to accelerate the rate of anesthesia prior to IV catheterization (1b for 46) [33, 46]. Laser-assisted delivery of 5% lidocaine cream through ablation of the stratum corneum with an Er:YAG laser was also found to increase the effectiveness of the topical anesthesia as compared to use of lidocaine cream alone (2b) [47].

Occlusion and heat can facilitate anesthetic penetration into the skin; however, caution must be taken as there is no data supporting standard practice recommendations. Application of EMLA cream with heat provides improved anesthesia at 20 min as compared to EMLA cream alone, although EMLA cream applied for the recommended 60 min remains superior for analgesia (4) [48]. A topical local anesthetic patch containing lidocaine 70 mg and tetracaine 70 mg with an incorporated oxygen-activated heating element (Synera, USA and Rapydan, parts of Europe) has been shown to provide significantly more pain relief prior to IV cannulation than a non-heated patch (1b) [49]. The heated patches are intended for use on intact skin only, and anesthesia may be achieved within 20 min with an average depth of 6.8 mm (5 for 50) [2, 50]. The S-Caine Peel incorporates the same formula as the Synera patch but is applied as a pliable peel that forms a skin-like mask upon exposure to air for easy removal. A recent meta-analysis found that the lidocaine/tetracaine patch or peel consistently and significantly provided more anesthesia than placebo with minimal difference in efficacy and safety. Common adverse effects include transient mild erythema, burning sensation, itching, blistering, and edema, all of which were resolved without intervention [13]. In another study of

heated lidocaine/tetracaine patches, plasma concentrations of lidocaine increased rapidly in the initial 2 h, then remained relatively stable through 12 h; however, the rate of drug delivery reached a peak at 2 h and diminished by 25% by 12 h. No tetracaine was detected in the serum at any time. Serum lidocaine levels were found to be five times higher at 30 min of patch application and three times higher at 60 min of patch application for heated patches as compared to non-heated patches (2b) [51].

There are several methods that physically enhance the ability to permeate through the barrier of the stratum corneum. Iontophoresis is a method of actively delivering a drug under the influence of mild electric current to enhance absorption and penetration across the skin barrier through existing pathways such as hair follicles and sweat glands. Studies have found that effective anesthesia on the skin can be achieved within 10 min for both children and adults, may last up to 15 min, and penetrate to a depth of 1–2 cm (1b for 52, 4 for 53, 4 for 54) [40, 48, 52–54]. Side effects include mild erythema and a burning or stinging sensation and are typically dose dependent. This method can also be cumbersome and complex to administer. Lidosite is an FDA-approved iontophoretic patch containing 10% lidocaine and 0.1% adrenaline for use on intact skin (5) [55].

Electroporation creates temporary aqueous pathways ("pores") across the lipid bilayer membrane through high-voltage electrical impulses and passively transports drug molecules dissolved in solution by diffusion or electrophoretic forces. Between pulses, the skin depolarizes and therefore maintains its native barrier properties. The procedure typically is quick and causes minimal irritation of the skin [53]. Electroincorporation is a similar method of creating transient pores in the stratum corneum, where polarizable particle suspensions, as opposed to solutions, are brought in close contact and transported through to the stratum corneum through pulsed dielectric fields. This procedure is also quick; however, it has increased risk of developing skin irritation depending on the specific particles transported. It has been suggested that iontophoresis, electroporation, and electroincorporation result in a similar level of anesthesia for warm and hot pain sensations, but that iontophoresis is more effective for cool pain sensation and can produce a greater depth of anesthesia into the dermis [53].

Ultrasound can be used to improve the delivery of topical anesthesia into the dermis. Low-frequency ultrasound results in cavitation and formation of transient aqueous channels through the stratum corneum. Treatment of the skin with low-frequency ultrasound prior to application of topical anesthesia has been shown to speed the onset of anesthesia with similar discomfort felt by those receiving ultrasound and topical anesthesia for 5 min as those receiving topical anesthesia alone for 30 min (2b) [56].

Microchannels created through microneedling by force of hand have been found to penetrate through the stratum corneum with a depth of penetration ranging from <100 μm to nearly 150 μm. A recent study showed that after two rounds of microneedling pretreatment, there was up to a 340% increase in topical anesthetic (lidocaine) uptake into the tissue (4) [57].

Needleless jet injection systems use compressed air to transmit topical anesthesia across the skin barrier to help promote a more rapid onset of anesthesia; examples include J-Tip, PowderJect, Dermojet, and PowderMed [2]. A prospective, randomized, controlled trial for children 8–15 years of age compared the anesthetic effectiveness of needle-free jet injection of 1% buffered lidocaine to 4% topical ELA-Max applied for 30 min prior to peripheral intravenous (PIV) catheter insertion and found that the needle-free jet injection method was associated with significantly less pain when assessed immediately after PIV catheter insertion (2b) [58].

Safety

The use of topical anesthetics is generally regarded as safe and well tolerated in appropriate doses; however, localized and systemic reactions may occur. Dermatological procedures that disrupt the epidermis, such as cutaneous laser surgery, may allow for increased absorption of the topical anesthetic and increased risk of toxic effects. Minor adverse effects include mild

erythema, skin irritation, pruritus, pallor if epinephrine is a component, vasoconstriction with EMLA, and vasodilatation with amethocaine (2b for 59) [2, 41, 59].

Amide topical anesthetics are metabolized by hepatic microsomal enzymes, including cytochrome P450 (CYP) 3A4, and should be used in caution in patients with liver dysfunction. Generally, there is minimal systemic absorption of topical anesthetic. Evaluation after application of occluded LMX4 (topical 4% liposomal lidocaine) cream in moderate amounts, 30 gm and 60 gm, did not show any clinical signs of toxicity or serum levels of lidocaine or metabolite monoethylglycinexylidide (MEGX) >0.5 mcg/mL through 24-h post-application [54]. However, when systemic absorption does occur, it can be associated with severe side effects including central nervous system (CNS), respiratory, and cardiopulmonary toxic effects. Lidocaine is associated with dose-dependent toxicity effects, so it is important to adhere to the correct dose as per manufacturer recommendations (Table 33.3). Therapeutic levels for anti-arrhythmia occur at 2–5 mcg/mL, and toxicity range occurs at >5 mcg/mL. A recent review of the literature of systemic toxicity due to EMLA yielded three adult and nine pediatric cases of toxicity. Several factors were noted as possible contributors to the development of systemic toxicity including excessive amount of EMLA over a large application area, prolonged application time, diseased and/or inflamed skin, age <3 months, and concomitant use of a methemoglobin-inducing agent (2c) [60]. EMLA exposure to the eye has resulted in corneal abrasions and ulcerations (5 for 61) [38, 61].

Table 33.3 Signs and symptoms of lidocaine toxicity [31]

Blood lidocaine level (mcg/mL)	Signs and symptoms
1–5	Anxiety, tinnitus, nausea, vomiting, lightheadedness, circumoral numbness, diplopia, metallic taste
5–8	Slurred speech, nystagmus, muscle twitching, tremors
8–12	Seizures (focal activity to generalized tonic-clonic seizures)
20–25	Cardiopulmonary and or respiratory arrest, coma

Methemoglobinemia is another potential serious side effect of topical anesthetics and has been associated with lidocaine, prilocaine, and most significantly, benzocaine. Hemoglobin is oxidized from a ferrous state (Fe^{2+}) to a ferric state (Fe^{3+}), resulting in methemoglobin, and is no longer able to bind oxygen, which lowers the oxygen-carrying capacity of the blood (5 for 62, 5 for 63) [62, 63]. Early symptoms of methemoglobinemia include cyanosis, headache, dyspnea, dizziness, fatigue, and loss of consciousness. An elevated methemoglobin level in arterial blood may result in a chocolate brown discoloration of the blood. With methemoglobin levels >50% (severe methemoglobinemia), symptoms include cardiac dysrhythmias, seizure, coma, and death. A retrospective case-control study revealed that, in general, the overall prevalence of procedure-related (including TEE, EGD, ERCP, bronchoscopy, and NG tube placement) methemoglobinemia is low at 0.035%; however, there was an increased risk noted with benzocaine-related topical anesthetics, with hospitalized patients, as well as with patients taking other methemoglobin-forming medications such as sulfonamides, dapsone, phenytoin, phenobarbital, acetaminophen, and nitrous oxide [2, 63]. Benzocaine has been reported to cause methemoglobinemia with as little as a single spray [1]. A recent study reported eight cases of methemoglobinemia after repeat mucosal exposure to benzocaine within 0–10 days of the initial exposure. In addition, five cases of rebound methemoglobinemia to initial mucosal application of benzocaine occurred up to 18 h after methylene blue administration with values as high as 59.9% [41, 44]. Treatment includes supplemental oxygen, IV methylene blue, and hyperbaric oxygen [1].

Ester anesthetics are metabolized to para-aminobenzoic acid (PABA) by hydrolysis and have rarely been associated with allergic reactions in a small number of patients (5) [64]. Ester topical anesthetics are contraindicated in patients with allergies to PABA, hair dyes, and sulfonamides [38].

The creation of compounded topical anesthetics, including TAC and LET, is not federally regulated or consistent between pharmacies. They are custom-produced for a specific patient by compounding pharmacies per physician prescription

and have been associated with variability in their composition including mixture and strength of topical anesthetics, labeling, and packaging. Dosing recommendations are not standardized, and the maximum recommended dosage is often not known which increases the risks of adverse events and even death (5) [65]. A public health advisory was issued in 2006 regarding the risk of life-threatening side effects associated with compounded topical anesthetics, and warnings were issued to five companies to stop the creation and distribution of compounded topical anesthetics produced for the general public rather than individualized for specific patients [65]. The United States Food and Drug Administration (FDA) has reported the death of two women due to compounded topical anesthetics after the unsupervised application and occlusion of topical lidocaine to their legs prior to laser hair removal (5) [66]. Therefore, it is imperative that topical anesthesia be used correctly and be applied for the shortest duration of application possible and to the smallest surface areas possible to avoid toxicity problems.

There is minimal data regarding the safety of topical anesthesia for pregnant and nursing women. Infiltrative lidocaine anesthetic has been reviewed most thoroughly and is a pregnancy category B medication based on animal studies. However, there have been no well-controlled studies in pregnant women. Per manufacturer recommendations, lidocaine and prilocaine are safe in small amounts for pregnant women. Both medications are excreted in human milk, with a 0.4 milk-to-plasma lidocaine ratio (not yet reported for prilocaine) and should be used with caution in nursing women (2c) [34, 67]. Blood and milk lidocaine levels in 27 epidural cases were found to be low, with no adverse effects noted due to excretion of the anesthetic into breast milk (4) [68]. The American Academy of Pediatrics considers lidocaine as safe for use during lactation (2c for 69, 2c for 70, 2c for 71) [69–71]. However, it is recommended to postpone use of topical anesthesia until after delivery or until the second trimester, at the very earliest, for more urgent procedures [69].

Postoperative Care and Follow-Up

With uncomplicated application, no specific follow-up care is required. Adverse effects should be managed according to their acuity and severity. The most common reactions, irritant or allergic contact dermatitis, may be managed with topical corticosteroids in moderate to severe cases or monitored for resolution in mild cases. Ocular complications should be evaluated by an ophthalmologist.

Systemic toxicity and/or anaphylaxis from topical anesthetics, though exceedingly rare, has/have resulted in death [68]. If signs of toxicity are encountered (Table 33.3), transfer to an emergency facility may be warranted.

Alternative Procedures and Modifications

For procedures requiring prolonged anesthesia, direct injection of local anesthetic agents is a common strategy, either via dermal infiltration or regional nerve blocks. Direct comparison studies are limited, but the use of topical agents was shown to be of equivalent efficacy to intradermal infiltration of anesthetics in harvesting split-thickness skin grafts, arterial cannulation, and repair of minor dermal lacerations [19–24]. Local infiltration of injected agents may be impractical for large surface areas of skin, unless regional blocks or tumescent techniques are utilized. Both techniques are more technically challenging to execute, and tumescent anesthesia requires the use of specialized equipment.

Ethyl chloride spray can provide immediate and transient anesthesia of the skin, which can be helpful in situations when waiting for topical anesthesia to take effect is impractical. The spray vaporizes immediately upon cutaneous contact, briefly dropping the temperature to −10 to −20 °C. It can be associated with mild pain and erythema [39, 41]. A study comparing the application of EMLA cream (45 min prior to procedure) to ethyl chloride spray (4–8 s of spray) prior to botulinum toxin injection showed that patients

experienced significantly less pain with ethyl chloride spray, with all patients in the study preferring this method of topical anesthesia (4) [72]. Review of other studies has shown variability in the efficacy of ethyl chloride in providing reduction of pain during venous cannulation, venipuncture, and skin prick testing, with some finding ethyl chloride as effective and others finding lidocaine infiltration to be superior in achieving anesthesia (4 for 73, 4 for 74, 4 for 75, 2b for76) [73–76].

Transcutaneous electronic nerve stimulation (TENS) is a strategy which uses electricity to provide nerve stimulation and analgesia. A single small randomized, prospective dental trial compared the use of TENS, 20% topical benzocaine (2 min application), and no pretreatment on pain associated with injected inferior dental blocks and lingual blocks. TENS was shown to be superior to both the topical benzocaine and no pretreatment (1b) [77].

At present, no available studies directly compare topical anesthetic agents to skin vibration, vapocoolant sprays, skin rubbing, or distraction techniques.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE).

Findings	GRADE score: quality of evidence
Topical anesthesia offers a safe and well-tolerated alternative to regional anesthesia when applied appropriately. FDA-approved pharmaceutical agents provide more consistency than compounded agents and are supported by reliable efficacy and safety studies.	D
Cocaine-free formulations should be used preferentially to cocaine-containing formulations.	A
Topical anesthetic agents are safe and effective for repair of skin lacerations in children.	A
Topical anesthetic agents are effective for minor procedures involving instrumentation of the skin.	C
Lidocaine usage should be limited in pregnancy. Insufficient data exists regarding other topical agents, so these should be avoided. Consider delaying procedures requiring topical anesthesia until after delivery.	C
Topical anesthetic agents may be effectively used for cutaneous laser surgery.	C

Self-Assessment Questions

1. EMLA cream may be safely applied to:
   (a) Open lacerations
   (b) Conjunctiva
   (c) Intact skin
   (d) Genital mucosa
   (e) C and D
2. Which of the following topical agents is contraindicated in patients with known PABA allergy?
   (a) Lidocaine
   (b) Prilocaine
   (c) Benzocaine
   (d) Etiodocaine
   (e) EMLA
3. Initial signs of lidocaine toxicity (blood level 1–5 mcg/mL) include all of the following EXCEPT:
   (a) Circumoral numbness
   (b) Tinnitus
   (c) Metallic taste
   (d) Nystagmus
   (e) All of the above are initial signs of lidocaine toxicity
4. Patients on systemic dapsone therapy are at increased risk of what complication of benzocaine use?
   (a) Contact dermatitis
   (b) Methemoglobinemia
   (c) Anaphylaxis
   (d) Aphthous ulcers
   (e) B and C
5. Topical and infiltrated intradermal anesthesia have been shown to be of equivalent efficacy in each of the following applications EXCEPT:
   (a) Split-thickness skin graft harvesting
   (b) Ablative laser resurfacing
   (c) Arterial cannulation
   (d) Minor dermal laceration repair
   (e) None of the above

Correct Answers

1. e: Per package insert, "EMLA cream (a eutectic mixture of lidocaine 2.5% and prilocaine 2.5%) is indicated as a topical anesthetic for use on normal intact skin for local analgesia and genital mucous membranes for superficial minor surgery and as pretreatment for infiltration anesthesia."
2. c: Ester anesthetics are metabolized to para-aminobenzoic acid (PABA) by hydrolysis and have rarely been associated in allergic reactions in a small number of patients [64]. Ester topical anesthetics are contraindicated in patients with allergies to PABA, hair dyes, and sulfonamides [38].
3. d: See Table 33.3.
4. b: A retrospective case-control study revealed an increased risk of methemoglobinemia with benzocaine-related topical anesthetics and patients taking other methemoglobin-forming medications, such as sulfonamides, dapsone, phenytoin, phenobarbital, acetaminophen, and nitrous oxide [2, 63].
5. b: The use of topical agents was shown to be of equivalent efficacy to intradermal infiltration of anesthetics in harvesting split-thickness skin grafts, arterial cannulation, and repair of minor dermal lacerations [19–24].

Local and Regional Infiltrated Anesthesia (Excluding Topical Anesthesia)

Meredith Orseth and Divya Srivastava

Abstract

The dermatologic indications for local and regional infiltrated anesthesia are abundant. Local infiltrative anesthesia is considered safe and effective for an array of procedures including excisions, biopsies, wound closures, skin grafting, cauterization, nonablative laser, and ablative skin resurfacing. Few contraindications to local and regional infiltrated anesthesia exist but should be screened for during the preoperative consultation. Numerous techniques for achieving adequate local and regional anesthesia have been described, including practices to lessen the pain associated with injection. Common side effects of local infiltrative anesthesia include pain, erythema, edema, bleeding, and ecchymoses. While overall well tolerated and commonly used, local and regional infiltrative anesthetic procedures do carry risks for toxicity and death. A comprehensive understanding of the pathophysiology, technique, and potential adverse events of various local and regional infiltrated anesthetics is critical to improve patient satisfaction and safety.

Keywords

Local anesthesia · Lidocaine · Injectable Epinephrine · Sodium bicarbonate · Cutaneous surgery · Systemic toxicity

Indications

The number of office-based procedures performed using local anesthesia continues to rise in dermatologic settings. The dermatologic indications for local and regional infiltrated anesthesia are abundant. Evidence-based guidelines from an American Academy of Dermatology (AAD) expert panel published in 2016 included a nonexhaustive list of office-based procedures in dermatology for which local infiltrative anesthesia is safe and recommended, including excisions, biopsies, wound closures, skin grafting, cauterization, nonablative laser, and ablative skin resurfacing (5) [1]. Tumescent local anesthesia, a technique using large volumes of a dilute anesthetic agent to produce swelling of the target areas, is commonly used in tumescent liposuction [2, 3]. A combination of infiltrative anesthesia with tumescent local anesthesia is recommended for follicular unit hair transplantation (5) [1]. Regional anesthesia, most often in the form of peripheral nerve blocks, may be used to anesthetize large areas while minimizing the amount of anesthetic utilized. Peripheral nerve blocks are helpful on the face, digits, and palmoplantar

surfaces as a way to minimize tissue distortion and patient discomfort [4–6]. Data supports nerve block anesthesia during botulinum toxin injection of the palm (4) [7] and ablative laser resurfacing of the face (5, 4) [8, 9]. Peripheral nerve blocks of the forehead and scalp lead to a considerable reduction in pain during photodynamic therapy (PDT) (1b, 1b, 1b) [10–12]. Local infiltrative anesthesia and peripheral nerve block for ptosis surgery are associated with equal levels of patient satisfaction and are both accepted anesthetic methods for this procedure (1b) [13]. With appropriate technique and few exceptions that are discussed below, local and regional anesthesia may safely be used for localized pain reduction in patients of all ages [14].

Effectiveness

Local infiltrative anesthesia is considered effective for the procedures described above. However, there are few studies comparing the efficacy of local infiltrative anesthesia to other forms of local anesthesia [1].

Depending on the anesthetic agent used, the effect on pain reduction may vary significantly. The potency, duration of anesthesia, and speed of onset of local infiltrative anesthetics are dependent on their structural characteristics: lipid solubility of the aromatic ring, degree of protein binding, and drug dissociation constant, respectively. The closer the drug dissociation constant (pKa) of the medication is to tissue pH, the faster the time to effect [15–17]. With a pKa higher than physiologic pH, local anesthetics will have a faster onset of action when buffered or alkalinized with sodium bicarbonate [17]. Conversely, in tissues that are acidic due to inflammation or infection, the time to effect will be slower (5) [18].

Lidocaine is the most commonly used local anesthetic in dermatology and has a near immediate onset of action and moderate duration of 0.5–2 h [19]. Bupivicaine has a comparatively longer duration of action and may be useful for lengthier procedures such as Mohs micrographic surgery, flaps, and grafts. The onset of action for bupivacaine is 5–8 min and duration of anesthesia is 2–4 h [6, 19]. Anesthesia with either lidocaine or bupivicaine is prolonged by a factor of two with the addition of epinephrine (1b) [20]. Table 34.1 includes characteristics of common anesthetics used for local infiltration.

Table 34.1 Commonly used local anesthetics and their time to onset and duration of action [1, 19]

Name	Onset (min)	Duration without epinephrine (min)	Duration with epinephrine (min)
Amides			
Bupivicaine	5–8	120–240	240–480
Lidocaine	<1	30–120	60–400
Prilocaine	5–6	30–120	60–400
Esters			
Procaine	5	15–90	30–180
Tetracaine	7	120–240	240–480

Of note, the efficacy of local anesthesia may vary depending on patient characteristics. For example, subcutaneous lidocaine has been found to be significantly less effective in red-haired compared to dark-haired women (2b) [21]. Redheads and African Americans appear to be more sensitive to pain in general (2b) [21, 22].

Preoperative Evaluation

Prior to administering local infiltrative anesthesia or regional anesthesia, an appropriate history and physical should be performed as part of the preoperative consultation. Patients should be questioned regarding medication use and past medical history, including history of hypersensitivity to anesthetics as well as liver or cardiac disease. Additionally, the weight of the patient should be obtained prior to the procedure to accurately calculate the maximum recommended dose of infiltrated anesthetic (see Table 34.2). There are few absolute contraindications to local or regional infiltrative anesthesia.

True hypersensitivities are rare, but patients with a known history of hypersensitivity to local anesthetics of the ester (e.g., procaine, tetracaine) or amide (e.g., lidocaine, mepivacaine, bupivacaine, prilocaine) class should not receive

Table 34.2 Maximum recommended dosing of lidocaine and lidocaine with epinephrine per 2016 AAD Guidelines [1]

	Lidocaine	Lidocaine with epinephrine
Adults – single treatment	4.5 mg/kg	7.0 mg/kg
Children – single treatment	1.5–2.0 mg/kg	3.0–4.5 mg/kg
Tumescent liposuction in patients weighing 43.6–81.8 kg		55 mg/kg

medications of that type [1]. If a true allergy is suspected, preoperative allergy testing may be conducted using patch testing (type IV reaction), skin prick testing (type I reaction), or intradermal or subcutaneous challenges [23–26]. Alternatives to amide or ester anesthetics include diphenhydramine 1% and bacteriostatic saline [1]. These alternative medications will be discussed in further detail below.

Amide-type anesthetics such as lidocaine are metabolized by the liver and excreted by the kidneys [18, 27]. Liver disease, therefore, is a relative contraindication to using amide anesthetics as an increased risk for toxicity exists. Studies looking at plasma concentrations of lidocaine following intravenous bolus injection in patients with hepatic dysfunction found the elimination half-life to be prolonged by up to a factor of three [27]. No clear guidelines have been established to direct care.

Lidocaine may prolong cardiac atrioventricular conduction, and caution is advised in patients with impaired cardiovascular function, especially those with heart block [28]. Plasma clearance is reduced by a factor of two in patients with heart failure [27]. While caution is prudent, patients with stable cardiac disease may receive local infiltrative anesthesia with epinephrine (1a) [1, 29, 30]. If concern about a patient's ability to undergo local or regional infiltrative anesthesia exists, a consultation with the patient's cardiologist is recommended [1].

Concurrent use of epinephrine with monoamine oxidase inhibitors, phenothiazines, or tricyclic antidepressants may produce severe hypertension (4) [31]. Although rare, there are reports of severe hypertension developing in patients taking beta-blockers such as propranolol (4) [32]. A review of 114 patients taking beta-blockers undergoing minor surgical procedures with small amounts of epinephrine reported no hypertensive crises or minor cardiovascular episodes (4) [33].

Lidocaine is pregnancy category B. While it does cross the placenta, lidocaine did not demonstrate harm to the fetus in animal reproductive studies. Epinephrine also crosses the placenta and is considered pregnancy category C as one study showed increased risk of malformations in children of mothers exposed to systemic epinephrine during the first trimester (4) [34]. As per recent AAD evidence-based guidelines, small controlled amounts of lidocaine with epinephrine do appear safe for local anesthesia in pregnant women (4). In urgent situations, surgery should be delayed until second trimester if possible and all nonemergent procedures should be delayed until after delivery. Discussion with the patient's obstetrician may be helpful for risk analysis (5) [1].

Anesthetics containing paraben preservatives should be avoided in newborns with jaundice as parabens may displace bilirubin from albumin and worsen the condition (5, 5) [35, 36]. Neonates in general are at increased risk of toxicity due to immature hepatic metabolism and diminished plasma protein binding, and caution is advised (5) [14].

Best Techniques and Performance

There are numerous techniques described to successfully achieve local and regional anesthesia. Furthermore, there are several additives to local anesthesia that can enhance efficacy.

Common routes for local anesthesia administration include a combination of local infiltration in the dermis and subcutaneous tissue, field or ring block, peripheral nerve block, and tumescent infiltration. The specific technique chosen often depends on the procedure performed, anatomic site, and patient factors. The goals include achieving effective anesthesia while minimizing pain of

injection, volume injected, and side effects. Intradermal injection has the advantage of immediate onset and prolonged duration but is associated with increased pain of injection and tissue distortion. Subcutaneous infiltration is associated with less pain and a greater diffusion but has a shorter duration, increased absorption, and requires a greater volume of anesthetic (5) [37]. Commonly, a combination of intradermal and subcutaneous infiltration is used to achieve anesthesia. Field blocks involve injecting anesthesia around the surgical site when direct injection is not optimal, such as in a cyst excision. Nerve blocks have the advantage of prolonged duration and minimal volume injected; however, local infiltration is necessary to achieve hemostasis with the epinephrine effect. Also, there is a risk of nerve damage with nerve blocks [19]. Tumescent anesthesia involves infiltration of the subcutaneous fat with large volumes of dilute lidocaine through spinal needles or cannulas [3].

Whichever technique is utilized, safe patient positioning prior to the procedure is critical. In a large retrospective review, 1.9% of patients experienced presyncope and 0.16% of patients experienced true syncope during in-office procedures involving local anesthesia for simple excisions and shave biopsies (2b) [38]. Vasovagal reactions are characterized by warmth, diaphoresis, and pallor in response to upright posture, emotional stress, pain, or medical settings and may ultimately lead to syncope [39]. Clinicians should be careful to position patients in a way in that if this reaction occurs, neither the patient nor the clinician is injured. Additionally, patients should be positioned in a manner that is comfortable for both the patient and the clinician to complete the procedure. A review of reported sharps injuries in employees at an academic center from 2004 to 2013 revealed a significant increase in sharps injuries associated with local anesthesia over that time period despite a statistically significant decrease in overall sharps injuries (4) [40].

Discomfort associated with local infiltrative anesthesia may be considerable, and numerous studies have examined techniques aimed at reducing pain of injection [41–45]. The addition of sodium bicarbonate to buffer acidic lidocaine solutions has been well established (1b, 1b, 1b) [46–48] and is recommended in local infiltrative anesthesia. Most often, 8.4% sodium bicarbonate is mixed with 1% lidocaine with epinephrine in a 1:9 or 1:10 ratio [1].

Cold air skin cooling prior to injection, slow rate of infiltration, and warming the anesthetic solution to body temperature have been shown to be effective at reducing pain associated with anesthetic injection in single randomized controlled trials (1b, 1b, 1b) [41, 42, 44]. Distraction techniques have been shown to decrease distress behavior in the pediatric population during procedures such as immunization and venipuncture (1b, 1a) [49, 50] and have been suggested as helpful during dermatological procedures (5) [51]. However, there is limited data in the dermatological literature supporting the use of verbal or behavioral distraction techniques during local or regional anesthesia.

Skin-vibrating devices have been studied in upper eyelid surgery and during botulinum toxin and filler injections for cosmesis and were found to lead to a significant reduction in pain during the procedures (1b, 1b, 1b) [52–54]. Repetitive pinching of the skin has been found to be effective at reducing pain of injection of local anesthetic (1b) [43].

Data on the use of cooling the skin with ice prior to injection is limited. A prospective comparison of bicarbonate-buffered lidocaine to preoperative cooling for 2 min with ice prior to unbuffered lidocaine injection showed no significant difference between the two methods (2b) [45]. An ice-saline-xylocaine method has been suggested in which the skin is cooled with ice, then preinjected with normal saline prior to lidocaine injection (5) [55]. Data supporting this is scarce, and currently there is no clinical consensus regarding the use of ice or preinjection with normal saline to lessen pain associated with local anesthetic injection [1].

Commonly epinephrine is added to anesthetic agents for its vasoconstrictive effect and to reduce the dose of anesthetic required, thereby decreasing systemic toxicity [15]. The time to vasoconstriction when using lidocaine with epinephrine is often cited as 7–15 min [37, 56]. However, a

recent prospective, randomized, triple-blind study in 12 volunteers suggests 25 min to be the ideal wait time to begin a procedure after injection of 1% lidocaine with 1:100,000 epinephrine (1b) [57]. The optimal concentration of epinephrine is unclear and using the lowest effective concentration to provide pain control and vasoconstriction is recommended [1]. A comparison of 1% lidocaine with epinephrine in concentrations of 1:100,000, 1:200,000, and 1:400,000 during neck surgery showed no significant difference in blood flow; however, epinephrine 1:800,000 resulted in significantly less vasoconstriction (2b) [58]. Similarly, there was no significant difference in vasoconstriction between 1% lidocaine with 1:100,000 epinephrine and 1% lidocaine with 1:200,000 epinephrine during facial injections (1b) [56]. A randomized, double-blind comparison of 0.5% lidocaine with 1:200,000 epinephrine and traditional 1% lidocaine with 1:100,000 epinephrine demonstrated no significant difference in pain control during Mohs micrographic surgery. The dose of lidocaine administered in the 0.5% lidocaine with 1:200,000 epinephrine group was approximately half that administered in the 1% lidocaine with 1:100,000 epinephrine group (1b) [59]. In dermatologic surgery, epinephrine concentrations of 1:100,000 and 1:200,000 are most commonly used [1]. These concentrations have been shown to increase duration of anesthesia by approximately 200% [20].

While historically there was concern regarding the use of local infiltrative anesthetics with epinephrine on areas such as the ear, nose, penis, hands, feet, and digits, multiple systemic reviews, randomized controlled trials, and retrospective studies have found the addition of epinephrine to local infiltrative anesthesia to be safe for use in these locations [60–63]. There were no reported cases of necrosis and benefits described included improved view and extended effect of anesthesia [60, 63, 64]. Based on this data, the 2016 AAD guidelines state local infiltrative anesthesia with epinephrine is safe and recommended for use on the ear, nose, hand, feet, and digits (1a) and may be considered for use during procedures on the penis (2b) [1].

Buffered lidocaine both with and without epinephrine may be stored in a controlled room or controlled cold temperature environment and be safe for use for up to 4 weeks, although effectiveness of the solution may decrease (5) [65]. A 1989 study showed the addition of bicarbonate to lidocaine with epinephrine leads to a weekly 25% decrease in concentration of epinephrine in the buffered solution [47]. Stewart et al. demonstrated that there is no difference in clinical effectiveness between buffered 1% lidocaine with epinephrine solution prepared within 5 h and solution stored at room temperature for 7 days [46].

More recent data showed lidocaine in buffered solution with epinephrine remained over 95% of its original concentration while stored in a controlled cold temperature environment for up to 4 weeks. Concentration of epinephrine in the solution decreased to 95.9% of original and 61.8% of original at weeks 1 and 4, respectively (5) [66]. In comparison, lidocaine in buffered solution with epinephrine at room temperature showed a respective decrease in lidocaine concentration of 88.73% and 66.11% of original at 1 and 4 weeks, respectively. Epinephrine concentration in the solution stored at room temperature decreased to 72.65% and 1.34% at 1 and 4 weeks, respectively (5) [67]. Therefore, while buffered lidocaine with epinephrine is safe for use for up to 4 weeks, due to concern for diminished effectiveness, some authors recommend use of the solution within 1 week of compounding [47].

Hyaluronidase promotes increased absorption of local anesthetics by digestion of the extracellular matrix. Most often described in ophthalmology and plastic surgery literature, there is limited data regarding its use in dermatological surgery [68–70]. The mixing of hyaluronidase and infiltrative anesthesia did not retard wound healing and was deemed safe in a prospective, double-blind, randomized, placebo-controlled, single-center study (1b) [69]. Hyaluronidase is thought to ease dissection through tissue planes; however, no data supports this, and its role in dermatological surgery is unclear [1, 70]. Patients with a history of bee sting allergy should not receive hyaluronidase as there are reports of cross-

reactivity and type I hypersensitivity with its use (5, 5) [71, 72].

There is a gap in research examining the use of regional anesthesia in dermatology. Despite this, supraorbital, supratrochlear, mental, infraorbital, and digital nerve blocks are commonly used in dermatological surgery [6] and are an accepted alternative to local infiltrative anesthesia for surgeries on the face and digits [1]. Similarly to local infiltrative anesthesia, several anesthetic agents are utilized for peripheral nerve blocks, with 1% lidocaine with epinephrine and sodium bicarbonate being the most common [19]. A randomized control trial examining the duration of anesthesia in digital nerve blocks found bupivacaine 0.5% to have a significantly longer digital anesthesia time (24.9 h) compared to 2% lidocaine with 1:100,000 epinephrine (10.4 h) and 2% lidocaine (average 4.9 h) (1b) [64].

Several techniques for digital nerve blocks have been described including a traditional two-injection (also known as four-sided or "ring") block, subcutaneous block (one or two palmar punctures), transmetacarpal/metatarsal block, or transthecal block (local anesthetic is injected into the flexor tendon sheath) [73]. Traditional two-injection blocks are the form most commonly used in dermatology to block the sensory nerves coursing laterally along the digit [19]. Data specific to dermatology is lacking, with most trials to date published in emergency medicine and plastic surgery literature [73–76]. A randomized control trial comparing traditional two-injection digital block to transthecal digital block found the two techniques to be equivalent based upon associated pain and time to anesthesia (1b) [74]. A comparison of subcutaneous block to traditional digital block found the subcutaneous method to be as effective as the traditional method with outcome measures favoring the former but no significant difference in success of anesthesia or patient distress between the two (1b) [75]. A comparison of subcutaneous block, transthecal block, and transmetacarpal block in healthy volunteers found no significant difference on average pain level between methods, although time to onset was significantly longer for the metacarpal block, and the transthecal block had prolonged discomfort lasting 24–72 h in 40% of the subjects. Therefore the authors of the study favored subcutaneous block (1b) [73]. A trial in patients who had injured two or four fingers and served as their own controls compared transthecal versus subcutaneous digital block techniques and found that while transthecal block was equally efficacious, it was significantly more painful. Subcutaneous block was also preferred in that scenario (1b) [76]. A 2006 meta-analysis found evidence favoring less pain with traditional digital block and subcutaneous injection block techniques compared to transthecal block. No significant difference in associated pain was found between traditional digital block and subcutaneous block (1a) [77].

If a tourniquet is used during the procedure, the clinician should be sure it is removed at termination as forgotten tourniquets have been associated with digital necrosis [78]. Excessive injection volume has also been associated with digital necrosis [1, 78], and while there is no clear safe cutoff, some authors recommend 1.5 ml of volume or less per nerve (5) [79].

Pain and psychological stress associated with digital nerve blocks can be significant. Use of buffered lidocaine and lidocaine warmed to 42°C during digital nerve blocks was examined in single, randomized control trials, and both techniques were found to reduce pain associated with injection (1b, 1b) [80, 81]. Additionally, a two-stage method in which a small amount of infiltrated anesthetic was delivered prior to the main injection during digital blocks was found to be associated with less intense pain compared to the traditional one-stage method (1b) [82].

Tumescent anesthesia with lidocaine and prilocaine is safe and recommended for office-based liposuction (2b) [1, 83]. Other anesthetics such as bupivacaine have not been studied in tumescent liposuction [1]. Epinephrine as an additive has been shown to be safe for use and is recommended in tumescent local anesthesia for liposuction (2b, 2b) [84, 85]. Warm anesthetic solutions and a slow rate of infiltration lead to a significant decrease in pain associated with the administration of anesthetic (1b, 2b) [86, 87].

Safety

Local infiltrative anesthesia, peripheral nerve blocks, and tumescent local anesthesia are considered safe for use in office-based settings [1]. While overall well tolerated and commonly used, local and regional infiltrative anesthetic procedures do carry risks for toxicity and death [88]. Common side effects of local infiltrative anesthesia include pain, erythema, edema, bleeding, and ecchymoses [10, 19, 31]. Certain sites such as the periorbital area carry more risk for bruising and edema. Transient motor nerve paralysis may occur [19]. The addition of epinephrine to lidocaine may lead to tachycardia and an associated sensation of anxiousness [31, 33]. Peripheral nerve blocks carry many of the same risks as local infiltrative anesthesia, including hematoma and local skin infection [10] but are also associated with comparatively higher rates of nerve damage [6]. If a sensory nerve is injured during nerve block, a prolonged sensory nerve paresthesia may develop [19].

Vasovagal reactions are a relatively common adverse event associated with injectable local anesthesia [38] and must be distinguished from anesthetic toxicity, epinephrine effect, or an anaphylactic reaction [31]. Less than 1% of all adverse reactions to local anesthetics are due to a true IgE-mediated immunologic reaction [23, 31]. Historically, reactions to ester anesthetics appeared to be more common than reactions to amide anesthetics [23]. A recent review demonstrated amide anesthetics are associated with the most reported true cases of local anesthetic immediate hypersensitivity (4) [31]. This may be due to the preponderance of use of amide over ester anesthetics in current practice. Cross-reactivity exists within the amide group and patients with a true allergy to one amide anesthetic should not be given other anesthetics from that group [23]. Both ester and amide local anesthetics may contain methylparaben, a preservative agent that is metabolized to para-aminobenzoic acid (PABA) and may contribute to a significant number of adverse reactions [23, 89]. Allergic contact dermatitis (type IV hypersensitivity) reactions to local anesthetics appear to be increasing (2b) [90], with one retrospective study estimating a 2.4% prevalence based on patients who had undergone patch testing (2b) [91]. Suspected allergy to an anesthetic agent may be investigated with skin prick testing as well as intradermal and subcutaneous challenges; however, no firm guidelines have been established [23–25]. Patch testing is useful to identify type IV hypersensitivities [23, 26].

Toxicity with local anesthetics may occur due to underlying impaired metabolism, inadvertent overdose, or intravascular injection [36, 88, 92]. Local anesthetics differ in regard to their central nervous system and cardiovascular toxicity, with bupivacaine associated with a higher risk of cardiac toxicity compared to other agents [93]. Toxicity with lidocaine has been well studied [see Table 34.3] with dose-dependent effects typically starting at serum levels of 1–6 μg/ml [36]. As serum levels increase, side effects span nonspecific dizziness to peri-oral and digital paresthesias and tinnitus to seizures and cardiac arrest [36, 92]. In the 2010 American Society of Regional Anesthesia and Pain Medicine Practice Advisory, the expert panel notes that in their overall analysis and review of the literature, less than 20% of cases of local anesthetic systemic toxicity involved "classic" prodromal symptoms such as metallic

Table 34.3 Serum lidocaine levels, associated signs and symptoms, and management of toxicity [19, 36, 92]

Serum lidocaine levels (μg/ml)	Signs and symptoms	Management
1–6	Circumoral and digital paresthesias, metallic taste, lightheadedness, euphoria	Observation, supplemental oxygen
6–9	Nausea, vomiting, tremors, slurred speech, localized muscle twitching, tinnitus, psychosis	Diazepam, airway maintenance, EMS activation
9–12	Seizures, respiratory and cardiopulmonary depression	Respiratory support
>12	Respiratory and cardiac arrest, coma, death	Cardiopulmonary resuscitation and life support

taste and auditory changes. Seizure was the most common presenting symptom of local anesthetic toxicity, occurring in two-thirds of cases [88, 92]. If toxicity is suspected, vital signs should be immediately obtained and supplemental oxygen should be administered. Airway management and prevention of hypoxia and acidosis may prevent cardiovascular collapse [94]. Seizures should be treated with benzodiazepines [88].

Various precautions are recommended to decrease the risk of local anesthetic toxicity. These include using the lowest effective dose of local anesthetic needed and continually assessing and communicating with the patient for early recognition of potential toxicity. Additionally, intravessel injections may be avoided by aspirating the needle or catheter prior to each injection [1, 88].

Recent recommendations from the AAD for maximal safe dosing of lidocaine with and without epinephrine is summarized in Table 34.2 [1]. During multistage procedures that span several hours such as Mohs micrographic surgery, the maximum recommended dose of local infiltrative anesthesia is 50 ml of 1% lidocaine solution (500 mg) based upon a 2010 prospective cohort study (2b) [95]. Tumescent local anesthesia for office-based liposuction is a safer alternative to liposuction under general anesthesia [2] with no reports of death [83] and a total complication rate in one review of 9478 cases of less than 1% (2b) [96].

As discussed above, epinephrine is recommended and considered safe for use in procedures involving the digits [1]. In a large retrospective review, cases of digital necrosis associated with local anesthetic use were reported in the setting of previously damaged tissue in patients with diabetes mellitus, arteriosclerosis, or thromboangiitis obliterans (4) [97], and careful attention is recommended in patients with these comorbidities. There is an association with the use of large amounts of epinephrine and exacerbations of severe hypertension or severe cardiovascular disease [29, 30, 98]. This effect is rare, however, and recent reviews and consensus guidelines accept the use of local infiltrative anesthesia with epinephrine in patients with stable cardiac disease [1, 29]. Patients with a history of hyperthyroidism, severe hypertension, or pheochromocytoma may be more sensitive to epinephrine's effects, and caution is advised [31, 78].

Postoperative Care and Follow-Up

There is minimal follow-up required after local or regional infiltrated anesthesia. Reviewing common side effects with patients, including bruising, discoloration, and swelling around injection sites, may help relieve patient concern. Additionally, reminding patients that sensory nerves may return to normal several hours before motor nerve paralysis resolves may help reduce anxiety [19].

Alternative Procedures and Modifications

It is unknown if local infiltrated anesthesia is more effective than other forms of local anesthesia [1]. Studies comparing topical and infiltrated anesthesia in a variety of clinical situations including split-thickness skin graft harvest (1b) [99] and minor laceration repair (1a) [100] found topical anesthesia at least as effective as infiltrated anesthesia. Peripheral nerve blocks have been found to have superior pain reduction compared to cold air skin cooling alone in the setting of frontotemporal scalp photodynamic therapy [7, 12].

The use of ethyl chloride in dermatological procedures has not been well studied, and there is contradictory evidence about its effectiveness. Several reports examining ethyl chloride during venipuncture did find it effective for reducing pain of the procedure (1b, 1b) [101, 102]. In one study, while ethyl chloride did induce statistically significant anesthesia, it was comparatively less effective than anesthesia with intradermal 1% lidocaine [101]. A randomized control trial examining injection pain in children found significantly less pain with the use of a topical refrigerant spray and placebo aerosol spray as compared to no spray use at all. There was no significant difference in pain reduction between the topical refrigerant and placebo sprays (1b)

[103]. Given the limited data, use of ethyl chloride as a sole anesthetic agent for dermatological procedures is not recommended [1].

In patients with a true hypersensitivity reaction to lidocaine, bacteriostatic normal saline (0.9% benzyl alcohol in normal saline) or 1% diphenhydramine are alternatives for local infiltrative anesthesia in addition to ester-type local anesthetics [1]. In a study comparing 0.9% buffered lidocaine, 1% diphenhydramine, and 0.9% benzyl alcohol with epinephrine, the investigators found no difference in duration of anesthesia between diphenhydramine and benzyl alcohol with epinephrine. Buffered lidocaine revealed a significantly longer duration of anesthesia compared to the other two local infiltrated anesthetics. Additionally, the injection of diphenhydramine was significantly more painful compared to buffered lidocaine and benzyl alcohol with epinephrine (1b) [80]. Another prospective, randomized, double-blind comparison found 0.5% diphenhydramine with epinephrine to be both less effective anesthetically and more painful compared to buffered 1% lidocaine with epinephrine and unbuffered lidocaine 1% with epinephrine (1b) [104]. A comparison of the effectiveness of 1% diphenhydramine, 1% buffered lidocaine, 1% lidocaine, and normal saline found diphenhydramine reached a significantly larger diameter of analgesia compared to placebo (normal saline) by 5 min after injection. By 30 min after injection, the diphenhydramine diameter of anesthesia was equivalent to placebo while buffered 1% lidocaine and 1% lidocaine diameter of anesthesia remained significantly larger than placebo (1b) [105]. Based on this data, bacteriostatic normal saline and 1% diphenhydramine may be considered for minor dermatological procedures in patients unable to tolerate lidocaine [1].

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: quality of evidence
Indications:	
1. Local infiltrative anesthesia is safe and recommended for excisions, cauterization, obtaining biopsy specimens, nonablative laser, skin grafting, tissue rearrangement, and ablative skin resurfacing	C
2. Lidocaine and prilocaine are safe for use during tumescent local anesthesia for liposuction	A
3. In patients with a true allergy to lidocaine, accepted alternatives include bacteriostatic normal saline, diphenhydramine, and ester-type local anesthetics	C
Dosage and administration:	
4. For a single treatment, the maximum recommended dose of lidocaine with epinephrine in adults is 7.0 mg/kg, without epinephrine is 4.5 mg/kg	C
5. For a single treatment, the maximum recommended dose of lidocaine with epinephrine in children is 3.0–4.5 mg/kg, without epinephrine is 1.5–2.0 mg/kg	C
6. For multistage procedures such as Mohs micrographic surgery, the maximum recommended dose of lidocaine is 500 mg	B
7. For tumescent liposuction, the maximum recommended dose of lidocaine with epinephrine is 55 mg/kg for patients weighing 43.6–81.8 kg	A
8. The addition of sodium bicarbonate to local anesthetics is recommended to reduce pain associated with injection of the anesthetic	A
9. Techniques shown to decrease pain associated with delivery of local infiltrative anesthetics include vibration, cold air skin cooling, use of a warm solution, and slow rate of infiltration	B
Safety of local infiltrated anesthetics and additives:	
10. True IgE-mediated hypersensitivity to lidocaine is very rare	B
11. Buffered lidocaine with epinephrine stored at room temperature is effective and safe for use at 1 week after compounding	B

Findings	GRADE score: quality of evidence
12. Local anesthetics with epinephrine are safe for use on the ear, nose, and digits	A
13. Local anesthetics with epinephrine may be used during procedures on the penis	B
14. Lidocaine with epinephrine is safe for use during tumescent local anesthesia for liposuction	A
15. Small amounts of lidocaine with epinephrine may be used in pregnant women	C
Nerve block anesthesia:	
16. Nerve block anesthesia is recommended for botulinum toxin injection of the palm, ablative laser resurfacing of the face, and upper lid ptosis surgery	B
17. Digital nerve blocks performed in a traditional two-injection or subcutaneous manner are associated with less pain compared to transthecal digital blocks	C

Note: recommendations 1–9, 12–16 are reproduced with permission from the 2016 AAD guidelines

Self-Assessment Questions

1. What is the maximum recommended dose of 1% lidocaine with 1:100,000 epinephrine for a 55-kg woman?
   (a) 8 ml
   (b) 16 ml
   (c) 24 ml
   (d) 38 ml
   (e) 300 ml
2. Which agent is NOT recommended for use in tumescent anesthesia?
   (a) epinephrine
   (b) lidocaine
   (c) bupivacaine
   (d) prilocaine
   (e) sodium bicarbonate
3. A patient reports a history of anaphylaxis to a bee sting. What medication is contraindicated?
   (a) epinephrine
   (b) lidocaine
   (c) sodium bicarbonate
   (d) hyaluronidase
   (e) prilocaine
4. The following have been shown to reduce pain associated with infiltration of local anesthesia *except*:
   (a) Buffering lidocaine with sodium bicarbonate
   (b) Rapid infiltration of lidocaine
   (c) Warming the anesthetic prior to injection
   (d) Vibration
   (e) Cold air cooling
5. A 70 kg patient is undergoing Mohs micrographic surgery. What is the maximum dose of 1% lidocaine with 1:200,000 epinephrine he can be given over several hours?
   (a) 10 ml
   (b) 30 ml
   (c) 50 ml
   (d) 100 ml
   (e) No limit

Correct Answers

1. d: The correct answer is 38 ml. 55 kg (weight of patient) multiplied by 7 mg/kg (maximum recommended dose) divided by 10 mg/ml (1% lidocaine) = 38.5 ml. The other answers are incorrect. Answer c (24 ml) is the maximum recommended dose for plain lidocaine without epinephrine. Answer e (300 ml) is the recommended dose for tumescent anesthesia using a 1% solution.
2. c: All agents listed above except for bupivacaine have been studied and found safe for use in tumescent local anesthesia. There is no data regarding bupivacaine.
3. d: Hyaluronidase is contraindicated in patients with a history of bee sting allergy given reports of cross-reactivity and type I hypersensitivity with its use.
4. b: All of the above, except for answer b (rapid infiltration of lidocaine), have been shown to reduce pain associated with infiltration of local anesthesia. Slow (not rapid) infiltration of lidocaine is associated with reduced pain.
5. c: During multistage procedures that span several hours, the maximum recommended dose of lidocaine is 500 mg. 500 mg divided by 10 mg/ml (1% lidocaine) = 50 ml of 1% lidocaine solution.

Nail Procedures

Daniel R. Knabel, Nathaniel J. Jellinek, and Thomas J. Knackstedt

Abstract

The evidence-based treatment of nail disease remains a challenge. Unlike in the skin, the nails are slow growing and many interventions will not be readily apparent for several months. Many practitioners do not feel comfortable with invasive nail procedures and, relative to the remaining skin, nail biopsies are done by fewer practitioners. Indeed, most residents perform less than ten nail procedures in their training, and 30% of residents do not feel competent in nail diseases at the conclusion of their residency (4) (Clark et al. Dermatol Surg 42:696–698, 2016). Experts have noted significant knowledge gaps among practitioners for nail procedures (5) (Hare and Rich, Dermatol Clin 34:269–73, 2016). Especially in the procedural realm, high-level evidence in the form of randomized trials and prospective cohorts is rarely available. Oftentimes, case reports, case series, and expert opinion dictate the standard of care for nail procedures.

Introduction and Perioperative Considerations

Evidence-Based Treatment of Nail Disease

The evidence-based treatment of nail disease remains a challenge. Unlike in the skin, the nails are slow growing and many interventions will not be readily apparent for several months. Many practitioners do not feel comfortable with invasive nail procedures and, relative to the remaining skin, nail biopsies are done by fewer practitioners. Indeed, most residents perform less than ten nail procedures in their training, and 30% of residents do not feel competent in nail diseases at the conclusion of their residency (4) [1]. Experts have noted significant knowledge gaps among practitioners for nail procedures (5) [2]. Especially in the procedural realm,

high-level evidence in the form of randomized trials and prospective cohorts is rarely available. Oftentimes, case reports, case series, and expert opinion dictate the standard of care for nail procedures.

Patient Evaluation

As with any surgical procedure, preoperative considerations in nail surgery include a detailed history and physical exam; review of systems; a discussion of the risks and benefits of the procedure with the patient (illustrations are often helpful); a sound understanding of the anatomy, physiology, and pathology of the nail unit; and competent surgical skills. Smoking is discouraged. Immunosuppression may increase the risk of postoperative infection but is not normally a contraindication. Imaging studies may occasionally be indicated—for example, to better delineate and localize space-occupying defects or to assess underlying soft tissue or bony abnormalities (5) [3]. Such perioperative considerations apply to all nail procedures including nail bed and matrix surgeries and en bloc excisions. Examination of nail plate pigment under dermoscopy may assist the clinician in decision to biopsy and aid further procedure planning. For instance, nail apparatus melanoma has been associated with irregular spacing, thickness, and coloring of longitudinal nail lines within a brown background on dermoscopy (3b) [4]. Furthermore, end-on dermoscopy of the free edge of the nail plate allows for localization of pigment in the proximal (dorsal nail plate) or distal (ventral nail plate) matrix (5) [5]. Although proximal nail matrix pigmented lesions are less common, proximal matrix disruption is associated with higher rates of postoperative dystrophy; thus, knowledge of the location of a lesion within the matrix assists with preoperative counseling and setting appropriate patient expectations (5) [6].

Cleanliness/Preparation

Acral sites are prone to contamination and a number of antimicrobial preparations have been advocated in nail surgery. A prospective, randomized trial of 127 patients found chlorhexidine scrub and isopropyl alcohol superior to povidone iodine in reducing the rate of post-preparation positive bacterial cultures in foot and ankle surgery (1b) [7]. Use of a sterile glove with fingertip removed, and then rolled back, exposing only the affected finger provides an elegant sterile field and reliable tourniquet and has been promoted virtually unanimously by nail surgeons [3]. Soaking the affected digit in tepid water or in a combination of water and chlorhexidine may soften the nail and facilitate procedures, especially on the toes.

Instruments

Few special instruments are required for nail surgery [3]. In fact, many procedures can be performed with a standard surgical tray. A comprehensive list of instruments appropriate for nail surgery is not within the scope of this publication. As there are no evidence-based criteria for most nail instruments, the reader is referred to additional references for a more thorough discussion of nail instruments (5) [8]. However, it is generally agreed that fine instruments in addition to the nail elevator, dual action nail clippers, and English anvil-action nail splitter are among the most important equipment unique to nail surgery [8]. Fine sutures, such as 5-0 or 6-0 nylon, coated polyglactin 910, or chromic gut sutures, are most appropriate for repair of fine anatomical structures of the nail apparatus.

Effective Anesthesia

When approaching anesthesia of the nail apparatus, the surgeon must consider choice of anesthetic agent, the technique of anesthetizing, as well as various comfort measures. The most commonly used local anesthetics in nail surgery are lidocaine, bupivacaine, and ropivacaine. Due to its availability, low toxicity, and quick onset of action, many nail surgeons use lidocaine. Although it has a slightly slower onset of action, ropivacaine is preferred by

some due to its inherent vasoconstrictive activity and prolonged duration of anesthesia when compared with lidocaine (5)(2b) [3, 9, 10]. A prospective study comparing ropivacaine to lidocaine in 70 patients receiving digital nerve blocks demonstrated that lidocaine had a faster onset of anesthesia (mean time 1.3 min [range 1–2.7 min]) than ropivacaine (mean time 4.5 min [range 3.5–5.5 min]). However, the duration of postoperative anesthesia was significantly higher in ropivacaine digital nerve blocks (mean 21.5 h) than in lidocaine nerve blocks (mean 2.4 h) [10]. These findings were further substantiated in a small prospective, double-blinded, randomized study with 20 volunteers (2b) [11] and in a systematic review of 6 studies with 335 nerve blocks (1a) [12]. It should be noted that most of these studies were conducted in the emergency room or hand surgery arena and apply directly to traditional digital blocks rather than other methods of nail unit anesthesia (see below).

The two most commonly used techniques for anesthetizing the nail apparatus are the wing block—a method of infiltrating anesthesia targeting the distal digit—and the traditional digital block, a nerve block targeting the volar and dorsal digital nerves (5) [13]. A wing block can provide additional hemostasis of the nail apparatus by virtue of its local tumescent effect. These techniques have been recently reviewed [13].

Refrigerant spray, ice application, psychological distractions (conversation, music), tactile vibrational stimuli, and topical anesthetics have been employed to diminish pain associated with local anesthetic injection (4) [13, 14]. In addition, local anesthetic warmed to body temperature, buffered to physiologic or near-physiologic pH, and injected with a 30-gauge needle has been proven to reduce pain associated with injection in a meta-analysis and systematic review (2b)(1a) [15, 16].

Obtaining Hemostasis

Hemostasis during nail surgery is reliably obtained with a tourniquet or tourniquet-like device. The rolled sterile glove technique (described above) or use of a Penrose drain provides reliable and easily reversible exsanguination of the fingertip. Several proprietary tourniquets are also available. Notably, tourniquets not only apply pressure on the vasculature but may concomitantly traumatize the underlying skin, muscle, and neurovascular structures either via excessive pressure, shearing forces, or long periods of tourniquet application (5) [17]. A simulation measuring pressure gradients applied by Toe-niquet™ (Orthotic-Lab Limited, Middlesex, UK), T-ring™ (Precision Medical Devices LLC, San Clemente, USA), and Biogel™ (Mölnlycke Health Care, Gothenburg, Sweden) surgical gloves demonstrated that the lowest mean pressures were produced by larger glove sizes (size 8) (25 mmHg), while the highest pressures were produced by Toe-niquet (1560 mmHg). Small size and large size T-ring pressures were 146 mmHg and 427 mmHg, respectively (2b) [18]. A prospective study completed in 2016 surveying users of T-ring digital tourniquets in emergency hand surgery reported simple application, good quality exsanguination, easy finger positioning, and easy tourniquet removal (4) [19].

Although not necessary in most cases, in the absence of contraindications, epinephrine in dilute concentrations has been repeatedly shown to be safe and effective in achieving digital hemostasis and prolonging the effect of short acting local anesthetic (5)(1b)(3a) [20–22]. Most recently, a retrospective review of 1111 cases reported no complications with the use of 1% lidocaine with epinephrine (1:100,000) in a dose range of 0.5–10 cc (mean dose of 4.33 cc) in digital nerve blocks (3b) [23]. This study added to a previous more broad multicenter prospective study of 3110 consecutive cases of elective epinephrine (1:100,000 or less) use in the fingers and hand which demonstrated no cases of digital tissue loss [21].

Nail Plate Avulsion

The goal of nail avulsion is usually to optimize exposure of the nail bed and distal matrix while minimizing trauma and postoperative

complications and only occasionally is the treatment of choice (4) [24]. Traditional nail plate avulsion involves the complete separation of the nail plate from the nail unit. Many recently described, targeted, and elegant partial nail avulsion techniques have made the traditional nail plate avulsion obsolete when performing most nail procedures (4) [8, 25, 26]. Many nail surgeons advocate partial nail avulsion due to an observed lower risk of postoperative dystrophy, decreased pain, and improved healing (4) [3, 27]. In nail unit trauma, post repair splinting of the nail fold and bed with the native nail plate has been associated with lower rates of nail deformity when compared to artificial splints in a retrospective study (2b) [28]. Overall, total nail avulsion should be avoided and partial nail avulsion is preferred whenever possible.

Nail Bed Biopsy

Nail bed biopsies are nearly as simple as at other skin sites and may provide valuable information to diagnose inflammatory conditions (e.g., psoriasis) and nail tumors, differentiate mycotic from inflammatory disease, or demonstrate the pathogenicity and invasiveness of fungal organisms. Generally speaking, reconstruction after nail bed biopsy is deferred for healing by second intention. The tight and friable epithelium of the nail bed is difficult to mobilize and suture and heals with minimal dystrophy and only occasionally results in onycholysis.

A nail bed biopsy may be performed with or without nail plate avulsion. Alternatively, a longitudinal ellipse biopsy can be performed after a partial plate avulsion.

Matrix Biopsies

Several techniques for nail matrix biopsy have been reported including nail matrix punch biopsy, tangential matrix shave biopsy, and lateral or midline longitudinal excisional biopsy. Throughout this chapter, perioperative considerations including patient evaluation, appropriate anesthesia, and management of hemostasis remain the same regardless of the technique employed.

Nail Matrix Punch Biopsy

Indications

Punch biopsies may be performed to aid in the diagnosis of nail bed or nail matrix pathology.

Effectiveness

Traditional teachings suggest that matrix punch biopsies, 3 mm or less, are unlikely to cause a permanent dystrophy and avoid dystrophic nail plate scarring. In practice, however, only small, full thickness biopsies from the distal matrix are considered low risk in terms of causing permanent nail dystrophy; the proximal matrix, responsible for a majority of the nail plate production as well as the superficial nail plate, is more susceptible to scarring or developing a split nail, even with a 3-mm punch. In the absence of direct matrix visualization with partial or complete nail avulsion and proximal nail fold reflection as needed, punch biopsies are susceptible to a sampling bias with false-negative results as well as incomplete lesion extirpation.

In addition to obtaining tissue histology, the punch tool has also been utilized to remove the nail plate to facilitate drainage of subungual hematomas (4)(5) [29, 30] and diagnose proximal subungual onychomycosis.

Best Techniques and Performance

After appropriate anesthesia has been obtained, the patient is prepped and draped in the standard fashion. A tourniquet may or may not be utilized, depending on the complexity/duration of the procedure. Practitioners may choose to biopsy through the nail plate in a single punch, with a double-punch technique, utilizing a larger punch to remove the nail plate and a second smaller punch to sample the lesion (4)(5) [31, 32], or may perform a partial or complete nail avulsion first to appropriately visualize the lesion. If a standard punch biopsy of 3 mm or

smaller is used, the surgical site does not need to be closed and is allowed to heal by secondary intention.

Tangential Matrix Shave Biopsy

Indications

The tangential matrix shave biopsy is a surgical technique designed for the sampling of clinical entities affecting the nail matrix. It is valuable in establishing a diagnosis in longitudinal melanonychia of any width but in particular lesions greater than 3–4 mm in width, as it serves to minimize nail plate dystrophy (5)(3b) [33, 34]. Longitudinal melanonychia has a differential diagnosis that includes melanocytic activation (from drugs, systemic conditions, ethnic predisposition, and trauma, among other causes), nevi, lentigines, infection, blood, and melanoma. This broad differential combined with the risk of nail dystrophy with traditional biopsy techniques poses a dilemma for many practitioners. A delay in biopsy can be catastrophic (3b) [35]. A cross-sectional cohort study of 148 cases of adult longitudinal melanonychia found 20 to be melanoma (13.5%) upon biopsy [4]. Another retrospective observational study found 25 of 82 adult cases of longitudinal melanonychia to be melanoma (30.5%) upon biopsy (2b) [36]. While certain physical exam characteristics and dermatoscopic findings are more suggestive of malignancy, histopathologic analysis remains essential in the diagnosis of nail apparatus melanoma (5) [37]. In the appropriate clinical context, any new, atypical, or evolving pigmented band in adults should be evaluated and potentially biopsied.

Effectiveness

The goal of the tangential matrix shave biopsy is to obtain a broad and adequate sample of a pigmented lesion of the nail matrix while minimizing unnecessary damage to the nail apparatus. As a diagnostic tool, the procedure has demonstrated its ability to provide adequate tissue depth for establishing a histological diagnosis. A retrospective study of 22 patients with longitudinal melanonychia involving the matrix, biopsied via tangential shave, found a mean specimen depth of over 7 times thicker than the lesion of concern, allowing histological diagnosis in all cases (3b) [38]. In a retrospective study of 23 cases of longitudinal melanonychia sampled via tangential matrix shave, a diagnosis was possible in all cases [34]. Furthermore, follow-up of at least 6 months (median follow-up of 19.7 months) demonstrated that 17 of the 23 patients (74%) had no postoperative nail dystrophy. However, 16 of 23 patients (70%) did have recurrence of pigmentation.

Best Techniques and Performance

A complete discussion of this biopsy technique is beyond the scope of this chapter. Haneke and Baran first described the tangential matrix shave biopsy and it has since been described in depth by others [33, 34, 37]. Following appropriate preoperative evaluation, disinfection, and anesthesia, incisions are made with a #15 blade scalpel at the junction of the proximal and lateral nail fold. With an elevator or hemostat the proximal nail fold is dissected gently from the underlying nail plate and reflected proximally until the origin of the longitudinal pigment is fully identified. At the proximal third to 50% of the nail plate, an English anvil action nail splitter is inserted perpendicularly into the lateral nail fold and advanced beneath the nail plate to cut the nail plate transversely. This freed portion of the proximal nail plate is then reflected laterally with a hemostat exposing the nail matrix and proximal nail bed. Using a new, sharp (Teflon or silicone coated) scalpel blade, the origin of the longitudinal band of pigment is scored at a depth of approximately 1 mm with 1–2-mm margins. The blade is then turned parallel to the scored lesion and a tangential shave of the lesion is delicately performed. The matrix specimen should be less than 1 mm thick in most instances. The specimen should be raised with the blade (without using forceps) and placed carefully on a piece of cardboard or paper (to prevent curling) and covered with filter paper or moist gauze. A map of the nail apparatus and corresponding location of the sample is helpful in orienting the lesion (available for download at: https://www.cta-lab.com/pdfs/CTALab_Nail_Cutouts.pdf). The sample is then immersed in

formalin and sent to pathology. Repair involves trimming the elevated free edge of the laterally reflected nail plate and returning it to the nail bed. The proximal nail fold is returned to its original position and may be sutured. Securing the reconstructed proximal nail apparatus with suture, adhesive wound dressing, and/or a postoperative pressure dressing is also helpful.

Safety

When performed by an experienced nail surgeon, the tangential matrix shave biopsy is an extremely safe, well-tolerated, and effective procedure for sampling and diagnosing pigmented lesions of the nail matrix. As with any procedure involving the matrix, nail dystrophy is of primary concern. The risk of dystrophy is increased if the lesion of interest involves the proximal matrix [6]. Current literature is scarce; however, Haneke and Baran reported no postoperative dystrophy in the 12 cases in the original description of the procedure [3]. A subsequent retrospective study including 23 patients undergoing tangential matrix shave biopsy demonstrated a 26% rate of dystrophy at follow-up, 13% being classified as severe. However, in this study, no postoperative dystrophy was observed with tangential shave of the distal matrix, even when sampling over 50% of the distal matrix [34]. Other experienced nail surgeons report similar findings of minimal long-term dystrophy [27, 37]. A valuable photographic series documenting the healing process in one patient over 12 months has been published and may be a helpful tool to align patient and physician expectations [27].

Postoperative Care and Follow-Up

Follow-up is dictated by the histological diagnosis obtained in each case. In cases of histological atypia or melanoma, complete nail apparatus ablation (see later) can be performed within days following biopsy [3]. For benign lesions, patients are typically seen at 1 month for wound check and 4–6 months to monitor nail growth and recovery. Malignancies are followed up at the intervals recommended for the respective disease (3,6, or 12 months). The rate of nail growth varies by digit, age, nutritional status, patient comorbidities, and systemic medications. Healthy fingernail growth at monthly rates of 2.94–3.47 mm and toenail growth at monthly rates of 1.65–2.09 mm has been reported (2b) [39]. After complete surgical nail avulsion, complete nail regrowth within 4–5 months and 10–18 months for fingernails and toenails, respectively, has been reported (3b) [40]. It should be noted that re-pigmentation of the nail bed has been reported in up to 70% of patients undergoing tangential matrix shave biopsy in one study [34]. This may require patient reassurance.

Alternative Procedures and Modifications

Alternative procedures include matrix punch biopsy for lesions 3 mm or less, lateral longitudinal excision for pigmented lesions of the lateral nail, or en-bloc excision of the entire nail apparatus for cases of melanonychia involving a large portion of the nail. The tangential matrix shave biopsy is superior to these alternatives in cases involving longitudinal melanonychia larger than 3–4 mm due to lower risk of post-procedural nail dystrophy [3, 33, 37]. In the absence of high-level clinical trials comparing various biopsy techniques, a valuable, single-author expert-opinion diagnostic algorithm for nail matrix biopsy of longitudinal melanonychia has been published [37] (Fig. 35.1).

Lateral and Paramedian/Midline Longitudinal Excisional Biopsy

Indications

The longitudinal biopsy encompasses tissue sampling extending anywhere from the most proximal aspect of the nail matrix to the digit pulp. In comparison to the punch biopsy, this full thickness excision specimen maintains fixed anatomic reference points and visualizes the anatomic relationship of all nail structures.

Longitudinal excisions can be performed anywhere along the nail but are frequently considered as lateral or midline/paramedian in location. Lateral longitudinal excisions are preferentially

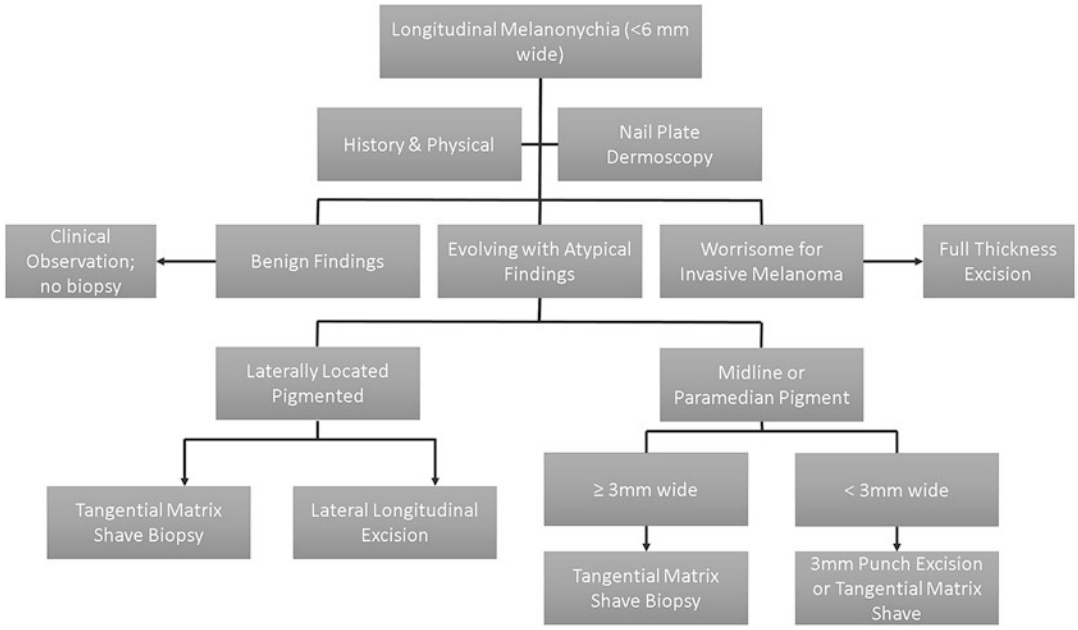

Fig. 35.1 Algorithm for the approach to biopsy of longitudinal melanonychia. (Adapted from Jellinek [37])

used in the setting of generalized nail dystrophy without a diagnosis or a localized abnormality of one digit involving the lateral nail margin. More medial longitudinal nail biopsies that divide the matrix into two parts may lead to permanent deformity of the nail plate or a split nail. Historically, an excision width of <3 mm has been deemed safe anywhere on the nail. However, the authors have observed permanent splitting when midline or paramedian longitudinal defects involving the mid- or proximal matrix are left to granulate. Reconstruction with alignment of the epithelium may prevent this complication.

Effectiveness

High-level comparative studies between various nail biopsy techniques have not been performed. In the setting of inflammatory nail dystrophy, longitudinal biopsy confirmed the clinically suspected diagnosis in 8 of 20 clinically suspicious lichen planus cases and in 4 of 6 psoriasis (3b) [41]. The authors note that the diagnostic yield may be higher *without prior nail avulsion.* They have since altered this practice to avoid disrupting the nail bed epithelium secondary to traumatic plate avulsion. Grover and colleagues reported longitudinal nail biopsies to be diagnostic by providing confirmatory evidence of the underlying nail disease in 11 of 21 patients with 20 nail dystrophies (3b) [42].

Best Techniques and Performance

Following appropriate preoperative evaluation, disinfection, and anesthesia, an elliptical excision is designed incorporating the nail plate, nail bed, nail matrix, and relevant nail folds. The incisions are carried out to the bone. This wedge shape ellipse should be long and narrow, paralleling the longitudinal ridges of the nail. After successful tissue extirpation, the wound may be left to heal via granulation by second intention or closed primarily. At times, lateral relaxing incisions or undermining may be useful to achieve closure. Detailed teachings have been published (5)(4) [43, 44].

Safety

A lateral longitudinal excision predictably heals with a more narrowed nail. The excision defect is either allowed to heal by second intention with granulation or reapproximated with sutures. Full thickness midline excisions have the potential for

nail dystrophy including a permanently split nail. Collins et al. suggest matrix reconstruction with nail matrix advancement flaps to mitigate this risk (4) [45]. The advanced proceduralist may wish to explore additional reviews on nail flap reconstruction (4) [46].

Therapeutic Interventions

Mohs Micrographic Surgery

Mohs micrographic surgery (MMS) has several applications in nail surgery. The primary advantage of MMS is the tissue (and thus often digit)-sparing nature and achievement of histologically clear margins. Keratinocytic tumors and melanocytic neoplasms have been successfully treated with MMS. In general, the conceptual technique remains unchanged when operating on or near the nail. A complete discussion of Mohs surgery is beyond the scope of this chapter. However, there are nuances that should be kept in mind for successful work around the nail unit.

Historically, a complete nail avulsion was performed prior to MMS. Although improving visualization, this approach is hampered by nail bed epithelium occasionally missing from the frozen section slides given the adherence to the overlying nail plate. Experts suggest that avulsion prior to surgery is not necessary and indeed, the plate can be maintained in an anatomic position and easily cut (after presoaking with a mixture of warm water and chlorhexidine), yielding high-quality histologic specimens with preserved epithelium over the entire cut surgical margin [26]. This technique is not used by all (5) [47].

The treatment of nail apparatus squamous cell carcinoma (SCC) with MMS is well established. Several retrospective case series demonstrate its utility in achieving clear margins and long-term surgical cure. Dika et al. described the successful use of MMS in 57 SCC cases with a 3.5% 10-year recurrence rate (2b) [48]. Earlier, Jellinek et al. reported the use of MMS in 35 SCC with an 8.5% recurrence rate (2b) [49]. Recurring tumors had a history of prior recurrence or aggressive nodular tumor growth at presentation. The use of a bone rongeur or dual action nail nipper has been proposed by some to further achieve clearance of the deep MMS margin [49]. Periungual basal cell carcinoma is rare and its treatment with MMS has only been documented in case reports (4) [50–52].

The use of MMS for the treatment of in situ and invasive cutaneous melanoma is increasingly well-established but infrequently reported specifically for nail apparatus melanoma. The difficulty in visualizing nail matrix melanocytes on routine frozen hematoxylin and eosin sections is enhanced through the use of Melanoma antigen recognized by T cells (MART-1) immunostains (2b)(4) [53, 54]. Several authors have successfully used MMS for the treatment of nail apparatus melanoma in situ but this technique has only been documented in case series, albeit with slowly increasing case numbers (3b)(4)(2b) [55–57]. On the basis of the published data MMS does not appear to have cosmetic, oncologic, or cost benefits over en bloc excision (see later) with traditional serial sectioning.

En Bloc Excision of All Nail Tissues

Indications

En bloc excisions refer to the complete removal of the entire nail apparatus including matrix, nail bed, nail plate, proximal nail fold, lateral nail folds, and hyponychium, oftentimes to the level of the tendon and periosteum. This technique is primarily indicated for the management of nail apparatus melanoma in situ and superficially invasive melanoma and squamous cell carcinoma. The technique has been described in detail (5) [58] and utilized in several nail apparatus melanoma studies.

Effectiveness

Several retrospective case series have reported on the treatment of nail apparatus melanoma in situ and early invasive melanoma with en bloc excision. In this setting the treatment efficacy is compared to digital amputation at various anatomic levels (which was historically the treatment of choice).

Randomized studies comparing the treatment of nail apparatus melanoma and/or nail apparatus melanoma in situ with en bloc excision versus amputation are lacking. Moehrle et al. compared results of 31 patients with invasive nail apparatus melanoma treated with en bloc excision plus removal of the ungual process (termed "functional surgery") and 31 patients treated with amputation at or proximal to the distal interphalangeal joint (2b) [59]. This comparative study was limited by its retrospective design and lack of randomization; however, no difference in recurrence-free survival and overall survival between the two techniques was identified. Others have shown that recurrence rates for invasive nail apparatus melanoma do not improve with more proximal or more radical amputations (2b) [60–62]. Neczyporenko et al. treated 11 patients with biopsy-proven melanoma in situ by en bloc excision (3b) [63]. The authors highlight the late presentation of the two known local recurrences (7 and 11 years) and the importance of long-term patient follow-up. Nukamura, et al. published data on 48 patients with nail apparatus melanoma in situ treated with wide local excision, with only two instances of incomplete excision, four recurrences, and no upstaging or development of subsequent metastasis (2b) [64]. Similar results have been published by others: Duarte et al. recently presented six cases of nail apparatus melanoma in situ treated with en bloc excision with no recurrences noted at a mean of 25 months (3b) [65]. Sureda et al. performed en bloc excisions in seven nail apparatus melanomas in situ and superficially invasive nail apparatus melanoma (3b) [66]. No recurrences were noted after a mean of 45 months. The data in favor of en bloc excision for nail apparatus melanoma in situ and early invasive disease are increasing. Nevertheless, significant technical variability remains among proceduralists performing this surgery, and technical details and margin width and status are inconsistently reported in the literature.

Preoperative Evaluation

Specific testing beyond a routine history and physical exam is not indicated for en bloc excisions. A musculoskeletal examination of the digit prior to surgery may reveal any preexisting changes to the joints proximal to the surgical site or (in the setting of invasive melanoma or other subungual tumors) may reveal invasion into the bone or extensor tendon. Should imaging be necessary, x-ray allows for evaluation of bony structures, and magnetic resonance imaging (MRI) appropriately studies the soft tissue of the nail apparatus and digital pulp to identify any mass lesion. Criteria for sentinel lymph node biopsy and adjuvant therapy remain the same as on the skin. Perioperative considerations established for other surgical sites should otherwise be followed. Review of medications, anticoagulation, infection risk is key for successful and complication-free surgery.

Best Techniques and Performance

Following appropriate preoperative evaluation, disinfection, and anesthesia, the excision is designed proximally by a transverse line overlying the distal interphalangeal joint (DIPJ) crease and continued to the midlateral line bilaterally, with a right angle turn at the midlateral line onto the lateral nail fold. The two lines are extended and joined, 3–4 mm distal to the hyponychium onto the distal digital tip skin. Appropriate tumor margins established for malignancies in other skin sites of 5–9 mm are incorporated into this design. The nail apparatus extirpation is performed directly over the distal phalanx, with care to avoid transecting the tissue when dissecting distally over the ungual process (due to the adherent periosteum) and proximally at the cul-de-sac (due to the anatomic constraints of nail anatomy). This process is continued distal to proximal over the waist (often but not always including periosteum on this narrow bony section), with the deep proximal extent of dissection ending at the insertion of the extensor tendon, taking care to maintain the integrity of the tendon. Detailed teachings have been published [58].

Safety

En bloc excisions require a thorough understanding of digital and nail anatomy. As such, they should be performed by proceduralists well versed in nail procedures to avoid complications.

Complications after en bloc excision are similar to those at other sites including bleeding, infection, and damage to deeper structures. Exposed tendon and bone pose an increased risk for deeper infections including osteomyelitis, and patients should be treated with appropriate antibiotic prophylaxis although this has not been further studied to our knowledge. Few publications have addressed surgical complications after nail surgery and more specifically en bloc excision. Unique complications after en bloc excision include nail spicule formation and cyst formation. Spicule formation represents incomplete excision of the nail matrix. In the setting of a malignancy, this requires re-excision. Lazar et al. retrospectively studied epidermal cyst formation in 5 of 13 patients. Cysts may represent traumatic implantation of epidermis at the time of suturing or with needle trauma, rather than remnant matrix epithelium. Some have reported cysts to be the most common complication following nail unit excision (3b) [67], although this is not the authors' experience. Surgery overlying the tendon predisposes to tendon injury. To our knowledge, this injury, termed mallet finger deformity, has only been presented in one conference abstract and is a rare complication requiring splinting and immobilization as the first-line approach for treatment.

Postoperative Care and Follow-Up

Patients are routinely seen at 1- and 3-week follow-up periods. After successful healing by second intention or skin grafting, patients are seen at intervals appropriate for the underlying malignancy (i.e., 3-, 6-, or 12-month intervals).

Alternative Procedures and Modifications

When en bloc excisions are not desired or possible, amputation is the treatment of choice [66, 67]. In cases of advanced malignancy, amputation may be the only feasible treatment. According to the American Medical Association Guide to the Evaluation of Permanent Impairment, proximal (metacarpophalangeal joint) or distal (interphalangeal joint) amputation of the thumb corresponds to 50% or 100% impairment of the digit. On the other fingers, amputation at the DIPJ, proximal interphalangeal joint, and metacarpophalangeal joint corresponds to 45%, 80%, and 100% impairment, respectively (2b) [68]. After the surgical recovery period, en bloc excisions would appear to have less morbidity when compared to amputation but this has not been published in the literature. Mohs micrographic surgery is a treatment alternative that primarily differs in the method of margin assessment (complete margin assessment with frozen tissue rather than serial longitudinal sections through the en bloc specimen). The nail unit is ultimately still removed with margins in its entirety.

Observations and Recommendations

Evidence-based summary: Grading of Recommendations Assessment, Development and Evaluation (GRADE)

Findings	GRADE score: Quality of Evidence
Diagnostic and therapeutic nail procedures rely largely on expert opinion and retrospective case series	D
Dermoscopy may aid in the visualization and localization of pigment and surgical planning	C
Local anesthesia with lidocaine or ropivacaine	A
With or without epinephrine can be safely administered during nail procedures	A
Complete nail avulsion is not necessary for most nail procedures	C
Available evidence supports the tangential matrix shave biopsy as an elegant, safe, and effective method for sampling lesions of the nail, especially for longitudinal melanonychia. This technique avoids total nail avulsion, provides adequate tissue for histological diagnosis, and limits post-procedural nail dystrophy	B
Biopsy techniques must be tailored to the anatomic location harboring the pathology and may include nail punch biopsy, matrix shave biopsy, and longitudinal excisions	B
More definitive treatments for malignancies include Mohs micrographic surgery, en bloc nail unit excisions, and amputation	B

Self-Assessment Questions

1. What biopsy technique is most appropriate for sampling a 4-mm pigmented lesion of the central nail matrix?
   (a) Nail avulsion followed by 4-mm punch biopsy of the matrix
   (b) Lateral longitudinal excision
   (c) Tangential matrix shave biopsy
   (d) En bloc excision
   (e) 4-mm punch biopsy through nail plate and nail matrix
2. According to current evidence, patients are at most risk of which of the following after tangential matrix shave biopsy of a pigmented lesion of the distal matrix?
   (a) Dystrophy of the nail plate
   (b) Re-pigmentation of the nail bed
   (c) Digital ischemia and necrosis due to use of epinephrine
   (d) Osteomyelitis
   (e) Pterygium
3. Which of the following has been shown to most reduce positive bacteria cultures following antimicrobial preparation of the surgical site?
   (a) Povidone iodine scrub and paint
   (b) Chlorhexidine scrub and isopropyl alcohol paint
   (c) Chlorhexidine scrub
   (d) Isopropyl alcohol paint
   (e) Hexachlorophene
4. Which of the following techniques is not an appropriate diagnostic tool for the diagnosis of longitudinal melanonychia and presumed nail apparatus melanoma in situ?
   (a) Nail matrix punch biopsy
   (b) Nail bed punch biopsy
   (c) Longitudinal excision
   (d) Tangential matrix shave biopsy
   (e) En bloc excision of the nail apparatus
5. Full thickness biopsy in which anatomic area of the nail unit is most likely to cause permanent nail dystrophy?
   (a) Proximal nail matrix
   (b) Distal nail matrix
   (c) Proximal nail fold
   (d) Nail bed
   (e) Hyponychium

Correct Answers

1. d: The correct answer is tangential matrix shave biopsy. Especially for broad pigmented lesions, this is the procedure of choice. Larger-diameter punch biopsies create full thickness defects that have a higher risk of nail dystrophy, especially with more proximal biopsy sites. En bloc excisions are occasionally used for very broad pigmented lesions but are otherwise reserved as a therapeutic treatment following initial diagnosis by biopsy.
2. b: The correct answer is re-pigmentation of the nail bed. The cause for this is unclear but may be due to melanocytes adherent to the nail plate which is routinely partially avulsed, reflected, and then returned to its native anatomic position. Patient education and reassurance is valuable. In the absence of contraindications, with appropriate concentrations of epinephrine, and reasonable volumes of local anesthesia, digital ischemia and necrosis due to epinephrine is not seen. Pterygium refers to scarring of the nail matrix to the overlying proximal nail fold, oftentimes in the setting of scarring inflammatory nail conditions (e.g., lichen planus) or as an iatrogenic complication with biopsies involving the matrix, proximal nail fold, and complete nail plate avulsion. Osteomyelitis remains as a theoretical concern with any digital surgery via deeper extension from a primary superficial wound infection. This complication is exceedingly rare.
3. b: According to the current level of evidence, chlorhexidine scrub and isopropyl alcohol are the most effective preparations to reduce positive bacteria cultures following application.
4. b: The correct answer is nail bed punch biopsy. Longitudinal melanonychia originates in the nail matrix and thus, a biopsy of only the nail bed is unlikely to provide valuable diagnostic information.
5. a: The correct answer is the proximal nail matrix. The proximal nail matrix is responsible for producing the majority of the nail plate, including the more visible dorsal nail plate. Despite this, melanocytic lesions of the proximal nail matrix are much less common than melanocytic lesions of the distal matrix. Scarring in the proximal nail plate may produce nail dystrophy and ridging whereas any injury to the distal nail matrix more frequently results in thinning along the ventral (underside) of the nail plate.

Superficial/Soft Radiation Therapy for Nonmelanoma Skin Cancer

36

Christopher M. Wolfe and Armand B. Cognetta

Abstract

Similar to surgical modalities such as excision or Mohs micrographic surgery, the bulk of research forming the foundation for radiation therapy has come from retrospective analyses over the past 100 years of patients chosen for radiation therapy. Superficial radiation therapy is a viable and effective treatment option for patients over the age of 60 who are not ideal candidates for surgery. Superficial radiation therapy is curative for 90–95% of primarily treated nonaggressive basal cell and squamous cell carcinomas of the skin.

Keywords

Superficial radiation treatment · Superficial radiotherapy · Dermatologic radiotherapy Nonmelanoma skin cancer · Basal cell carcinoma · Squamous cell carcinoma

Preamble to *Evidence-Based Procedural Dermatology*: Superficial Radiation Therapy

The inclusion of superficial radiation therapy (SRT) in a textbook on *Evidence-Based Procedural Dermatology* appropriately underscores that radiation therapy is a physical procedure just as laser and ultraviolet therapy are and that clinical experience, best evidence, and patient preference all play a role in the selection of the most appropriate procedure for each individual and unique patient.

Evidence-based practice involves three essential components: evidence, clinical expertise, and patient values, preferences, and characteristics [1]. It has been described as a three-legged stool, wherein a bottom-up approach supports evidence-based practice to optimize patient care. As clinicians we are in the practice of giving and obtaining informed consent for surgical procedures, a process which has its basis in legal doctrine going back to 1914 where Justice Cardozo ruled "every human being of adult years and sound mind has a right to determine what shall be done with his own body" and "the surgeon who performs an operation without (his) patients consent commits an assault." This has been refined by case law and summarized more recently by the American Medical Association (AMA) defining informed consent as a "dialogue between patient and physician in which both parties exchange information and questions culminating in the patient's agreement to a specific medical or surgical intervention." Recently, some have gone as far as to state that "as practiced, informed consent has become a ritualistic signature on a form that does not reflect bidirectional communication between provider and patient about relative risks, benefits and limitations." [2] There is a move

afoot to supplant informed consent as we know it with a modern model termed shared decision-making (SDM) which can be viewed as informed preference versus informed consent.

Briefly let us explore what SDM means and how it can be used as an adjunct to informed consent and help fulfill the patient value and preference portion of evidence-based practice. Mulley [3] states that "no decision should be made in a state of a avoidable ignorance on the part of the patient about what is possible based on evidence, or on the part of the clinician what would be valued most" (by the patient).

He goes on to say that "the personal harm caused by a clinician's failure to accurately diagnose a patient preference can be just as severe as that caused by failure to accurately diagnose the disease itself." In 2012 Mulley [4] goes so far as to state that "preference misdiagnosis is medical error." What may not be obvious, in the case of a patient referred by another colleague for Mohs surgery, is that even though the referring physician has discussed treatment options with the patient, in order to qualify as evidence-based medicine, the patient must be thoroughly educated and versed on other treatment options in addition to Mohs surgery.

A good starting point is to discuss the fact that patients all have a choice. Once they understand this, the discussion can proceed to include all reasonable options with them and their caregivers to include surgical, nonsurgical, or no treatment, along with the pros and cons of each of these avenues. While many patients may not at first appear to want a choice, universally all feel empowered by having been given adequate attempts to look at various choices and what they entail. Once we have given them choice and knowledge of options, a "decision talk" with the patient will solidify their choice. All of the above describes the shared decision-making model of Elwyn and colleagues [5], where three talks are described and detailed.

1. Choice talk: the step of making sure that patients know that reasonable options are available.
2. Option talk: providing more detailed information about options.
3. Decision talk: supporting the work of considering preferences and deciding what is best.

In the literature, it is intimated that these talks should be on separate days with multiple inputs and second opinions. From a practical standpoint, this expanded informed consent or what has been termed informed preference can be done on the day of surgery. When discussing the pros and cons of various surgical and nonsurgical treatments, it is important that the physician be nondirective. Patients have a natural tendency to want to please the provider and "be a good patient," and some may feel awkward asking questions. Allowing family members to discuss options in the absence of the physician will allow expression of questions that could be suppressed otherwise.

Tools are available to aid in all of the above steps. One such tool is the "making GRADE the irresistible choice" (MAGIC) project which makes use of Grading of Recommendations Assessment, Development, and Evaluation (GRADE) guidelines to improve SDM. It urges patients to "ASK THREE QUESTIONS": (1) What are my options? (2) What are the possible benefits and harms of those options? (3) How likely are each of these benefits and harms to happen to me? This "Ask, Share, Know" (ASK) puts the onus on the patient to start the dialogue and allows the physician to continue it. Both the option talk and decision talk can be aided by patient decision aids (PDAs). We have these in our offices and specialties, and state societies have gone on to certify these after review. The option talk and the choice talk can start with the scheduling nurse's first phone call and include mailing informational packets containing patient decision aids to the patient. On arrival, all members of the healthcare team can be utilized to assure that the patient understands their option to choose Mohs surgery or another procedure.

Factors influencing a patient's choice are what we must strive to understand. As Mohs surgeons, we often see treatment failures from previous procedures elsewhere and are very keen to avoid this on our watch. We tend to feel most comfortable, especially in the framework of appropriate

use criteria (AUC) as a justification, to recommend Mohs. In doing so, we may be imposing our values on the patient and not following the spirit of the AUC process. When determining fitness for surgery, we evaluate the patient's overall health, comorbid medical conditions, coagulation status, and age when deciding whether Mohs surgery is appropriate. We must also give adequate weight to patient values and preference when prescribing Mohs versus non-Mohs modalities even if the cure rate is not equal to Mohs surgery.
